Platelets in Thrombotic and Non-thrombotic Disorders

Platelets have attracted increasing interest among clinicians and basic scientists over recent years, and are now known to play a part in many physiological and pathological conditions. In fact, platelets are involved in diseases responsible for the majority of disability and death worldwide, including myocardial infarction, stroke, peripheral vascular disease, cancer, and many infections. Platelets are also studied as a model in many areas of neurobiology, pharmacology, biochemistry and molecular biology.

This timely reference provides a comprehensive, detailed, up-to-date resource for clinicians and researchers, covering the structure and function of platelets and their role in pharmacology, pathogenesis and therapeutics. It is organized into sections covering platelet physiology, laboratory and methodological issues, platelet involvement in disease, including hemostatic and non-hemostatic conditions, platelet pharmacology, and treatment in the clinic.

With contributions from leading authorities including some of the founders of modern platelet studies, this is the definitive reference and guide to the diagnosis and therapeutics of diseases involving platelets. Chapters are devised to provide a critical review of the most clinically relevant aspects of the subject, with extensive references and easy-to-read take-home messages. It will be an essential resource for biomedical scientists and clinicians in hematology, vascular medicine, cardiology, thrombosis and related disciplines.

Paolo Gresele is Associate Professor of Internal Medicine, Section of Internal and Cardiovascular Medicine, Department of Internal Medicine, University of Perugia, Italy

Clive Page is Professor of Pharmacology, Division of Pharmacology and Therapeutics and Director of the Sackler Institute of Pulmonary Pharmacology and Therapeutics, Guy's, King's and St Thomas' School of Biomedical Sciences, London

Valentin Fuster is Director of the Zena and Michael A. Wiener Cardiovascular Institute and the Richard Gorlin, M.D./Heart Research Foundation Professor of Cardiology at the Mount Sinai Medical Center and School of Medicine, New York, New York

Jos Vermylen is Professor of Internal Medicine, Centre for Molecular and Vascular Biology, University of Leuven, Belgium

Contents

List of contributors ix
Editors' preface xxi

PART I PHYSIOLOGY

1 **History of platelets** 3
J. Fraser Mustard, Raelene L. Kinlough-Rathbone and Marian A. Packham

2 **Production of platelets** 25
Arnaud Drouin and Elisabeth Cramer

3 **Morphology and ultrastructure of platelets** 41
James G. White

4 **Platelet heterogeneity: physiology and pathological consequences** 70
Anthony Mathur and John F. Martin

5 **Platelet membrane proteins as adhesion receptors** 80
Yoshiaki Tomiyama, Masamichi Shiraga and Sanford J. Shattil

6 **Dynamics of the platelet cytoskeleton** 93
Kurt L. Barkalow, Hervé Falet and John Hartwig

7 **Platelet organelles** 104
Francine Rendu and Brigitte Brohard-Bohn

8 **Platelet receptors for thrombin** 113
Lawrence F. Brass, Marina Molino, Peter J. O'Brien and Mark Kahn

9 **Platelet receptors: ADP** 127
Christian Gachet and Jean-Pierre Cazenave

10 **Platelet receptors: prostanoids** 140
Roberta Vezza and Garret A. FitzGerald

Cambridge Books Online © Cambridge University Press, 2009

11 **Platelet receptors: collagen** 158
Pia R-M. Siljander and Richard W. Farndale

12 **Platelet receptors: von Willebrand factor** 179
Jerry Ware and Zaverio M. Ruggeri

13 **Platelet receptors: fibrinogen** 188
Edward F. Plow, Thomas A. Haas and Tatiana V. Byzova

14 **Platelet signalling: GTP-binding proteins** 204
Jan-Willem N. Akkerman

15 **Platelet phospholipases A_2** 221
Michael H. Gelb, Carine M. Mounier, Ying Hefner and Steve P. Watson

16 **Roles of phospholipase C and phospholipase D in receptor-mediated platelet activation** 238
Mauro Torti and Eduardo G. Lapetina

17 **Platelet signalling: calcium** 260
Juan A. Rosado and Stewart O. Sage

18 **Platelet signalling: protein kinase C** 272
Charles S. Abrams and Marcelo G. Kazanietz

19 **Platelet signalling: tyrosine kinases** 281
Sylviane Levy-Toledano

20 **Platelet signalling: cAMP and cGMP** 290
James L. Daniel, Barrie Ashby and Fabio M. Pulcinelli

21 **Platelet adhesion** 304
Philip G. de Groot and Jan J. Sixma

22 **The platelet shape change** 319
Adrian R.L. Gear and Renata K. Polanowsa-Grabowska

23 **Aggregation** 338
Marian A. Packham, Margaret L. Rand and Raelene L. Kinlough-Rathbone

24 **Amplification loops: release reaction** 357
Marc F. Hoylaerts

25 **Amplification loops: thromboxane generation** 369
Paola Patrignani and Maria G. Sciulli

26 **Platelet procoagulant activities: the amplification loops between platelets and the plasmatic clotting system** 381
H. Coenraad Hemker

27 **Platelets and chemotaxis** 393
Stefania Momi and Paolo Gresele

28 **Platelet–leukocyte interactions relevant to vascular damage and thrombosis** 412
Chiara Cerletti, Virgilio Evangelista, Roberto Lorenzet and Giovanni de Gaetano

29 **Vascular control of platelet function** 432
Scott Willoughby and Joseph Loscalzo

PART II METHODOLOGY

30 **In vitro assays for evaluating platelet function** 459
Perumal Thiagarajan and Kenneth K. Wu

31 **Monitoring antiplatelet therapy** 471
Dermot Cox and Desmond Fitzgerald

32 **Flow cytometric analysis of platelet function** 485
Alan D. Michelson, Marc R. Barnard, Lori A. Krueger, A.L. Frelinger III and Mark I. Furman

33 **Animal models of platelet-dependent thrombosis** 499
Paolo Golino and Francesco Loffredo

PART III PATHOLOGY

A **Hemostasis**

34 **Hereditary thrombocytopenias** 515
Chris Van Geet, Kathleen Freson, Rita Devos and Jos Vermylen

35 **Thrombocytopenias due to bone marrow disorders** 528
Beng H. Chong and Colin Chesterman

36 **Immune-mediated thrombocytopenia** 542
Kathryn E. Webert and John G. Kelton

37 **Thrombocytopenia in childhood** 556
Cécile Kaplan, M. Dreyfus, V. Proulle and G. Tchernia

38 **Alloimmune thrombocytopenia** 569
E. Anders Kolb and James B. Bussel

39 **Drug-induced and drug-dependent immune thrombocytopenias** 584
Andreas Greinacher, Petra Eichler and Norbet Lubenow

40 **Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome** 610
Miha Furlan

Cambridge Books Online © Cambridge University Press, 2009

41 **Thrombocytosis and thrombocythemia** 623
Tiziano Barbui and Guido Finazzi

42 **Platelet adhesive protein defect disorders** 639
Kenneth J. Clemetson and Jeannine M. Clemetson

43 **Congenital disorders of platelet secretion** 655
Marco Cattaneo

44 **Congenital platelet signal transduction defects** 674
A. Koneti Rao

45 **Acquired platelet function defects** 689
Joel S. Bennett

46 **Platelet storage and transfusion** 707
Scott Murphy

B **Thrombosis**

47 **Pathophysiology of arterial thrombosis** 727
Lina Badimon, Juan-Jose Badimon and Valentin Fuster

48 **Platelets and atherosclerosis** 738
Peter Verhamme and Paul Holvoet

49 **Platelet involvement in venous thrombosis and pulmonary embolism** 753
Andrew D. Blann and Gregory Y. H. Lip

50 **Gene regulation of platelet function** 760
Thomas J. Kunicki

C **Non-hemostatic disorders**

51 **Platelets and bacterial infections** 783
Mark C. Herzberg and Ke Gong

52 **Interactions of viruses and platelets and the inactivation of viruses in platelet concentrates prepared for transfusion** 807
Laurence Corash

53 **Platelets and parasites** 815
Michel Joseph

54 **Platelets and tumours** 824
Maria Benedetta Donati and Virgilio Evangelista

55 **Platelets and renal diseases** 837
Paola Boccardo, Miriam Galbusera and Giuseppe Remuzzi

56 **Platelets and allergic diseases** 852
Simon Pitchford and Clive P. Page

57 **Platelet interactions with other cells related to inflammatory diseases** 869
Patrice E. Poubelle and Pierre Borgeat

58 **Platelets and the preimplantation stage of embryo development** 885
Christopher O'Neill

59 **Platelets in psychiatric and neurological disorders** 894
B. E. Leonard

60 **Platelets in inflammatory bowel disease** 907
Elizabeth Carty, David S. Rampton and Carole E. Collins

PART IV PHARMACOLOGY

61 **Aspirin** 919
Carlo Patrono

62 **Pharmacology of ticlopidine and clopidogrel** 929
Jean-Pierre Cazenave and Christian Gachet

63 **Platelet membrane glycoprotein (GP) IIb–IIIa antagonists and acute arterial thrombosis** 940
David R. Phillips and Lisa Nannizzi-Alaimo

64 **Other antiplatelet agents** 955
Luigi Iuliano, Fausta Micheletta and Francesco Violi

65 **Pharmacogenetics as a new antiplatelet strategy** 964
Giovanni de Gaetano, Chiara Cerletti and Licia Iacoviello

66 **Cardiovascular gene therapy: implications for platelet vessel wall interactions** 978
Pierre Zoldhelyi, Harold Eichstaedt, Thomas Jax, Janice M. McNatt, Zhi Qiang Chen, Harnath S. Shelat, Harris Rose and James T. Willerson

67 **Pharmacological modulation of the inflammatory actions of platelets** 991
Carla Cicala and Giuseppe Cirino

PART V THERAPY

68 **Design of trials to evaluate antiplatelet agents** 1003
Shamir R. Mehta, John W. Eikelboom and Salim Yusuf

Cambridge Books Online © Cambridge University Press, 2009

69 **Antiplatelet therapy in cardiology** 1013
Herbert D. Aronow and Eric J. Topol

70 **Antiplatelet therapies in neurology** 1040
Graeme J. Hankey

71 **Antiplatelet treatment in peripheral vascular disease** 1055
Raymond Verhaeghe

Afterword 1063

Preface

Blood platelets have attracted an increasing interest among clinicians and basic scientists over the last three decades due to the progressive understanding of the role that these cells play in different physiological phenomena and pathological conditions. Indeed, blood platelets not only participate in normal hemostatis and are a central element in atherothrombosis but are also involved in inflammatory and allergic reactions, in some forms of gastroenterological, renal and dermatological disorders, in tumour metastasis and in viral, bacterial and parasitic diseases. It is impressive to realize that blood platelets play a primary role, or are involved, in the diseases responsible for the large majority of disability and death worldwide, and namely not only in myocardial infarction, stroke or peripheral vascular disease but also in cancer and its dissemination and several types of infection. Moreover, platelets, due to their easy sampling and to the fact that they possess a rather complex and complete signal transduction machinery typical of excitable cells, are often taken as a model for neurochemical, biochemical and molecular biology studies. It is also important to underline that, based on the expanding knowledge of platelet biology and pharmacology, recent developments in the field of antiplatelet agents have led to relevant therapeutic advancements with great excitement among cardiologists, neurologists, angiologists and internists.

The wide interest that platelets raise among clinicians and basic investigators is reflected in an explosive, exponential increase of publications involving platelets. It seemed thus useful to finally provide a comprehensive, detailed, up-to-date text for clinicians and basic scientists collecting all the available information on platelet structure, function, participation in disease, pharmacology and therapeutics. Provided the book will meet with the interest of the readership, it is planned that new editions updating the advances on this topic will be published every 3–4 years.

The book has been organized in five sections covering platelet physiology, laboratory methodological aspects, platelet involvement in disease, subdividing the latter into hemostatic and non-hemostatic conditions, platelet pharmacology and finally antiplatelet treatment in the clinic. Within these sections, 72 chapters cover all conventional and unconventional aspects of platelet function, involvement in disease or therapeutics. An emphasis was given to novel or upcoming aspects of platelet physiology, pharmacology and therapeutics, such as gene regulation of platelet function, pharmacogenetics, gene therapy, etc. A large group of leading experts and some of the 'fathers' of modern platelet studies have willingly accepted to contribute to the book, making up an outstanding crew of 157 scientists coming from disparate fields and thus giving a real interdisciplinary view of the subject. All chapters have been edited for homogeneity and to help in providing a balanced view of the various subjects. It is, of course, impossible to avoid some degree of overlap and repetition in such a book, but it was the intention of the Editors that, especially on some important or hot topics, the subject would be discussed and presented from different angles. An effort to provide schemes and tables with easy-to-read take-home messages has been made; extensive and updated bibliographic citations are given to provide the interested reader with access to greater detail than can be included in an already large book. Many investigators and clinicians, even if not primarily interested in platelets, cross the platelet field in their daily work: this book should serve them as a comprehensive and authoritative guide to the diagnosis and therapeutics of diseases involving platelets.

Our thanks go first of all to the authors who have accepted to spend a considerable amount of their busy time in writing their chapters, undergoing pressure to adhere to a tight time schedule and requests to revise and update their work. The preparation of this book would not have been possible without the help of our editorial assistants and of several coworkers in the Institutions of the individual editors. An excellent collaboration with some members of Cambridge University Press, in particular Richard Barling, Mary Sanders and Lucille Murby, has helped in pushing forward what, in some moments, seemed to be a titanic task in a reasonably rapid, though to us exasperatedly slow, way.

Looking back, having forgotten the long tiring hours spent on the project, the preparation of this book has been interesting, enriching and amusing to us; we hope it will also be so for the readers.

Introduction

In this chapter, we have concentrated on early observations that helped to open up new avenues of research, brought about greater understanding of hemorrhagic and arterial thromboembolic disorders, and in some instances led to new diagnostic methods and novel treatments for the complications of atherosclerosis. Over the years, technological developments have provided more and more tools for investigation. In the 1950s, electron microscopy began to reveal the fine structure of platelets, platelet aggregates, and thrombi. In the 1960s, aggregometers stimulated experiments with aggregating agents and their inhibitors; now, the pace has quickened with the introduction of flow cytometry, molecular biology techniques, monoclonal antibodies, genetically engineered animals and other new approaches.

Findings from research in other fields have frequently been applied to platelets, and knowledge about platelet functions has increased exponentially in the last 50 years. Time and time again, several groups almost simultaneously reported similar new results, but seldom has the rivalry been acrimonious. Some of the key players in the years between 1950 and 1980 have retired or are no longer with us, but this brief history mentions a few of the many contributions they made when the field was young.

Since other chapters will deal with recent findings, we have not attempted to provide a detailed history of the many new topics under investigation, such as the signalling pathways in platelets.

Platelets, hemostasis and thrombosis

In the nineteenth century, only microscopy was available for studies of platelets, which were first detected by Donné in 1842[1]. Although Wharton-Jones in 1852, and Zhan in 1875 described the formation of white thrombi in frogs, they thought that they were made up of leukocytes because thrombocytes in frogs are nucleated[2,3]. In 1882 Bizzozero[4] noted that, in guinea pigs and rabbits, platelets adhered to vascular lesions and to each other, forming a 'white thrombus', and Hayem[5] predicted that a low level of circulating platelets would lead to impaired hemostasis. This suggestion was soon shown to be true[6,7]. In 1885, Lubnitzky[8] pointed out that in flowing blood, platelets have the primary role in the formation of hemostatic plugs that arrest bleeding, and fibrin formation is only secondary. Although the similarities in the composition of hemostatic plugs and arterial thrombi had been recognized by early investigators, these findings were largely ignored until the middle of the twentieth century. They were eventually reemphasized by the Zuckers[9,10] in the late 1940s, and by French, Macfarlane and Sanders[11] in 1964.

Tocantins[12] published a major review of knowledge about platelets in 1938, but platelets were largely disregarded for many years until their contribution to the intrinsic coagulation pathway became of interest. Research during the 1940s and 1950s was focused on blood coagulation because of the need to regulate dosages of dicoumarin drugs[13]; new factors were discovered and eventually the cascade scheme of coagulation was developed by Macfarlane[14]. In it, the role of platelets was recognized as supplying the phospholipid needed for the interaction of factors V and Xa in the intrinsic pathway of coagulation.

However, in the middle of the twentieth century, it was

thought that anticoagulant drugs would inhibit arterial thrombosis as well as venous thrombosis by reducing fibrin formation, because many believed that arterial thrombi were largely blood clots. This idea began to be questioned and interest in platelets increased in 1948 when Duguid[15] revived the concept first developed 100 years before by von Rokitansky[16] that incorporation into the vessel wall of mural thrombi consisting of platelets and fibrin played a role in the development of atherosclerotic lesions. Fisher's observation in 1959 of platelet-rich embolic material passing through retinal vessels during transient monocular blindness[17] further emphasized the importance of platelet thromboemboli in the complications of atherosclerosis. It became clear that studies of the mechanisms involved in platelet adhesion, aggregation, and participation in blood coagulation were relevant to understanding the formation of arterial thrombi and their stability, organization and eventual resolution, as well as the formation of hemostatic plugs and their stability.

Platelets and the endothelium

The conclusion that platelets maintain the integrity of capillary endothelium was derived from perfusion experiments of Danielli[18], and later of Gimbrone and coworkers[19], as well as from several other approaches. In the 1950s, the findings that platelet transfusions controlled the hemorrhagic phase of postirradiation syndromes[20,21] gave credence to Danielli's observation. In other studies by Cronkite and coworkers, autoradiograms of capillaries of X-irradiated rats that had been injected with platelets that were heavily labelled with radioactive sulfur indicated that platelets (or ^{35}S-mucopolysaccharides derived from platelets) were deposited along the capillary walls[22]. Later studies clearly showed that red blood cells and a variety of particles in the circulation crossed capillary walls in thrombocytopenic animals; this did not occur in animals with normal platelet counts[23–25]. The ultrastructural changes of the endothelium that occurred in thrombocytopenia were reversed by platelet transfusions[25,26]. The mechanisms by which platelets support endothelial integrity were explored by Johnson and colleagues[23,27,28], but as Jaffe has pointed out[29], the molecular basis of this important physiological function is still not totally clear.

Platelets and vessel injury

Platelets do not adhere to undamaged endothelium, but when a vessel wall is injured, platelets adhere almost instantaneously – well before fibrin forms[9,10]. In 1959, Bounameaux[30] observed platelet adhesion to subendothelial fibers that were soon shown to be collagen[31]. Zucker and Borrelli[32] reported platelet aggregation in vitro by connective tissue or collagen, and Hovig[33] demonstrated that the aggregating agent ADP was released from platelets stimulated with a saline extract of tendons. Inhibition of collagen-induced aggregation by aspirin was observed in 1967[34–36], and in 1974 and 1975 shown to be due to inhibition by aspirin of the production of prostaglandin endoperoxides and thromboxane A_2 which platelets form when they adhere to collagen[37,38]. It became apparent that ADP and thromboxane A_2 from adherent platelets stimulated platelets flowing by to stick to the adherent platelets and to each other, forming a hemostatic plug or thrombus.

In comparing hemostatic plug formation in normal dogs and dogs with congenital deficiences of coagulation factors, Hovig and colleagues in 1967 observed that the formation of fibrin around the initial mass of aggregated platelets was crucial in stabilizing the plug and preventing rebleeding[39]. This observation indicated the importance of localized thrombin formation around the aggregated platelets at the injury site. Earlier, Jørgensen and Borchgrevink[40] had observed that, in hemophilic subjects, although the time for formation of a hemostatic plug was not appreciably greater than in normal subjects, prolonged rebleeding occurred when the initial hemostatic plug was dislodged, indicating a change in the injured vessel wall (or the platelets adherent to it) that inhibited further platelet accumulation. In accord with this concept, in 1979, Groves and colleagues[41] used ^{51}Cr-labelled platelets to show that following removal of the endothelium from the rabbit aorta, an initial monolayer of platelets formed on the subendothelium, but the number of adherent platelets gradually decreased and the surface attracted fewer and fewer fresh platelets. The reasons for this development of nonthrombogenicity of an injured vessel wall are unknown, but may be relevant to attempts to prevent thrombosis on vascular grafts and in arteries injured by other procedures.

The pattern of blood flow in the arterial circulation determines the events subsequent to platelet adherence at an injury site[42]. In animal experiments in which a vessel wall was injured diffusely, it was shown that only a thin layer of adherent platelets formed when blood flow was laminar, but in regions of disturbed flow, large platelet-rich thrombi formed[43–46].

In 1973, Baumgartner used balloon catheterization to remove the endothelium of rabbit aortas and developed an apparatus in which he could assess the adherence of platelets in flowing, human blood to the subendothelium[47]. In further studies, his group showed platelets adherent to

Cambridge Books Online © Cambridge University Press, 2009

several components of the subendothelium, including collagen[48], and found that platelets from patients with von Willebrand's disease[49] or Bernard–Soulier syndrome[50] adhered poorly.

It was not until the late 1970s that the role of plasma von Willebrand factor in platelet adherence to collagen and the subendothelium under conditions of high shear was recognized[51–54]. (At that time, von Willebrand factor had not been separated from factor VIII, and was often referred to as factor VIII or factor VIII-related antigen.) In accord with these observations about platelet adherence, in 1978 Fuster's group at the Mayo Clinic demonstrated that in pigs with von Willebrand disease platelet adherence to the vascular wall was impaired and the pigs were resistant to the initiation and progression of atherosclerosis[55]. In addition, the pigs had a very severe bleeding tendency.

Fate of arterial thrombi and atherosclerosis

von Rokitansky[16] and Virchow[56] were early investigators who reported that in some instances, the development of atherosclerosis involved vessel wall injury, thrombosis, and the incorportation of thrombi into the vessel wall. In 1887, Welch[57] gave a clear description of arterial thrombi, based on the experiments of a number of investigators, showing that they begin as platelet-rich thrombi and are then transformed into masses rich in fibrin. Much later, these observations were reinforced by Duguid[15], Morgan[58], More and Haust[59] and French[60]. In the 1960s, we observed that platelets were deposited on, and interacted with, the walls of arteries in regions of disturbed blood flow[61–63]; these are sites where atherosclerotic lesions develop and increased vessel permeability is demonstrable.

In 1973, Moore[64] induced 'thromboatherosclerosis' in rabbits by continuous damage of the endothelium of the aorta with an indwelling catheter, and in 1976, he and his group showed that prior administration of anti-platelet serum to induce thrombocytopenia prevented the development of these lesions[65]. The finding by Ross and his colleagues[66] in 1974 that stimulated platelets release a mitogen for smooth muscle cells (platelet-derived growth factor, PDGF) arose from a chance observation. They noticed that serum prepared from platelet-free plasma did not support the proliferation of smooth muscle cells in culture, but when they prepared serum by clotting platelet-rich plasma, the serum supported cell growth as effectively as serum prepared from whole blood. These results gave even more credence to the theory that platelets are involved in the development of atherosclerotic plaques because they promote the proliferation of smooth muscle cells.

The progression of atherosclerotic plaques also involves platelets since platelet-rich thrombi have been shown to be incorporated into the vessel wall at sites of injury[15,59,67]. Platelet-rich thrombi that form on ruptured atherosclerotic plaques may occlude the lumen of a vessel, or may embolize. When the thromboemoli impact in smaller, downstream vessels, organ damage occurs[68–70].

These concepts about platelets and atherosclerosis have stood the test of time. The picture developed by Ross[71] of the development of an atherosclerotic plaque is now well known, and the signalling pathways PDGF activates are being explored[72]. The importance of platelet interaction with the components of ruptured atherosclerotic plaques in the thromboembolic complications of atherosclerosis is now generally accepted[73].

Clot retraction

One of the earliest recorded observations, eventually shown to be a function of platelets, was clot retraction, described by Hewson in the late eighteenth century[74]. About 100 years later, in 1878, Hayem reported that platelets had a tendency to change their form, aggregate, and interact with fibrin strands[75]. Although he called platelets 'hématoblastes' because he thought they were precursors of erythrocytes, he counted them accurately and described their role in clotting and in clot retraction. In 1906, Le Sourd and Pagniez[76] established the unique ability of platelets to cause clot retraction. This early history was reviewed by Budtz-Olsen[77] in 1951, in connection with his studies of clot retraction, and in the same year, Øllgaard[78] described using clot retraction as a quantitative test of the function and agglutinability of platelets. Bettex-Galland and Lüscher[79] later showed that metabolic energy was required for clot retraction.

Source of platelets

For many years after the discovery of platelets there was considerable disagreement about their source. Wright's work in the early 1900s with stained sections of tissue and supravital preparations, provided the first evidence that platelets were derived from megakaryocytes[80,81], but it was the work of Humphrey[82] in 1955, on the basis of studies with fluorescent antibodies, that provided irrefutable evidence that the megakaryocyte was the precursor cell of platelets. Finally, Kinoshita and colleagues[83] in 1961 developed a technique for placing windows in bone that allowed the marrow to grow in the thin space between the windows

Cambridge Books Online © Cambridge University Press, 2009

where platelet production from megakaryocytes could be observed directly.

Thrombopoietin

Although the existence of a substance responsible for controlling platelet production (thrombopoietin, TPO) had been postulated for many years, all attempts to isolate it had failed. In 1992, the proto-oncogene c-mpl was cloned, leading to the identification of TPO. In 1994, five groups were able to either purify TPO or clone the cDNA. Since then, there has been an impressive amount of research on this topic, reviewed by Kaushansky[84] in 1999.

Platelet lifespan

The initial approaches used to determine platelet lifespan fall into three main categories: (i) Depletion studies, in which thrombocytopenia was induced and the rate of platelet regeneration determined[85]; (ii) Transfusion studies in which normal platelets were transfused into thrombocytopenic individuals and the platelet count monitored[86,87] (this gave considerable variability in assessments of lifespan depending on the nature and extent of the thrombocytopenia); and (iii) Labelling techniques in which various radioisotopes were introduced into platelets and the length of time that radioactivity remained in the circulation was measured. More recently, particularly in infants, a return of the ability of platelets treated with aspirin to produce malondialdehyde was used to measure platelet survival[88]. The most commonly used method now involves labelling with ^{51}Chromium[89] or ^{111}Indium[90].

It is now generally accepted that the normal lifespan of platelets in humans is 9–11 days, but it is not clear whether this is a measure of the role of platelets in maintaining the integrity of the vascular tree. Thrombin-induced release of granule contents in vivo or in vitro does not shorten platelet survival[91,92], but when platelet membrane glycoproteins have been cleaved by proteolytic enzymes the platelets do not survive in the circulation[93]. Platelet survival tends to be shortened in individuals with diseases associated with thrombosis and thromboembolism[94,95].

The controversy over the question of how platelet survival curves should be analysed (linear or exponential) was settled in 1971 when Murphy and Francis introduced the gamma function method of calculation and the International Committee for Standardization adopted it[96,97].

Platelet transfusion

The first transfusion in man is said to have been carried out in 1667 by Jean Baptiste Dennis who transfused a young man with the blood of a lamb[98]. Italian physicians in the early part of the twentieth century are known to have employed blood transfusions for the treatment of thrombocytopenic purpura, but since anticoagulants were not available at that time, transfusion was performed with paraffin-coated syringes. Gradually, there were improvements in transfusion techniques to avoid activation of platelets. These included the introduction of silicones to provide non-wettable surfaces for glass containers, differential centrifugation techniques under temperature control for the separation of blood components, the introduction of plastic containers, and refinement of the composition of anticoagulant solutions[99]. The conditions of storage have been readjusted frequently to provide incremental improvements in the viability and function of platelet concentrates for transfusion[100].

Isolation of platelets

In the early 1970s, we developed methods to isolate platelets, wash them, and resuspend them in artificial media so that they retain most of the properties of platelets in plasma[101,102]. Important conditions were determined to be the choice of anticoagulant, use of a balanced salt solution (Tyrode's) containing a physiological concentration of calcium, a source of metabolic energy (glucose), inclusion of a system (e.g. apyrase) to remove ADP that leaks from the platelets, and the addition of a protective protein (albumin)[103].

Platelets have also been separated from plasma on an albumin gradient[104] or by gel filtration[105–107].

Since the artificial media in which platelets are resuspended can be readily modified, and the formation of fibrin does not interfere with studies involving thrombin, these isolation techniques have allowed considerable advances in the elucidation of the mechanisms underlying platelet functions.

Platelet aggregation and platelet receptors

Up until 1963, platelet aggregation was observed by visual or microscopic examination of platelet-rich plasma when it was shaken with an aggregating agent. In 1962 Born[108] published his paper describing the development of the platelet aggregometer and shortly thereafter O'Brien[109]

Cambridge Books Online © Cambridge University Press, 2009

Table 1.1. Highlights of platelet research

Year	Event
1842	Platelets detected microscopically
1882	Platelet adherence to damaged blood vessels and aggregation
1882	Thrombocytopenia shown to impair hemostasis
1885	Platelets shown to have primary role in formation of hemostatic plugs
1906	Platelets shown to be derived from megakaryocytes
1906	Platelets shown to cause clot retraction
1918	Glanzmann's thrombasthenia recognized
1938	Major review by Tocantins
1948	Incorporation of thrombi into vessel wall shown to be involved in the development of atherosclerotic lesions
1948	Bernard-Soulier syndrome described
1950s	Electron microscopy began to reveal the fine structure of platelets
1950s	Serotonin recognized as a platelet constituent taken up from plasma
1950s	Platelets shown to maintain integrity of capillary endothelium
1959	Platelets shown to contain a contractile protein – thrombosthenin
1959	Transient monocular blindness due to platelet emboli
1959	Platelets shown to adhere to collagen
1961	ADP from red cells identified as an aggregating agent
1962	Aggregometer based on light transmission developed
1963	Collagen and thrombin shown to release ADP from platelets
1963	Epinephrine shown to aggregate platelets
1964	Introduction of use of ^{14}C-serotonin to measure release of granule contents
1967	Aspirin shown to inhibit collagen-induced aggregation and release
1967	Stimulated platelets shown to give rise to microparticles
1967	Prostaglandin E_1 shown to inhibit aggregation
1970	Storage pool disease recognized
1971	Agglutination of platelets by ristocetin developed as a means of detecting vWD and later, Bernard-Soulier syndrome
1971	Aspirin shown to inhibit formation of prostaglandins in platelets
1972	Platelet-activating factor (PAF) recognized
1972	Methods developed for isolation and resuspension of platelets in artificial media
1973	Arachidonic acid shown to aggregate platelets

Year	Event
1974	Role of phosphoinositides in platelet functions recognized
1974	Release of platelet-derived growth factor (PDGF) by stimulated platelets
1974	Abnormal glycoprotein pattern noted in thrombasthenia platelets
1975	Thromboxane A_2 found to be an aggregating agent whose formation is inhibited by aspirin
1975	Ticlopidine developed as an inhibitor of ADP-induced aggregation
1976	Prostacyclin (PGI_2) identified as a strong inhibitor of platelet reactions
1970s	Plasma von Willebrand factor implicated in platelet adherence to collagen and the subendothelium under conditions of high shear
1978	Fibrinogen shown to bind to platelets during aggregation
1979	Identification of a patient with a defect of platelet procoagulant activity (Scott syndrome)
1980	Investigations of receptors, G-proteins, signalling
1981	Fibrinogen receptor identified as glycoprotein IIb/IIIa (αIIbβ3)
1982	Fibrinogen γ-chain identified as a binding site for platelets
1982	Fluorescent indicators used for measurement of cytosolic calcium
1983	Monoclonal antibodies to GPIIb/IIIa developed
1984	P-selectin identified as an α-granule constituent that can be detected by flow cytometry on the platelet surface after stimulation
1985	Peptides with RGD sequence shown to inhibit binding of fibrinogen and vWf to platelets
1986	Defects in collagen receptors on platelets identified
1988	Meta-analysis of 25 clinical trials of non-steroidal anti-inflammatory drugs show 25% reduction in risk of a thromboembolic event
1991	Thrombin shown to activate platelets by cleavage of a protease-activated receptor
1992	Identification of a patient with platelets unresponsive to ADP
1994	Thrombopoietin purified
1990s	Many inhibitors of fibrinogen binding to platelets entered clinical trials
1990s	Three ADP receptors identified

Cambridge Books Online © Cambridge University Press, 2009

described a similar device. As a result, it became possible to assess the rapidity and extent of aggregation by recording changes in light transmission through a stirred suspension of platelets. Almost immediately, other investigators adopted this technique and during almost 40 years it has had the major role in tens of thousands of studies of aggregating agents, inhibitors of aggregation, and conditions that influence aggregation.

Thrombin

Eberth and Schimmelbusch[110] in 1888 and Wright and Minot[111] in 1917 used the term 'viscous metamorphosis' to describe the changes in platelets when they stick to surfaces and to each other. Because thrombin induced these changes, it was originally thought that fibrin formation was involved in platelet-to-platelet adherence[112]. It was not until 1946 that this concept was questioned by Pinniger and Prunty[113] who showed that thrombin aggregated platelets in the blood or platelet-rich plasma of patients with afibrinogenemia. Following the demonstration by Gaarder and her colleagues[114] that ADP from red cells could cause platelet aggregation and Grette's observation that thrombin induces the release of ADP from platelets[115], Haslam suggested that released ADP was responsible for thrombin-induced aggregation[116]. This conclusion was based on his observation that enzymatic removal of ADP was inhibitory. However, other investigators, including ourselves[117], showed that thrombin could aggregate platelets even when released ADP was removed and thromboxane A_2 formation was blocked with aspirin or indomethacin. This observation led to the concept of a 'third pathway' responsible for thrombin-induced aggregation. At one time, formation of platelet-activating factor (PAF) by thrombin-stimulated platelets was considered as a candidate for this role[118], but further studies have not supported this suggestion[119,120].

It was not until 1991 that the way in which thrombin stimulates platelets was elucidated by Coughlin's group[121]. They obtained evidence for a unique protease-activated receptor, now designated PAR-1. The finding that platelets from some species did not respond to the newly exposed peptide, SFLLRN, whereas human platelets did so[122,123], indicated that there might be other receptors for thrombin, and Coughlins's group has now identified PAR-3 on mouse platelets and PAR-4 on mouse and human platelets. The development of knowledge about these receptors has been reviewed recently by Coughlin[124].

Collagen

Interest in collagen as an aggregating agent arose from observations in the early 1960s that, when blood vessels were injured, platelets adhered to collagen[30,31] and in doing so, released ADP[32,33]. Aspirin inhibited collagen-induced aggregation[34–36], an effect shown to be caused by inhibition of cyclo-oxygenase[125]. It became apparent that platelets adherent to collagen were stimulated to release ADP and form thromboxane A_2, and that these aggregating agents acted synergistically to cause aggregation of the non-adherent platelets[117].

The nature of the collagen receptor on platelets has been controversial with GPIa/IIa, GPVI and GPIV as candidates. Hemostasis is impaired in patients with a deficiency of GPIa/IIa[126] or GPVI[127], but a defect in GPIV does not lead to hematologic problems[128]. The current concept is that both GPIa/IIa and GPVI are involved in platelet adherence to collagen[129,130]. (See Chapter 11.)

ADP

The finding by Hellem[131] and by Øllgaard[132] that a factor from red blood cells caused platelet aggregation was quickly followed in 1961 by its identification as ADP by Gaarder and her coworkers[114] in Owren's Institute for Thrombosis Research in Oslo. At first ADP was considered to be the factor responsible for aggregation by all the agonists that caused its release from platelets[116]. Later, it became apparent that this concept was untenable, although the role of released ADP in potentiating aggregation by collagen, thrombin and other release-inducing agents is well accepted.

In some species (including man), ADP-induced aggregation was observed to occur in two phases in citrated platelet-rich plasma[133–135], the second phase being associated with the release of serotonin and ADP[133–137], and not readily reversible. (Subsequent studies showed that thromboxane A_2 formed under these conditions was responsible for secondary aggregation[138].) However, there were several observations showing that ADP-induced aggregation in vivo was reversible[69,133,139], leading to the suggestion by Mustard and Packham[140] in 1970 that 'this apparent ability of ADP to induce irreversible platelet aggregation in vitro may be an artifact of the experiments'. In 1975 we reported that the low calcium concentration produced by the use of citrate as the anticoagulant was responsible for the second phase of ADP-induced aggregation[141]; it does not occur in platelet-rich plasma from blood anticoagulated with heparin, hirudin or PPACK[142,143]. Nevertheless, because so

Cambridge Books Online © Cambridge University Press, 2009

many studies of platelet aggregation are done in citrated platelet-rich plasma, the notion has persisted that ADP causes extensive release of granule contents and the formation of thromboxane A_2. Failure to understand this artefact has sometimes led to misleading conclusions.

In the early 1970s, two groups[144,145] reported that ADP inhibits the increase in cyclic AMP caused by exposure of platelets to prostaglandin E_1; the ADP receptor responsible for this down-regulation of adenylyl cyclase has been identified recently[146]. It is now known that metabolites of the thienopyridine derivative, ticlopidine, and its analogue, clopidogrel, which are specific inhibitors of primary ADP-induced aggregation[147–149], irreversibly block this ADP receptor[150–152]. The unstable, active metabolite of clopidogrel has recently been identified[153]. Clinical trials of these drugs have been carried out[154–156] (See Chapters 9 and 62).

Following the discovery of individuals whose platelets do not aggregate in response to ADP[157], interest intensified in ADP receptors, three of which have been identified (Chapter 9).

Arachidonic acid and thromboxane A_2 (TXA_2)

Aggregation by arachidonic acid was reported in 1973 by Silver and colleagues[158] and shown to be due to its conversion to PGG_2, PGH_2 and TXA_2[38,125]. Receptors for these products have been characterized (Section 1, Chapter 9) and some abnormalities have been identified.

Serotonin

The flurry of interest in serotonin began in the 1950s when Rand and Reid[159] discovered that platelets contained it. Serotonin was shown to be released from platelets by Bigelow[160] and by Zucker and Borrelli[161] and actively taken up by them[162,163] into the dense granules[164,165]. Platelets carry all the serotonin in blood. Serotonin was demonstrated to be a weak aggregating agent by Mitchell and Sharp[166] in 1964, and to act synergistically with other agonists by Baumgartner and Born[167] in 1968. The extensive research on serotonin up to 1970 was summarized by Mustard and Packham[140]. At that time, platelets were beginning to be recognized as a model for serotonergic neurons[168].

Epinephrine (adrenaline)

In the early 1960s, O'Brien[169] and Mitchell and Sharp[166] discovered that epinephrine and norepinephrine caused platelets to aggregate in two phases in citrated human platelet-rich plasma. Haslam[170] examined the role of ADP in epinephrine-induced aggregation and concluded that ADP was involved in both phases.

The ability of epinephrine to potentiate aggregation by other agonists was first noted by Ardlie and colleagues[171] in 1966 and further documented in 1967 by Mills and Roberts[172]. It is now apparent that epinephrine by itself is not an aggregating agent, but acts in a strong, synergistic fashion with other aggregating agents[173,174].

Epinephrine acts by stimulation of alpha adrenergic receptors[172,175] and causes a decrease in cyclic AMP in platelets if its concentration has been raised by prostaglandin E_1[176].

Platelet activating factor (PAF)

In 1972 Benveniste, Henson and Cochrane[177] introduced the term 'platelet-activating factor' for the soluble factor, released from basophils upon IgE stimulation, that caused aggregation and release by rabbit platelets. Seven years later, Hanahan's group identified PAF as a phosphoacyl glycerol[178]. Although human platelets are aggregated by PAF, the concentration required is much higher than for aggregation of rabbit platelets[119,179]. PAF is synthesized by rabbit platelets when they are stimulated by thrombin, but it does not appear to play a part in thrombin-induced aggregation of human platelets[119,120]. The PAF receptor has been investigated by Izumi and Shimizu[180].

Ristocetin, von Willebrand factor, and glycoprotein I

Ristocetin was withdrawn from clinical use as an antibiotic because many patients who received it became thrombocytopenic. In 1960, Gangarosa and colleagues[181] noted aggregation of platelets in vitro upon the addition of ristocetin, but it was not until 1971 that Howard and Firkin[182] confirmed this observation and introduced ristocetin as 'a new tool in the investigation of platelet aggregation'. They showed that ristocetin could be valuable in subdividing types of von Willebrand disease. Platelets fixed with paraformaldehyde agglutinate in response to ristocetin in normal plasma (but not in plasma from patients with some types of von Willebrand's disease) and this reaction has become a standard clinical test for von Willebrand's disease[183].

In 1973, two groups reported that platelets from patients with Bernard–Soulier syndrome (BSS)[184] did not aggregate

Cambridge Books Online © Cambridge University Press, 2009

in response to ristocetin[185,186]. Weiss and coworkers[50] suggested that BSS platelets lacked a receptor for von Willebrand factor involved in platelet adherence, and in 1975, Nurden and Caen[187] reported that a major glycoprotein (GPI) was not visible among the membrane proteins of platelets from patients with BSS. The current state of knowledge about BSS has been reviewed recently by López and colleagues[188].

Fibrinogen, von Willebrand factor, and GPIIb/IIIa

Although it was known as early as 1964 that fibrinogen was required for ADP-induced aggregation of human platelets[189,190], it was not until 1978 that we reported the rapid association and dissociation of radiolabelled fibrinogen during ADP-induced platelet aggregation and deaggregation[191]. The concept was developed that ADP induces a saturable receptor for fibrinogen on human platelets[192–194] which is missing on the platelets of patients with Glanzmann's thrombasthenia[195]. Nurden and Caen[196] had already noted an abnormal glycoprotein pattern in the membranes of platelets from patients with this disorder. In 1981, the fibrinogen receptor was identified as GPIIb and IIIa forming a calcium dependent complex on the surface of activated platelets[197,198]. Meanwhile, Pierschbacher and Ruoslahti[199] had identified Arg–Gly–Asp (RGD) as the amino acid sequence in the cell binding domain of fibronectin responsible for its attachment to fibroblasts. This RGD sequence also occurs in both fibrinogen[200] and von Willebrand factor[201] and peptides containing this sequence were shown by several groups to inhibit the binding of these proteins to activated platelets[202–204]. A different binding site for GPIIb/IIIa on fibrinogen had been found at the C-terminus of the gamma chain, which includes the dodecapeptide sequence 400–411[205], and it now appears that it is more important for the binding of fibrinogen to human platelets than is the RGD sequence, as shown by Farrell and colleagues[206,207] using mutant fibrinogen molecules. The result of the finding about the inhibitory effect of RGD peptides has been the development of drugs containing this sequence as inhibitors of platelet aggregation in patients during percutaneous coronary intervention or as treatment of acute coronary syndromes[208].

Another approach to inhibition of platelet aggregation began in 1983 from the use by Coller and his colleagues[209] of hybridoma technology to produce monoclonal antibodies to GPIIb/IIIa (10E5 and 7E3). In 1995, Coller[210] reviewed the development of a mouse/human chimeric monoclonal antibody fragment (c7E3 Fab, abciximab, ReoPro™) for use in patients to reduce complications after angioplasty. Clinical trials of its efficacy have been carried out[208].

Platelets in infectious diseases and immune reactions

For many years there has been considerable interest in platelet interactions with tumor cells, antigen–antibody complexes, viruses, bacteria and bacterial products such as endotoxin. These subjects have been reviewed elsewhere[94,211], and are discussed in Section III.C.

Platelet granules and the release reaction

Although it is now known that platelets have three main types of storage granules – dense or amine storage granules containing adenine nucleotides, serotonin and divalent cations; alpha granules containing many proteins; and lysosomal granules containing acid hydrolases – in the early days these distinctions had not been made.

In the 1950s, serotonin was the first substance to be recognized as originating from platelets during blood coagulation[160,212]. Then Humphrey and Jaques[213] noted the release of histamine and serotonin from platelets by antigen-antibody reactions. Grette[115] observed thrombin-induced release of serotonin, adenine nucleotides and fibrinogen in 1962 and introduced the term 'release reaction'. Zucker and Borrelli[32] and Hovig[33] reported collagen-induced release of ADP, and in 1964, Spaet and Zucker[214] showed that collagen also released ^{14}C-serotonin previously taken up in vitro. This method of measuring the extent of the release of dense granule contents has been widely used ever since.

Haslam[116,170] was the first to draw attention to the role of the release reaction; he showed that when an extracellular ADP-removing system was present, aggregation by several agents was inhibited, thus obtaining evidence that released ADP was responsible for aggregation. Haslam also proposed that ADP was released directly and was not the product of hydrolysis of ATP. In 1964, Buckingham and Maynert[215] suggested that the substances released had different subcellular localizations from those retained, and in keeping with this suggestion, in 1967 Ireland[216] showed that thrombin induced the release of metabolically inactive nucleotides while the active ones were retained by the platelets. Mills and his colleagues[137] showed that ADP was released during the second phase of ADP-induced aggregation. Three groups reported that strong aggregating

Cambridge Books Online © Cambridge University Press, 2009

agents (but not ADP or epinephrine) caused the release of lysosomal enzymes[137,217,218]. In 1969, release of platelet factor 4 and calcium were reported[219,220], and a major review about the release reaction was written by Holmsen, Day and Stormorken[221]; they pointed out that the process consists of extrusion of material from the platelet granules to the external medium in a process similar to secretion. At that time it was known that the metabolically inert adenine nucleotides were located in the dense granules, but lysosomal enzymes were thought to be in α-granules that had been differentiated from dense granules by electron microscopy. In 1977, Fukami and Salganicoff[222] reviewed the evidence for the various types of storage organelles in platelets, pointing out that in addition to dense granules and alpha granules, there may be at least two types of lysosomal granules.

A hereditary defect caused by a deficiency in the storage pool of adenine nucleotides (storage pool disease) was discovered by Holmsen and Weiss[223] in 1970. Subsequently, a number of congenital abnormalities of granule contents or their release have been identified.

Mustard and coworkers[224] reported release of a permeability factor in 1965, and in 1974 Ross and his colleagues[66] discovered that a platelet-derived growth factor (PDGF) for smooth muscle cells was released from blood platelets upon clotting of blood or platelet-rich plasma.

The finding in the mid-1980s that an alpha granule membrane protein (PADGEM, GMP 140, P-selectin, CD62P) appeared on the surface of platelets as their contents were released[225–227] has led to its detection by flow cytometry as a means of determining the extent of release of alpha granule contents[228]. P-selectin has been shown to mediate adhesion of platelets to neutrophils and monocytes[229].

Platelet procoagulant activity, PF3, and microparticles

Activated platelets contribute to coagulation by providing a catalytic phospholipid surface for the 'tenase' and 'prothrombinase' reactions. As early as 1936, Chargaff and coworkers[230] demonstrated that a phospholipid fraction from horse platelets accelerated clotting in cell-free chicken plasma, but this finding was ignored, possibly because of the cross-species complication. It was not until the early 1950s that van Crevald and Paulssen[231,232] and Alkjaersig, Abe and Seegers[233] studied the role of platelets in coagulation and called the procoagulant material platelet factor 3 (PF3, now known as platelet procoagulant activity or PCA). For some time there was debate about how this activity became available on the surface of platelets since it appeared to be masked on intact platelets[234]. In 1965, Hardisty and Hutton[235] concluded that adhesion of platelets to an activating surface was necessary for an optimal effect, and that ADP-induced aggregation alone did not make PF3 available. In the same year, Spaet and Cintron[236] showed that connective tissue particles caused platelets to develop PF3 activity. Later, Joist and colleagues[237] used washed platelets in an artificial medium to demonstrate that PF3 becomes available on the surface of platelets that have undergone a release reaction.

In the 1980s, phosphatidyl serine (PS) was identified as responsible for the procoagulant activity of stimulated platelets[238,239], and the evidence obtained from experiments with red cells was applied to platelets regarding the asymmetric nature of membrane phospholipid distribution. Between 1987 and 1996, three enzymes – an ATP-dependent translocase, a floppase, and a scramblase – were shown to be responsible for transbilayer movement of phospholipids and the exposure of PS on the surface of stimulated platelets[240–243]. The identification in 1979 by Weiss and coworkers of a patient with a defect in platelet procoagulant activity (Scott syndrome) has contributed significantly to our understanding of these mechanisms[244,245].

A characteristic event that accompanies the availability of platelet procoagulant activity is the shedding of membrane-derived microvesicles or microparticles from the surface of activated platelets. Although these microparticles were reported by Wolf[246] in 1967, only a few investigators took an interest in them[247–249] until Sims and his group[250] in 1988 began investigating the effect on platelets of the membrane attack complex of the complement system (C5b-9) and found that membrane vesicles were released. These microparticles provided a catalytic surface for the prothrombinase complex and were highly enriched in alpha-granule-derived factor V (or Va); they also contained GPIb, GPIIb/IIIa and P-selectin. Microparticles are also formed when platelets are stimulated with the calcium ionophore A23187, or with the combination of thrombin and collagen[251], and they have been detected in the blood of patients exhibiting intravascular platelet destruction[252]. Flow cytometry has facilitated the study of microparticles[228]. It has been speculated that since microparticles possess many of the properties of intact platelets, they might be stored and transfused as agents promoting hemostasis[253].

Aspirin

Although prolongation of the bleeding time by aspirin had been recognized as early as 1955 by Beaumont and coworkers[254], and then by others[255,256], including Quick in 1966[257], it was not until 1967 that several groups of investigators reported that aspirin inhibited platelet aggregation and the release of granule constituents.

Our group's involvement in the discovery of the inhibitory effect of aspirin on platelet aggregation began as the result of serendipity. In 1963, we were measuring platelet survival times in elderly, atherosclerotic World War I veterans, many of them suffering from gout[258]. Upon examining the data, we realized that those who were taking the uricosuric agent sulfinpyrazone had longer platelet survival times than those who were not receiving this medication. We then showed that administration of sulfinpyrazone prolonged shortened platelet survival and reduced platelet adhesiveness to glass[259]. This finding led to in vitro tests of the effect of the pyrazole compounds, sulfinpyrazone and phenylbutazone, on platelet aggregation induced by several agonists, and the discovery that these non-steroidal anti-inflammatory drugs blocked aggregation induced by collagen, antigen–antibody complexes and gamma globulin-coated surfaces and inhibited release of adenine nucleotides, although the drugs did not affect the primary phase of ADP-induced aggregation[260]. In addition, with rabbits, intravenous infusion of sulfinpyrazone or phenylbutazone impaired hemostatic plug formation at the ends of transected mesenteric vessels[260,261]. Since aspirin was a well-known anti-inflammatory drug, we tested it in vitro and reported similar inhibitory effects in June of 1967 at the Oak Ridge Platelet Symposium[34]. (A full paper about these findings was published in 1968[35].) At this time, Weiss and Aledort[36] were following up on Quick's[257] observation of prolonged bleeding times in subjects who had taken aspirin, and observed that aspirin ingestion impaired collagen-induced aggregation and inhibited release of ADP. Also in 1967, Zucker and Peterson[262] noticed that the second phase of ADP-induced aggregation did not occur in citrated platelet-rich plasma from individuals who had consumed aspirin, and O'Brien[263] found that epinephrine-induced aggregation in citrated platelet-rich plasma was also inhibited; this inhibitory effect persisted for 2–6 days after ingestion of a single subclinical dose. Although it was known from experiments with ^{14}C-labelled acetylsalicylic acid in 1969 that a protein in platelets was acetylated by aspirin[264], it was not until 1975 that Roth and his colleagues[265] demonstrated irreversible acetylation of cyclooxygenase by aspirin, thus accounting for the persistence of the aspirin effect.

In the early 1990s, it was recognized that there are two isoforms of cyclooxygenase, a constitutive form, COX-1, and an inducible form, COX-2. Only COX-1 is present in platelets, whereas COX-2 is expressed in other cells after an inflammatory insult. Aspirin and other non-steroidal anti-inflammatory drugs inhibit both COX-1 and COX-2, but drugs have now been developed that selectively inhibit COX-2, for the treatment of arthritis and possibly other conditions[266].

With the realization that platelet aggregation could be inhibited by sulfinpyrazone or aspirin, large scale clinical trials were launched in the early 1970s, before there was a thorough understanding of the enzymatic reactions in platelets that were inhibited by these drugs. The earliest trials varied in their designs, but they all involved male subjects who had already suffered from myocardial infarction, and the end points were short term reinfarction or death[267]. Later trials of secondary prevention enrolled patients who had a history of stroke, transient cerebral ischemia, myocardial infarction, or unstable angina. By the late 1980s, it was calculated that meta-analysis of 25 trials showed that aspirin caused a 25% reduction in the risk of developing a subsequent important vascular event[268,269]. Interestingly, these clinical trials were well under way before it was discovered that in the 1950s, Craven[270,271] had reported in the *Mississippi Valley Medical Journal* that aspirin prevented coronary and cerebral thrombosis. He had studied approximately 8000 men taking 5 to 10 grains of aspirin daily.

Aspirin is now routinely administered to patients at risk of the thromboembolic complications of coronary artery disease. The demonstration by Barnett and colleagues that aspirin reduced the incidence of transient ischemic attacks and ischemic stroke[272] has led to its continued use in this condition also[273]. However, there has been controversy over the most suitable dose of aspirin, with suggestions of as little as 40 mg every other day as an appropriate dose.

Prostaglandins

While the findings that sulfinpyrazone and aspirin inhibited platelet aggregation were unfolding, research on prostaglandins was accelerating although, initially, it did not involve platelets. Prostaglandins had been isolated from human seminal plasma and sheep seminal vesicles in the early 1930s and crystallized in 1957[274]. The prostaglandins are formed from polyunsaturated fatty acids. It was not until 1967 that there were reports of PGE_1 inhibiting platelet aggregation[275–277]; it was shown to increase cyclic AMP in platelets by stimulation of adenylyl cyclase[278]. Zucker[279]

Cambridge Books Online © Cambridge University Press, 2009

had reported in 1965 that cyclic AMP inhibited platelet aggregation and the release reaction.

However, PGE_1 is not produced by platelets; it was PGE_2 and $PGF_{2\alpha}$ that were first detected as being formed by platelets during aggregation, and neither of them caused platelet aggregation[280]. In 1969, Piper and Vane[281] reported that formation of an unstable 'rabbit aorta contracting substance' (RCS) from sensitized guinea pig lungs was inhibited by aspirin-like drugs; the activity of this short-lived substance was later shown to be due to prostaglandin endoperoxides[282], designated PGG_2 and PGH_2[125]. Two publications showing that aspirin inhibited the formation of prostaglandins were published simultaneously in 1971[283,284], although only one of them dealt with platelets[283]. In 1973, arachidonic acid was reported to aggregate platelets[158], and platelets aggregated by arachidonic acid were shown to release RCS[285]. In 1974, three groups showed that the endoperoxides PGG_2 and PGH_2 were formed by platelets and released into the medium upon stimulation by collagen, epinephrine, arachidonic acid, or thrombin[37,125,286,287]. Also in 1974, Hamberg and his colleagues isolated and determined the structure of PGG_2 and PGH_2 that cause platelet aggregation and proposed that aspirin inhibited the cyclooxygenase responsible for their formation[125]. In 1975, Hamberg and his coworkers identified thromboxane A_2 as a short-lived, potent inducer of platelet aggregation that was derived from the prostaglandin endoperoxides[38]. It is now well established that the inhibitory effects of aspirin on platelet functions are due to its irreversible acetylation of cyclooxygenase, thus preventing the formation of the prostaglandin endoperoxides and thromboxane A_2[288].

In 1976, Moncada and his colleagues in Vane's group[289] discovered PGX (later named PGI_2 or prostacyclin) as a prostaglandin metabolite formed from arachidonic acid in vascular tissue; prostacyclin is a strong inhibitor of platelet aggregation and thrombus formation[290]. Platelet adhesion is also inhibited by prostacyclin, but the concentration required is about ten times greater than the concentration that inhibits platelet aggregation. In 1977 two groups showed that the inhibitory effect of prostacyclin on aggregation was due to its ability to raise the concentration of cyclic AMP in platelets[291,292].

Cyclic AMP

Several drugs that inhibit phosphodiesterase and hence maintain levels of cyclic AMP in platelets were investigated before their mechanism of action was understood. Dipyridamole was already in use in man as a coronary vasodilator before its weak inhibitory effects on platelet aggregation were recognized in 1965 by Emmons and his colleagues[293]. Ardlie and coworkers[294] documented inhibition of platelet aggregation by the methylxanthines, caffeine and theophylline in 1967. Papaverine, dipyridamole and other pyrimido-pyrimidines were shown to enhance the inhibitory effects of adenosine on platelet aggregation[295,296] and block the incorporation of adenosine into platelets. In a major study in 1971, Mills and Smith[297] showed that adenosine increased the concentration of cyclic AMP in platelets and that methylxanthines, papaverine, dipyridamole and other pyrimido-pyrimidines acted as phosphodiesterase inhibitors, preventing the conversion of cyclic AMP to AMP and thus greatly increasing the inhibitory effects of PGE_1 and adenosine on platelet aggregation. Normally, any adenosine formed in plasma is rapidly taken up by red blood cells, but Gresele and his colleagues[298] have suggested that since this uptake is prevented by dipyridamole, the drug may exert most of its inhibitory effect in whole blood by increasing the concentration of adenosine in plasma.

In 1972, Harker and Slichter[299] reported that shortened platelet survival was prolonged by administration of dipyridamole, an effect that was similar to that exerted by sulfinpyrazone which was already being tested in clinical trials for secondary prevention of myocardial infarction. The effect of dipyridamole on platelet survival, the recent new knowledge about its inhibition of platelet aggregation, and the fact that it was already in use in man, led to clinical trials of this drug. However, large clinical trials comparing dipyridamole plus aspirin with aspirin alone for the secondary prevention of coronary artery disease have not shown a significant additional benefit by the inclusion of dipyridamole[269].

Cyclic GMP and nitric oxide

There were reports in 1975 that cyclic GMP increased during platelet aggregation[300], but in 1981, Mellion and colleagues[301] provided evidence for inhibition of aggregation by cyclic GMP when its concentration was increased by nitric oxide, nitroprusside or related vasodilators. It had already been shown that nitroprusside inhibited platelet aggregation[302,303], and that it caused the formation of cyclic GMP in platelets[304]. In 1987 Palmer and coworkers[305] showed that nitric oxide accounted for the activity of EDRF (endothelium-derived relaxing factor) which had been discovered by Furchgott and Zawadzki[306] in 1980. Nitric oxide inhibits platelet adhesion as well as aggregation[307]. In 1993 Radomski and Moncada[308] suggested that the small

Cambridge Books Online © Cambridge University Press, 2009

amount of nitric oxide synthesized by stimulated platelets could account for the early observations of an increase in cyclic GMP caused by platelet aggregating agents.

Signal transduction

Although the results of activation of platelets – adhesion, aggregation, release of granule contents – had been thoroughly studied, it was not until the 1980s that the focus of attention shifted to receptors and the internal signalling events responsible for these platelet functions. The recent history on signal transduction is too voluminous to be reviewed in detail here and can be found in other chapters in this section.

Calcium and phosphoinositides

It was known in the 1960s that external Ca^{2+} is required for platelet aggregation[115,309], but most of the evidence about the role of increases in internal calcium was indirect[310] until 1982 when Rink and colleagues[311] began the use of fluorescent indicators such as Quin 2 developed by Tsien to measure increases in intracellular calcium during platelet activation. The Ca^{2+}-sensitive photoprotein, aequorin, was also used by some investigators[312]. The role of calcium as an intracellular messenger was reviewed by Salzman and Ware[313] in 1989 and Rink and Sage[314] in 1990 (see Chapter 17).

In 1953, Hokin and Hokin[315] had pointed out that phosphoinositide metabolism was involved in stimulus-response coupling in cells, and eight years later Firkin and Williams[316] provided evidence of turnover of platelet phosphinositides in vivo. Using $^{32}PO_4$-labelling, Lloyd and his colleagues in our group showed rapid turnover of phosphatidylinositol 4,5-bisphosphate (PIP_2) and phosphatidylinositol 4-phosphate (PIP) when platelets were activated with ADP[317] or with collagen or thrombin[318]. In 1975, Michell[319] proposed that hydrolysis of phosphoinositides is responsible for mobilizing internal calcium. This hydrolysis is due to the activation of phospholipase C which acts on PIP_2 to form inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG)[320,321]. IP_3 is responsible for mobilizing calcium from internal stores[322]. (Calcium influx from the external medium also occurs[323].) DAG activates protein kinase C which phosphorylates pleckstrin and myosin light chain kinase[324]. Platelet signalling through the action of tyrosine kinases is reviewed in Chapter 19.

G proteins

It was not until the late 1980s that it became evident that when aggregating agents interacted with their receptors on the platelet membrane, intracellular signalling began with GTP-binding regulatory proteins called G proteins. As this subject has developed, it has been frequently reviewed[325–328] and is discussed in Chapter 14.

Contractile proteins and the cytoskeleton

Bettex-Galland and Lüscher[329] isolated a crude preparation of actin and myosin from human platelets in 1959, providing the first definite evidence that there are contractile proteins in vertebrate nonmuscle cells. They called this actomyosin-like protein 'thrombosthenin'[330]. Interest in it was slow to develop, although its involvement in platelet shape change, spreading, release of granule contents, and clot retraction was assumed[331,332], and has now been established. Detailed studies of the platelet cytoskeleton began in the early 1980s when Phillips and coworkers introduced a technique to obtain a Triton-insoluble filament network from stimulated and unstimulated platelets[333,334] (see Chapter 6).

Conclusion

In the last 50 years there has been an explosive growth in the knowledge of how platelets function, their role in sustaining the integrity of the vascular system, and their response to vessel injury in relation to hemostasis and arterial thrombosis. A better understanding has developed of factors necessary for platelet adhesion to biological surfaces, and how constituents of the vessel wall, particularly collagen, can activate platelets, leading to release of granule contents and formation of thromboxane A_2. Investigations of reactions at the molecular level are providing fresh insights into the basic biological processes through which cells respond to stimuli. The new knowledge has led to substantial advances in our management of disorders of hemostasis and the prevention and treatment of thromboembolism. We still face the challenge that inhibition of platelet function to reduce the risk of arterial thromboembolic problems carries with it the risk of bleeding.

All the chapters in this volume will describe advances built on the work of earlier generations. As Caws[335] wrote in 1969, 'The development of science is a stepwise process; nobody starts from scratch, and nobody gets very far ahead of the rest.'

Production of platelets

Arnaud Drouin and Elisabeth M. Cramer

Institut Cochin Département d'Hématologie and Faculté de Médicine Paris-Ouest, Paris, France

Introduction

Platelets are small anucleated cell fragments, which are essential components of primary haemostasis. They are derived from the cytoplasmic fragmentation of a giant precursor cell, the megakaryocyte (MK). MKs arise and mature in the bone marrow, along with the other blood cell precursors, e.g. granulocytes and erythroblasts. 150 to 400×10^9/l platelets usually circulate within normal human blood with an average lifespan of approximately 10 days. Therefore one would predict that about $15 \times 10^9 - 40 \times 10^9$ platelets have to be produced each day to maintain normal levels. Appropriate platelet production is not only dependent upon a normal rate of thrombopoiesis but also upon the delivery of platelets of the correct size and functionality with normal subcellular organization. Therefore, the qualitative as well as the quantitative aspects of thrombopoiesis will be discussed in this chapter.

Cellular aspect of platelet production

MK localization

Normal human MKs, are mainly located in the bone marrow (Fig. 2.1, see colour plate). They are often gathered into small groups usually up to three, which consist of different cells of various size, ploidy and maturation stages. They are usually located in close proximity to a vascular sinusoid[1]: This is important as MKs and endothelial cells can communicate by many potential pathways: MKs contain mitogenic factors for endothelial cells, e.g. vascular endothelial growth factor (VEGF)[2], whereas endothelial cells express receptors and adhesion molecules which can potentially retain MK close to the bloodstream where future platelets could be delivered[3]. Their accumulation near the sinusoids also potentially represents a physical barrier for other marrow cells migrating into the circulation. However, foreign cells are able to penetrate the MK through the open channels of the demarcation membranes and transmigrate across the whole MK volume without any significant damage to either cell. This natural phenomenon, termed 'emperipolesis', is occasionally observed within normal bone marrow but is distinct from phagocytosis[4]. However, in pathological conditions, e.g. myeloproliferative syndromes with myelofibrosis, the frequency of emperipolesis is not only increased but becomes pathogenic to both cell types with disastrous consequences to the immediate cellular environment[5]. In animal species such as mice and rats but not humans, maturing MKs are equally distributed in the bone marrow and the spleen, and to a lesser extent in the liver[6,7]. In addition, MKs are also observed within the pulmonary circulation of both human and animals[8].

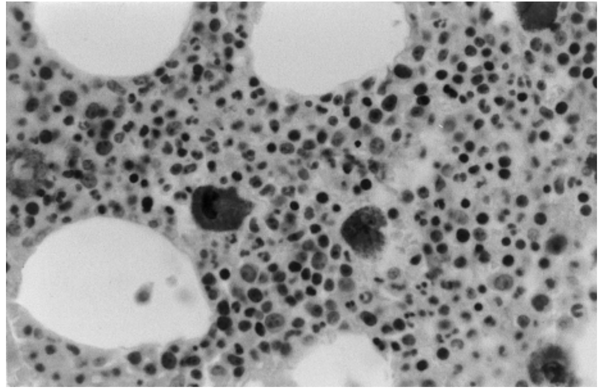

Fig. 2.1 (see also colour plate). Human bone marrow section stained for fibrinogen by the APAAP technique: MKs specifically stain red. They display a large size and polylobulated nucleus, and are quite seldom in the marrow space compared with the other hematopoietic cell lines. They often stand close to a vascular sinusoid.

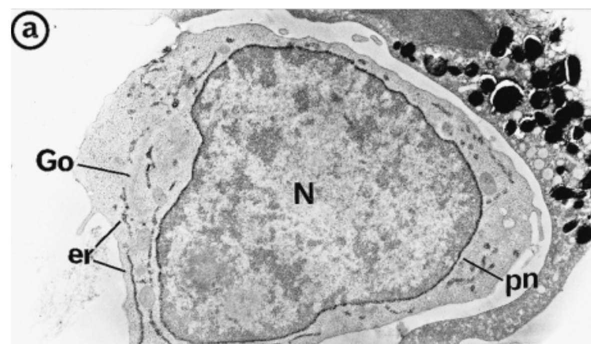
Remarkably, mature bone marrow MKs are extremely deformable and are not only able to adhere to, but transmigrate across, the sinusoidal endothelial barrier to enter the circulation[9]; the first capillary bed that they encounter is the pulmonary microcirculation in which they can be easily entrapped. Intact, fully mature, large MKs have definitely been recovered in the lung circulation, while large MK naked nuclei can be found downstream from the lungs, in the aorta[10]. These observations, which implicate the lung as a major site of platelet production are discussed in detail within the last section of this chapter.



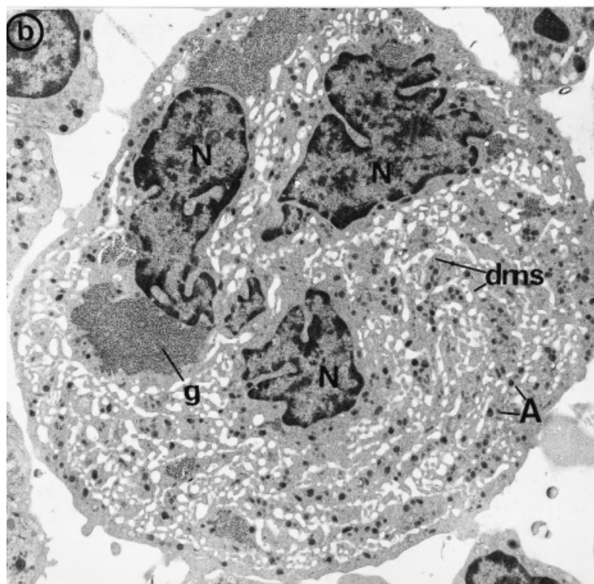


Fig. 2.2. Electron microscopic aspect of MKs at various maturation stages. (*a*) The diploid MK precursor lacks distinctive morphological features, but can be identified based on its content of peroxidase activity revealed by a cytochemical reaction which specifically opacifies the perinuclear cisternae (pn) and endoplasmic reticulum (er). Golgi complex (Go) (apart from an occasional cisternae) and the rare secretion granules are consistently negative. N = nucleus (M × 4367). (*b*) Mature bone marrow MKs are characterized by their large size and multilobed nucleus (N). They contain specific organelles, i.e. numerous α-granules (A) and a well-developed demarcation membrane system (dms) regularly scattered throughout the cytoplasm. This system is formed by the invagination of the plasma membrane, develops extremely rapidly and is the precursor of the platelet membrane systems. g = glycogen (M × 2594).

MK diploid precursor

MKs are derived, together with the other hematopoietic cell lines, from a pluripotent hematopoietic progenitor, which becomes committed to the megakaryocytic lineage that is present in the bone marrow. They can also be recovered from either the peripheral blood or cord blood where they are particulary abundant. During the proliferation stage, the diploid MK progenitors multiply by conventional mitosis. These progenitors are not yet morphologically recognizable and can only be identified through some of their properties obtained in culture[11,12].

The diploid committed precursors have a proliferative capacity but display no distinctive morphological features, and have been characterized based on their functional capacities: BFU (burst forming unit) -MK, the earliest identifiable progenitor, is present in the bone marrow as a CD34+ blast cell which has a proliferative capacity, and gives rise to large colonies of MK (40–500 cells per colony) after 16–20 days of culture. CFU (colony forming unit) -MKs are a heterogeneous population of cells (colony forming cell), and express the CD34 antigen and HLA-DR, and eventually platelet specific glycoproteins (Gp) such as GpIIb/IIIa[13]. Electron microscopy is also a sensitive tool which can be utilized to cytochemically detect the presence of platelet peroxidase (PPO) in the perinuclear cisternae and endoplasmic reticulum; the enzyme is absent from the Golgi apparatus and specific to the human species[14]. In contrast, acetylcholinesterase is a useful marker of the MK lineage of rodents and cats[6,7].

MK maturation and differentiation

Cell maturation and differentiation is a continuous and progressive process. However, three sequential MK maturation stages have been identified according to observations by light microscopy[15].

MK stage I or megakaryoblast is the first morphologically recognizable MK cell. Under the light microscope, it resembles the pluripotent hematopoietic stem cell or hemoblast: high nucleus/cytoplasm ratio, immature thin chromatin, prominent nucleoli, and a small rim of basophilic cytoplasm. The distinctive feature is its large nuclear size, which reflects the fact that its ploidy has increased. At

Cambridge Books Online © Cambridge University Press, 2009

the electron microscope level, the nuclear chromatin is mainly clear, transcriptionally active euchromatin. The cytoplasm is rich in ribosomes undergoing active protein synthesis and responsible for basophilia. A few mitochondria of large size are randomly scattered (Fig. 2.2(*a*)). At the next maturation stage, MK stage II, the nucleus displays a budding shape, having nearly completed its final ploidy maturation, and the cytoplasm extends and becomes deeply basophilic. MK stage III is the platelet forming stage: the cell reaches its maximal size, the nucleus is polylobulated – on squash bone marrow preparations, the number of nuclear lobes appears to be correlated to ploidy – and the cytoplasm becomes progressively azurophilic with a platelet-like red stippling progressively replacing the basophilia.

Ultrastructural examination facilitates the delineation of subcellular events accompanying MK growth and differentiation: the nucleus increases its DNA content and ploidy by a unique phenomenon called endomitosis. In parallel, two specific types of organelles: the demarcation membrane system and the secretion granules develop simultaneously[16].

Nucleus and endomitosis

Nucleus

Upon cell maturation, the nucleus displays several sparse rounded lobes with abundant euchromatin, and conspicuous nucleoli. Its maturation is characterised by constant size increase and segmentation, and by chromatin clumping. Close to the final maturation stage of MK, the structure and texture of the nucleus begin to change. The nuclear lobes tend to elongate and gather together, the chromatin becomes coarser, and long clefts of cytoplasm extend between each lobe. Finally, the nucleus has usually terminated its growth when the main events of the synthesis of cytoplasmic organelles are taking place.

Endomitosis

At the end of the proliferative phase, 2N MK precursors endomitose until a level ranging from 4N to 64N is reached; most cells which give rise to platelets are thought to be 8, 16 or 32N with a modal number of 16N in humans. However, the exact signal(s) which switch the cell from normal mitosis to endomitosis are still unknown. Polyploidization of MK is unique among normal mammalian cells in that multiples of 2N chromosomes are enclosed within a single nucleus and surrounded by a single nuclear membrane. To achieve this, MKs undergo a unique process called endomitosis during which DNA duplicates, followed by nucleus segmentation appropriately, but without apparent nuclear or cytoplasmic division[17,18]. Morphological studies on the structure of MK endomitosis have shown that a multipolar mitotic spindle is formed, with the number of spindle poles in a single MK varying from 4 to 64 N. The nuclear membrane breaks down and disappears during polyploidization as in any classical diploid mitosis. Metaphase occurs and multiple mitotic spindles form with spindle poles symmetrically located at right angles from one another. During anaphase, many bundles of sister chromatids are pulled apart toward the spindle pole they face. However, each pair of centrioles remains closer to each other than in normal cell division and neither telophase, nor cytokinesis (cellular division) follow the unusual truncated anaphase. Eventually, spindles remain shorter than normal ones, connected to each other, a single pole connecting to several of them. In addition, the multiple pole mitotic spindle creates a spherical structure, but does not cross the cell centre and is often located aside within the sphere. Finally, the chromosomes segregate near each pole, forming the nuclear lobes.

Cytoplasmic differentiation

Demarcation membrane system

During the maturation process, a network of smooth membrane channels are formed, i.e. the demarcation membrane system (Fig. 2.2(*b*)). This is a large complex of intracytoplasmic channels formed by the invagination of the plasma membrane forming multiple channels throughout the entire cytoplasm[16,19]. Their lumen remain connected to the extracellular space, as demonstrated by the penetration of electron dense tracers, like horseradish peroxidase. This membrane system expands very rapidly and becomes widespread within the whole cytoplasmic volume, expanding more than 700% within 72 hours. This system is designed to furnish a large reserve of membrane, which is destined to form the future platelets. The protein composition of both plasma membrane and demarcation membranes remains remarkably similar. The major platelet receptors, which are usual components of the mature MK membrane, are equally expressed within the demarcation membrane system: GpIIb/IIIa which becomes activatable only in the mature cell, the GPIb/IX/V complex, and GPIV (CD36) appear sequentially during early stages of maturation along with GPVI[20–23].

Secretion granules

The secretion granules of three main types are formed in parallel: alpha-granules, dense granules and lysosomes.

Cambridge Books Online © Cambridge University Press, 2009

Alpha-granules

These initially arise in the trans-Golgi network (TGN), originating from the assembly of endogenously synthesized proteins. They contain a wide variety of components. They are mostly involved in hemostasis such as the adhesive proteins (fibrinogen, von Willebrand factor, thrombospondin, fibronectin . . .) and other specific factors like β-thromboglobulin (β-tg) and platelet factor 4 (PF4); other components are implicated in wound healing, mainly growth factors (PDGF, TGF-β, EGF, VEGF). Alpha-granule components are not only synthesized by the MK itself but also originate from plasma proteins endocytosed during MK maturation[24–27]; endocytosis is either fluid-phase (albumin, immunoglobulins) or receptor-mediated, e.g. fibrinogen through its receptor GpIIb/IIIa[28,29]. Endocytosed proteins seem to appear later in the MK than endogenously synthesized proteins (von Willebrand Factor), and their distribution patterns within the maturing MK cytoplasm are distinct, i.e. centrifugal and maximal at the cell periphery for the former, but centripetal and predominant in the juxtanuclear area for the latter[30]. The alpha-granule membrane contains numerous receptors which appear during MK maturation, e.g. CD62p (P-selectin), GpIIb/IIIa, CD36, CD9, and PECAM1. Most of them appear to be expressed first at the plasma membrane, and become subsequently internalized. Tagging plasma membrane GpIIb/IIIa indicates that the internal pool of alpha granular GpIIb/IIIa directly originates from the internalized plasma membrane pool[31].

Dense granules

These are formed early during MK maturation, since specific components of their limiting membrane such as granulophysin, are detected in megakaryoblasts[32] but they acquire their dense content (Ca^{2+}, active uptake of serotonin) at the terminal stage of maturation. They also share some common components with the α-granular membrane, e.g. CD62p and GpIIb/IIIa[33,34]. An intermediary compartment, the multivesicular body has recently been identified as an apparent crossroad located downstream from TGN, where endogenously synthesized and endocytozed granule components are sorted to their correct respective intracellular locations[32,35].

Lysosomes

These are scarce and their content can be visualized by electron microscopic cytochemistry. They contain acid hydrolases, such as acid phosphatase, β-galactosidase and β-glucuronidase[36].

Mitochondria

Mitochondria are more sparse and smaller in size within the mature cell when compared to megakaryoblasts.

The endoplasmic reticulum

This is scarce and scattered in the cytoplasm. It contains the specific platelet peroxidase activity (PPO), which is also present in the perinuclear cisternae and reflects the cell content in cyclo-oxygenase[37].

Platelet production

Platelet production by MK still appears to be a poorly understood event. No consistent study has been able to document the phenomenon in vivo particularly within humans. Nevertheless, the mechanism of platelet formation and shedding by MK has been approached by several means. In the early 1970s, Thiery et al. observed preparations of bone marrow MKs squashed on a glass slide by using a microcinema technique. They could demonstrate the ability of MK to deform and extend long cytoplasmic filaments called proplatelets[38].

Mechanism and site of platelet release by MKs

Several theories have been raised concerning the formation of platelets by MKs: budding of platelets from the cell surface; delineation within the MK cytoplasm of small preformed cytoplasmic territories ready to fragment, eventually released at the end of cell maturation (static model)[39]; or demarcation membranes as a reservoir for the emission of long filaments named proplatelets which cross the endothelial barrier in order to enter the circulation, break, and form small fragments ready to detach as platelets (flow model)[40–45]. Recent images obtained on cells having reached full cytoplasmic maturity in culture, in the presence of TPO, favour a third hypothesis of proplatelet formation (Fig. 2.3). Although an extension of the above flow model, formation of platelets is apparently preceded by the extension of proplatelets as well as dilatation of the demarcation membrane system. The following events leading to platelet formation are sequentially observed in vitro[45]: peripheral redistribution and alignment of demarcation membranes; dilatation of the demarcation membranes; extension of proplatelets displaying regular constriction zones; with transverse microtubules disposed along longitudinal bundles of microtubules at the constriction zones; breakage at the constriction area and liberation of a newly formed platelet from the tip of the proplatelet where the classical loop of microtubules is formed[46] (Fig. 2.3, see colour plate, 2.4, 2.5(*a*)).

An alternative theory proposes that proplatelet fragmentation and platelet shedding may occur in the circulation,

Cambridge Books Online © Cambridge University Press, 2009

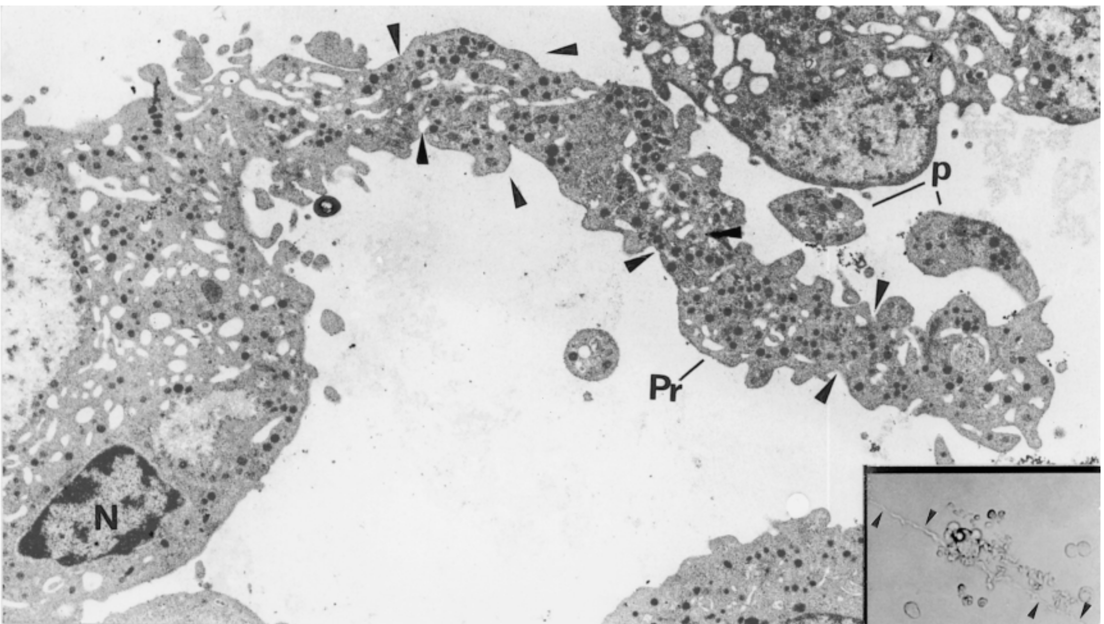

Fig. 2.3 (see also colour plate). After reaching full maturation, MK cytoplasm extends away from the cell core of the mother cell forming one or several long extensions called proplatelets (pr). Some platelets (p) have detached from its tip. N = nucleus (M × 3354).
Inset: Phase contrast microscopic view of a mature MK extending proplatelets (arrowheads).

following a circadian rhythm, with an apparent peak of platelet liberation in the early morning hours[47]. New platelets display longitudinal microtubules along their long axis, similar to the microtubule organisation in proplatelets[42,45] (Fig. 2.5(*b*)). Then they curve, both their extremities fuse, generating a central vacuole which tends to decrease until it vanishes, leading to the formation of a mature platelet with a circumferential marginal bundle of microtubules.

Transendothelial migration of MK: MK chemotaxis

MKs express the chemokine receptor CXCR4. The action of its ligand, the chemokine stromal cell-derived factor-1 (SDF-1) was found to induce MK chemotaxis, i.e. migration towards a chemotactic gradient[48]. The experiment was conducted in a modified Boyden chamber, showing that whole intact mature MKs can orientate themselves with the formation of a unilateral cytoplasmic pseudopod, the nuclear lobes being gathered at the opposite pole, and can migrate through a transwell of bone marrow endothelial cells. MKs are also able to react to agonists in a similar fashion to platelets[49] (Fig. 2.6), therefore their presence in the circulation might be pathogenic in some situations such as lung diseases. Thrombin induces dramatic morphological changes as early as the megakaryoblastic stage, showing that the protease-activated receptors (PAR) are expressed early on this cell line. Two other groups made comparable studies and also observed that CXCR4 expression increases with MK maturation, but mature MKs as well as platelets do not respond to SDF-1, suggesting that the signalling induced by SDF-1 is not operating: these results were interpreted as a potential mechanism for retaining immature MKs in the marrow[50,51].

Knockout and transgenic animal models

Targeted disruption of genes, i.e. the knockout approach has recently been extensively developed and has proved to provide useful models for understanding the role of receptors and transcription factors in MK differentiation. Knockout mice for either the mpl-receptor[52] or its major ligand TPO[53] develop severe thrombocytopenia, but platelet levels of approximately 10–15% of normal are still maintained. The transcription factor p45–NFE2 has also been shown to be essential for MK cytoplasmic development since NFE2 −/− mice fail to produce any platelets, although (dysmorphic) MKs are found within the bone marrow[54]. These cells remain with a cytoplasm of drastically reduced size and also fail to show any apparent signs of proplatelet formation[55]. In addition, the nucleus remains hypoploid. Thromboxane synthase and β1-tubulin are also absent

Cambridge Books Online © Cambridge University Press, 2009

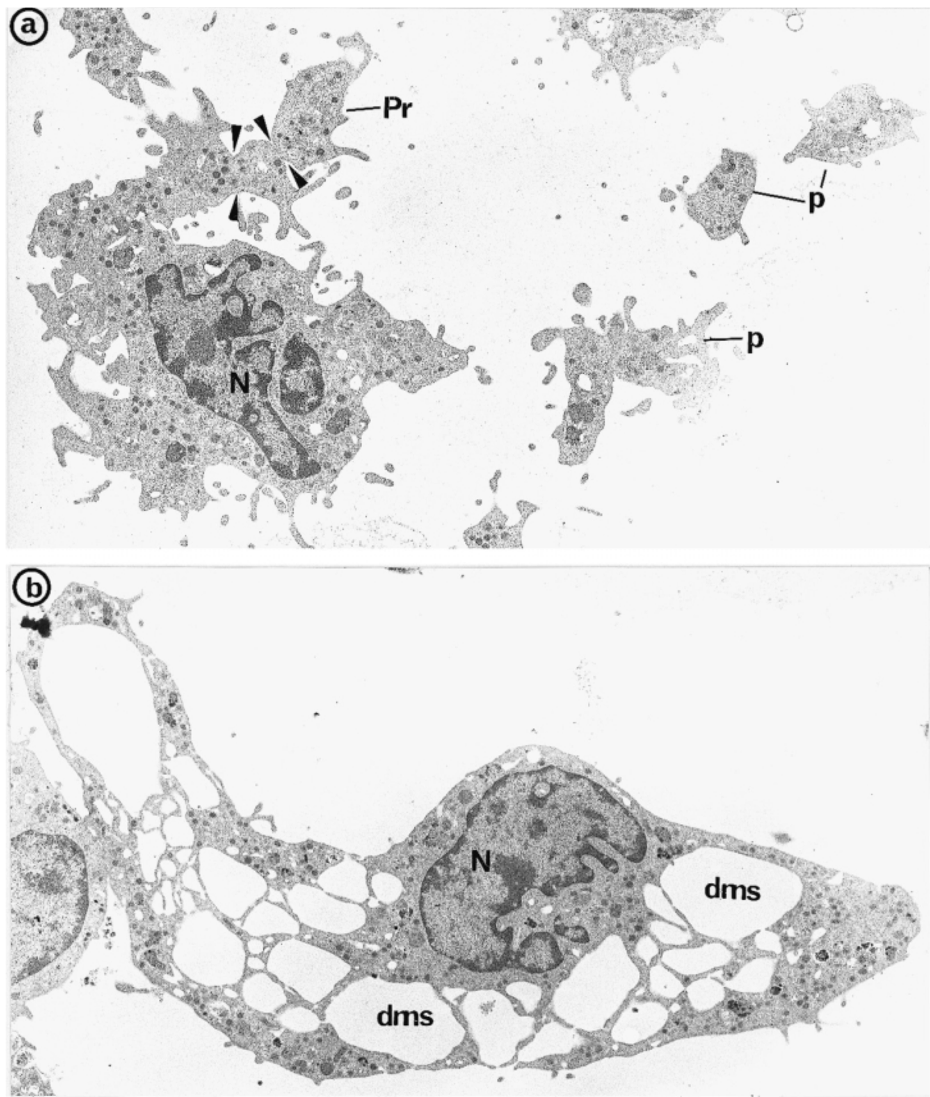

Fig. 2.4. At the platelet shedding stage. (*a*) The peripheral sheet of cytoplasm unfolds from the cell core, forming an elongated proplatelet process (pr). Constriction zones are regularly disposed along this cytoplasmic extension (arrowheads), delimitating future platelet territories. Platelets (p) detach from the tip of the proplatelet (M × 2660). (*b*) The MK demarcation membrane system (dms) widens and allows future proplatelets and platelet territories to be formed (arrowheads). N = nucleus (M × 2660)

from these MKs[56,57]. This is an important observation as β-tubulin is an important cytoskeletal protein within platelets and MK (endo)mitotic spindle structures. As a consequence of these defects, the thrombocytopenia induced in this model is more severe than for either c-mpl and TPO knockout mice. GATA1 knockout mice also exhibit severe thrombocytopenia with both a proliferation defect of MK progenitors and a marked cytoplasmic maturation defect leading to the production of giant platelets[58]. Mice lacking the transcription factor Fli1 (Fli1 −/− mice) develop thrombocytopenia with abnormal platelet morphology resembling the defects observed in Paris–Trousseau thrombocytopenia[59]. Finally, GpIb knockout mice present phenotype very close to the analagous human disease, Bernard–Soulier syndrome. The mice exhibit severe thrombocytopenia and giant platelets demonstrating the direct role of the receptor for MK cytoplasmic development and delineating platelet territories[60].

Regulation of platelet production

At least three main successive events are involved in megakaryopoiesis. First, proliferation of progenitor cells (CD34+) evolving to more differentiated but less proliferative cells, expressing CD41, the thrombopoietin receptor (c-Mpl) and the alpha chemokine receptor CXCR4. Secondly, the megakaryoblastic stage where cells increase their DNA content without proliferating through the specific mechanism of endomitosis. Thirdly, the megakaryocytic stage, at which cells are involved in the maturation process that yields to proplatelet formation and platelet shedding (either *in situ* or after MK migration into the bone marrow capillary system and further fragmentation within the pulmonary blood circulation). Many cellular signals are required to regulate these stages, e.g. cytokine-induced proliferation and differentiation, cytokine-induced migration, cell–matrix interactions and cell–cell interactions (microenvironment). Megakaryopoiesis appears to be promoted by multiple interacting, often redundant mechanisms. We will now develop these mechanisms separately, especially the influence of growth factors, observations from both in vitro then in vivo experiments, preclinical studies and finally clinical trials and future prospects.

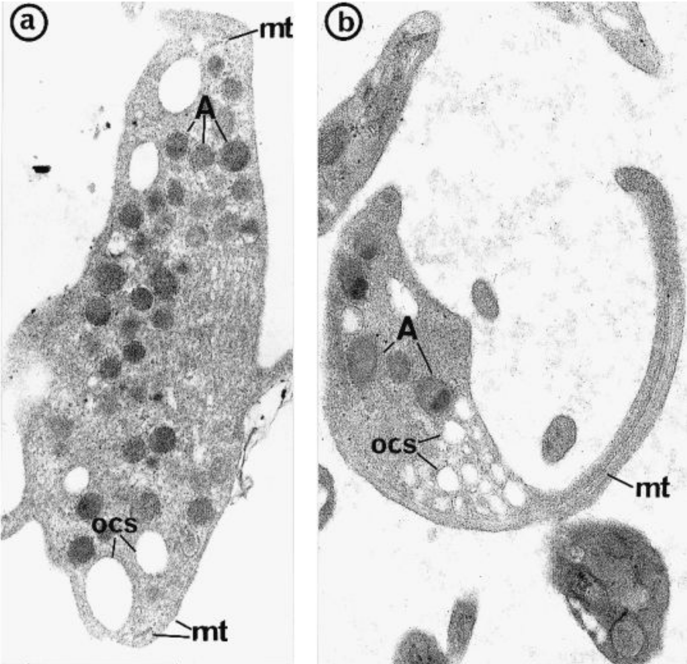

Fig. 2.5. (*a*) Ultrastructure of a platelet shed by a cultured MK in vitro. It resembles blood platelets, with an ellipsoid shape, peripheral microtubules (mt), scattered α-granules (A) and open canalicular system (ocs) (M×8220). (*b*) Ultrastructure of a platelet from the peripheral blood, with a spindle shape and a longitudinal bundle of microtubules (mt), which resembles the one found along proplatelets. This type of platelet may represent the newly born ones, encountered when platelet production is accelerated. A = α-granule (M×8220).

Thrombopoietin (TPO) search and discovery

It was suspected for a long time that a lineage specific growth factor, thrombopoietin (TPO), promotes megakaryopoiesis in a similar fashion to erythropoietin (EPO) in the model of erythropoiesis. This factor was eventually discovered from the study of the MPLV (myeloproliferative leukemia virus). This retrovirus, when acting on murine hematopoietic progenitors, induces myeloproliferative disorders, and MPLV-infected hematopoietic cells can grow and differentiate usually without a growth factor requirement[61]. From molecular studies, transforming properties of MPLV were attributed to v-mpl, a viral envelope-coding oncogene[62]. c-mpl, the human homologue of v-mpl, was then cloned, and the primary sequence suggested that the receptor was a member of the cytokine receptor superfamily[63,64]. c-mpl RNA appears to be specifically expressed within fetal liver cells, CD34+ cells, MK precursors, MKs and platelets. In mice, the c-mpl transcript is found in all hematopoietic tissues but thymic cells. In humans, c-mpl mRNA is not expressed in non-MK hematopoietic cells. Low expression has also been reported in endothelial cells. c-mpl mRNA expression was also found in almost all megakaryocytic-derived cell lines, e.g. UT-7, Mo7E, TF-1, HEL, DAMI, and KU-812[65]. c-mpl major expression is detected on primitive stem cells (CD34+/CD38−), CD34+, GpIIb/IIIa+ and on mature MKs and platelets[66]. Within hematopoietic progenitor cells in culture, transfected antisense oligodeoxynucleotides to c-Mpl mRNA totally inhibited the growth of MK colonies without inhibition of other lineage proliferation[67]. c-mpl-deficient mice also exhibited specific megakaryocytic lineage and platelet production defects[52]. These results therefore strongly implicated c-Mpl as a major MK-lineage specific growth factor receptor. Soon after the description of this specific receptor, a specific ligand and activator of c-Mpl was purified, sequenced and cloned using a number of different strategies by several research teams in 1994[68,55,69–73]. This ligand, named c-Mpl ligand or megapoietin, is now referred to as thrombopoietin (TPO).

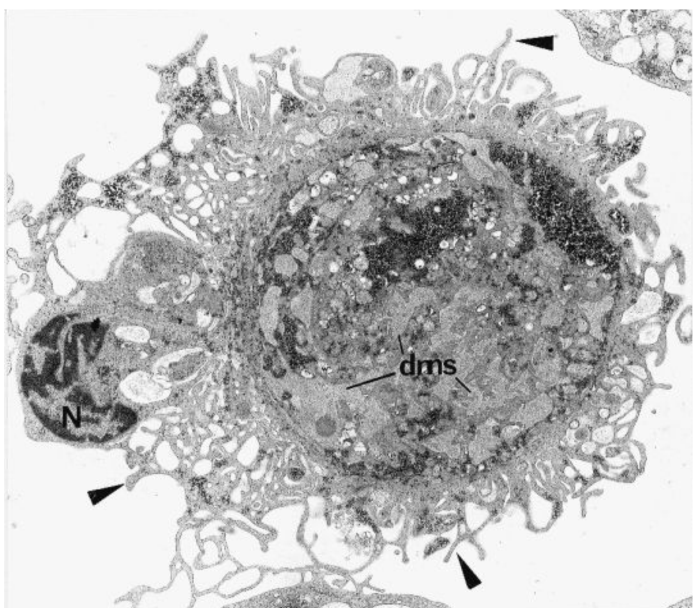

Fig. 2.6. Like platelets, MKs can become activated: thrombin induces shape change, pseudopod emission from the plasma membrane (arrowheads), organelle centralization and granule secretion into the dilated channels of the demarcation membrane system (dms). The nucleus (N) is pushed towards the cell periphery (M×2581).

TPO gene, cDNA and protein[68,74,75]

TPO cDNA (1.8 kb) reveals strong inter-species homologies (70 to 80%) and codes for a 353 amino acid protein. The TPO gene locus was reported on the long arm of the human chromosome 3 (3q26–27), a region previously shown to be involved in myeloproliferative disorders. TPO mRNA is expressed strongly in liver and kidney in humans. Expression could also be detected in smooth muscle cells and low amounts within bone marrow stromal and spleen cells; TPO mRNA can also be detected in primary cultures of endothelial cells.

TPO is a 75 to 80 kD protein, with two distinct domains: one N-terminal biologically active domain, 153 amino acids long, with 50% homology to EPO (EPO-like domain); and one carboxy-terminal domain, glycosylated, with no primary sequence homology to any other known cytokine. This latter domain has a putative role in protein secretion and in protein lifespan increase in the systemic circulation.

In cell culture media, in vivo, and in clinical trials, two recombinant forms of TPO have been used: one is the *Escherichia coli* expressed part of the EPO-like domain of TPO, the rHu-MGDF for recombinant human MK growth and development factor. A polyethylene glycol (PEG) derivative form is sometimes used, the PEG-rHuMGDF. It has a longer serum half-life. Another form is a full-length recombinant TPO glycosylated and produced in mammalian cells, named rhTPO. Moreover, and importantly, c-Mpl ligand peptides without any primary sequence homology to the natural c-Mpl ligand compete specifically with TPO for the binding of c-Mpl and display similar megakaryopoietic properties[76].

TPO production and regulation

TPO synthesis occurs mainly in liver production. A lower TPO production takes place in the bone marrow stromal cells (which may constitute an important *in situ* source) and also in splenic cells.

The regulation of TPO level and its correlation to platelet production is the centre of debate. In mice, TPO mRNA expression in induced thrombocytopenic or thrombocythemic states was reported to be unchanged[77]. Moreover, in TPO −/+ genetically modified mice (heterozygous), a 50% reduction in platelet count but with no TPO mRNA overexpression, was observed[78]. These data therefore suggest that mRNA expression of TPO is constitutive.

The systemic level of TPO is usually inversely correlated to platelet count[72]. For instance, in c-mpl−/− mice, a low platelet count in conjunction with low MK number but high TPO plasma level are observed[78]. Transfusion of normal platelets into these mice induces a rapid decrease in TPO level[79].

Platelet mass as well as total MK total mass are responsible for TPO level regulation: internalization and subsequent degradation of TPO/c-Mpl complex in platelets (and also within MKs) explains the constant regulation of TPO concentration via a post-transcriptional mechanism[80,81]. A similar post-transcriptional regulation of macrophage colony-stimulating factor (M-CSF) level, by monocytes, was previously demonstrated[82].

Patients with immune thrombocytopenic purpura (ITP) often present with thrombocytopenia, an elevated number of bone marrow MKs, and normal systemic TPO level[83]. Implication of the bone marrow microenvironment has also been emphasised: in ITP patients, a correlation was observed between TPO level in the bone marrow and TPO mRNA expression in bone marrow stromal cells, showing that regulation mainly occurs *in situ*[84]. In bone marrow, TPO is provided by stromal cells, and its mRNA expression modulated by platelet alpha-granular proteins. Dual effects of transforming growth factor-beta 1 (TGF-beta1), a cytokine present at a high concentration in platelets, were

Cambridge Books Online © Cambridge University Press, 2009

reported, i.e. enhancement or inhibition of TPO mRNA expression in stromal cells[85,86]. However, there seems to be a consensus that TGF-beta exerts an inhibitory effect on MK growth (see further discussion on 'Negative regulation of megakaryopoiesis').

Autocrine and paracrine mechanisms could be involved to modulate TPO production by bone marrow stromal cells, and also by MK *in situ* release of α-granules proteins. Many interacting mechanisms then participate to regulate TPO levels.

TPO biological activities in vitro (cell culture)

Primary culture studies have established several megakaryopoietic effects of TPO. It appears to be multifunctional by inducing progenitor cell proliferation, MK colony-stimulation and MK maturation.

TPO can promote MK colony formation

In serum-free cultures TPO induces proliferation of hematopoietic progenitor cells (CD34+, GpIIb/IIIa + or −) from human or murine bone marrow. However, the proliferative effect is relatively weak and TPO only promotes small MK colony formation. To induce the formation of larger colonies from CD34+ cells, the additive effects of cytokines such as Steel factor or interleukin (IL)-3 are also required[87]. Moreover, TPO appears to be dispensable at this stage and a combination of Steel factor, IL-3 and IL-6 can induce similar MK colony formation and MK production from CD34+ cells[87].

TPO promotes MK differentiation and maturation

Endomitosis, cytoplasmic maturation and proplatelet formation can be obtained from either blood or bone marrow CD34+ cells, in serum-free media supplemented with TPO alone[88]. These effects were reported to be independent of other cytokine production from MKs, stromal cells, or other cells[74]. Cytoplasmic maturation and proplatelet formation were observed at both optical and ultrastructural levels[18,45]. TPO was reported as the strongest cytokine to induce MK maturation. A combination of cytokines, e.g. IL-11 especially have been shown to also support in vitro maturation[89].

TPO effect on proplatelet and platelet formation is controversial

In vitro produced platelets are morphologically and functionally normal[44,45]. However, TPO has no direct effect on MK cytoplasmic fragmentation and platelet production. The application of TPO on mature MKs in culture only gives limited proplatelet formation. TPO appears to promote this last stage by inducing proper megakaryocytic cytoplasmic maturation, a critical step for efficient platelet production[90–92]. TPO could be retrieved from culture media when MKs reach end-of-maturation stages without interfering in proplatelet and platelet production.

TPO has also in vitro effects on platelets

Normal platelets express a small number of TPO receptors[93] and TPO ligation to its receptor can induce platelet homodimerization and cell signal transduction. This cell signal transduction involves downstream events including tyrosine phosphorylation of the intracellular Mpl-R domain, various Janus proteins (JAK2, Tyk2 and sh2) and signal transducers and activators of transcription (STAT3 and STAT5). TPO primes platelet activation: it changes platelet aggregation induced by shear stress or agonists, and also increases fibrinogen binding, platelet adhesion to collagen and CD62p expression[94]. However, and importantly, the TPO levels in these experiments are much higher than physiological levels.

TPO shows pleiotropic biological effects and can act on various cell types

After c-Mpl ligation, TPO induces c-Mpl intracytoplasmic chain phosphorylation and consecutive activation of the JAK/STAT cell signal transduction pathway[95].

On hu-AML (acute myeloid leukemia) cells in culture, TPO can induce proliferative effects in a fraction of the cell population; some cells even undergo megakaryocytic differentiation associated with the expression of a set of erythroid/megakaryocyte-specific transcription factors such as NF-E2, GATA-1 and GATA-2; but the precise cascade of molecules involved in cell signal transduction remains to be elucidated[92,96]. These transcription factors are also involved in MK differentiation[97–99,58].

TPO are also reported to have positive effects on other hematopoietic lineages by synergistically and/or additively cooperating with several hematopoietic growth factors, as EPO by enhancing erythroid lineage production[100] and on early hematopoietic precursors, in synergy with other cytokines[88,101–102].

In vivo TPO biological activities: genetically manipulated mice confirm the major megakaryocytopoietic effects of TPO

Mpl−/− deficient mice express approximately 10% residual MKs and platelets with normal ultrastructural morphology

Cambridge Books Online © Cambridge University Press, 2009

and granule content, with excessive but usually non-lethal bleeding. This demonstrates that TPO is the major growth factor which regulates platelet production[77]. The residual platelet production also demonstrates that other redundant mechanisms also control a limited part of megakaryopoiesis. No significant decrease in white and red blood cells could be measured, but reduced quantity of other lineage progenitor cells were reported, confirming that TPO is efficient at a very early stage of hematopoiesis[103].

Overexpression of TPO gene transfected in murine hematopoietic stem cells leads to MK lineage hypertrophy, and thrombocythemia[104].

Other thrombopoietic growth promoting cytokines[105,106]

Before the discovery of TPO, various studies reported the megakaryopoietic action of cytokines such as GM-CSF, IL-3, IL-11, SCF, EPO, and G-CSF. However, interest in these cytokines has waned since TPO emerged as the principal thrombopoietic regulator. Although IL-3 and GM-CSF have clear thrombopoietic properties, clinical studies showed that these effects were not useful in vivo. The same observation was made for G-CSF. However, the IL-6 cytokine family was potentially more interesting. This family shares a signal-transducing pathway through the gp130 receptor, and includes IL-6, IL-11, oncostatin M (OSM) and the leukemia inhibitory factor (LIF). IL-11 and IL-6 exhibit both pleiotropic and some common hematopoietic effects. Both however seem to be dispensable for megakaryopoiesis. Despite this, a synergy of IL-3, SCF and IL-11 with TPO on the MK colony-stimulating activity in culture, was reported: IL-11 alone or in synergy with IL-3 induces some patterns of megakaryocytic maturation (increased size, ploidy and acetylcholine-esterase production). In vivo animal experiments have also demonstrated that IL-11 can enhance both MK progenitor and platelet production. IL-11 was also used in clinical trials for the treatment of aplastic anemia.

Thrombopoietic negative regulators[107]

TGF-beta

TGF-beta especially isoform 1, is a growth inhibitor of megakaryocytopoiesis in vitro. It acts on human and murine MK precursors.

PF4 and other cytokines of the CXC family

Platelet factor 4, an alpha-granular platelet protein, inhibits in vitro proliferation of normal MK progenitors as well as progenitors from thrombocythemic patients[108]. PF4 has two different biologically active domains, C-terminal and overlapping C-terminal/central domains. The inhibitory activity could be reproduced with mimetic synthetic peptides. Interestingly it was abrogated by heparin, but only for the peptides mimicking the C-terminal sequence. PF4 inhibition of MK proliferation could, for instance, be reversed by glycoasminoglycans and heparinase[109–111]. PF4 exhibits a high affinity for heparin-like proteins, which bind growth factors as a prerequisite for their biological effects. One possible mechanism of PF4 action could then be mediated through the delocalization of other heparin-binding factors, i.e. IL-1, IL-3, Il-6 and GM-CSF.

Thrombin

This can inhibit MK growth through receptor-mediated activation. Thrombin also inhibits proplatelet formation from MKs[112] which is expected, knowing the drastic changes induced on MKs morphology and demarcation membrane distributions (Fig. 2.6).

Microenvironment and megakaryocytopoiesis regulation

Several lines of evidence have recently exemplified the implications of *in situ* mechanisms of megakaryopoiesis regulation:

Glycosaminoglycan components of the extracellular matrix interact with PF4 and other heparan sulfates bind the cytokines IL-1, Il-3, IL-6 and GM-CSF[111,113].

Gp Ib/IX expression on mature MKs could be a growth arrest signal of the lineage[114]; Bernard–Soulier, a bleeding disorder with giant platelets and thrombocytopenia accompanying the genetic deficiency of the GpIb/IX complex, demonstrates the link between actin, MK fragmentation and platelet formation.

Microvascular endothelial cells are known to be major contributors to hematopoietic cell regulation, by providing both cytokines and adhesion molecules. It was reported that the CXC chemokine SDF-1 could also be involved in the induction of cell proliferation of hematopoietic progenitors. This suggests cytokine induction that promotes early stage progenitor proliferation and late-stage platelet release that is not TPO dependent. This induces MK chemoattraction, adhesion to endothelial cells and transendothelial migration of MKs[48,115,116].

Preclinical studies

A major role for TPO in regulating platelet production has been confirmed by preclinical studies:

Normal mice which daily receive rhTPO during 7 days, develop a fourfold increase in platelet level after 5 days with a return to baseline within 10 days. Simultaneously, a

Cambridge Books Online © Cambridge University Press, 2009

20-fold increase in bone marrow MK progenitors and a tenfold increase in MK occur. These effects were much stronger than those obtained with any other cytokine combinations[69,72–73]. In myelosuppressed (either chemically or sublethally irradiated) animals[117], daily TPO injections can also reverse thrombocytopenia with a dose-dependent effect. Agonist peptides of the TPO receptor also increase platelet level of 80%, when injected into mice[75].

Perspectives of gene therapy from adenovirus delivering human TPO have also been tested in mice[118–121]: when normal mice are infected by TPO-adenovirus, the plasma level of TPO is high and platelet levels reach high levels. However, some mice developed antibodies, i.e. anti-murine TPO and subsequent thrombocytopenia, with depletion of bone marrow MKs and of bone marrow hematopoietic progenitors. This suggests that the transgene can induce immune dysfunction and auto-immune disorders. In mice with immune defects, nude mice, severe combined immune deficient (SCID) or non-obese diabetic (NOD)–SCID mice, thrombocytosis was accompanied with granulocytosis and increased hematopoietic bone marrow progenitors. SCID but not NOD–SCID mice developed subsequent osteomyelofibrosis and extramedullar hematopoiesis. NOD–SCID mice have functionally deficient monocytes and macrophages that are active cells in osteomyelofibrosis genesis. These data demonstrate that a chronic high level expression of TPO can be deleterious.

Non-human primates treated with recombinant TPO during several days exhibit increased platelets counts with a dose-dependent correlation[122]. Platelet counts are significantly increased after a 6 day delay, peak within 13 days and return to baseline progressively after treatment arrest. In the bone marrow, MK number, volume and ploidy are also increased. No significant changes in platelet morphology, lifespan and reactivity are observed.

Human clinical trials

Initial trials demonstrated that PEG-rHuMGDF or rhTPO administered before chemotherapy to patients with cancer efficiently increased platelet levels, with normal morphological and functional features, and no evidence of spontaneous in vivo activation[123–125]. No effects on white blood cell count nor hematocrit were reported.

Trials using repetitive administrations of PEG-rHuMGDF were reported to induce severe and persistent thrombocytopenia after the appearance of neutralizing antibodies which cross-react with endogenous TPO[126,129]. Therefore, clinical developments of this recombinant form were terminated by the pharmaceutical company in September 1998[128]. In contrast, in a recent study conducted in the United Kingdom[130], healthy human volunteers received a unique PEG-rHuMGDF bolus vs. placebo, and no immune thrombocytopenia was observed. The platelet levels doubled, with a peak at 12 days of injection, and returned to basal level within 28 days. Functional normal and viable platelets were produced with increased platelet lifespan and turnover. A 1.6 fold MK increase was observed in the bone marrow. Moreover, since TPO increases platelet aggregative reponsiveness to physiologic agonists in vitro, it was then anticipated that TPO treatment could induce vascular thrombotic secondary effects. But no deleterious thrombotic effects were reported in this study.

Therefore, rhTPO appears for the moment as the most specific, effective and safe growth factor for increasing platelet production. It is used for avoiding platelet transfusions and for accelerating thrombocytopenia recovery after chemotherapy of cancer patients. The presumed non-antigenic TPO mimetic peptides are under evaluation for their therapeutic interests[131], and seem to be less immunogenic than PEG-rHuMGDF, but still require extensive clinical investigation[132].

Morphology and ultrastructure of platelets

James G. White

University of Minnesota, Laboratory of Medicine and Pathology, Minneapolis, USA

Introduction

Platelets are deceptively simple cells. Their small size, lack of a nucleus and clear cytoplasm made recognition difficult for early microscopists[1–4]. As a result, platelets were the last of the cellular elements of circulating blood to be identified[5]. Also, recognition was not helped by the tendency of platelets to remain nondescript. They hide as far from the centre of the flowing column of blood as possible[6]. Other cells are busy carrying oxygen and removing carbon dioxide, supplying nutrients, transporting waste, reacting to foreign invaders or leaving the circulation to participate in inflammatory and immunological responses, but not platelets. This cell desires anonymity and remains as quiet as possible as it rolls along the intact endothelium for its 10 to 12 day lifespan. If it can retire to the spleen without becoming involved in any physiologic activity, the platelet's life can be considered a complete success.

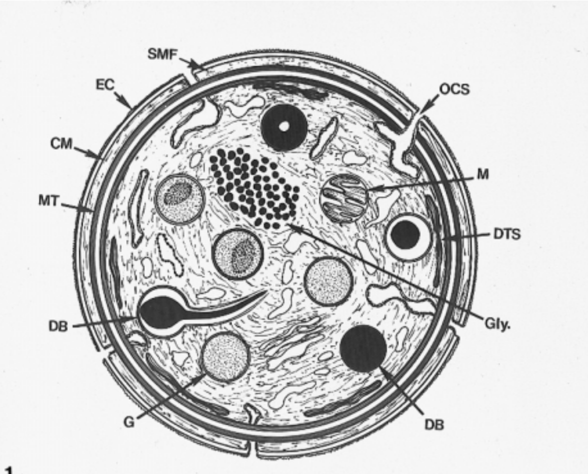
Thus, in this sense the platelet has no function in the circulation, except one: to be there when it is needed to keep blood flowing. It is the sentinel on guard at all times to react immediately at sites of vascular injury as soon as subendothelium is exposed. Within microseconds, platelets undergo dramatic changes in their morphology and biochemistry, fill the site of damage with aggregates to form a hemostatic plug, contract to prevent further loss of blood and restore integrity to the vascular system[7–10]. The platelet serves its function as sentinel of the circulation very well, but it does have a blind side. It often fails to distinguish its role in hemostasis from involvement in thrombosis. As a result, platelet participation in in vivo-occlusive phenomena leading to heart attacks, strokes or other ischemic events often overshadows its major contribution as the basic cellular unit of hemostasis[11].

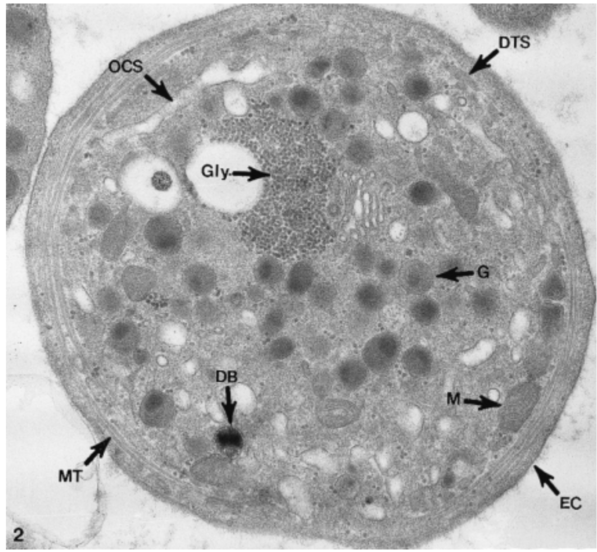
It is the task of the clinical and basic scientist to separate these two missions of the platelet, one desirable and the other potentially catastrophic, so that hemostasis can be achieved and thrombosis prevented. To accomplish this, we must learn as much about the platelet as possible. Our particular niche in this effort has been to dissect the fundamental relationships between platelet structure and function, and relate them to physiology and pathology. This chapter will focus on our current knowledge of platelet morphology and ultrastructure.

Structural organization

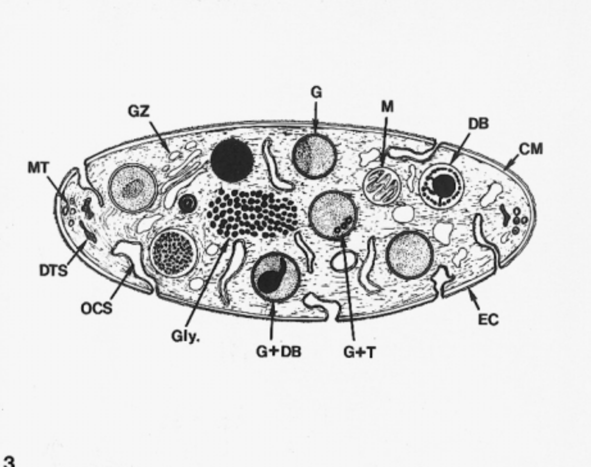
In order to simplify the complicated structural features of platelets and relate them to functional and biochemical activities, we divided the anatomy into three major regions[12,13] (Figs. 3.1–3.4). The peripheral zone consists of the external and internal membrane systems that provide the exposed surface of the platelet and walls of the tortuous channels making up the surface-connected open canalicular system (OCS). An exterior coat or glycocalyx, rich in glycoproteins, constitutes the outermost covering of the peripheral zone. Its chemical constituents provide the receptors for stimuli triggering platelet activation and the substrates for adhesion–aggregation reactions[14,15]. The middle layer of the peripheral zone is a typical unit membrane. It is rich in asymmetrically distributed phospholipids that provide an essential surface for interaction with coagulant proteins[16]. The area lying just inside the unit membrane represents the third component of the peripheral zone. It is closely linked to the unit membrane and translates signals received on the outside surface into chemical messages and physical alterations required for platelet activation[17].

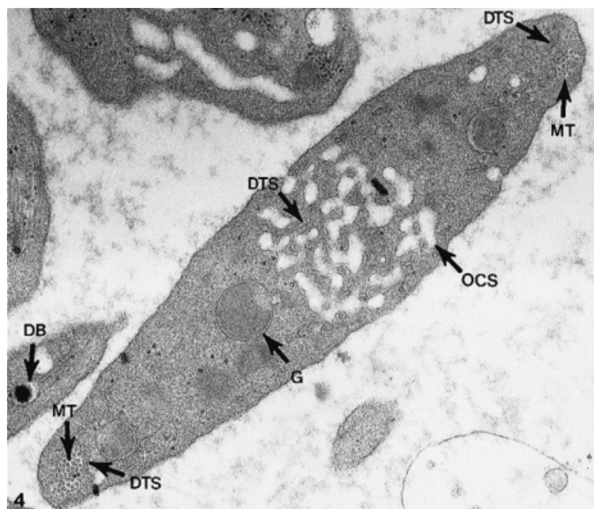
The internal membrane systems include the OCS, even though it is continuous with, and part of, the external membrane system. Channels of the dense tubular system





Figs. 3.1 and 3.2. Discoid platelets. The diagram in Fig. 3.1 summarizes ultrastructural features observed in thin sections of discoid platelets cut in the equatorial plane. Components of the peripheral zone include the exterior coat (EC), trilaminar unit membrane (CM), and submembrane area containing specialized filaments (SMF), which form the wall of the platelet and line channels of the surface-connected canalicular system (CS). The matrix of the platelet interior is the sol–gel zone containing actin microfilaments, the circumferential band of microtubules (MT), and glycogen (Gly). Formed elements embedded in the sol-gel zone include mitochondria (M), granules (G), and dense bodies (DB). Collectively they constitute the organelle zone. The membrane systems include the surface-connected canalicular system (CS) and the dense tubular system (DTS), which serve as the platelet sarcoplasmic reticulum. Fig. 3.2 is a platelet sectioned in the equatorial plane which reveals most of the structures indicated on the diagram (2 Mag ×28 000).





Figs. 3.3 and 3.4. Discoid platelets. The diagram in Fig. 3.3 summarizes the structures observed in platelets in cross-section, and Fig. 3.4 demonstrates an example of a cross-sectioned platelet. The designations for the structural features are given in the legend of Fig. 3.1. Occasionally, a Golgi Zone (GZ) can be found in circulating platelets; and some α-granules contain tubules (G.T.) resembling microtubules (4 Mag ×33 000).

(DTS) and the membrane complexes (MC) formed by elements of the OCS and DTS are internal membrane systems[18], but function with and are considered part of the peripheral zone.

The sol–gel zone is the matrix of the platelet cytoplasm. It contains several fibre systems in various states of polymerization that support the discoid shape of unaltered platelets and provide a contractile system involved in shape change, pseudopod extension, internal contraction, and secretion[19]. Elements of the contractile system appear to be major com-

Cambridge Books Online © Cambridge University Press, 2009

ponents, since they constitute approximately 30–50% of the total platelet protein. Masses as well as discrete particles of glycogen are distributed in the sol–gel matrix.

The organelle zone consists of granules, electron-dense bodies, peroxisomes, lysosomes, glycosomes, and mitochondria randomly dispersed in the cytoplasm. It serves in metabolic processes and for the storage of enzymes, non-metabolic adenine nucleotides, serotonin, a variety of protein constituents, and calcium destined for secretion.

Division of platelet anatomy into three functional zones is arbitrary. However, it does provide a framework for relating structure to function, as well as pathology.

Peripheral zone

It has long been appreciated that the platelet has a sphere of influence that extends beyond its physical limits[20,21]. The cell is affected by chemical signals and various phenomena occurring in flowing blood and in damaged areas of the microcirculation distant from its immediate environment. Chemical messengers originating from activated platelets influence other cells, including neighbouring platelets, leukocytes, and tissues of the vessel wall. Platelets are surrounded by dissolved constituents of blood, in particular the coagulant proteins, with which they interact. This relationship was recognized many years ago, and the term 'atmosphere plasmatique' was employed to describe it[20]. It is important to appreciate the dynamic implications of the peripheral zone and realize that the physical boundaries do not restrict or confine the platelet's biologic activities.

The major structural elements of the platelet peripheral zone are the cell surface and channels of the surface-connected OCS (Figs. 3.1–3.4). Since channels of the OCS represent invaginations of the cell wall, the peripheral zone is a continuous structure and the surface area exposed to surrounding plasma is far greater than might be expected from the usual measurements of the cell size or volume. In this sense, the platelet resembles a sponge more than any other blood cell[21]. The OCS shares the same characteristics of structural organization as more exposed portions of the cell membrane.

The peripheral zone is made up of the three structural domains: the exterior coat, the unit membrane, and the submembrane region as mentioned above. Most cell surfaces follow this same pattern of organization. However, differences in the chemical composition of each layer contribute to the unique properties of different cell types.

Exterior coat

The glycocalyx of the platelet is thicker and more concentrated than similar layers covering the outer surfaces of other blood cells (Fig. 3.5). Many different glycoproteins have been defined by immunocytochemistry and other methods on the exterior coat, including glycoproteins (GP), Ia, Ib, Ic, IIa, IIb, IIIa, IV, V, and VI[22]. Unlike other granule-containing cells, the platelet has a characteristic appearance, rather than the spherical form manifested by lymphocytes, monocytes, neutrophils and other organelle-filled leukocytes[12,13]. Its form is similar to that of the red blood cell, but platelets lack the biconcavity of the erythrocyte (Fig. 3.6). Thus, the platelet is the only flattened or slightly oval, disc-shaped cell in circulating blood. Yet, the smooth discoid appearance of the resting platelet is somewhat deceiving. Studies with electron dense tracers revealed that the exterior surface was frequently interrupted by pores at sites where channels of the open canalicular system (OCS) communicate with the outer membrane[23]. Freeze-fracture revealed pores of the OCS to particular advantage[24] (Fig. 3.7).

Despite the slight irregularity caused by communications of the OCS, techniques of light microscopy, particularly phase contrast and interference phase contrast, transmission electron microscopy of thin sections, whole mounts or replicas of freeze–fractured platelets and conventional scanning electron microscopy have all suggested

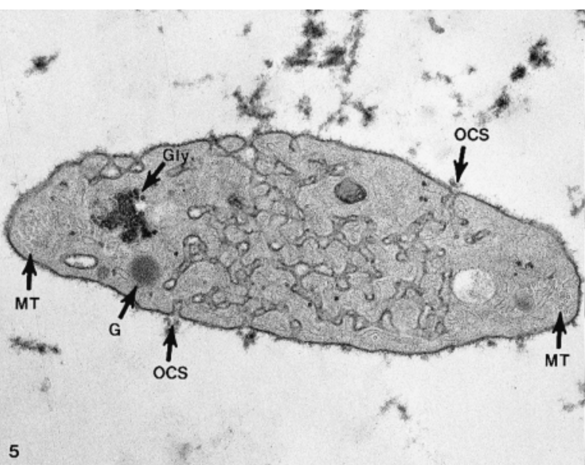


Fig. 3.5. Discoid platelet; the channel system. Cross-section of discoid platelet from sample of C-PRP stained with tannic acid during glutaraldehyde-osmium fixation. Circular profiles of microtubules (MT) supporting platelet discoid shape are evident at each pole of the cell. Tannic acid has acted as a mordant to deposit osmic acid in the exterior coat covering the exposed surface and channels of the open canalicular system (OCS). The OCS forms a system of interconnected channels stretching from one side of the cell to the other. Granules (G) and masses or single particles of glycogen (Gly) are dispersed in the cytoplasm (Mag × 33 000).

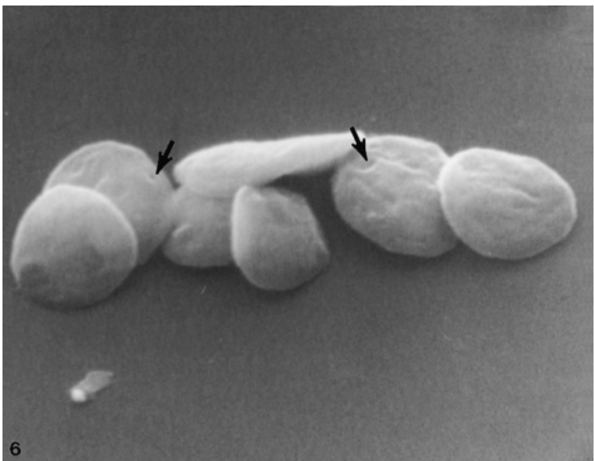

Fig. 3.6. Discoid platelets. The characteristic discoid form of the circulating blood platelet is evident in this scanning electron micrograph (SEM). Surfaces of the unaltered cells are relatively smooth, except for indentations (*arrows*) where channels of the surface-connected OCS communicate with the cell surface (Mag ×12 000).

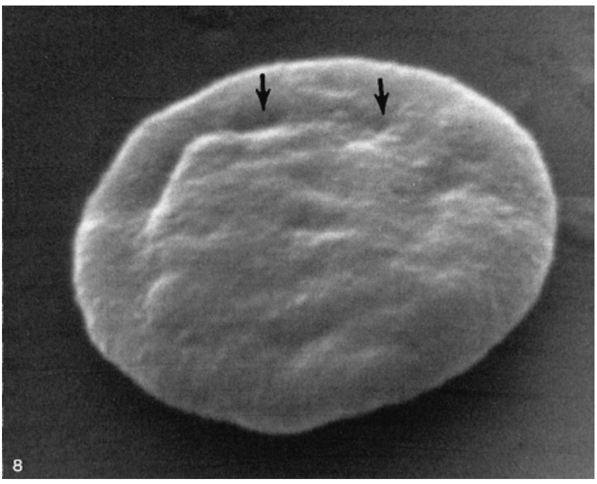

Fig. 3.8. Discoid platelet. Surface features of resting platelets are revealed to advantage in the SEM. The resting platelet has a discoid appearance and relatively smooth contours. Indentations (↑) represent communications between channels of the open canalicular system and the cell wall (Mag ×30 000).

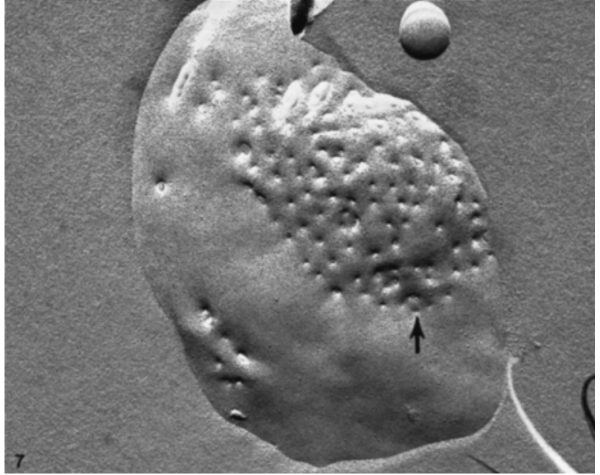

Fig. 3.7. Discoid platelet. Replicas of freeze–fractured platelets reveal communications between channels of the surface membrane to advantage. The fracture plane in this example has cleaved the lipid bilayer exposing the outside portion. Numerous pores (↑) are clustered in one area, and others are apparent along the outer edge (Mag ×30 000).

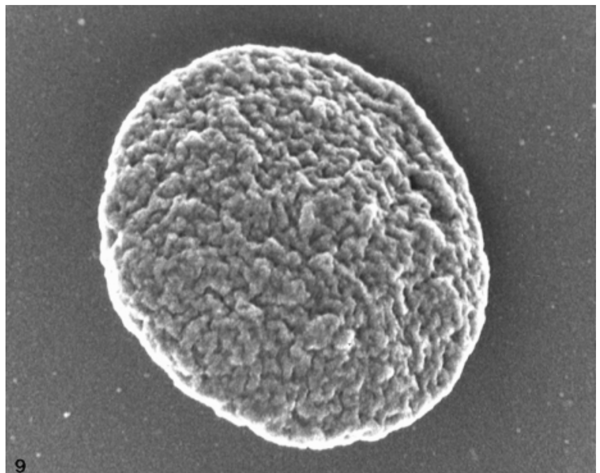

Fig. 3.9. Discoid platelet photographed in the low-voltage, high-resolution scanning electron microscope (LVHR-SEM). The outside of the cell resembles the surface of the brain. Gyri and sulci alternate in a convoluted fashion resulting in the wrinkled appearance (Mag ×40 000).

that the platelet surface is smooth[25] (Fig. 3.8). Low voltage high resolution scanning electron microscopy (LVHR-SEM), however, has suggested a different appearance[26]. Discoid platelets visualized by this technology have a corrugated appearance resembling the surface of the brain (Fig. 3.9). The gyri and sulci produced by the convolutions might result from shrinkage during preparation for study. However, red blood cells present in the same samples are smooth while leukocytes have a totally different appearance.

There are technical reasons why the appearance may have been missed by other methods. Light microscopy and its variants do not have the resolving power to identify the corrugations. Transmission electron microscopy sees

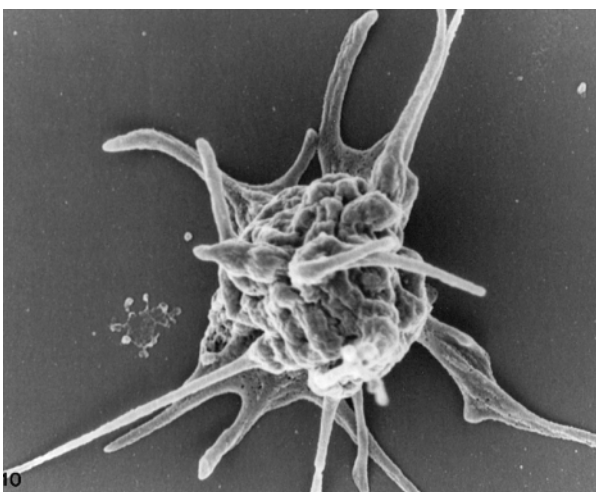

Fig. 3.10. Early dendritic platelet viewed by LVHR–SEM. Fine processes extend in all directions. Surfaces of the pseudopods are smooth compared to the central body from which they extend. Convolutions similar to those on the discoid cell in Fig. 3.8 are present on the platelet body (Mag ×16 000).

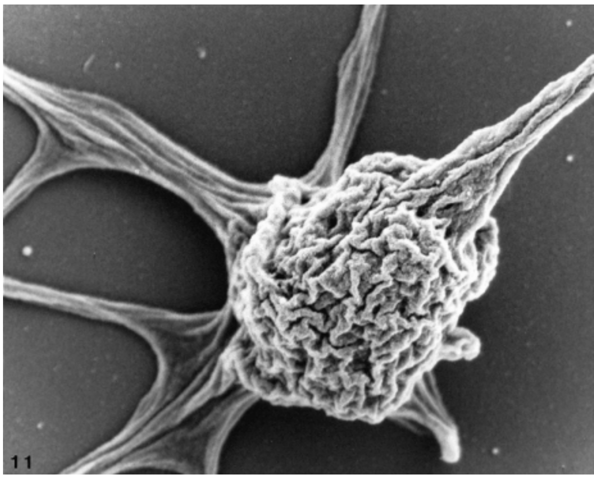

Fig. 3.11. Dendritic platelet. Pseudopods on this example are thicker than those on the cell in the last illustration. Convolutions on the central body extend into folds on the pseudopods (Mag × 33 000).

through transparent membranes of whole mounted platelets and surface details are not apparent. Freeze–fracture splits the membrane lipid bilayer and replicas do not reveal the outside returning from deeper in the specimen. The image generated tends to blur convolutions on the cell surface. Back-scattered electrons under conditions of low voltage derive mainly from the specimen surface and result, not only in high resolution, but a clearer definition of surface details. Thus, the convoluted surfaces on discoid platelets observed by LVHR–SEM may more accurately reflect the true organization of the resting platelet membrane than the smooth surfaced appearance provided by other techniques.

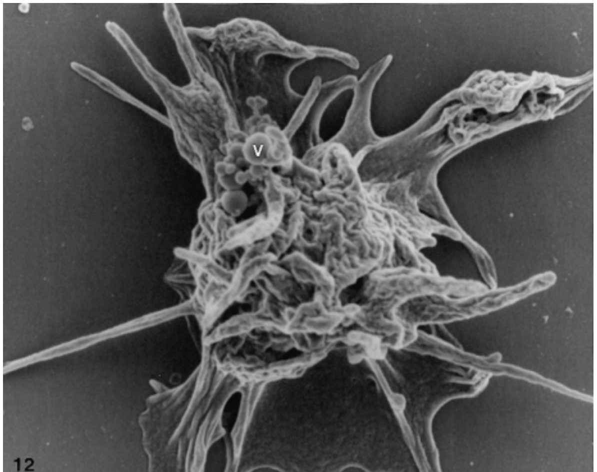

Fig. 3.12. Dendritic platelet. The complex process of surface interaction is revealed on this example. Some pseudopods are beginning to spread out on the formvar surface, while others remain long and smooth. Vesicular elements (↑) present on the convoluted central body may be microvesicles in the process of formation (Mag ×18 000).

Effects of surface activation

The advantage afforded by the convoluted surface of the resting platelet is readily apparent during interaction with surfaces. Extension of long, filiform processes is the first response of the platelet to the foreign surface (Fig. 3.10). They are not as delicate in appearance as those extending from other cell types, and are thicker and more spike-like on human platelets than on bovine cells. The difference is not due to the presence or absence of microtubules. All bovine platelet pseudopods contain at least one microtubule[27] while only one-third of the extensions emanating from human cells reveal a microtubule on cross-section.

The organization of the membrane covering the surface pseudopods on dendritic platelets viewed by LVHR–SEM is quite different than the irregular corrugations formed by gyri and sulci on discoid cells. Convolutions on the central body of the dendritic cell straighten out into long folds (Figs. 3.11, 3.12). The change in organization of surface membrane on extensions of the activated cell while the body retains the convoluted, brain-like pattern adds additional support to the suggestion that this appearance of the platelet surface is not an artefact of fixation. On late dendritic and early spread platelets the folds disappear resulting in a smooth membrane surface. (Fig. 3.13). Clearly, the

Cambridge Books Online © Cambridge University Press, 2009

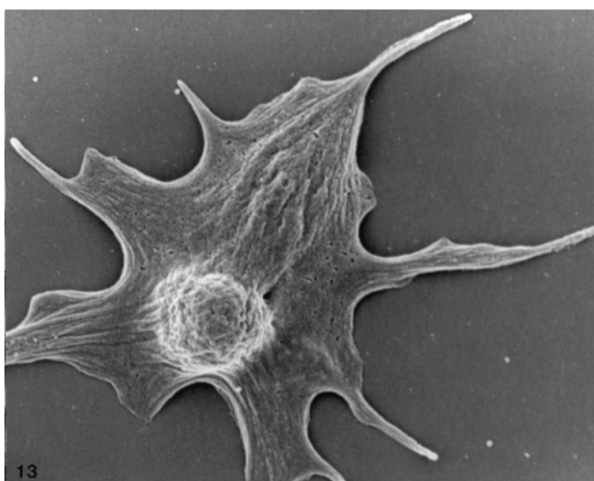

Fig. 3.13. Early spread platelet. The central body of the cell remains convoluted, but is gradually disappearing as the cytoplasm spreads and fills the spaces between pseudopods (Mag × 16 000).

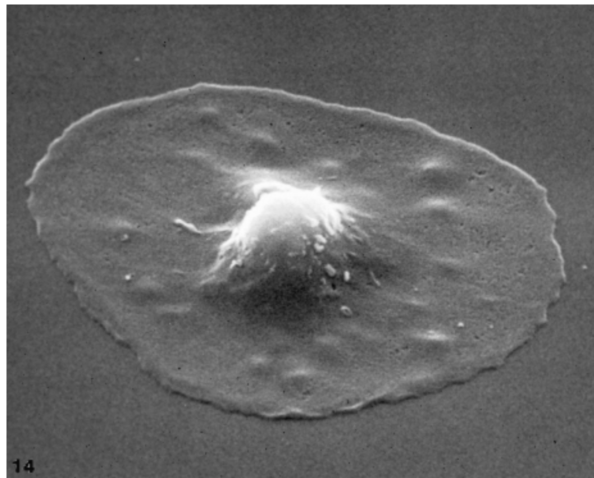

Fig. 3.14. Spread platelet viewed by conventional SEM (Mag × 12 000).

wrinkled surface of the resting cell provides a significant amount of membrane to cover the elongations as discoid cells are converted to dendritic forms.

A major objective of the platelet in hemostasis is to cover as much of the damaged area as possible to restore vascular integrity[11]. It accomplishes this mission by tethering, then sinking into the surface and expanding its cytoplasm to fill spaces between pseudopods. The process converts the flattened disc into a dendritic platelet, and then into a fully spread form. Convoluted membranes of the discoid cells play a significant role in the cytoplasmic expansion, as well as in pseudopod development. Gyri and sulci flatten into a smooth surface as the cytoplasm thins out and expands causing obliteration of the pseudopods. The result is a smooth-surfaced, completely spread cell resembling a pancake (Fig. 3.14).

The force generating mechanism underlying pseudopod formation and spreading is the assembly of cytoplasmic actin[28] (Fig. 3.15). Organization of the newly assembled filaments into parallel bundles produces battering rams to drive out spiky surface extensions. The convoluted surface would provide much less resistance to their extension than a skin tight, smooth membrane. Actin filaments assembling near the cell wall form a peripheral weave under the membrane forcing the expansion and filling in of spaces between pseudopods. Evidence favouring the proposed mechanism of platelet spreading has come from investigations employing cytochalasins B, D, and E[29]. Cytochalasins at concentrations that block development of new actin filaments prevent platelet pseudopod formation and spreading.

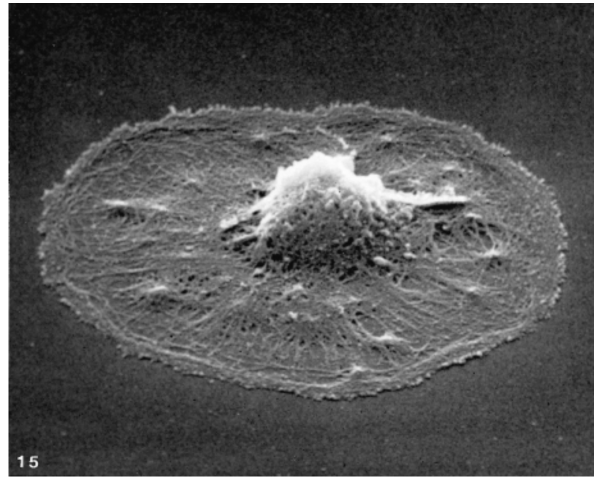

Fig. 3.15. Spread platelet extracted with Triton X-100 and examined in a conventional SEM. The cytoplasm is filled with detergent resistant actin filaments. Small raised areas in the cytoplasm of the extracted cell are adhesion plaques (Mag × 12 000).

During the conversion of discoid platelets to fully spread forms, the exposed surface area increases by over 400%. The origin of the membrane necessary for this large expansion requires consideration. Early workers may not have realized that the lipid bilayer of the surface membrane is incompressible like that of the red blood cell[30], and cannot expand in one direction without contracting in the other. The platelet has no capacity to synthesize lipids or protein. As a result, the expanded surface area cannot originate from new membrane synthesis. Studies in our laboratory

Cambridge Books Online © Cambridge University Press, 2009

suggested that channels of the surface-connected, open canalicular system might serve as a major membrane reservoir[31]. Experiments demonstrating that OCS channels are evaginated onto the cell surface during spreading have been reported[32], and their membranes clearly contribute to the increase in surface area.

However, the reservoir provided by the OCS may be too small to supply enough extra membrane for the fourfold increase in surface area observed during disc to spread platelet transformation. As a result, the corrugated appearance of the discoid platelet resembling the surface of the brain may be particularly important. It could, and apparently does, serve as an additional membrane reservoir for expansion of the platelet surface membrane. Discoid bovine platelets have the same crenelated appearance as human platelets, but lack channels of the open canalicular system[33]. Surface activation of bovine platelets results in extension of pseudopods and conversion into late dendritic forms, but they do not spread like human cells[34]. Yet, they do double their exposed surface area during disc to late dendritic transformation. The gyri and sulci on discoid bovine platelets appear to serve as the major, if not exclusive, source of additional membrane for this expansion.

Thus, the convoluted organization of resting platelets appears to serve a very useful purpose in the hemostatic reaction. It may also be involved in platelet pathology. Sims and his colleagues have shown that the complement proteins, C5b–9, cause release of membrane vesicles from the platelet surface enriched in the membrane receptor for coagulation factor Va and express prothrombinase activity[35]. Similar microvesicles form on platelets during long-term storage and may represent a significant storage lesion (Fig. 3.12). The microvesicles clearly evolve from platelets, but the membrane of origin has not been clear until recently[36]. Platelets do not appear to decrease in volume despite considerable microvesicle formation, and internal membranes are an unlikely source because the cells remain intact. The pinching off of small vesicles from convoluted surfaces of platelets and membranes enclosing secretory organelles would seem a likely explanation for membrane loss without shrinkage of cell volume.

Platelet receptors: In order to exercise their fundamental role in hemostasis, platelets must adhere to the sites of damage on injured vessel walls. Discoid platelets in circulating blood or in platelet-rich plasma and washed suspensions in vitro are not sticky. Contact with subendothelium or other foreign surfaces results in adhesion and initiation of the shape change events. A variety of receptors covering the platelet membrane surface facilitate conversion of the cell to a sticky state[14–16,37–39]. Attachment to extracellular matrix proteins is mediated primarily by a family of heterodimeric cell surface proteins, each composed of α and β subunits. $\alpha_5\beta_1$ is a receptor for fibronectin and $\alpha_6\beta_1$ is a receptor for laminin on human platelets. Other platelet integrin receptors appear to be less specific. $\alpha_v\beta_3$ is a receptor for vitronectin, fibrinogen, fibronectin, thrombospondin and von Willebrand factor.

In addition, platelets carry non-integrin receptors on their surface, such as glycoprotein Ib–IX, the receptor for von Willebrand factor, and glycoprotein IV that binds thrombospondin and collagen. Glycoprotein Ia–IIa ($\alpha_2\beta_1$) is also a receptor for collagen as in GPVI. Although existence of so many molecules serving similar functions may seem redundant, they all appear to play a role in hemostasis.

The major platelet integrin is $\alpha_{IIB}\beta_3$ (glycoprotein IIb–IIIa). About 80 000 copies of $\alpha_{IIB}\beta_3$ are detectable on resting platelets. The complex is not expressed until the cell is activated in suspension or by surfaces. As soon as activation occurs, platelets bind avidly to exposed subendothelium and to each other. The principal substrate for $\alpha_{IIB}\beta_3$ is fibrinogen, but the expressed complex can also bind vitronectin and von Willebrand factor. In terms of overall involvement in platelet physiology and pathology, $\alpha_{IIB}\beta_3$ appears to be the most important integrin receptor, while glycoprotein Ib–IX has that distinction amongst the nonintegrins. At high shear rates GPIb–IX is the primary receptor involved in platelet adherence to subendothelium, while at low shear rates $\alpha_{IIB}\beta_3$ serves that function. Thus, there is a physiologic basis for the redundancy of receptors and receptor complexes.

Receptor mobility: The morphology of platelet receptor interactions with surfaces has been difficult to visualize in the electron microscope because they occur at a molecular level beyond the resolution of available instruments. However, the use of immunofluorescent microscopy and immunocytochemical methods combined with electron microscopy have largely circumvented this problem. Fluorescence microscopy revealed that platelets in suspension exposed first to monoclonal antibodies against GPIIb–IIIa $\alpha_{IIB}\beta_3$ and then fluorescein tagged antiimmunoglobulin revealed a sequence of clustering, patching, capping and endocytosis similar to events observed on lymphocytes exposed to immune reactions[40–42]. Studies with fluorescein conjugated concanavalin A revealed a similar sequence of patching/capping on platelets.

Polley et al.[43] were probably the first to demonstrate movement of receptors on platelets at the ultrastructural level. Immunocytochemical methods combined with a membrane fragmentation procedure were used to demonstrate that thrombin treatment caused clustering or patching of GPIIb–IIIa receptors on platelet surfaces. Eisenberg

Cambridge Books Online © Cambridge University Press, 2009

and colleagues[44] used a replica technique to demonstrate that ADP induced ligand binding and fibrinogen receptor clustering on platelet surface membranes. Santoso and associates[45] demonstrated receptor patching on platelets exposed to monoclonal antibodies or incubated with concanavalin A at the ultrastructural level, confirming the observations made by immunofluorescence. Loftus and Albrecht[46] and, subsequently, Albrecht et al.[47–49] introduced the use of fibrinogen-coated, colloidal gold particles to study GPIIb–IIIa receptors on surface-activated platelets. Their findings suggested that the shape change and spreading caused by surface activation stimulated redistribution of GPIIb–IIIa receptors into caps on spread platelets.

Investigations by Hourdille et al.[50] have shown that thrombin causes spontaneous clearance of GPIb–IX from the platelet surface to channels of the open canalicular system. More recently, she and her colleagues[51] demonstrated that von Willebrand factor bound to glycoprotein Ib–IX is cleared from the platelet surface following activation by thrombin. The dynamic redistribution of major platelet surface receptors following surface activation and spreading has been confirmed and extended by Kieffer et al[52]. Thus, evidence coming from many investigations indicates that major integrin and nonintegrin receptors on platelets are mobile and undergo relocation, clustering, patching, capping and clearance following exposure to potent stimuli in suspension or after contact with foreign surfaces.

Work in our laboratory has confirmed many of the findings reported by others and added additional information to the knowledge of mobile receptors on platelet surfaces[53]. Initial experiments were carried out on platelets allowed to spread on carbon-stabilized, formvar-coated grids for 20 minutes and then exposed to fibrinogen-coated gold particles (Fgn/Au) for 5 minutes at 37 °C. Most cells retaining a discoid configuration failed to bind Fgn/Au, though some did (Fig. 3.16). The morphological difference between discoid cells expressing GPIIb–IIIa and those not binding the electron dense probe was not apparent. Early dendritic forms were covered by particles of Fgn/Au (Fig. 3.17). The distribution appeared random and discrete, though a suggestion of clustering may have been due to the convoluted organization of the platelet surface discussed above. On late dendritic cells manifesting early signs of pseudopod and cytoplasmic spreading, Fgn/Au particles moved away from the edges to the midlines of surface extensions and from them and the cell body toward the central region (Fig. 3.18).

The tendency of the Fgn/Au bound to $\alpha_{IIB}\beta_3$ receptors to move away from peripheral margins toward cell centres

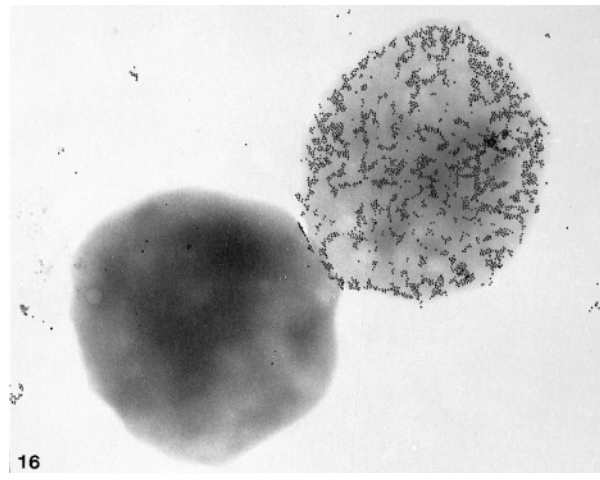

Fig. 3.16. Platelets incubated with 10^{-6} M cytochalasin E in suspension before contact with a formvar grid for 20 min and subsequent exposure to fibrinogen-coated gold (Fgn/Au) particles for 5′. Both cells have retained their discoid shape. However, only one platelet has expressed glycoprotein IIb–IIIa receptors and bound a significant number of Fgn/Au particles. Only a few receptors ligand complexes are apparent on the other discoid platelet (Mag ×16 000).

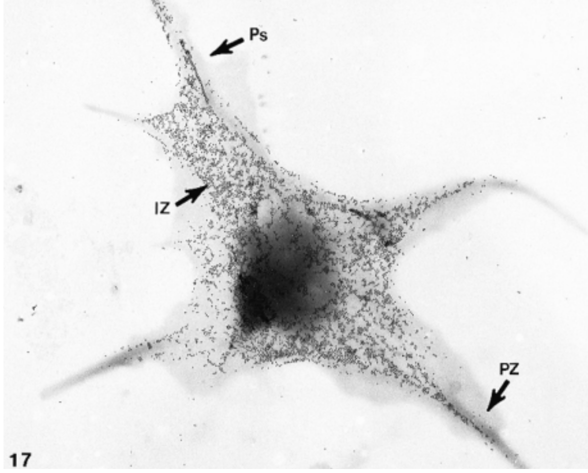

Fig. 3.17. Early dendritic platelet exposed to fibrinogen-gold (Fgn/Au) for 5 min after initial contact with a formvar-coated, carbon-stabilized grid for 20 min before fixation in glutaraldehyde. Fgn/Au spherules extend out onto pseudopods (Ps) and coat the intermediate zone (IZ) and central zone (CZ). Areas of the cell margin on pseudopods and along the peripheral zone (PZ) appear virtually free of gold particles (Mag ×12 000).

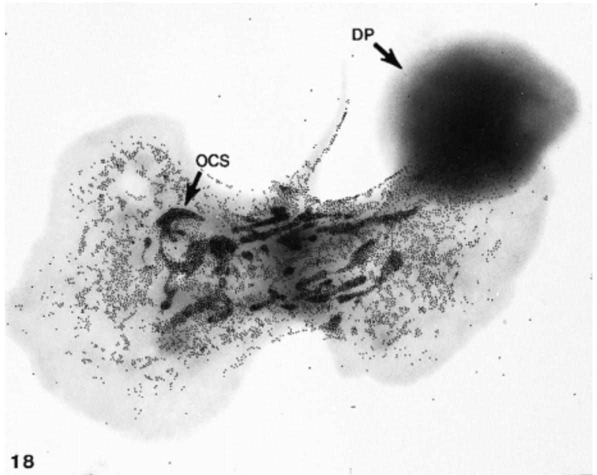

Fig. 3.18. Late dendritic platelet. Cell is from a sample prepared in the same manner as the cell in Fig. 3.17. Fgn/Au particles bound to GPIIb–IIIa receptors have moved from the peripheral border toward the platelet centre and into channels of the open canalicular system (OCS). A discoid, resting platelet has not expressed GPIIb–IIIa receptors and, as a result, has not bound Fgn/Au particles (Mag ×16 000).

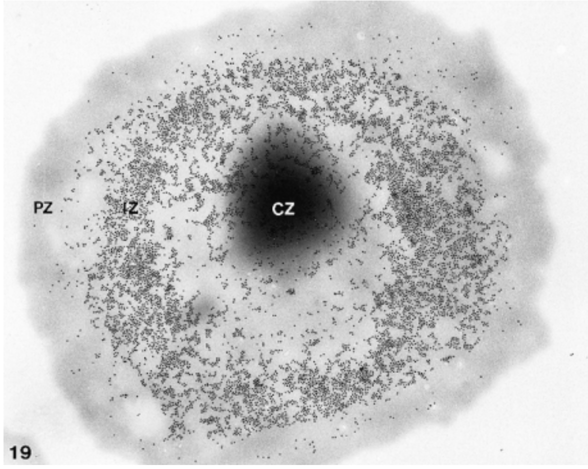

Fig. 3.19. Fully spread platelet exposed to Fgn/Au for 5 min. Electron-dense probes bound to GPIIb–IIIa receptors have moved from the peripheral zone (PZ) to form a concentrated ring in the immediate zone (IZ) around the central zone (CZ). The central area is nearly as devoid of receptor–ligand complexes as the peripheral zone (Mag ×18 000).

was more prominent on early spread and fully spread platelets[54]. Fgn/Au receptor complexes became concentrated in a ring located in the intermediate zone (Fig. 3.19). The central area of spread platelets was nearly as devoid of Fgn/Au probes for $\alpha_{IIB}\beta_3$ as the peripheral zone. Exposure

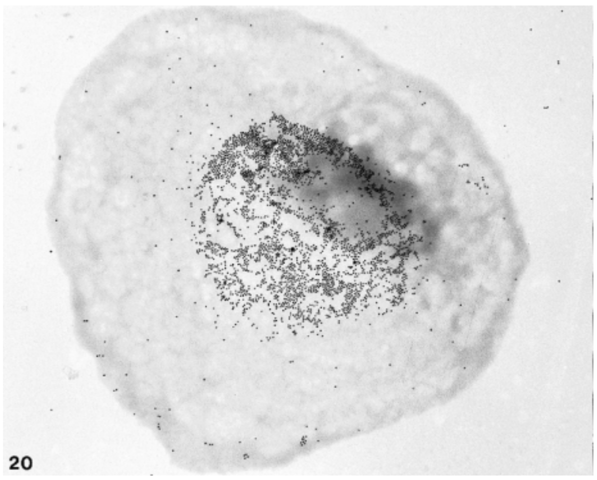

Fig. 3.20. Capping. Fully spread platelet exposed to Fgn/Au for 5 min, rinsed and then rested on a drop of Hank's balanced salt solution for 15 min at 37 °C. Fgn/Au bound to GPIIb–IIIa receptors have moved into a concentrated mass or cap on the central zone. The intermediate and peripheral zones are virtually devoid of Fgn/Au particles, suggesting that nearly all of the GPIIb–IIIa receptors have been translocated to the cell centre (Mag ×18 000).

of spread platelets to Fgn/Au for longer intervals of 10 to 30 minutes did not result in concentration of receptor–ligand complexes in the central zone. However, simply rinsing excess gold from the grid with Hank's balanced salt solution (HBSS) and allowing the grid to rest on a drop of HBSS for 10 minutes at 37 °C caused further central movement of Fgn/Au bound to $\alpha_{IIB}\beta_3$, resulting in cap formation[55] (Fig. 3.20). Precisely why this manoeuvre causes capping to occur when longer incubation fails remains obscure. It is possible that the Fgn/Au suspension inhibits further spreading of platelets during the 5-minute incubation, and that washing and resting on HBSS removes the inhibitory influence.

The appearance of the platelet with a central cap of Fgn/Au–$\alpha_{IIB}\beta_3$ complexes is striking. Intermediate and peripheral zones of the cells are virtually devoid of Fgn/Au particles, suggesting that nearly all of the $\alpha_{IIB}\beta_3$ receptors have been cleared to the cell centres. However, addition of another drop of Fgn/Au after capped cells are fixed results in edge to edge coverage of the peripheral and intermediate zones[56]. If capped cells are exposed to small latex spherules without prior fixation, these particles bind to the bare areas and move into a ring around the central cap of Fgn/Au–$\alpha_{IIB}\beta_3$ complexes, leaving the peripheral margin bare (Fig. 3.21). Rinsing the capped platelets ringed with latex particles, and subsequent exposure to a drop of Fgn/Au results in binding of the electron-dense probe for

Cambridge Books Online © Cambridge University Press, 2009

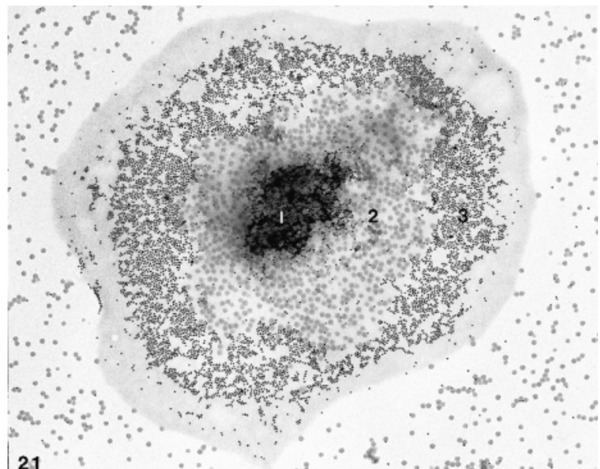

Fig. 3.21. Spread platelet exposed to Fgn/Au, rinsed and rested on HBSS, and then exposed in the same manner to small latex spherules, washed and arrested on HBSS and exposed again to Fgn/Au. The first wave of Fgn/Au–GPIIb–IIIa complexes are concentrated in a central cap (1). Latex spherules have concentrated into a ring around the cap (2) and the second wave of Fgn/Au has moved centrally into a ring around the latex (3). The peripheral margin is virtually clear of receptor–ligand complexes (Mag $\times$18 000).

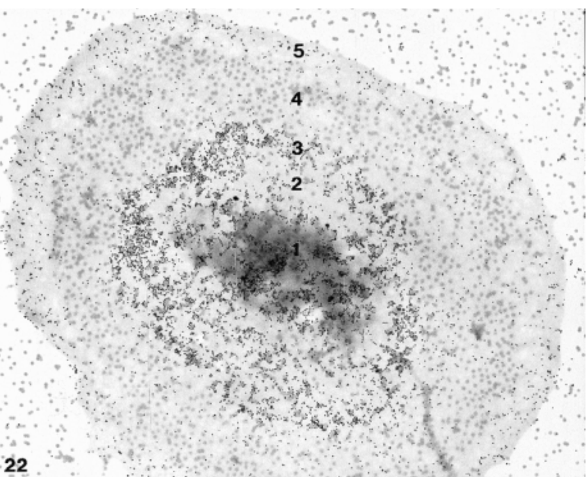

Fig. 3.22. The spread platelet in this example was exposed first to Fgn/Au (1) then to latex (2), then to Fgn/Au (3) followed by another incubation with latex (4), washed and fixed in 0.1% glutaraldehyde. Subsequently, the platelet was incubated in Fgn/Au (5) and examined in the electron microscope. The cap of Fgn/Au–GPIIb–IIIa complexes is surrounded by two rings of latex interspersed with two rings of Fgn/Au. Formation of the central cap of receptor–ligand complexes has not exhausted the supply of GPIIb–IIIa elsewhere on the exposed cell surface (Mag $\times$ 10 000).

$\alpha_{IIB}\beta_3$ to the barren area. The receptor–ligand complexes undergo central movement into a ring around the latex spherules, again leaving a bare peripheral margin. Repetition of the sequence resulted in capped cells with two rings of latex separating two of Fgn/Au–$\alpha_{IIB}\beta_3$ complexes (Fig. 3.22). Capping does not exhaust the supply of $\alpha_{IIB}\beta_3$ receptors on spread platelets. Yet, the origin of the $\alpha_{IIB}\beta_3$ receptors binding the second and third waves of Fgn/Au remains unclear. Evidence that they are being recycled from the central cap has not been convincing.

The major destination of Fgn/Au–$\alpha_{IIB}\beta_3$ complexes on spread platelets is not limited to the intermediate or central zones. About 5–10% of the spread platelets contain channels of the surface connected OCS filled with Fgn/Au bound to $\alpha_{IIB}\beta_3$ (Figs. 3.18, 3.23). Experiments to determine why more spread platelets did not contain OCS channels filled with Fgn/Au receptor complexes provided two answers, both of which appear to be correct[57]. First, most of the OCS channels in fully spread platelets had already been evaginated out onto the surface. Only a very large cell appeared less capable of completely evaginating the OCS, and was, therefore, much more likely to display Fgn/Au filled OCS channels. The second reason was that the spreading process produced sufficient tension, both horizontally and vertically, to seal off the residual OCS channels. Treatment of fully spread platelets after exposure to

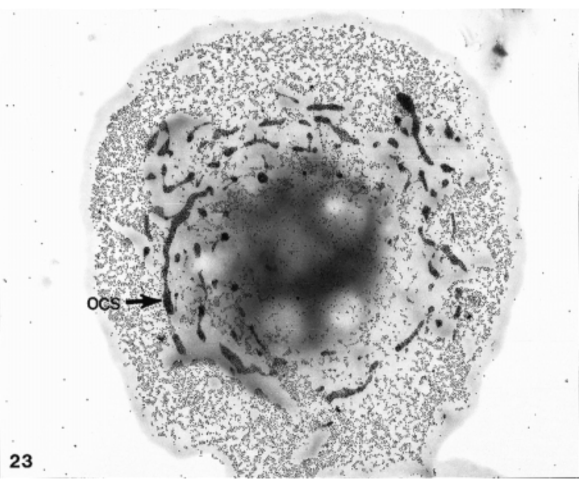

Fig. 3.23. Spread platelet exposed to Fgn/Au probes for 5 min. Receptor–ligand complexes have moved from the periphery toward the cell centre and into channels of the OCS (↑). The central area is more electron-opaque because it is the residual body. Few Fgn/Au markers for GPIIb–IIIa are present centrally (Mag $\times$15 000).

Cambridge Books Online © Cambridge University Press, 2009

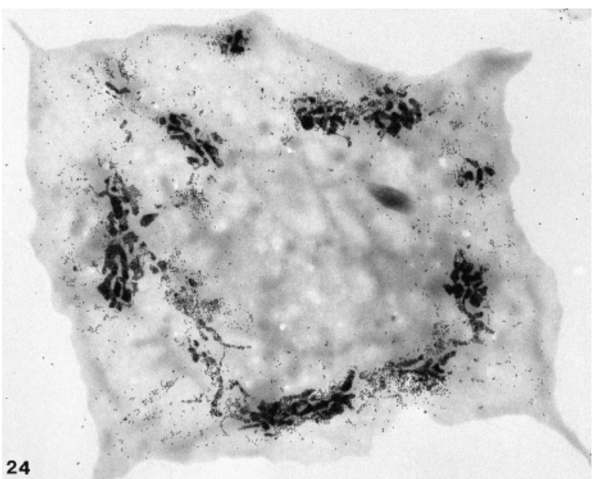

Fig. 3.24. Spread platelet exposed to Fgn/Au for 5 min and then to 10^{-4} M cytochalasin B. The agent has caused breakdown of new actin filaments near the cell periphery. Central movement has been reversed and Fgn/Au-GPIIb–IIIa complexes have moved back toward the periphery. Relaxation of the cell periphery by cytochalasin E has exposed residual short channels of OCS. The receptor–ligand complexes are deposited in the short OCS channels (Mag ×11 000).

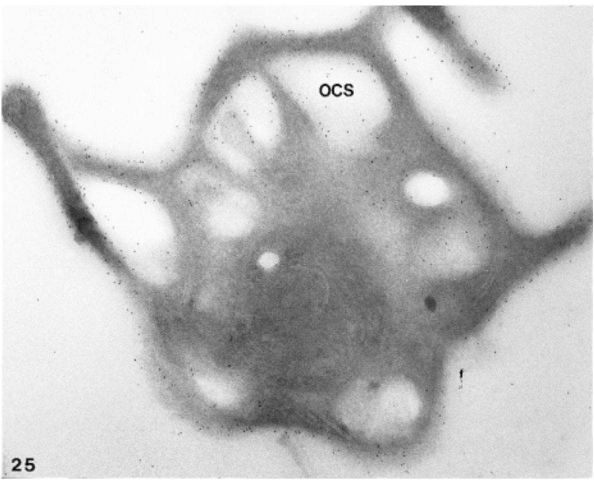

Fig. 3.25. Immunolocalization of GPIb in a frozen thin section obtained from platelets exposed to 1 U/ml of thrombin for 10 minutes in suspension. Section was incubated with a polyclonal antibody against glycocalicin followed by protein A-gold (5 nm). The cell has become irregular after exposure to thrombin and channels of the OCS (↑) are dilated. Exposed surface membrane and membrane lining channels of the OCS are evenly labeled with gold particles indicating sites of GPIb (Mag ×54 000).

Fgn/Au first with cytochalasin B resulted in softening of the peripheral margins due to new actin filament disassembly and appearance of Fgn/Au–receptor complexes in short segments of OCS near the cell margin (Fig. 3.24). Uptake of Fgn/Au bound to $\alpha_{IIB}\beta_3$ into OCS channels was always greater in early dendritic platelets than in spread cells, just as it is in thrombin-treated platelets in suspension. Thus, the OCS appears to be the principal destination for receptor–ligand complexes on surface-activated platelets, just as it is on suspension-activated cells[58,59].

Other studies have examined the distribution of GIb–IX and $\alpha_{IIB}\beta_3$ receptors on suspension and surface-activated platelets before and after exposure to 1 U/ml of thrombin for 10 minutes[60]. Frozen thin sections prepared from fixed suspension-activated platelets or grids containing fixed surface-activated platelets were stained with specific antibodies to GPIb–IX (anti-glycocalicin) and $\alpha_{IIB}\beta_3$ (AP_2 or 7E3), and incubated with the corresponding gold-coupled secondary antibody. GPIb–IX and $\alpha_{IIB}\beta_3$ were present in the open canalicular system of resting and, more prominently, in dilated OCS channels of cells activated by thrombin in suspension (Figs. 3.25, 3.26). On surface-activated platelets more intense labelling for GPIb–IX was observed along pseudopods of dendritic cells while $\alpha_{IIB}\beta_3$ receptors were slightly increased over the peripheral zone (Figs. 3.27, 3.28). The observations support previous investigations

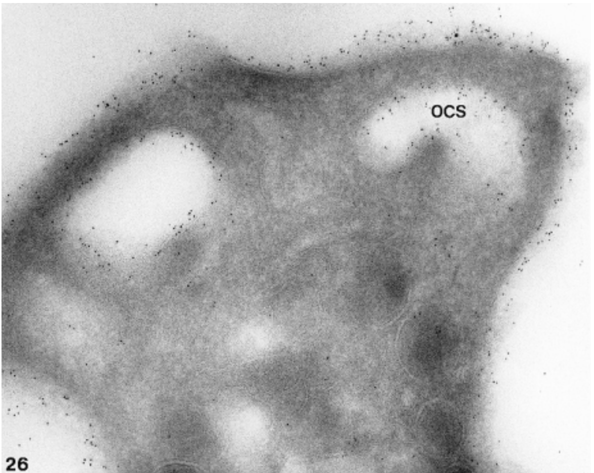

Fig. 3.26. Immunolocalization of GPIIb/IIIa in another frozen thin section from the sample shown in the previous illustration. In this section, a monoclonal antibody against GPIIb/IIIa (AP-2) was used followed by a goat antimouse IgG coupled to gold (5 nm). Gold particles indicating sites of GPIIb/IIIa are evenly distributed on the external membrane and membranes lining channels of the OCS (Mag ×54 000).

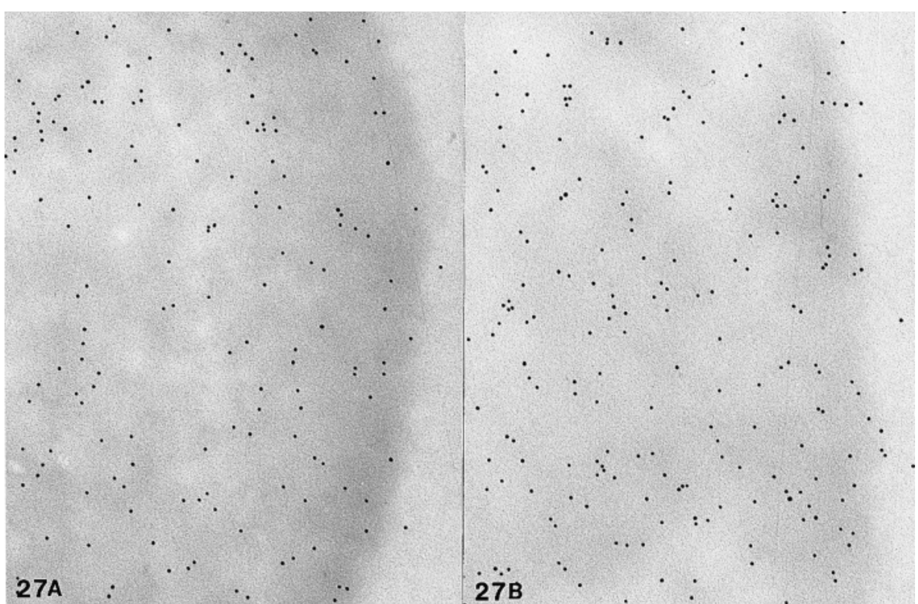

Fig. 3.27(*a*) and (*b*). Immunolocalization of GPIb on dorsal surface of fully spread platelets. The cells were allowed to interact with formvar coated grids for 20 minutes and for an additional 10 minutes to (*a*) buffer or (*b*) to thrombin, 1 U/ml. GPIb receptors are evenly dispersed over platelet surfaces from edge to edge before (*a*) and after (*b*) exposure to thrombin (Mag ×50 000).

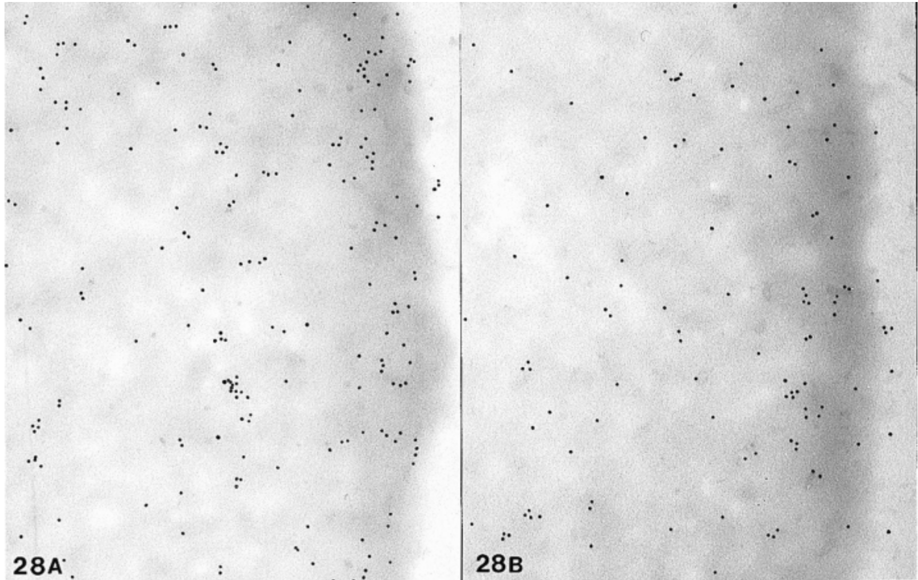

Fig. 3.28(*a*) and (*b*). Immunolocalization of GPIIb/IIIa on fully spread platelets (20 min) allowed to interact with (*a*) buffer or (*b*) thrombin, 1 U/ml, for an additional 10 min. The distribution of gold particles indicating sites of GPIIb/IIIa are essentially the same before and after exposure of spread platelets to thrombin (Mag ×50 000).

Cambridge Books Online © Cambridge University Press, 2009

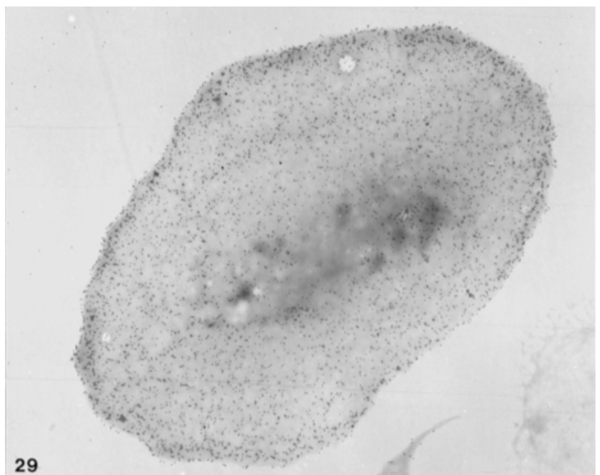

Fig. 3.29. Surface-activated, fully spread platelet fixed in 0.01% glutaraldehyde before exposure to Fgn/Au. Particles of Fgn/Au are evenly dispersed over the entire platelet from edge to edge. Thus, fibrinogen receptors marked by Fgn/Au do not spontaneously reorganize during the shape change stimulated by surface activation (Mag ×12 000).

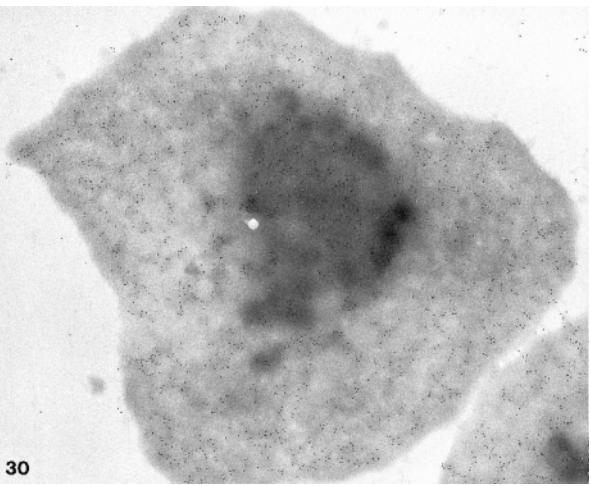

Fig. 3.30. Platelet from sample of washed cells exposed to 0–5 U/ml of thrombin in suspension for 10 min and spread on formvar grid for 20 min before fixation. The fixed cells were incubated with ristocetin-activated human plasma and then stained by anti-vWF and PAG_{10}. Multimers of vWF cover the cell surface from edge to edge (Mag ×16 500).

demonstrating that shape change and spreading do not cause spontaneous clearance of $\alpha_{IIB}\beta_3$ receptors, and also indicate that GPIb–IX receptors are resistant to spontaneous clearance from exposed membranes of surface- or suspension-activated platelets before or after exposure to thrombin.

The experiments described here, and in other work from our laboratory, strongly support the concept that major integrin and non-integrin receptors on platelet surfaces are mobile[61]. However, the receptors are not spontaneously cleared from the cell surface by exposure to thrombin in suspension, or treatment with this agent after the cells are already activated on surfaces[62,63] (Figs. 3.29, 3.30). $\alpha_{IIB}\beta_3$ receptors may be cleared to channels of the OCS from exposed membranes of surface- and suspension-activated platelets, but are by no means exhausted by the process. Rather, new populations of the fibrinogen receptors are ready to react, even though substantial numbers appear to have formed caps with the ligand or concentrated in channels of the OCS. GPIb–IX also resists spontaneous clearance on surface and suspension-activated platelets[64] (Figs. 3.31, 3.32). It remains to be determined whether clearance of GPIb–IX with von Willebrand factor to channels of the OCS following exposure of platelets to thrombin exhausts the supply of the receptor on exposed surfaces, or that they are replaced by new populations capable of interacting with vWF.

It should be appreciated, however, that nearly all the

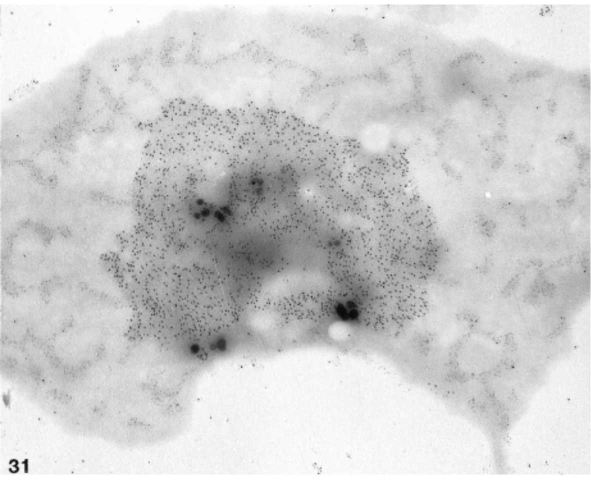

Fig. 3.31. Platelet from sample of washed cells treated with thrombin, 2 U/ml, in suspension for 10 min, spread on a grid for 20 min, incubated with bovine vWF for 15 min, followed by anti-vWF antibody for 20 min. The cells were fixed with 0.01% glutaraldehyde and stained with PAG_{10}. The grid was then washed, exposed again to bovine vWF, combined with anti-vWF antibody, and stained with PAG_5, before refixation. The cap of vWF multimers stained by PAG_{10} is concentrated in the cell centre. Multimers of vWF from the second exposure to bovine plasma are stained by PAG_5 and extend from the central cap to the cell margin (Mag ×23 000).

Cambridge Books Online © Cambridge University Press, 2009

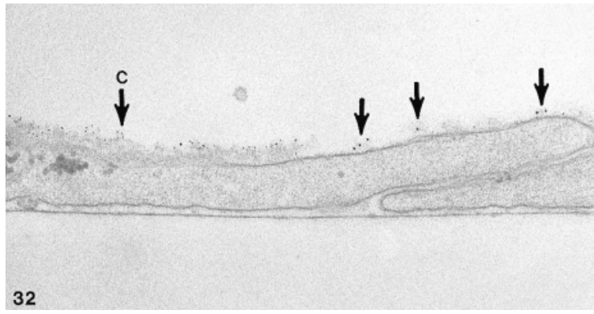

Fig. 3.32. Thin section of a platelet treated in the same manner as the cell in the previous illustration, except that it was spread on glass. PAG_5 was used for the first exposure to vWF, and PAG_{10} for the second. A cap (C) consisting of vWF, vWF antibody and PAG_5 covers the central area of the platelet surface. Multimers extending from the cap to the cell edge are stained by PAG_{10} (↓) (Mag ×40000).

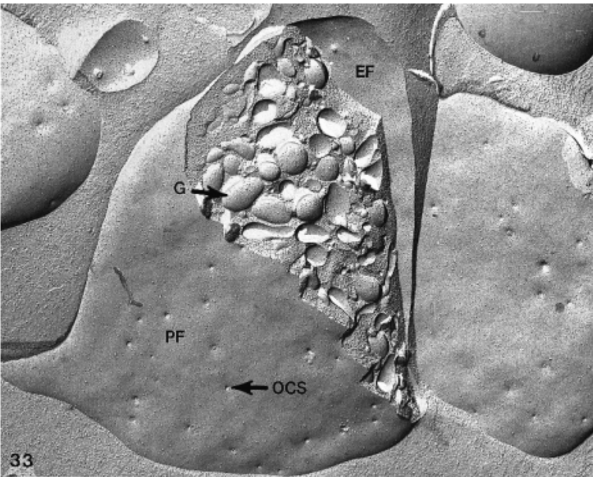

Fig. 3.33. Unit membrane. Platelets from a sample of citrated PRP fixed in glutaraldehyde, infiltrated with glycerol, frozen in liquid nitrogen, and fractured in a freeze–etch device. A carbon–platinum replica of freeze–fractured surface reveals many details of platelet unit membrane and membrane systems. Freeze–fracture splits the lipid bilayer exposing the outer surface of the inner leaflet (PF) or the inner side of the outer layer (EF). Each face is covered by randomly dispersed particles varying slightly in size. Communications between channels of OCS and cell surface appear as small indentations on PF and interiorly directed protuberances on EF. Granule (G) membranes in platelet cytoplasm are also coated with small particles (Mag ×26000).

experiments reported thus far have focused on the translocation of major non-integrin and integrin receptors bound to movable ligands across the cell surface to channels of the OCS. Yet, the ligands to which platelets adhere on damaged vascular surfaces are not mobile[61]. Therefore, mobile receptors must have some other function than to clear the surface of ligands, thereby eliminating their own availability for hemostasic reactions. Indeed there is. Experiments indicate that mobile receptors are critical to the process of platelet tethering and spreading on injured vessels, foreign surfaces, fibrin strands and each other. The mobile receptors, primarily GPIb–IX and $\alpha_{IIB}\beta_3$, bind to ligands exposed in the subendothelium and form stable complexes. The platelet cannot move these rigid receptor ligand complexes to channels of the open canalicular system. Instead, the platelet surface and membranes lining OCS channels move through the stable receptor–ligand complexes driven by assembling actin in order to achieve maximum spreading. While the major function of the receptors is to secure platelet adhesion, the reason why they are mobile is to facilitate extension of the surface membrane over as much surface area as possible. If the platelet had rigid, immobile receptors, adhesion of discs to a surface could not be followed by spreading.

Unit membrane

The platelet unit membrane provides a physico-chemical separation between intracellular and extracellular constituents and processes. Important components of the platelet unit membrane are the Na/K ATPase and the anion pump, which help maintain the appropriate transmembrane ionic gradients. Examination of trilaminar membranes of the peripheral zone in thin sections of platelets has failed to reveal any apparent differences from unit membranes of other blood cells. Replicas of freeze–fractured platelets, however, reveal significant variations in the number and distribution of intercalated particles[65] (Figs. 3.7, 3.33). The outside of the inner face (P face) and the interior of the outer lamellae (E face) of the split lipid bilayer of red cell membranes are coated with particles, whereas intercalated particles on similarly exposed surfaces of freeze-fractured platelets are few and randomly dispersed. Intramembranous particles are present in largest numbers on the P face of red cells, but are most numerous on the E face of platelet split lipid bilayers. It is likely that the intercalated particles represent portions of transmembrane proteins buried in lipid constituents.

Schick, Kurica, and Chacko[66] have used a nonpenetrating membrane probe, 2,4,5-trinitrobenzenesulfonate, in an attempt to localize phospholipid groups in the platelet surface membranes. Results of their study suggest that the bilayer is asymmetric with regard to its phospholipid composition. Phosphatidylserine does not appear to be part of the exposed surface, whereas a significant proportion of the phosphatidylethanolamine was labelled by the mem-

Cambridge Books Online © Cambridge University Press, 2009

brane probe in activated cells, particularly in thrombin-treated platelets. Thus, even though studies of chemical composition have not indicated striking differences in platelet lipids compared to other blood cells, the organization of specific molecules in the bilayer appears to impart unique properties to the surface.

Despite the absence of distinguishing physical characteristics, the platelet unit membrane is considered to be of critical importance in the physiology of hemostasis. During platelet aggregation and transformation, the cells provide an essential substance for acceleration of blood coagulation[67]. This substance, often referred to as platelet factor 3, is believed to reside in the lipoprotein-rich unit membrane. The mechanism by which the membrane phospholipid becomes exposed to serve as a catalytic surface for plasma proteins is not known with certainty.

The ability of the platelet unit membrane to maintain ionic gradients may rival its importance as a surface for accelerating coagulation. Simons and her colleagues have used fluorescent probes to follow changes in the pH gradient across platelet surface membranes[68]. Their studies suggest that neutralization of the transmembrane pH gradient is the earliest event to occur after exposure of platelets to an activating agent.

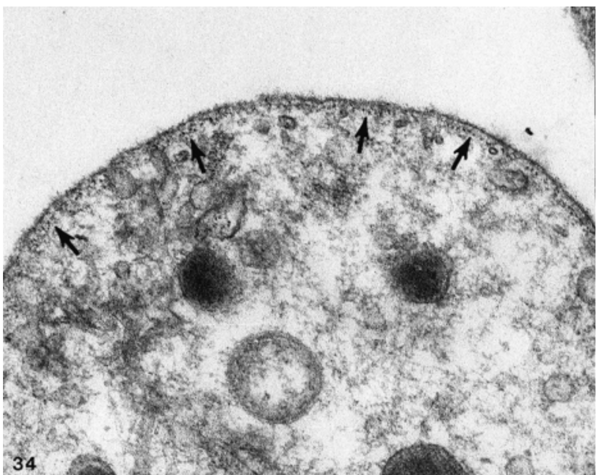

Fig. 3.34. Submembrane area. Filaments are the major constituents of this region but are difficult to resolve in well-fixed platelets because of the density of the cytoplasm (see Fig. 3.2). However, the submembrane filaments are revealed as a nearly continuous layer (*arrows*) just inside the surface following exposure of the cells to osmotic or chemical shock (Mag × 58 000).

Submembrane region

The area lying just under the unit membrane of the platelet surface has special characteristics that impel its inclusion with other structural components of the peripheral zone. It has been evident for some time that organelles inside the matrix of unaltered platelets never contact the cell wall. The nature of the special barrier under the cell surface has been unclear, but the submembrane area has been shown to contain a relatively regular system of filamentous elements[69] (Fig. 3.34). Submembrane filaments are obscured by the dense matrix of the sol–gel zone, but they can be seen peripheral to the circumferential band of microtubules in discoid cells. Treatment with chemical or osmotic shock renders them visible as a distinct system under the unit membrane. Submembrane filaments are physically similar to actin microfilaments[70] (Figs. 3.35, 3.36). However, it is possible that they are the physical equivalents of filamin, α-actinin, or some other anchoring protein for the platelet contractile system. The close association of submembrane filaments with the cell surface is the distinguishing feature of this system and the reason that it is considered part of the peripheral zone. Functionally, the submembrane filaments may cooperate with circumferential microtubules to maintain platelet discoid shape, contribute to the extrusion and stabilization of pseudopods, and interact with other elements of the

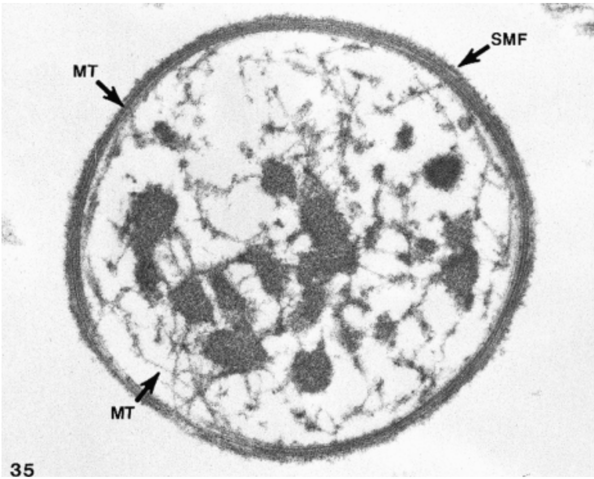

Fig. 3.35. Suspension cytoskeleton. Thin section of a platelet fixed after detergent extraction in the presence of lysine and phalloidin. The microtubule (MT) is well preserved. A rough amorphous coat is evident on its outer surface. Remnants of alpha granules are suspended in a matrix of actin microfilaments (MF) resistant to detergent extraction. Submembrane filaments (SMF) form a fine fuzz on the outer coil of the circumferential microtubule (Mag ×29 000).

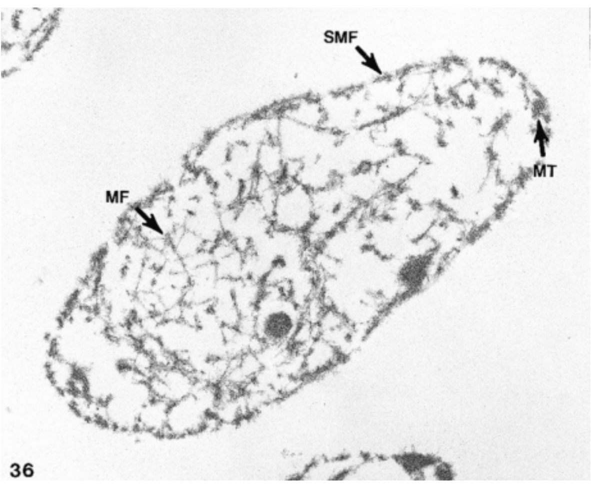

Fig. 3.36. Suspension cytoskeleton. Cross section of a discoid platelet cytoskeleton. The cell is from a sample of citrated-PRP treated with taxol (10^{-4} M) before extraction. Microtubule (MT) profiles are evident at the polar ends of the cell. A meshwork of the microfilaments (MF) replaces the cytoplasmic matrix. Although the surface membrane is gone, a fine amorphous layer of submembrane filaments (SMF) remains in its place (Mag × 29 000).

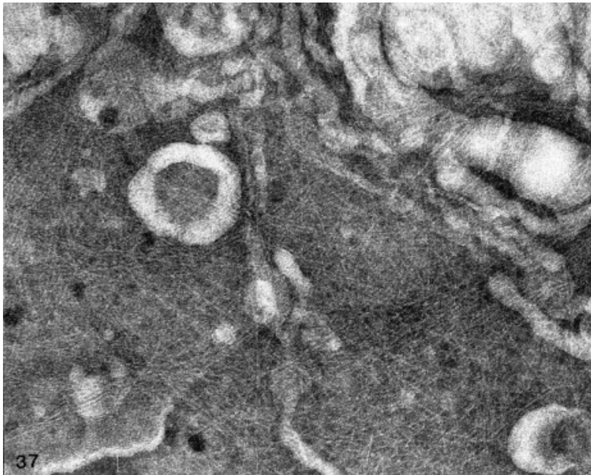

Fig. 3.37. Sol–gel zone. Cytoplasm of a negatively stained whole-mount of a spread platelet. The matrix of the cell is filled with an irregular meshwork of microfilaments. The 50 Å fibres are indistinguishable from the subfilaments of microtubules and submembrane filaments (Mag × 66 000).

platelet contractile mechanism to effectuate viscous metamorphosis and clot retraction[19,28,70].

Sol–gel zone

Early light and phase contrast microscopic studies revealed the presence of organelles inside blood platelets, but the transparency of the matrix prevented recognition of other structural components. The formed bodies were believed to be dispersed in a fluid suspension or salt solution, the clarity of which suggested the term hyaloplasm. Although it is now apparent that the internal environment of platelets is made up of many structural elements, the idea that these components are in solution or suspension remains prevalent. When thin sections of platelets were examined in the electron microscope the internal matrix appeared to consist of an irregular meshwork of fibrous material in which were embedded formed organelles. It was suggested that the matrix was an artefact created by precipitation of protein from solution during fixation. To some extent this concept was correct. However, the asymmetric shape of living platelets and separation of granules from one another visible in the light microscope should have suggested that the hyaloplasm must be extremely viscous. Since high internal viscosity results to a large extent from molecular interaction, it was predictable that protein polymers should be present in platelet hyaloplasm.

The introduction of glutaraldehyde fixation at 37 °C prior to treatment with osmic acid at low temperature revealed that the matrix of the platelet was a dense mat of fibrous elements[12,71] (Figs. 3.35–3.37). At first, these elements were thought to be artefacts of fixation, but studies by the negative stain whole-mount method revealed that fibers of various types were also present in unfixed platelets[4]. Subsequent investigations have shown that changes in the state of polymerization and movement of the fibrous components of the matrix are intimately related to support of platelet discoid shape and to internal contraction. Since it became clear that the matrix inside platelets resembles a gel, it seemed appropriate to focus on this characteristic by renaming the hyaloplasm and calling it the sol–gel zone[13].

Microtubules

At least three systems of fibres are present in the matrix of the platelet, including submembrane filaments, microtubules, and microfilaments. The most prominent of the three systems is the circumferential band of microtubules[72–74] (Figs. 3.1–3.4). Cross-sections of fixed platelets reveal microtubules as a group of 8–24 circular profiles, each approximately 25 nm in diameter, at the polar ends of the lentiform cell[29]. When platelets are sectioned in the equatorial plane, the bundle of tubules is apparent just under the cell wall along its greatest circumference. Circumferential tubules are always slightly separated from

Cambridge Books Online © Cambridge University Press, 2009

each other, though small bridges between tubules can occasionally be identified[17]. Although the bundle lies close to the cell wall it never appears to contact it. The space between the tubules and the surface is often occupied by submembrane filaments cut in cross-section[69]. In the unaltered circulating platelet evidence suggests that tubulin, the protein constituent of microtubules, exists almost exclusively in the polymerized (microtubule) form[75].

Study of circumferential band microtubules by the negative stain whole-mount method revealed their substructural characteristics[76]. Each tubule is in itself a fibrous system. When fully spread, the tubules consist of 12–15 subfilaments. The subfilaments lie in parallel association with a centre-to-centre spacing of approximately 70 Å. Each individual filament appears to consist of globular subunits stacked in an offset manner to yield a helical twist. At points where spread tubules are broken, individual subfilaments can be seen spreading out from the fracture. This finding suggests that subfilaments are more stable than the microtubule, and polymerization of subfilaments may precede their parallel association into the tubule form.

The location of the circumferential band of microtubules in the equatorial plane just under the cell wall in discoid platelets suggested its participation in cytoskeletal support (Figs. 3.2, 3.4). Further proof for this role came from several experimental approaches. Platelets were long known to lose their discoid form and become irregular and relatively spherical when exposed to low temperature for brief periods[77]. Discoid shape was restored if the chilled cells were warmed to 37 °C. The loss of discoid form was associated with disappearance of the circumferential band of microtubules, and recovery with reformation of the bundle in its usual position under the cell surface[78]. Colchicine, vincristine, and vinblastine, agents that inhibit mitosis by disassembling or preventing formation of microtubules, were also found to dissolve platelet microtubules[79]. The disappearance of the circumferential band of microtubules in platelets treated with these agents resulted in loss of platelet discoid shape. These studies strongly supported the concept that circumferential microtubules were involved in maintaining platelet lentiform appearance.

Other experiments, however, were not as easily explained. For example, when platelets were exposed to ethylenediamine tetracetic acid (EDTA) they lost their discoid shape and became 'spiny spheres'[77]. Yet, the band of microtubules remained intact and organelles were randomly dispersed within it[80]. Thus, shape change could take place in platelets despite persistence of the peripherally located circumferential coil of microtubules. However, if the blood was collected in citrate anticoagulant first, then the platelets washed and resuspended in buffer containing EDTA, cell discoid shape and circumferential microtubule coils were retained, though the effects of EDTA on membranes were the same as in platelets anticoagulated with EDTA alone. Therefore, the effect of EDTA on platelet shape change was due to interaction with exposed membranes of the surface and OCS, and not on the microtubule coils[81]. The mechanism by which EDTA produces this effect on platelet shape remains unknown.

The bovine platelet also raises a question regarding the central role of circumferential MT in cytoskeletal support of discoid shape[82]. Bovine platelets must be exposed to colchicine or vinca alkaloids for at least 1 hour longer than human cells to disassemble the microtubule rings. Chilling requires up to 2 hours to dissolve bovine platelet microtubules, and their removal does not cause loss of discoid shape[83]. Even after disappearance of the rings in bovine platelets the cells remain discoid and just as resistant to aspiration into a micropipette as untreated, control platelets. The basis for these differences in human and bovine platelets appears due to variations in their intrinsic anatomy and functional expression[84]. A peripheral arrangement of assembled actin filaments plays a role in supporting the discoid shape of bovine platelets. As a result, both disassembly of microtubules by colchicine and prevention or reversal of actin filament assembly by cytochalasin B were required to cause bovine platelets to lose their discoid form[82].

Perhaps the strongest arguments supporting a major role for actin filaments, rather than microtubules, supporting the discoid form of human platelets were raised by the work of Hartwig and his colleagues[85,86]. Their work indicated that the spectrin-reinforced surface membrane cytoskeleton and the actin-rich cytoplasmic cytoskeleton are responsible for maintaining discoid form, for shape change caused by surface or suspension activation, and for recovery when stimulation is incomplete. This concept has led to a new proposal to explain the mechanism involved in the shape changes induced in platelets by chilling and rewarming[87]. Exposure to low temperature caused severing of actin filaments associated with the surface membrane cytoskeleton. Cold also caused an elevation of cytoplasmic calcium, activation of gelsolin, uncapping and severing of established cytoplasmic actin filaments, formation of multiple nucleation sites, and rapid assembly of new actin filaments. The cooled platelets lost their discoid form, became swollen in appearance, and extended filopodia and lamellipodia. Rewarming to 24 to 37 °C did not restore the irregular, cold platelets to their resting, lens-like

Cambridge Books Online © Cambridge University Press, 2009

form. Rather, the new actin filament bundles formed in the cold underwent reorganization resulting in elimination of pseudopodia and formation of irreversible spheres.

This challenge to the concept placing circumferential microtubules as the major cytoskeletal system for maintaining platelet discoid shape was retested in our laboratory using the chilling-rewarming model together with microtubule stabilizing (Taxol) and destabilizing agents[88]. Washed platelet samples were rested at 37 °C and chilled to 4 °C; chilled and rewarmed to 37 °C for 60 minutes; or chilled, rewarmed, and exposed to the same cycle in the presence or absence of vincristine or Taxol and fixed for study by disseminated interference phase contrast microscopy and electron microscopy. Rhodamine phalloidin and flow cytometry were used to measure changes in actin filament assembly. Chilling caused loss of disc shape, pseudopod extension, disassembly of microtubule coils, and assembly of new actin filaments. Rewarming resulted in restoration of disc shape, pseudopod retraction, disassembly of new actin filaments, and reassembly of circumferential microtubule coils. Vincristine converted discoid platelets to rounded cells that extended pseudopods when chilled and retracted them when rewarmed, leaving spheres that could undergo the same sequence of changes when chilled and rewarmed again. Taxol prevented cold-induced disassembly of microtubules and limited pseudopod formation. Rewarming caused retraction of pseudopods on Taxol-treated, discoid cells. Cytochalasin B, an agent that blocks new actin filament assembly, alone or in combination with Taxol, inhibited the cold-induced shape change but not dilation of the open canalicular system. Rewarming eliminated open canalicular system dilation and restored lentiform appearance. The results indicate that microtubule coils are the major structural elements responsible for disc shape and its restoration after submaximal stimulation or rewarming of chilled platelets.

Questions may remain after these investigations, but they have been largely resolved by study of a child with a new bleeding syndrome[89]. The patient has a prolonged bleeding time, a history of easy bruising since infancy and abnormal platelet aggregation despite normal levels of GPIb–IX and GPIIb–IIIa receptors. Dense body frequency in his platelets was normal, indicating absence of platelet storage pool deficiency. Light and electron microscopy revealed that his platelets were spherical in form. Thin sections of his spherocytes revealed an absence of MT and MT coils in 98% of the cells. The 2% that contained microtubule coils were discoid. Immunofluorescence microscopy with an antibody against tubulin, the protein precursor of microtubules, revealed amounts similar to normal platelets, but none was assembled into tubules or coils. Addition

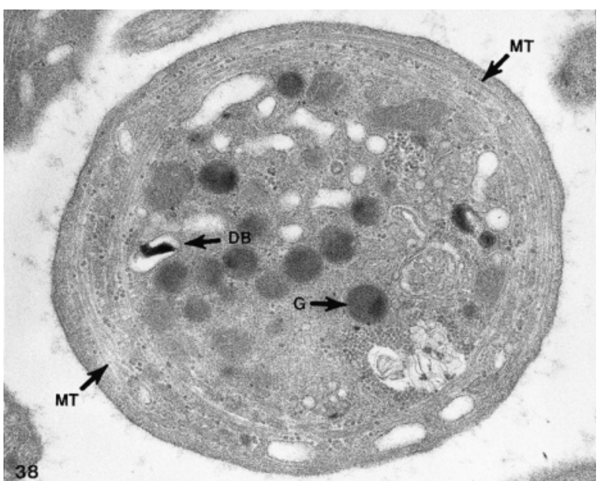

Fig. 3.38. Sol–gel zone. The platelet in this example has been sectioned in the equatorial plane and contains normal organelles including dense bodies (DB) and granules (G). A circumferential bundle of microtubules (MT) is apparent just under the cell surface. The bundle probably consists of a single tubule wrapped many times on itself like coils of a lariat. In this cell it forms several complete circles (Mag ×28 000).

of Taxol, an agent that stabilizes microtubules or stimulates their assembly, caused formation of microtubules and MT coils in his platelets and their conversion to discs. Results of the studies in this patient demonstrate that the circumferential coil of microtubules is the major cytoskeletal support system responsible for maintaining the discoid shape of human platelets (Fig. 3.38).

Microfilaments

Microfilaments constitute the second system of fibres in the platelet sol-gel zone. They appear more numerous than other polymers and are so concentrated in the matrix of unaltered platelets that they cannot be resolved in thin sections[12,90] (Figs. 3.35–3.37). However, they can be identified readily in whole mounts of spread platelets and in thin sections of platelet pseudopods. The state of microfilaments in unaltered platelets is not yet clear[28,75]. Subunit proteins of microfilaments exist primarily in a pregel, resembling the viscous state of hemoglobin molecules in intact erythrocytes. Polymerization into filaments may be a constant or alternating process, or may occur only as a result of stimulation during the hemostatic reaction of platelets. Whichever the case may be, it is apparent that the organization of the platelet internal matrix is governed by the balance of sol–gel transformation. Although many other components may be present in the sol–gel zone, microfilaments are the primary structural constituents involved in

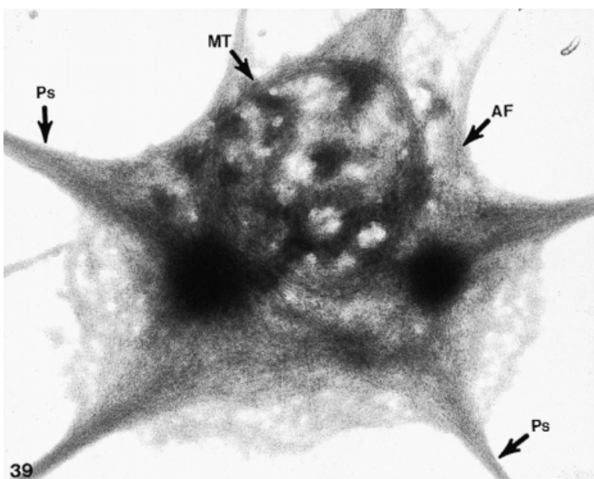

Fig. 3.39. Cytoskeleton of spread dendritic platelet. Surface stimulation has caused this cell to extend long, relatively rigid pseudopods (Ps). The spike-like extensions are filled with parallel bundles of actin microfilaments (AF). A loosely interconnected network of randomly arranged actin filaments fills spaces between the spike-like pseudopods. The circumferential microtubule (MT) is constricted and some of its free ends radiate into the cytoplasm and pseudopods (Mag ×23 000).

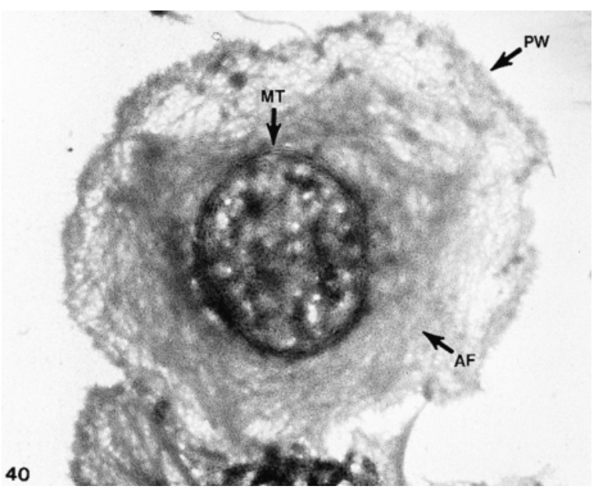

Fig. 3.40. Spread platelet cytoskeleton prepared from citrated-PRP. Coils of the circumferential microtubule (MT) are constricted in the cell centre. Actin microfilaments form a peripheral weave at the cell border and are organized in concentric layers around the MT coil (AF) (Mag ×23 000).

activation induced shape change and pseudopod formation[28,29,70,85,86] (Figs. 3.39, 3.40).

Organelle zone

The formed elements inside platelets have been of interest to investigators for many years. It was impossible to determine whether the cells contained one or several types of organelles in the light microscope, but early workers observed the disappearance of granules during hemostatic reaction and suggested that they contained secretory products important in platelet hemostatic function[5,91,92]. Electron microscopy revealed several types of organelles in the cytoplasm of platelets (Figs. 3.1–3.4). Mitochondria were easily differentiated from other structures by the plication of their internal membranes into cristae. Electron-dense bodies were distinctive because of their intensely opaque internal content, which was often separated from the enclosing membrane by a clear space[93]. Granules were the most numerous of the organelles in platelet cytoplasm and clearly different from mitochondria and electron-dense bodies.

Supporting the possibility that these organelles might be heterogenous were differences in the size of platelet granules; the electron opacity of their internal content; the presence of structures similar to microtubules in some, but not in others; and a zone of increased density resembling a nucleoid in many, but not in all. Investigations in several laboratories have strengthened this concept. Breton-Gorius and Guichard[94], employing a cytochemical technique that detects the peroxidatic activity of catalase, have shown that some of the small granules in platelets stain for this enzyme and resemble peroxisomes found in many other tissues. Bentfield and Bainton[95] have demonstrated that some vesicular elements contain acid phosphatase and aryl sulfatase, whereas granules do not. Da Prada et al.[96] have used biochemical and ultrastructural techniques to distinguish two populations of granules that can be separated by ultracentrifugation in urografin gradients. One population contains only platelet factor 4 and fibrinogen, whereas the other possesses only acid hydrolases. Thus, the organelle zone of normal platelets is more complex than was thought in early years. In addition to mitochondria, electron-dense bodies, and glycogen, it contains granules, vesicles, peroxisomes, lysosomes, and glycosomes.

Investigations on two patients with the grey platelet syndrome (GPS) have shed additional light on the chemical constituents localized within the several different types of granules of the organelle zone[97,98]. The two patients with the disorder have giant platelets. Thin sections reveal normal numbers of mitochondria and dense bodies but a marked reduction in granules. Levels of serotonin and adenine nucleotides were found to be within normal limits, as would be expected since the dense body content

Cambridge Books Online © Cambridge University Press, 2009

is normal. The catalase activity is normal and some of the granules stain for this enzyme, suggesting that peroxisomes are not abnormal in the GPS. Measurements of acid phosphatase, *N*-acetyl glucosaminidase and α-glucuronidase are normal, indicating that the majority, if not all of the few granules present are lysosomes. Thus, our studies suggested that GPS platelets are virtually devoid of α-granules and should be deficient in products confined to these organelles.

It seemed reasonable, therefore, to use GPS platelets to search for products normally present in α-granules. These studies have shown that GPS platelets are markedly deficient in thrombin-sensitive protein, α-thromboglobulin, fibrinogen, platelet factor 4, and the mitogenic factor. Thus, the use of the abnormal platelets has helped to confirm the existence of separate granule populations in platelets and permitted characterization of the specific chemical substances associated with α-granules[98].

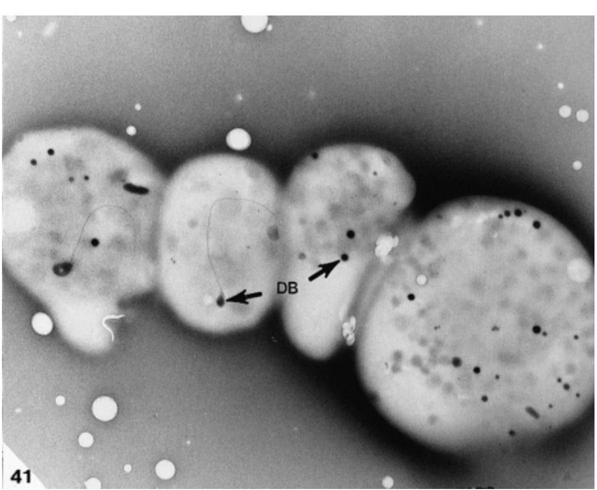

Fig. 3.41. Human platelets examined unfixed and unstained in the transmission electron microscope. Dense bodies (DB) inside the cytoplasm are inherently electron opaque, permitting visualization and enumeration by this technique (Mag ×10 000).

Dense bodies

The dense bodies of blood platelets have been a subject of particular interest. Electron microscopy, ultrastructural autoradiography, analytical electron microscopy, and biochemistry have demonstrated that the inherently electron-opaque dense bodies are the storage sites for the nonmetabolic pool of adenine nucleotides, serotonin, and calcium secreted by human platelets during the release reaction[92,99–103] (Figs. 3.41, 3.42). Dense bodies are virtually absent in platelets from patients with storage pool disease and the Hermansky–Pudlak syndrome[104]. Their absence is associated with defective aggregation in vitro and mild hemorrhagic symptoms in vivo. Richards and Da Prada[105] have introduced a cytochemical technique for localizing adenine nucleotides in organelles storing biogenic amines and have used this method to stain selectively the membranes surrounding platelet dense bodies. Platelets from animals and humans with storage pool disease and patients with Hermansky–Pudlak syndrome were completely negative for the uranaffin reaction. Thus, morphology and ultrastructural cytochemistry have played important roles in characterization of dense bodies, and in diagnosis of patients with platelet storage pool deficiency.

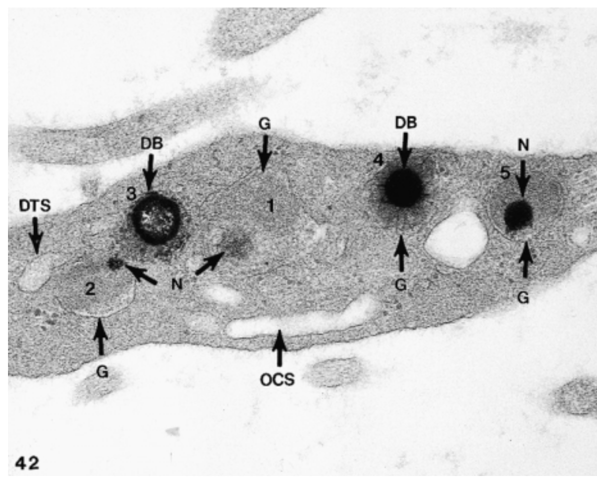

Fig. 3.42. Conversion of platelet granules to dense bodies. The precise origin of platelet dense bodies is still uncertain. In the past we have suggested that they originate from a population of α-granules containing nucleoids. This illustration demonstrates several stages in the development of dense bodies from granules. One granule (1) has a slightly dense nucleoid while the granule (2) next to it has a smaller but more electron-dense spot in its matrix. The nucleoid in a third granule (3) is larger and very dense. Without granule matrix it would be considered to be a dense body. The fourth (4) and fifth (5) organelles are typical dense bodies, but retain granule matrix. Although we no longer believe dense bodies originate from alpha granules, the origin of the dense nucleoids in granules remains uncertain (Mag × 40 000).

Alpha (α) granules

Alpha granules are the most numerous of the several types of organelles in platelet cytoplasm (Figs. 3.2, 3.4, 3.38). Despite relatively similar shape, size and internal matrix appearance, variations are common. Giant platelet α granules are frequent in platelets maintained at room temperature or 37 °C for over 24 hours. They result from fusion of normal sized α granules[106]. The giant granules are noted in

Cambridge Books Online © Cambridge University Press, 2009

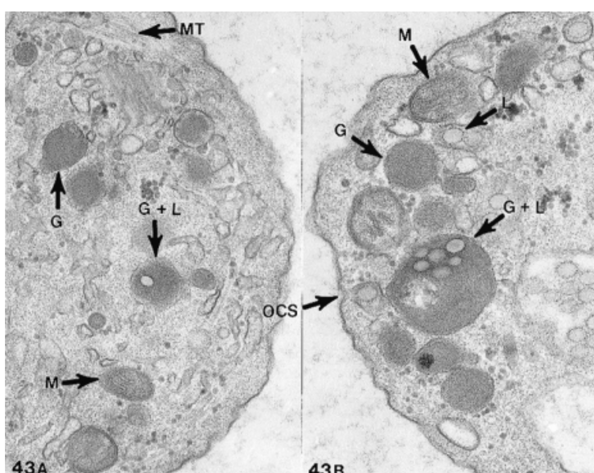

Fig. 3.43(*a*) and (*b*). Platelets from samples of C-PRP exposed to latex for 60 and 90 min, respectively, before fixation. The cells are still relatively discoid with circumferential microtubule (MT) and randomly dispersed organelles, including granules (G) and mitochondria (M). Some of the latex spherules (L) have been transferred from OCS channels to apparently intact granules (G and L) (Mag ×35 000).

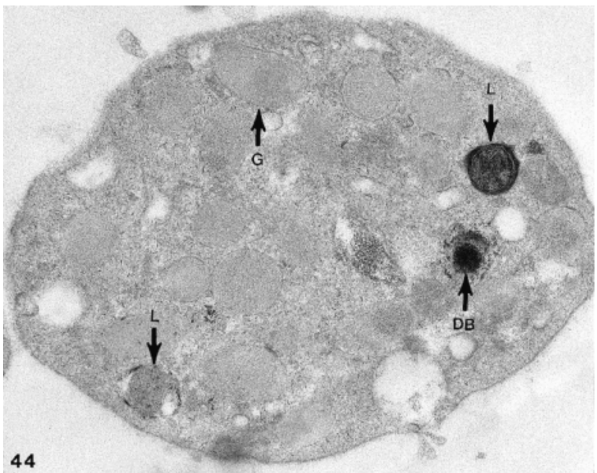

Fig. 3.44. Platelet from a sample of citrated PRP incubated in special medium to demonstrate acid phosphatase. Most granules (G) are devoid of reaction. One organelle is heavily stained by lead salt and another is lightly stained. Because they contain reaction product of acid phosphatase, both organelles are considered lysosomes (L). A dense body (DB) is also present in this cell (Mag ×43 000).

stored platelet samples and represent the earliest morphologically visible storage lesion in the cell[107]. Cross-sections reveal nucleoids as cores of alpha granule matrices that vary in electron opacity. Many nucleoids are as electron opaque as dense bodies and this observation gave rise to the speculation that dense bodies derived from alpha granules[103] (Fig. 3.42). This did not prove to be the case. Cross-sections also revealed microtubule-like structures at the peripheral margin of the matrix in some alpha granules[108], but not in all. Immunohistochemical studies have shown that the tubules are von Willebrand factor[109]. Alpha granules are the storage site for a long list of proteins that facilitate activation, aggregation, hemostasis, clot retraction and repair of the injured blood vessel. Behnke[110] proposed that the various proteins were taken up by coated vesicles formed at the platelet surface membrane and transferred across platelet cytoplasm to alpha granules. As he suggested, platelets were constantly 'sipping the soup'. However, the number of coated vesicles forming at the surface or present in the cytoplasm of resting and activated platelets is so small that the mechanism as a source for alpha granule proteins seems remote. The surface-connected open canalicular system may be a more likely route for uptake and transfer of proteins to alpha granules. It has been shown that small latex spherules (Fig. 3.43), colloidal gold particles and thorium dioxide can be taken up and transferred by the OCS to apparently intact alpha granules without causing platelet activation.[111] Recent studies have shown that platelet alpha granule membranes mirror the platelet plasma membrane in their content of glycoproteins GPIIb–IIIa, CD36, CD9, PECAM-1, Rap 1b, GPIb, GPIX and GPV[112]. This finding may reflect a constant interaction between alpha granules and membranes of the open canalicular system in platelets leading to uptake of proteins.

Lysosomes

Lysosomal organelles are relatively infrequent in human platelets. They have no distinguishing morphological features to separate them from alpha granules. Thus, they require cytochemical techniques to identify them (Fig. 3.44). Platelet lysosomes contain a full complement of hydrolytic enzymes similar to those found in the neutrophil lysosomes. One of them, acid phosphatase, is readily identified by ultrastructural cytochemistry. The only disorder in which platelet lysosomes are involved is the Chediak–Higashi syndrome (CHS)[113,114]. The lysosomes are often enlarged and irregular in form in platelets obtained from patients with CHS. It is uncertain what functions lysosomes serve in normal platelet physiology.

Internal membrane system

Surface-connected open canalicular system (OCS)

The introduction of aldehyde fixation techniques in the early 1960s resulted in markedly improved preservation of platelet ultrastructure and stabilization of the associations

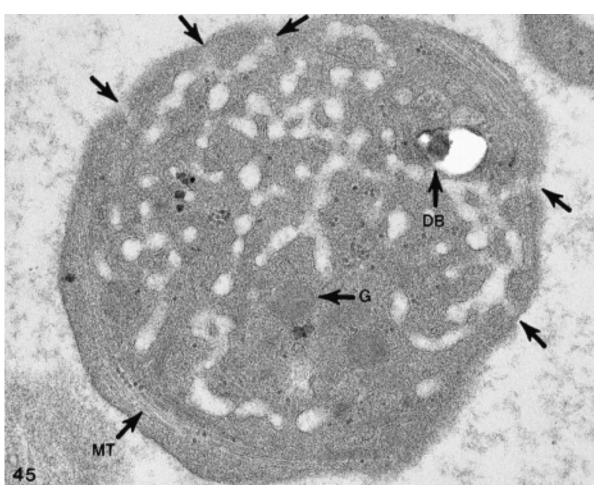

Fig. 3.45. Membrane systems. Discoid platelet sectioned near the horizontal plane. Portions of the circumferential band of microtubules (MT) are apparent near the cell periphery. Dense bodies (DB), granules (G) and other cytoplasmic constituents are spread randomly in the cell substances. Some of the larger black particles in the background are due to osmium precipitate. The tortuous nature of the OCS is apparent in this example. At least five openings (*arrows*) onto the cell surface can be identified. The alternating dilatations and constrictions in the channels produce a tortuous appearance. Channels branch shortly after entering the cell and communicate with each other. The result is a spider web-like maze of interconnecting channels that spreads throughout the cytoplasm and communicates directly with the cell surface at several sites (Mag ×43 000).

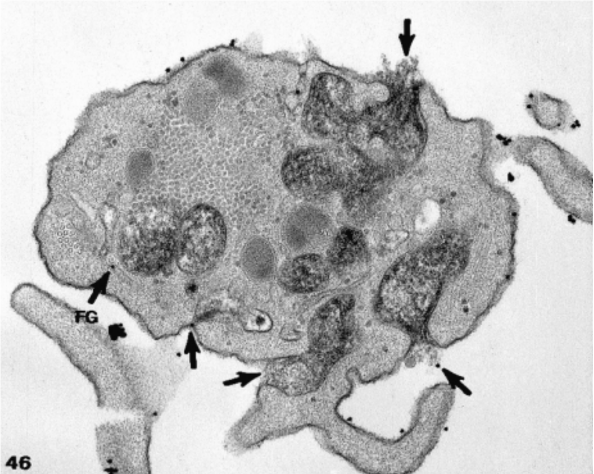

Fig. 3.46. Platelet fixed 15 seconds after exposure to 0.2 U/ml of thrombin in the presence of fibrinogen-coated gold particles. Shape change is limited, but many granules are tannic acid positive. Many have fused with channels of the open canalicular system (↑) and are in the process of discharge to the exterior. Fibrinogen-gold (FG) particles cover the exposed surface and have entered the OCS (Mag ×36 000).

between the surface membrane and what had been regarded as vesicles and vacuoles in early studies[115]. The OCS revealed by improved fixation consisted of tortuous invaginations of the cell wall tunneling throughout the cytoplasm in a serpentine fashion (Fig. 3.5, 3.45). Studies employing electron-dense tracers revealed that channels of the OCS were patent in activated and aggregated platelets as well as in unaltered cells[12]. Vesicles and vacuoles were virtually absent in doubly fixed platelets, suggesting that these elements were in reality components of the OCS. It was clear from these investigations that canaliculi of the OCS greatly increased the total surface area of the platelet exposed to plasma and provided a route for chemical or particulate substances to reach the deepest recesses of the cell. The observation that the OCS remained patent throughout the processes of platelet shape change, internal transformation, contraction, adhesion, and aggregation suggested that the channels might serve as conduits for substances extruded by platelets during the release reaction[116,117] (Figs. 3.46, 3.47). Experiments employing the cationic polyelectrolytes polylysine and polybrene dem-

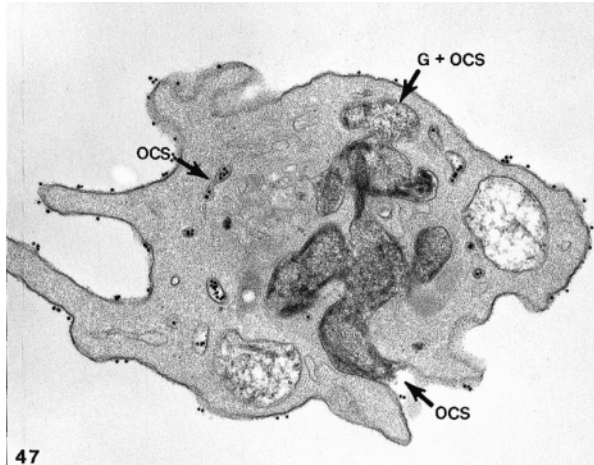

Fig. 3.47. Platelet exposed to fibrinogen gold and then to 0.2 U/ml of thrombin for 30 seconds before fixation and staining with tannic acid. Shape change and internal transformation are reasonably advanced and many tannic acid positive alpha granules are fused to OCS channels (G + OCS) delivering their contents to the exterior. Fibrinogen coated gold particles have penetrated many OCS channels (Mag ×36 000).

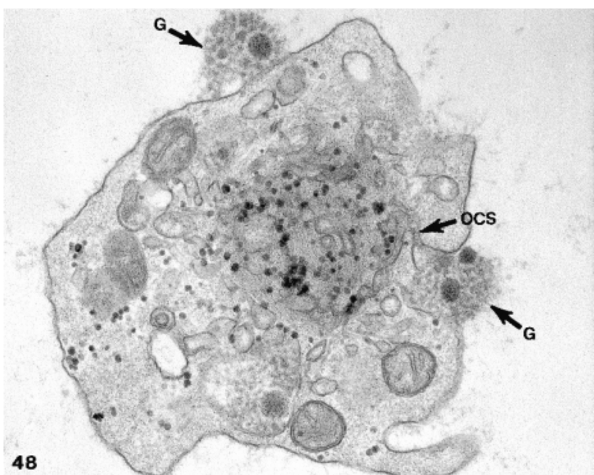

Fig. 3.48. Platelet from washed suspension combined with polylysine and then exposed to thrombin (0.5 U/ml) for 30 seconds before fixation. Polylysine has been taken up by alpha granules (G), some of which are connected to the OCS and in the process of discharging their contents to the exterior. The extruded granules remain intact outside the platelet, despite loss of their enclosing membranes (Mag ×36 000).

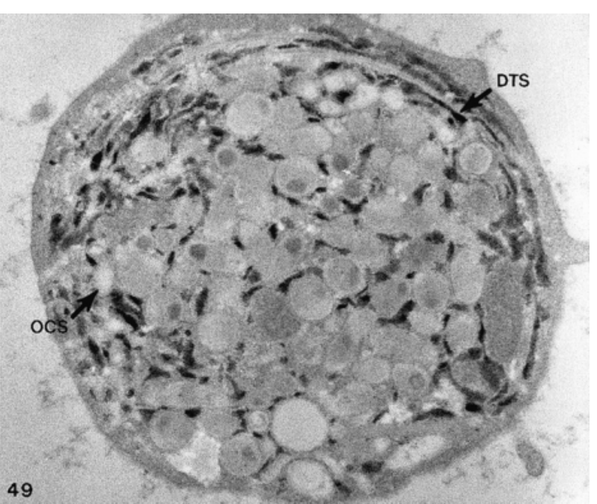

Fig. 3.49. Cytochemistry of membrane systems. This platelet is from a sample of PRP incubated for peroxidase activity. Enzyme reaction product is specifically localized to channels of the DTS and none is present in the surface-connected OCS (Mag × 31 000).

onstrated that this supposition was correct[118,119] (Fig. 3.48). Recent studies have shown that channels of the OCS remain open during clot retraction and continue to serve as the egress route for products of dense bodies and alpha granules[120].

Dense tubular system (DTS)

Channels of the DTS were distinguished from clear canaliculi of the OCS by an amorphous material similar in opacity to surrounding cytoplasm concentrated within them that stains for peroxidase (Fig. 3.49) and binds lead (Fig. 3.50)[115]. Like the OCS, channels of the DTS were randomly dispersed in the platelet cytoplasm. In addition, a channel or two of the OCS could be identified in close association with the circumferential band of microtubules in most thin sections of platelets (Figs. 3.2, 3.4). Investigations of this relationship suggested that the DTS might have an important role in the elaboration and stabilization of the circumferential microtubules supporting the discoid form of platelets. Additional studies demonstrated that the DTS originated from rough endoplasmic reticulum in the parent megakaryocyte and was, therefore, residual smooth endoplasmic reticulum[18]. There was no evidence of a physical communication between channels of the OCS and DTS, although such a communication had been suggested by some workers. Thus, platelets have two discrete membrane systems not found in other blood cells,

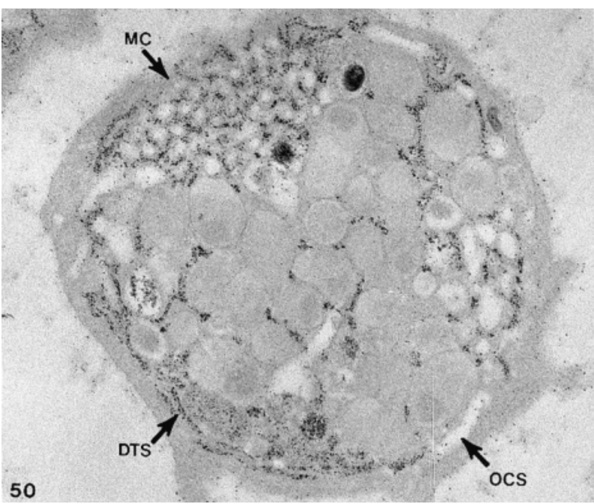

Fig. 3.50. Cytochemistry of membrane systems. The cell is from a sample of glutaraldehyde-fixed platelets incubated in a solution containing lead ions. Lead has selectively deposited in channels of the DTS. None is present in the surface-connected OCS. Note the proximity of lead-filled channels to open channels in the membrane complex (MC). The same procedure has been used to demonstrate calcium-binding sites in the sarcoplasmic reticulum of muscle (Mag ×38 000).

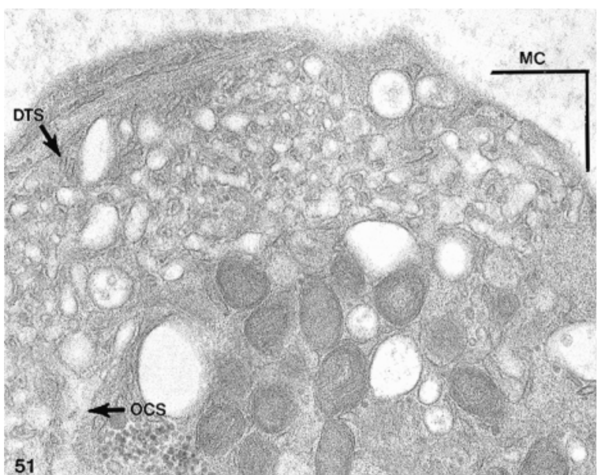

Fig. 3.51. Membrane systems. The sponge-like appearance of the peripheral cytoplasm in this cell is due to the interwoven associations between elements of the surface-connected OCS and the DTS. The resulting membrane complex (MC) strongly resembles the associations between transverse tubules and sarcotubules in muscle cells (Mag ×46 000).

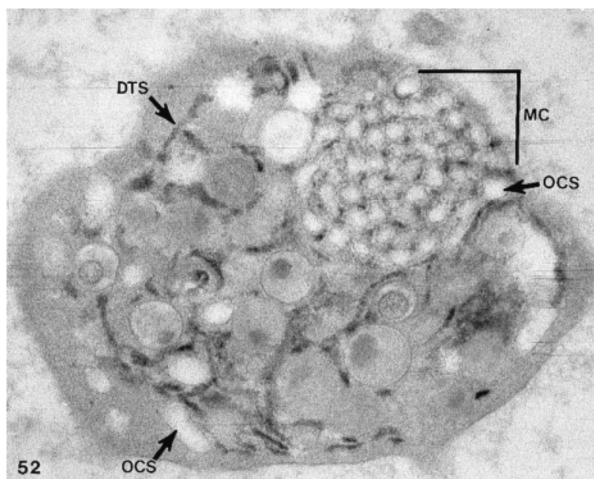

Fig. 3.52. Cytochemistry of membrane systems. The platelet is from a sample reacted for endogenous peroxidase activity. Reaction product is localized to channels of the DTS. Clear channels of the surface-connected OCS form very close associations with the DTS in membrane complexes (MC) (Mag × 48 000).

the OCS derived from the plasma membrane of the megakaryocyte and the DTS representing residual smooth endoplasmic reticulum of the parent cell.

Membrane complexes

The OCS and DTS are not completely isolated membrane systems. Close inspection of thin sections of well-preserved platelets revealed that canaliculi of the OCS and DTS form intimate physical relationships in nearly every cell (Figs. 3.50–3.52). The association of the two channel systems was usually restricted to one or two areas of the cytoplasm, and in most examples these areas were eccentrically located. Elements of the OCS in such areas were gathered in clusters or groups. Even though the open channels were closely approximated, small canaliculi of the DTS could be identified interspersed between them. The relationship was particularly prominent in platelets stained for peroxidase activity in which dense reaction product delineated channels of the DTS and outlined their extremely close relationship to cluster of open canaliculi[121] (Fig. 3.52). Examination of the membrane complexes at higher magnification revealed that elements of the DTS were the only structures interspersed between open canaliculi, and that membranes of the two channel systems were practically in apposition. Replicas of freeze–fractured platelets revealed an identical arrangement of the two channel systems in complexes[122]. When studied by this method, the OCS is clearly seen to be a fenestrated membrane system and channels of the DTS are located in each window or fenestra.

Electron-microscopic studies that defined the platelet as a form of muscle cell were crucial in identifying and characterizing the membrane systems involved in regulating activation of the contractile system. Contraction of platelet actomyosin, as in other muscle systems, is modulated by calcium flux. Calcium is maintained at low levels in the cell until the stimulus for contraction is received at the surface or sarcolemma. In skeletal muscle a system of channels, derived from the cell wall and referred to as the transverse tubular system, conducts the signal to the cell interior[123]. Transmission from the transverse tubular system is, in turn, mediated by a second group of channels called the sarcotubular system derived from endoplasmic reticulum in the embryonic muscle cell. The sarcotubules contain higher concentrations of calcium than the cytoplasm. Release of calcium from the sarcotubules to the cytoplasm triggers activation of the contractile elements, and relaxation develops when calcium is pumped back into the sarcotubules.

The similarity of the platelet membrane systems and membrane complexes to the transverse tubules and sarcotubules of muscle led to a series of investigations comparing them[122]. These studies have shown that the DTS is the calcium-sequestering site in platelets (Fig. 3.50), resembling the sarcotubules of muscle cells, and that the channels of the OCS are similar to the transverse tubules of muscle. Furthermore, the membrane complexes closely

Cambridge Books Online © Cambridge University Press, 2009

resemble the diads and triads formed between the transverse tubules and sarcotubules in muscle cells (Fig. 3.51). The proximity of the dual channel system in platelets to the contractile elements, and the demonstration that the DTS selectively binds divalent cations, that platelets do not require exterior calcium for activation, and that vesicles from platelet membranes can sequester calcium just as well as sarcotubular vesicles from muscle, strongly support the concept that the OCS and DTS in platelets are the equivalent of the sarcoplasmic reticulum of muscle cells[122] (Fig. 3.52).

In 1963, Grette[124] showed that pig platelets contained a relaxing factor that could prevent clot retraction presumably by sequestering calcium. This factor was identified as a membrane vesicle by Statland et al.[125] in 1969 and has been characterized by a number of groups since then[126]. Additional evidence has localized the Ca^{2+}/Mg^{2+} ATPase to the DTS, although some activity may be in the channels of the surface-connected canalicular system[127]. Thus, platelets appear to be able to pump calcium out of the cytoplasm into the DTS and perhaps also outside the platelet. The activity of this calcium pump is essential to maintaining a low cytoplasmic calcium concentration, which may in turn keep the microtubules polymerized and the cell in its resting discoid state[128]. The activity of the calcium pump is enhanced by the presence of intracellular cyclic adenosine 3′5′-monophosphate (cAMP), which is important as an inhibitor of platelet function[129]. Many agents that inhibit platelet function, including adenosine, prostaglandin E_1, prostaglandin D_2 and prostaglandin I_2, act by stimulating the platelet adenylate cyclases to cause a rise in intracellular cAMP. The mechanism whereby cAMP enhances the calcium pump activity is unknown. However, cAMP may well work through a protein kinase and phosphorylation of a protein associated with the calcium pump[130].

An interest in prostaglandin synthesis developed from investigations of platelets from patients with the Hermansky–Pudlak syndrome (HPS), the classic form of storage pool deficiency[131]. HPS platelets are deficient in dense bodies, serotonin, and adenine nucleotides and fail to undergo the second wave of aggregation when stimulated by agents that cause the release reaction. Normal platelets treated with aspirin also fail to develop second waves of aggregation when exposed to these agents because aspirin blocks prostaglandin synthesis. The similar defects in the response of aspirin-treated and HPS platelets to aggregating agents led us to carry out an unusual experiment. We combined equal volumes of HPS and aspirin-treated normal platelets and exposed samples to aggregating agents. The results demonstrated that the mixed population of aspirin-treated normal cells and HPS platelets responded as well as untreated normal control platelets to all aggregating agents.[132] In subsequent investigations, we demonstrated that an aspirin-sensitive factor in HPS platelets stimulated by exposure to the aggregating agent overcame the influence of aspirin on the normal cells, resulting in the release of their storage pool and normalization of the second wave of aggregation[133]. This was the initial demonstration of intercellular communication between platelets and revealed for the first time that two abnormal populations of platelets could compensate for each other's defect.

Results of this study led to investigation of platelets by combined biochemical and ultrastructural techniques for the site of prostaglandin synthesis. Ultrastructural cytochemical studies by Janine Breton-Gorius[134] and by us[18] had demonstrated that platelets contain a specific peroxidase activity localized to channels of the DTS. It is our practice to test agents that inhibit cytochemical reactions on living cell systems. As a result, we examined the effect of 3-amino-1,2,4-triazole (AMT),an inhibitor of platelet peroxidase, on platelet aggregation[135]. The effects of the agent were similar to those of aspirin. Concentrations of AMT that blocked cytochemical demonstration of peroxidase inhibited the second wave of aggregation stimulated by release-inducing aggregating agents. Subsequent studies revealed that AMT blocked prostaglandin formation and suggested that the peroxidase was involved in the synthetic process. Other workers have shown that peroxidase activity is contained on the prostaglandin endoperoxide synthetase enzyme during purification of the enzyme and that the heme groups of cyclooxygenase are essential for its prostaglandin synthetase activity. These findings and studies on platelet subcellular fractions showing that prostaglandin synthetic activity separates with endoplasmic reticulum enzymes and not plasma membrane enzymes[136] led to the conclusion that the DTS is the site of platelet prostaglandin synthesis[137].

In summary, morphology and ultrastructure have provided the palette on which to mix details of platelet biochemistry, physiology and pathology. Remaining details will soon be added to the final picture and, in essence, our work will be complete.

Platelet heterogeneity: physiology and pathological consequences

Anthony Mathur and John F. Martin

Centre for Cardiovascular Biology and Medicine, University College London, UK

Introduction

Individual platelets vary in terms of volume, density and reactivity. Ever since the seminal paper by Karpatkin[1], the biological significance of this platelet heterogeneity has been strongly contested.

Platelet volume, usually measured as mean platelet volume (MPV), has been the most frequently studied platelet physical variable. During steady-state hematopoeisis the platelet volume distribution approaches log normality with platelets ranging in size from $<2\ \mu m^3$ to $>15\ \mu m^3$ in volume. This variation in size is considerably greater than that observed for other circulating blood elements in any mammal. This heterogeneity forms the basis of the controversy with respect to the physiological relevance of platelet volume and reactivity[2].

Separation of platelets into size dependent subpopulations[3] has shown that the granular contents of these cells is directly proportional to their volume. Importantly, the ability of platelets to affect each other and their environment as measured by aggregation and total amount of granular contents released, is proportional to their size and confirmed by the finding that platelet volume correlates with absolute platelet function[4,5]. The physiological explanation for this lies in the observation that high-density platelets contain significantly higher concentrations of alpha granule proteins (β thromboglobulin, von Willebrand factor), dense granule markers (5-HT, calcium), mitochondrial marker enzymes (monamine oxidase, cytochrome oxidase, glutamate dehydrogenase and NADP-dependent isocitrate dehydrogenase), glycogen[6,7] and express more of the GPIIb/IIIa receptor[8].

Furthermore although only limited work has been performed on functional properties of platelet density subpopulations, Karpatkin's original report[1] showed that high-density platelets aggregated more quickly and released greater quantities of ATP, ADP and platelet factor 4 than low-density platelets in response to stimulation by ADP, thrombin and adrenaline (although the use of non-linear gradients in this work to determine platelet density-dependent subpopulations has been questioned by Martin & Trowbridge[9]).

However more recent work has shown that, although high-density platelets may produce more thromboxane β_2 in response to 0.5 mmol arachidonate than low-density platelets, response to thrombin stimulation remains the same[10]. Nubile et al.[11] reported a greater extent of aggregation in response to ADP in low-density platelets compared to high-density platelets, while the response to collagen and adrenaline was slightly greater in high-density platelets. Other groups have also reported no differences in 5-HT transport between platelet populations and, importantly, that all platelet populations lose similar percentages of their dense bodies in respect to thrombin stimulation[12].

This would suggest that any increase in function as measured by biochemical markers is solely due to the increase in platelet contents that occurs in proportion to their density and size and not due to an overproduction of these factors within high-density platelet populations.

Causes of heterogeneity

Two separate hypotheses which are mutually exclusive have been proposed to explain the origin of platelet heterogeneity. The first maintains that changes in platelet properties are the result of the ageing of platelets in the circulation. The second holds that platelets are created with properties that remain unchanged as the platelet ages. Both these possibilities shall be considered individually below.

Platelet ageing as a cause of heterogeneity

Considerable work, by several groups, has demonstrated that platelet density increases[13–15] decreases[1,16–22] or remains stable[14,23,24] as platelets age. Various models have been used to study the phenomenon of platelet ageing. Mezzano et al.[13] measured the survival of ^{51}Cr labelled unfractionated human platelets and radio labelled density cohorts. They concluded that newly formed platelets become denser with platelet ageing. They also found that platelet survival of fractions enhanced with low-density platelets were significantly longer than that of fractions enhanced with high-density platelets, data confirmed by Martin and Penington[14] using *Macaca fasicularis* monkeys. However, in another study using radio-labelled density dependent platelet cohorts in splenectomized dogs, they found that, in contrast to human studies, platelet density in dogs decreases with ageing. This confirmed work performed by Corash's group[17] using *Macaca mulata* monkeys in which high-density and low-density platelet cohorts were isolated, labelled with radiochromium (^{51}Cr), reinjected into donor animals and the survival and density distribution of the labelled cohorts followed with serial density gradient analyses. Corash and Shafer[18] also used another experimental model of injecting radio-labelled amino acids into rabbits followed by serial fractionation of platelets into density dependent platelet cohorts to again confirm that young platelets tend to be high-density and that with age, density decreased. Evidence to support the suggestion that platelet density does not change with ageing comes from observations of patients in whom thrombopoiesis could be switched on by plasma infusion[25]. Relatively young platelets were obtained 4 days after infusion and older platelets 18–21 days after infusion. Although older platelets were associated with longer bleeding times, decreased platelet adhesiveness and deficient platelet factor 3 availability, no structural differences between young and old platelets were observed by electron microscopy.

Thus, although platelets are heterogeneous with respect to size and density, evidence exists that links density changes with both young and old platelets suggesting that density is independent of ageing. Several groups[5,12] have used discontinuous gradients to separate platelets by density, but when Martin's group used this technique[9] they found that platelet populations taken from each 'density' interface comprised platelets with a variety of densities. The authors therefore questioned the validity of discontinuous gradients to measure absolute platelet densities. These observations vary depending upon the type of model used and method used for separating and determining platelet density. The fact that there are many different interpretations of these observations is in keeping that platelet heterogeneity is not related to platelet age and hence the second hypothesis.

Thrombopoiesis as the origin of platelet heterogeneity

Observations made during steady-state thrombopoiesis have shown that MPV and platelet counts are inversely related, suggesting that platelet production is regulated to maintain a constant circulating functional platelet mass[26]. This hypothesis has been tested by observing platelet count and MPV in Rhesus monkeys during continuous infusion of granulocyte – macrophage colony stimulating factor (GM–CSF). Infusion of GM–CSF leads to a significant increase in circulating platelet count and concomitant decline in MPV[27]. Other studies[28–32] have shown that stimulated thrombopoiesis, which occurs during periods of increased haemostatic demand can induce increases in firstly MPV and secondly number of platelets produced. Linking these observations to a mechanism that controls platelet size at the time of their production are the experiments of Corash et al.[29] using a murine model to examine the relationship between bone marrow megakaryocyte (MK) ploidy and platelet volume. In response to acute severe thrombocytopenia (reduction in platelet level of $<0.05\times10^6/\mu l$), platelet volume was noted to increase 40 hours before a detectable shift in bone marrow MK ploidy[29]. Less severe thrombocytopenia (reduction of the platelet level to 0.015 to $0.25\times10^6/ml$) resulted in a delay of the shift in ploidy distribution from 48 to 72 hours after the onset of thrombocytopenia. Moderate thrombocytopenia ($0.30–0.4\times10^6/\mu l$) did not result in a ploidy shift, but did produce a significant and prolonged increment in MPV. In response to moderate thrombocytopenia, MPV was significantly increased as early as 12 hours after administration of platelet antiserum and remained increased during the period of thrombocytosis following recovery[29]. These results lead Corash et al. to suggest that changes in MPV occur before any changes in MK ploidy but that these changes may arise secondarily to changes in the actual platelet release process. However, Martin and Penington[14] have shown that MK ploidy was found to increase in the presence of platelet destruction and that large platelets were released into the circulation. These platelets were found to have increased thromboxane A_2 production per unit volume of platelet cytoplasm suggesting a preceding change in MK cytoplasmic reactivity occuring within 24 hours following platelet destruction. These platelets

Cambridge Books Online © Cambridge University Press, 2009

reduced bleeding time more than controls per unit volume cytoplasm[33]. Changes in mean bone marrow MK ploidy are slow and associated with an increase in MK cytoplasmic volume[34]. Such a change is associated with a sustained increase in platelet volume when platelets are continuously destroyed to reveal the size of the newly produced platelets[35]. However, an increase in ploidy appears to be associated consistently with an increase in platelet count[23,34,36–38]. Kristensen et al.[39] have shown that in man, under normal conditions, there is a significant negative correlation between MK ploidy and bleeding time (which is determined by platelet behaviour). However, platelet volume was not related to MK ploidy in these normal individuals during steady-state platelet production. If changes in MK ploidy are induced without a change in the rate of destruction, e.g. by injection of vincristine, thrombocytosis occurs without a change of platelet volume[40]. These data therefore argue that the origins of platelet heterogeneity lie in the highly regulated and complicated process of thrombopoiesis itself as opposed to changes occurring in the circulation as platelets age.

Thrombopoietin (TPO) has been described as the most potent hormonal regulator of platelet production in man[41]. Its discovery, however, has occurred several years after most of the work on platelet heterogeneity was published. It is now thought that TPO is constitutively produced by the liver and kidneys[42] and that the combined MK/platelet mass is kept at a constant level by self-regulatory mechanism involving the TPO receptor c-mpl found on platelets and MKs. It is probable that TPO controls platelet number by causing changes in MK ploidy, although there is still no evidence concerning the controlling mechanism of platelet volume.

Theories of platelet production

Not only is the mechanism of platelet production disputed, but also the site.

MK fragmentation in the bone marrow

Wright in 1906 through observations of fixed sections of rat bone marrow, using a light microscope, first described loss of MK cytoplasm by detachment of buds of platelet-like fragments[43]. The presence of MKs with pseudopodia, in the bone marrow, has been confirmed by electron microscopy[44–48]. This subject has recently been revisited by Zucker-Franklin again to demonstrate in a static system filamentous extensions of MK cytoplasm[49]. Filamentous extensions of MK cytoplasm have also been observed in culture[50–53]. These have been thought to correspond to the cytoplasmic protrusions seen by Wright[43,54]. Taken together these observations would suggest that platelets are actively produced in the bone marrow. However, MKs have never been observed producing platelets in the marrow and these conclusions may result from artefacts related to in vitro conditions or preparation methods. Given that, in general, the majority of hematopoiesis occurs within the bone marrow, the concept that thrombopoiesis occurs at this site still remains a logical possibility, but lacks definitive evidence.

Platelet production from the demarcation membrane system (DMS)

MKs are approximately 10–500 times as large as a human red blood cell. Approximately four-fifths of this volume is cytoplasm, which contains various organelles. Observations of the contents of MK cytoplasm by Yamada[55] led to the proposal of an extensively invaginated demarcation membrane system (DMS) that delineated future platelets in the MK cytoplasm. The DMS appears as a tubular arrangement[56] but does not surround cytoplasm and therefore, by itself, cannot delineate platelets. Thus the suggestion by Shaklai and Tavassoli of a mechanism of tubular fusion followed by membrane fission was put forward to explain how a tubular system can be transformed into the flat membranes that are necessary for the enclosure of the platelet cytoplasm. Rather than the DMS, 'platelet territories' were therefore proposed as the site of platelet production in the MK. Further morphological data suggested that DMS was a misnomer and that the tubular invaginations act as a membrane reserve for the attenuated processes. However, this suggestion has been subsequently thrown into confusion following freeze–fracture studies of Shaklai and Tavassoli that showed the invaginated system to consist of a complex of interacting channels involving fusion and branching so that there is communication between many of the invaginations. White[57] has suggested that this complex of intracytoplasmic tunnels would be torn apart in simple evagination. Thus several inconsistencies appear in the platelet territory explanation of platelet production. Despite these problems, the process of growth and demarcation of platelet territories has been proposed as a mechanism for platelet volume heterogeneity which would explain the platelet log volume distribution[58]. This model does not address the problem of platelet release from the MK nor does it identify the mechanism of biological control over growth and demarcation which is supposed to determine platelet size.

Platelet production in the peripheral circulation

Electron microscopic evidence that MKs in their entirety migrate through the vessel wall[59] suggests that platelet production may occur at a site away from the bone marrow. It has also been demonstrated that megakaryocytic cytoplasm is capable of amoeboid movement[60], leaving the naked nucleus behind in the marrow. These observations suggest that both MKs and megakaryocytic cytoplasmic processes are capable of transendothelial migration into the bone marrow sinusoids and hence into the peripheral circulation. Direct evidence is also produced by the work of Kinosita and Ohno[61] in which windows were made in the femur of rabbits and the marrow tissue, once it had regenerated, examined by phase contrast microscopy. In these experiments, whole MKs were observed in the bone marrow sinusoids, but cytoplasmic processes were never observed projecting into the sinusoidal lumen. It was also noted that platelets were produced by cytoplasmic disintegration in the extrasinusoidal and sinusoidal spaces although the possibility that this was due to MK spreading on the glass of the windows cannot be excluded.

Circulating MKs (of the order of 25 MKs per ml of blood) have been found in the adult human vena cava[62]. Differential concentrations of cytoplasm bearing MKs have been demonstrated between arterial and venous blood (increased concentrations on the venous side) suggesting that either some filtering of MKs occurs between central venous blood and arterial blood[62] or that the MKs in venous blood fragment to form platelets[63]. Similar findings have been reported in other mammals including rat, dog and rabbits[64–66] suggesting potentially similar mechanisms of platelet production. This is logical since all mammals have a $\log_{10}$ normal distribution of platelet volume and polyploidy[67,68]. Due to the difficulties of studying MKs as they circulate, it is difficult to obtain evidence that shows platelet production in circulating blood. However, the pulmonary capillaries act as filters for large cells, and it has been suggested that they trap circulating MKs and form platelets at this site. The evidence for this shall be considered below.

Platelet production from circulating MKs in the lungs

An alternative theory regarding the site of platelet production was developed from observations made as long ago as 1893 by Aschoff[69] and subsequently by Wright in 1906[43], of the presence of MKs in the pulmonary vessels. Since these MKs were found mainly to consist of naked cytoplasmic material, the general opinion was that the MKs were migrants from the bone marrow (or spleen in some circumstances) which had lost their cytoplasm in the process of platelet formation before reaching the lungs, or shortly after being trapped in the pulmonary capillaries.

However, these observations were questioned following the observation of cytoplasmic processes extending from pulmonary MKs and pushing through pulmonary capillaries[70]. This data therefore seemed incompatible with the notion of pulmonary MKs representing degenerating cells that had been cast off from the bone marrow and it was postulated that MKs are formed or develop in the lungs themselves from myeoblastic cells.

Autopsy studies revealed the presence of pulmonary MKs in every one of 50 cases[71] as well as in other organs such as spleen, liver, kidney and heart. This led to the suggestion that these MKs originate in the bone marrow and their presence in other organs is therefore dependent upon the number of MKs entering the systemic circulation or the bone marrow and subsequently passing through the pulmonary bed to reach the other organs.

Experiments in dogs whereby blood to the left lung was shunted, bypassing systemic circulation, revealed that the lung receiving systemic blood (that had passed through the bone marrow) had almost 100 times higher concentration of MKs than the shunted lungs[72]. This therefore refuted the belief that MKs formed within lung tissue but still left the possibility of platelet production within the pulmonary capillary bed.

Other authors have also reported the presence of mature MKs in pulmonary arteries and the presence of naked nuclei in the pulmonary capillary[48,73]. They have also demonstrated a relationship between pulmonary MKs and microthrombosis, suggesting that conditions that involve generalized thrombus formation (e.g. disseminated intravascular coagulation) were also associated with increased concentrations of pulmonary MKs[73].

Thus considerable evidence suggests that MKs are found in pulmonary capillaries but what becomes of them? One possibility is that they change shape and pass through the pulmonary capillaries into the systemic circulation. Observational evidence suggests that this is not the case due to the finding of naked nuclei in the pulmonary bed[62] and the decreased amount of MKs with cytoplasm found in the systemic arterial circulation compared to the venous circulation[62,74]. The loss of MK cytoplasm within the pulmonary bed has led to the development of mathematical models to calculate MK cytoplasmic volume distribution in an attempt to demonstrate that sufficient MK cytoplasmic material reaches the lungs to account for circulating platelet counts[75,76]. Furthermore, the model

Cambridge Books Online © Cambridge University Press, 2009

proposes that platelet production through MK fragmentation involves two stochastic processes that would produce heterogeneity in the circulating platelet population. The log-normal platelet volume distribution would be explained by the fact that multiple fragmentation steps led to such a distribution in all physical fragmentation processes.

Pathophysiology

So far, the origins and mechanisms leading to platelet heterogeneity have been considered. An important question is what role if any does platelet heterogeneity play in human disease?

Since platelets are involved in arterial thrombus formation and drugs that inhibit platelet behaviour are beneficial in preventing arterial occlusion it is of interest that alterations in platelet size and density have been described in arterial disease[77–80]. Examination of platelet physiology in these conditions has produced interesting data that has led to some understanding of the role of platelet heterogeneity in the human. Platelet density has been extensively studied in the human suffering from myocardial infarction. Since myocardial infarction nearly always occurs in the presence of atherosclerosis, this disease provides a convenient means of studying the alterations in platelet size and density previously described. Martin et al.[79] discovered that the density of platelets from patients with myocardial infarction was significantly higher than from control subjects. This study also demonstrated a concomitant increase in platelet volume that has been confirmed by other authors[77,78]. Since large platelets are more reactive than small platelets[1,3,33,81], it is reasonable to suggest that if large platelets are present in the circulation before myocardial infarction, their presence may be causally linked to the occurrence of thrombosis in the coronary artery. In acute myocardial infarction, not only is the average MPV increased but also the whole of the platelet volume distribution is shifted to the right[82] (Fig. 4.1).

If the platelet volume distribution curve has its origin in thrombopoiesis, then this implies a change in the MK in myocardial infarction. Models describing the control of thrombopoiesis (outlined below) suggest that a low platelet count and large platelet volume (as found in acute myocardial infarction) may follow acute platelet destruction[9] or chronic slow platelet destruction[84]. In both these cases there is a change to larger, higher ploidy MKs, although the large platelets following acute destruction occur before changes in the MK ploidy[29,34].

Bone marrow biopsy of patients following acute myocardial infarction have confirmed that MKs are bigger than those from controls[80]. Autopsy studies also demonstrated that MKs in patients who suffered a sudden cardiac death were larger than from patients who died due to trauma, and had normal coronary arteries[80]. Since large MKs are associated with any increase in the rate of platelet production, the large platelets in acute myocardial infarction probably occur secondary to the stimulus from an increase in platelet destruction.

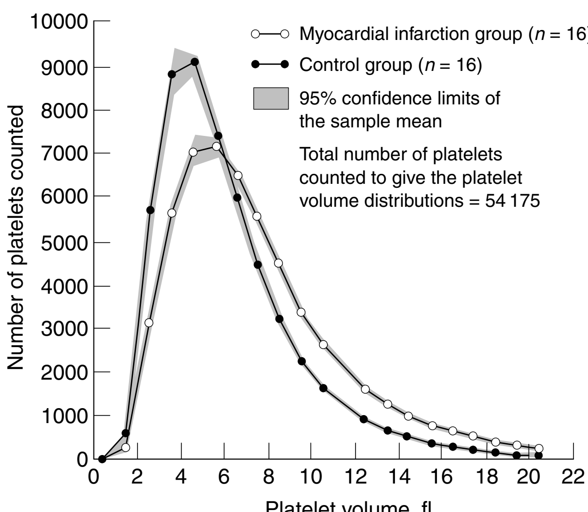

Fig. 4.1. Average platelet volume distribution of patients with acute myocardial infarction (open circles) and controls (closed circles). Note that the whole platelet volume distribution curve is shifted to higher values in myocardial infarction compared with controls. Since the log normal curve of platelet distribution has its origin in thrombopoiesis this shift probably implies a change in thrombopoiesis in myocardial infarction[82]. Although these platelets were taken from patients after myocardial infarction there is evidence in second myocardial infarction that these changes have preceded this second event[83].

The significance of an increase in platelet size in acute myocardial infarction has been studied in relation to the bleeding time. Milner and Martin[85] demonstrated that mean bleeding time in acute myocardial infarction is shortened compared to controls. It is also of interest that bleeding time was found to be inversely related to MK size and ploidy in normal subjects[39]. Thus the finding of a shortened bleeding time, large platelets and large MKs in acute myocardial infarction provides consistent independent evidence that these factors may be causally related to the acute event. Furthermore, in a study of 2000 men followed over 2 years, increases in platelet size 6 months after their first myocardial infarction was the strongest predictor of a second myocardial infarction or death[83]. Since these changes occurred before myocardial infarction, it is pos-

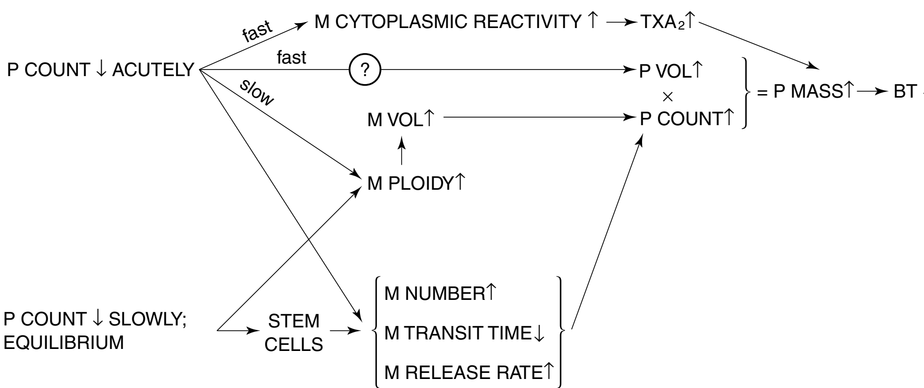

Fig. 4.2. Proposed system of relationships between change in platelet destruction rate, alteration in MK variables, change in platelet mass and bleeding time. P = platelet, M = megakaryocyte, TXA_2 = thromboxane A_2, BT = bleeding time, vol = volume, ↑ = increased, ↓ = decreased, → = an association[35].

sible that changes in platelet volume precede and may be causally related to the first myocardial infarction (in that subpopulation of the syndrome where platelet reactivity is a cause of coronary artery occlusion – reviewed in Van der Loo and Martin[86]).

Since platelet destruction is associated with increases in MK ploidy[23,29,31,38,87] and platelet hypertransfusion with decreases in ploidy[36,38], it could be concluded that ploidy change is the mechanism by which circulating platelet counts may be adjusted, probably to adjust to hemostatic needs. Thus presupposing that a change in platelet destruction rate is the event that signals changing hemostatic need and that in response, change in bleeding time is the ultimate physiological manifestation of the changes in cellular hemostasis, a mechanism controlling platelet production is outlined above (Fig. 4.2).

As already mentioned, in most acute myocardial infarction, platelet counts are reduced, producing a stimulus for the mechanism outlined above. Recently, our work has also explored the relationship of MPV between acute myocardial infarction and unstable angina[88] following on from an earlier study that demonstrated an increase in MPV in patients with unstable angina compared with controls[89]. We found that, in unstable angina, MPV is increased relative to that in acute myocardial infarction, and that platelet count is decreased. Although both conditions demonstrated an increase in expression of surface markers of platelet activation compared to controls, these variables were increased more in myocardial infarction than in unstable angina. Whilst these observations may be explained by postulating that platelet changes in unstable angina are due to a more chronic process of platelet destruction compared to acute myocardial infarction, it does not explain why the large platelets of unstable angina are not associated with an increase in activation or a decrease in bleeding time[90]. Little data exist that describe changes in bone marrow MKs in unstable angina, and without this part of the puzzle it is difficult to fully explain these findings.

Various models have been used in an attempt to study changes in platelet physiology in response to platelet destruction. Injection of antiplatelet antibodies into rats and mice has shown an increase in platelet volume several hours later[29,91]. A useful model of platelet destruction in man results from the study of changes in platelet parameters of patients undergoing cardio-pulmonary bypass at heart valve replacement. This demonstrates a rise in MPV with a fall in platelet count (Figure 4.3) induced by the operation[92]. Other operations[93] have also demonstrated this relationship as well as an increase in TPO levels in response to the decrease in platelet count, providing further evidence for the role of TPO in the control of platelet volume.

Conclusions

The significance of platelet heterogeneity still remains controversial in spite of the wealth of evidence that has been collected. This lack of full understanding of normal physiology is a major drawback to understanding several disease processes such as myocardial infarction. Although observational data has been collected from humans, without the ability to manipulate the system, this cannot be taken further. What we understand so far is that platelets are heterogeneous with respect to size and this may

Cambridge Books Online © Cambridge University Press, 2009

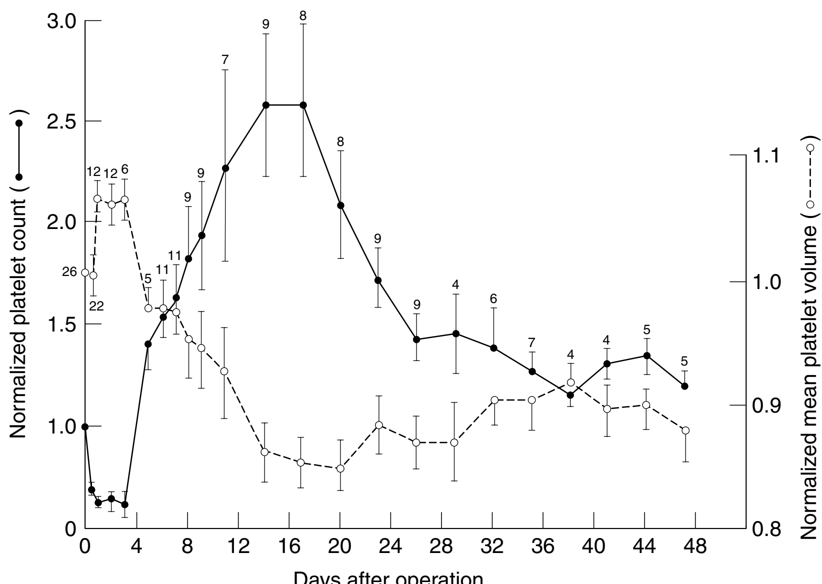

Fig. 4.3. The changes in platelet count and mean platelet volume following cardiopulmonary bypass surgery[92].

well reflect changes in platelet function. These changes probably occur at the time of platelet production, although the exact site at which platelets are produced remains controversial. Large platelets are denser and are functionally more reactive than small platelets. Changes in platelet size and density are not necessarily preceded by changes in MK size and ploidy, although these do increase with an increase in the size of circulating platelets.

Patients with acute myocardial infarction and unstable angina are found to have platelets with increased MPV. Increased MPV is associated with increased expression of surface markers of platelet activation in both of these conditions. Increased MK size and ploidy have been found in acute myocardial infarction suggesting that changes in platelet function may causally be related to acute coronary syndromes. The relationship between changes in platelet size and count post surgery with TPO levels would suggest that changes in TPO levels may control platelet behaviour and that these changes occur in an attempt to maintain haemostatic equilibrium.

This suggests that if changes in platelet physiology are causal to acute coronary syndromes, these may occur as a result of the pathological transformation of a physiological protective mechanism. The trigger for this transformation has yet to be determined.

Platelet membrane proteins as adhesion receptors

Yoshiaki Tomiyama[1], Masamichi Shiraga[1], and Sanford J. Shattil[2]

[1]Department of Internal Medicine and Molecular Science, Graduate School of Medicine, Osaka University, Japan

[2]Department of Vascular Biology, The Scripps Research Institute, La Jolla, USA

Platelets play a crucial role not only in the formation of a normal hemostatic plug but also in formation of a pathologic thrombus, particularly within arteries subjected to high shear stress. Platelets circulate passively as they traverse a vascular tree lined by an intact monolayer of endothelial cells. As an initial step in hemostasis and thrombogenesis, platelets adhere to altered vascular surfaces or exposed subendothelial matrices. Following adhesion, they become activated, change shape, secrete granule contents, and aggregate to each other to form a primary hemostatic plug and to provide a catalytic surface to enhance blood coagulation. Thus, thrombus formation depends primarily on platelet adhesive interactions with both extracellular matrix proteins [e.g. von Willebrand factor (vWF), collagen, fibronectin] and cellular surfaces (e.g. platelets, leukocytes). In order to mediate these adhesive events, platelets possess numerous receptors specialized for this task. In this chapter, we will focus on the structure and function of platelet plasma membrane glycoproteins that serve as important adhesion receptors. One theme that emerges is that many, if not all, adhesion receptors also function as signalling receptors. Other chapters in this book will focus on surface membrane proteins that function primarily as receptors for excitatory and inhibitory agonists and on granule proteins, such as P-selectin and CD40 ligand, that may mediate adhesive functions concomitant with granule secretion (Chapters 9–13).

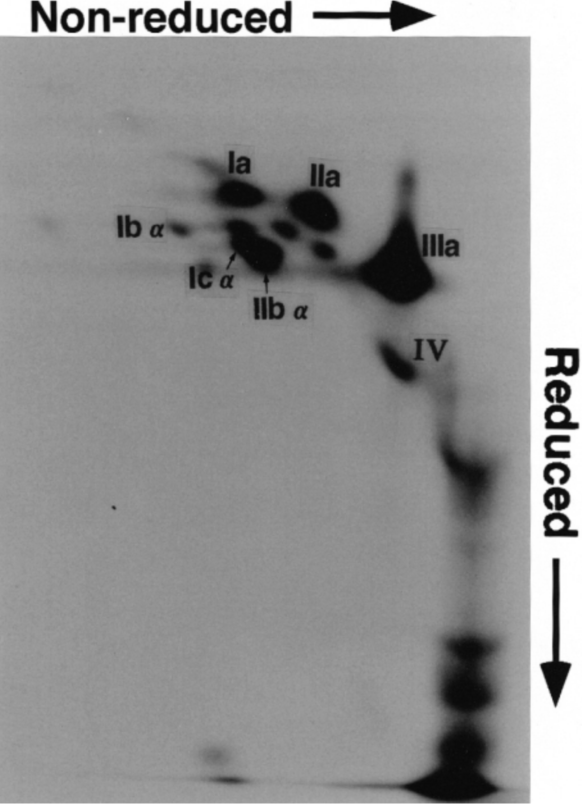

Fig. 5.1. Two-dimensional non-reduced–reduced SDS–polyacrylamide gel electrophoresis of surface-labelled intact platelets. ^{125}I-labelled platelets were electrophoresed in 5% polyacrylamide gels under non-reducing conditions in the first dimension. The gels were then electrophoresed in 7% polyacrylamide gels under reducing conditions in the second dimension. An autoradiograph of a dried gel is illustrated.

Platelet adhesion receptors

Surface labelling of intact platelets has shown that they possess numerous glycoproteins on their surface (Fig. 5.1)[1]. Initially, these glycoproteins were designated Ia, Ib,

Table 5.1. Platelet membrane glycoproteins that function as adhesion receptors

	Ligands	Platelet function	Molecules/platelet
Integrins			
β_1 integrins			
GPIa–IIa ($\alpha_2\beta_1$)	Collagen	Adhesion	<1000
GPIc–IIa ($\alpha_5\beta_1$)	Fn	Adhesion	<1000
GPIc′–IIa ($\alpha_6\beta_1$)	Laminin	Adhesion	<1000
β_3 integrins			
GPIIb–IIIa ($\alpha_{IIb}\beta_3$)	Fg/vWF/Fn/Vn	Aggregation/firm adhesion	~80 000
$\alpha_V\beta_3$	Fg/Vn/OP	?	50–100
Leucine-rich motif (LRK) family			
GPIb–IX	vWF/thrombin	Initial adhesion	~25 000
GPV			~12 000
GPIV (CD36)	TSP/collagen	Adhesion	12 000–19 000
GPVI	Collagen	Activation	~1000

Notes:
vWF: von Willebrand Factor, Fn: Fibronectin, Fg: Fibrinogen, Vn: Vitronectin, TSP: Thrombospondin, OP: Osteopontin.

Ic, IIa, IIb, IIIa, etc according to their apparent molecular sizes in SDS-polyacrylamide gels under non-reducing and reducing conditions. Among them, two major receptor complexes, GPIb–IX–V and GPIIb–IIIa, play essential roles in platelet adhesion and aggregation[2,3]. Platelet membrane glycoproteins have been cloned, sequenced and classified within known gene families (Table 5.1).

Platelet integrins

Integrins are a family of non-covalently associated $\alpha\beta$ heterodimers that mediate cellular attachment to the extracellular matrix and cell–cell cohesion[4,5]. To date, 18 different integrin α subunits and 8 different integrin β subunits have been defined, giving rise to more than 24 different integrins. They are often subdivided into groups based on integrin β subunits, such as β_1, β_2, and β_3 integrins[4,5]. Platelets possess at least five integrins ($\alpha_2\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_{IIb}\beta_3$, $\alpha_V\beta_3$), and $\alpha_{IIb}\beta_3$ (GP IIb–IIIa) is the most abundant and functionally significant.

Structure

$\alpha_{IIb}\beta_3$ is a prototypic and platelet/megakaryocyte-specific integrin[6]. The α_{IIb} subunit has been found only in combination with β_3. $\alpha_{IIb}\beta_3$ is expressed on the platelet surface at a density of approximately 80 000 copies per cell[7]. Synthesis of α_{IIb} and β_3 is regulated by separate genes, both of which have been localized to chromosome 17q12.32[8,9]. However, the β_3 gene appears ≥365 kb upstream of the α_{IIb} gene[10]. α_{IIb} consists of a heavy chain (871 amino acid residues) containing four repeats of a putative divalent cation binding motif disulfide-linked to a light chain (137 amino acid residues). β_3 consists of a single polypeptide of 762 amino acids containing 56 cysteines which form extensive intramolecular disulfides (Fig. 5.2). The N-terminus and most of the remainder of each subunit are extracellular, and the membrane-spanning domain is connected to a short C-terminal cytoplasmic tail consisting of 20 amino acid residues in α_{IIb} and 47 residues in β_3. Electron microscopy and other analyses of heterodimers shows an N-terminal globular head connected to two C-terminal stalks[11–13]. Although the atomic structure of $\alpha_{IIb}\beta_3$ is not known, recent studies indicate that ligand binding is primarily a function of the globular heads[11–13].

Multiple binding sites for Arg–Gly–Asp (RGD)-containing ligands have been identified on both α and β subunits[14,15]. The N-terminal region of integrin α subunits has seven repeats of homologous sequences of about 60 amino acid residues. In several α subunits (e.g. α_2, α_L, α_M) but not α_{IIb}, an inserted domain of about 200 amino acid residues (the I-domain) is present between the second and the third repeats, which is critically involved in ligand binding[16,17], and its crystal structure has been determined[18,19]. This domain adopts a classic 'Rossmann' fold, with a central parallel β-sheet surrounded on both sides by α-helices and it contains a unique divalent cation coordination sphere, which has been designated as the metal ion-dependent adhesion site (MIDAS) motif. The conserved features of

Cambridge Books Online © Cambridge University Press, 2009

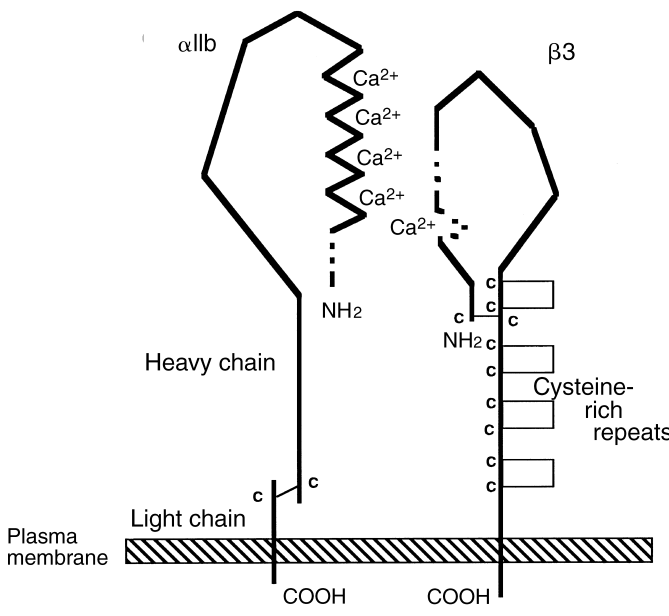

Fig. 5.2. Schematic representation of $\alpha_{IIb}\beta_3$. Dotted lines indicate putative ligand binding sites. α_{IIb} and β_3 are non-covalently associated at a stoichiometry of 1:1. α_{IIb} comprises a disulfide-linked heavy and light chain, while β_3 consists of a single polypeptide. Electron microscopic analyses of $\alpha_{IIb}\beta_3$ shows an N-terminal globular head connected to two C-terminal stalks.

this motif are an Asp X Ser X Ser (DXSXS) sequence, where X represents any amino acid. In the case of integrins like $\alpha_{IIb}\beta_3$ that do not contain the I domain in their α subunit. It has been proposed that β-subunits have an I-like domain located near the N terminus that contains an invariant DXSXS sequence (residues 119–123 in β_3). Using chemical cross-linkers, it has been shown that a ligand-mimetic RGD-containing peptide is cross-linked to β_3 residues 109–171[20]. A naturally occurring missense mutation at the first residue of DXSXS sequence (Asp119→Tyr) results in the inability of $\alpha_{IIb}\beta_3$ to recognize ligands, and alanine substitutions at these residues further support the hypothesis that this region of β_3 might engage ligands via a MIDAS-like motif[21,22].

Recently Springer proposed that the seven N-terminal sequence repeats of integrin α subunits are folded into a β-propeller domain, although there are as yet no high resolution structural data to support this model[23]. The proposed domains contain seven four-stranded β-sheets (W1–W7) arranged in a torus around a pseudosymmetry axis. Integrin ligands have been predicted to bind to the upper face of the β-propeller, especially within W2, W3 and W4[24,25]. Using chemical cross-linkers, it has been shown that a dodecapeptide derived from the C-terminus of the fibrinogen γ-chain is proximal to α_{IIb} residues 294–314, which contain the second putative calcium binding domain[26]. However, a recombinant α_{IIb} fragment comprising residues 1–233, which has no calcium-binding domains, can form a heterodimer with a recombinant β_3 fragment (residues 111–318) and bind to an RGD-containing peptide[27]. The residues 294–314 lie on the lower surface of the propeller far from the ligand-binding sites and may play a structural rather than ligand-binding role.

Function

$\alpha_{IIb}\beta_3$ recognizes several RGD-containing adhesive proteins in a divalent cation-dependent manner. In particular, the interaction with fibrinogen and vWF is crucial for platelet aggregation[28]. The ligand binding function of $\alpha_{IIb}\beta_3$ is dynamically regulated (Fig. 5.3)[29,30]. In resting platelets, $\alpha_{IIb}\beta_3$ is in a low affinity state and cannot bind soluble macromolecular ligands like fibrinogen or vWF. After platelet activation by agonists, intracellular signals are initiated that induce a high affinity/avidity state of $\alpha_{IIb}\beta_3$ with respect to these adhesive ligands. This process is frequently referred to as 'inside-out' signalling or 'integrin activation', and it encompasses at least two events: (i) modulation of receptor affinity through conformational changes and (ii) modulation of receptor avidity through facilitation of lateral diffusion and/or clustering of integrin heterodimers into oligomers. In the case of $\alpha_{IIb}\beta_3$, affinity modulation rather than avidity modulation seems to play the dominant role in initiating ligand-binding[30]. Based on mutational data, a model for the conformational switch in $\alpha_{IIb}\beta_3$ during platelet activation has been proposed[14]. Fibrinogen binding to $\alpha_{IIb}\beta_3$ itself alters the conformation of the integrin, which exposes neo-epitopes in the receptor known as ligand-induced binding sites (LIBS), and leads to 'post-receptor occupancy' events, including cytoskeletal reorganization[31–33]. Thus, $\alpha_{IIb}\beta_3$ and other integrins function as important signalling molecules that can mediate the bidirectional transfer of information across the platelet plasma membrane.

Evidence directly implicating the cytoplasmic tails in affinity modulation comes from studies of naturally occurring and experimental integrin mutations, from analyses of $\alpha_{IIb}\beta_3$ function in heterologous expression systems, and from identification of integrin tail-binding proteins[34–39]. Affinity modulation probably involves the propagation of a conformational change from the $\alpha_{IIb}\beta_3$ cytoplasmic domains to the extracellular domains. Concerning the potential structure of the α_{IIb} and β_3 cytoplasmic domains,

Cambridge Books Online © Cambridge University Press, 2009

Fig. 5.3. $\alpha_{IIb}\beta_3$ signalling. Conformation and function of $\alpha_{IIb}\beta_3$ are dynamically regulated. After platelet activation intracellular signals are initiated that induce a high affinity/avidity state of $\alpha_{IIb}\beta_3$ (inside–out signals). Fibrinogen binding to $\alpha_{IIb}\beta_3$ leads to outside–in signals.

a model has been proposed in which the membrane-proximal portions of the tails interact when the integrin is in a low affinity state, possibly through a salt bridge to form a hinge. Certain membrane-proximal mutations or deletions are hypothesized to break this hinge, converting $\alpha_{IIb}\beta_3$ to a high-affinity state[34,35,40]. This model predicts close but dynamic interactions between the α_{IIb} and β_3 tails, and synthetic peptides derived from these tails have been shown to interact in vitro[41].

Recently, mice have been generated that express $\alpha_{IIb}\beta_3$ in which the two tyrosine residues in the β_3 cytoplasmic tail (Y747 and Y759) have been switched to phenylalanine[42]. These mice exhibit normal inside-out but impaired outside-in signalling, with defective aggregation and clot retraction. Outside-in signalling through $\alpha_{IIb}\beta_3$ involves stimulation of numerous interacting pathways that feature activation of protein tyrosine kinases (e.g. Syk, Src family, FAK) and tyrosine phosphorylation of numerous substrates in addition to the β_3 tail[30]. How these pathways regulate cytoskeletal reorganization and other postligand binding events is an active area of investigation.

Deficiency

The importance of integrin $\alpha_{IIb}\beta_3$ is evident by the pathogenic consequence of its heritable deficiency, Glanzmann thrombasthenia (GT)[43]. GT is an autosomal recessive bleeding disorder that is due to a quantitative and/or qualitative defect in $\alpha_{IIb}\beta_3$. Molecular analysis in GT as well as transfection studies have demonstrated that a molecular abnormality in the genes for either α_{IIb} or β_3 can lead to the deficiency of $\alpha_{IIb}\beta_3$ on platelet surface. Absent and/or abnormally spliced mRNA due to a nonsense mutation or frame shift are common in severe $\alpha_{IIb}\beta_3$ deficiency (type I GT), whereas missense mutations in either subunit are common in moderate $\alpha_{IIb}\beta_3$ deficiency. Although various missense mutations leading to the impaired expression of $\alpha_{IIb}\beta_3$ are reported, it has been demonstrated that relatively well-conserved residues flanking the calcium-binding domains of α_{IIb} are particularly critical for $\alpha_{IIb}\beta_3$ expression[44–47]. The bleeding diathesis in GT is characterized by mucocutaneous hemorrhage with easy bruising, menorrhagia, epistaxis, and gingival bleeding. Platelet aggregation is absent in response to ADP, epinephrine, collagen, or thrombin, while ristocetin-induced platelet aggregation is observed (Fig. 5.4). GT due to a dysfunctional rather than an absent $\alpha_{IIb}\beta_3$ complex is referred to as variant GT, and the characterization of these variants has helped to identify residues on the integrin necessary for ligand binding and for bidirectional signalling[21,48–50].

Of particular interest are the Ser752→Pro substitution and the Arg724→Ter substitution in the cytoplasmic domain of β_3, each of which is responsible for disruption of the coupling between inside-out signalling and $\alpha_{IIb}\beta_3$ activation[38,39]. These GT variants provide strong evidence that the cytoplasmic domain of β_3 is involved in inside-out signalling. In addition, these GT variant platelets exhibit impaired outside-in signalling, resulting in reduced fibrin clot retraction and decreased cell spreading and cytoskeletal reorganization on fibrinogen[39,51]. Thus, while these

Cambridge Books Online © Cambridge University Press, 2009

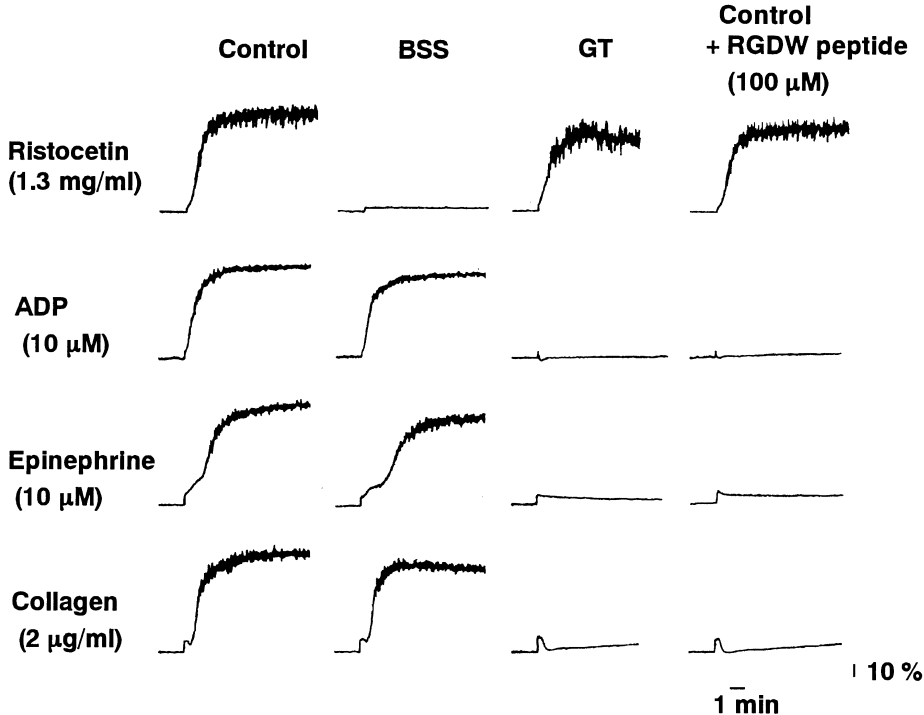

Fig. 5.4. Characteristics of impaired platelet aggregation observed in Bernard–Soulier syndrome (BSS) or Glanzmann thrombasthenia (GT). Ristocetin-induced agglutination depends on the interaction of von Willebrand factor (vWF) with GPIb–IX–V, while ADP-, epinephrine-, and collagen-induced platelet aggregation depend on the interaction of fibrinogen with $\alpha_{IIb}\beta_3$. Note that RGD-containing peptides induce the same defect in platelet aggregation observed in GT. These findings suggest that the interaction of fibrinogen with $\alpha_{IIb}\beta_3$ is mediated, at least in part, via the RGD sequence.

mutations in β_3 abrogate bidirectional transmembrane signalling via $\alpha_{IIb}\beta_3$, a β_3 Ser752→Ala mutation showed only minimal inhibitory effects on outside-in signalling when expressed in a CHO cell model system, suggesting that the presence of Pro752, rather than the absence of Ser752, is responsible for the phenotype[52,53].

Recently, β_3-deficient mice have been developed as an animal model for GT[54]. The β_3-null platelets show essentially the same defects as in human GT platelets. These mice show a greatly prolonged tail bleeding time and spontaneous hemorrhage. Moreover, they display additional defects that were not evident in studies of human GT, such as placental and bone resorption defects[54,55]. This animal model should prove to be a valuable tool for additional studies of GT pathogenesis and therapy.

Leucine-rich motif (LRM) family

The leucine-rich motif (LRM) family of proteins was first recognized as the result of a 24-residue motif present as 8 tandem copies in a human serum protein of unknown function called leucine-rich α_2-glycoprotein[56]. The LRM family, which is defined not by the similarity in the structure or function of its members, but by the presence of this structural motif, is a phylogenetically widespread family of proteins that is found in both eukaryotes and prokaryotes and as components of the nucleus, cytoplasm, cell membranes, extracellular matrix, and plasma. Four members of the LRM family, GPIbα, GPIbβ, GPIX and GPV, associate on the platelet surface to form the GPIb–IX–V complex[57,58]. This complex is the most prominent sialoglycoprotein in the platelet membrane and serves as a major receptor for vWF[58–60].

Structure

Each platelet contains approximately 25 000 copies of the GPIb–IX complex[61,62]. The four distinct transmembrane polypeptide subunits, GPIbα, GPIbβ, GPIX, and GPV, appear to be expressed at a stoichiometry of 2: 2: 2: 1, respectively (Fig. 5.5). A separate gene encodes each com-

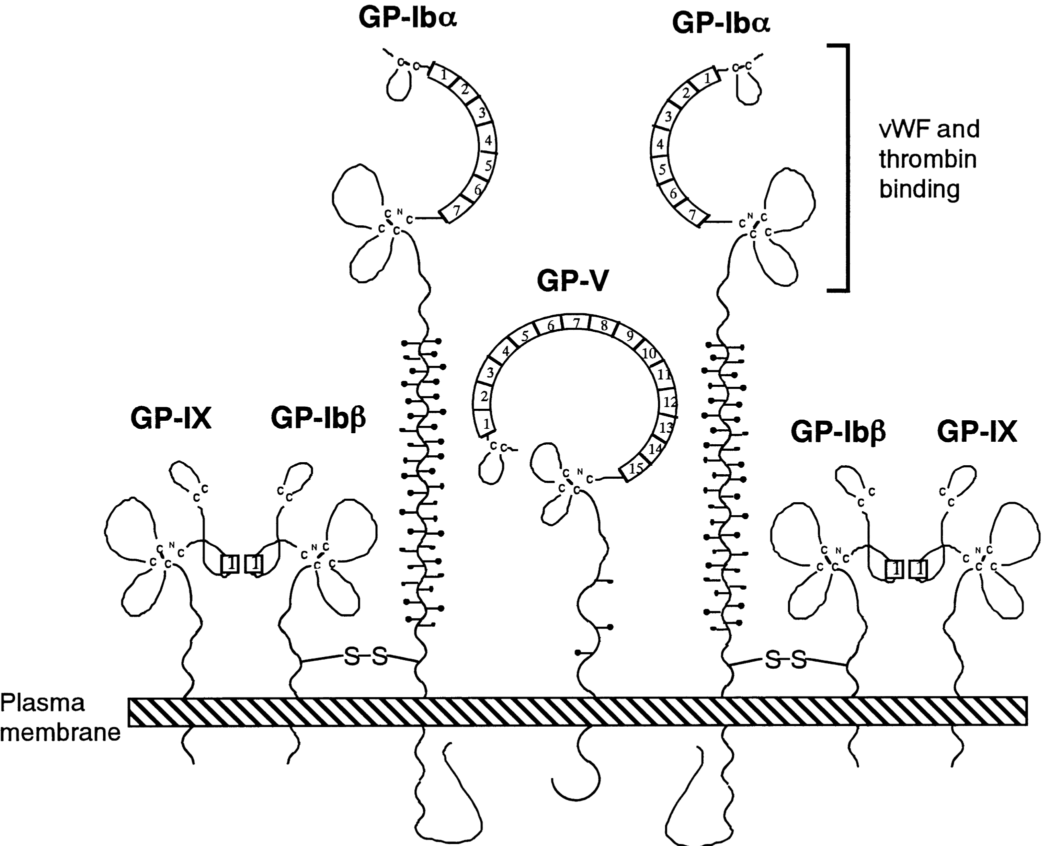

Fig. 5.5. Schematic representation of the GPIb–IX–V complex. Four members of the leucine-rich (LRM) motif family, GPIbα, GPIbβ, GPIX and GPV associate to form the GPIb-IX-V complex at a stoichiometry of 2:2:2:1. Box indicates leucine-rich repeat sequences (LRR), and GPIbα, GPIbβ, GPIX and GPV contain 7 tandem LRRs, one LRR, one LRR, and 15 LRRs, respectively. The N-terminal globular domain of GPIbα contains binding sites for von Willebrand factor (vWF) and thrombin. (Adapted from López et al., 1998 with permission.)

ponent of the GPIb–IX–V complex: the GPIbα, GPIbβ, GPIX, and GPV genes are located on chromosomes 17q12, 22q11.2, 3q21, and 3q29, respectively[63–66]. GPIb consisting of GPIbα (135 kDa, 610 amino acids) disulfide linked to GPIbβ (25 kDa, 181 amino acids) is noncovalently associated with GPIX (22 kDa, 160 amino acids). On electron microscopy, the purified GPIb–IX complex appears as a flexible rod with globular domains at either end and an overall length of 60 nm, which is 20–30 nm longer than $\alpha_{IIb}\beta_3$[67]. The smaller globular domain represents the N-terminal ligand-binding region of GPIbα, while the larger globular domain consists of the GPIbα transmembrane and cytoplasmic domains associated with GPIbβ and GPIX. The leucine-rich repeat sequences (LRR) are approximately 24 amino acids in length, and GPIbα, GPIbβ, GPIX and GPV contain 7 tandem LRRs, one LRR, one LRR, and 15 LRRs, respectively. The structure of GPIbα is divided into four distinct domains as follows: an N-terminal globular domain that contains ligand-binding sites, a mucin-like segment (macroglycopeptide), a transmembrane segment, and a cytoplasmic domain that interacts with intracellular proteins, such as filamin α and 14–3–3ζ[58–60].

Function

The major physiological role of the GPIb–IX–V complex is to mediate initial adhesion of circulating platelets to vWF in the subendothelial matrix under conditions of high shear. The transient and reversible platelet adhesion mediated by GPIb–IX–V then proceeds to irreversible platelet attachment mediated by the interaction of vWF with $\alpha_{IIb}\beta_3$[2,3]. The GPIb–IX–V complex interacts with vWF through a binding site in GPIbα located in the N-terminal 45-kDa domain (residues 1–293)[68,69]. The interaction between GPIb–IX–V and vWF appears to require a change in conformation in vWF and/or the GPIb–IX–V complex,

Cambridge Books Online © Cambridge University Press, 2009

induced either by the effects of shear on the ligand or receptor or by immobilization of vWF onto the subendothelial matrix. In the aggregometer, soluble vWF can support platelet–platelet interaction mediated through GPIb–IX–V using non-physiological modulators, such as ristocetin and the snake venom protein–botrocetin[58]. Although the vWF binding site has been localized to the 45-kDa domain of GPIbα, it has become evident that vWF binds to more than one site within this domain, and that binding is dependent upon the modulators by which the interaction is induced. One of the binding sites is the sulfated tyrosine sequence (residues 276, 278, 279) that is preferentially used for botrocetin-dependent vWF binding[70–72]. In addition, naturally occurring mutations have suggested that ligand-binding function requires the proper conformation of the 45 kDa domain[73,74]. Other potential roles for the GPIb–IX–V complex are to serve as a high affinity α-thrombin binding site, and as a receptor that participates in signal transduction to regulate the activation state of $\alpha_{IIb}\beta_3$[60,75].

Deficiency

The importance of the GPIb–IX–V complex is exemplified by the inherited bleeding disorder, Bernard–Soulier syndrome (BSS)[76]. BSS is an autosomal recessive disorder due to a quantitative and/or qualitative defect in the GPIb–IX–V complex. BSS is also characterized by a decrease in the platelet count with the striking phenotype of abnormally large or 'giant' platelets. A characteristic laboratory abnormality is an isolated defect in ristocetin-induced platelet agglutination (Fig. 5.4). In BSS the expression of all four subunits is impaired, however the defect in the expression of each subunit may not always be in the same proportion[77–79]. To date, molecular defects in BSS have been described in the GPIbα, GPIbβ and GPIX genes. However, no molecular defects have as yet been reported in the GPV gene[76]. As in GT, characterization of molecular defects leading to qualitative dysfunction of GPIb–IX–V has been informative. Two mutations leading to missense mutations within the extracellular LRR domain of GPIbα (Leu57→Phe and Ala156→Val) are associated with the impaired binding of vWF. These mutations reveal an important role of the LRR of GPIbα, which may function by maintaining the proper conformation and exposure of ligand-binding site[73,74]. In contrast, platelet-type von Willebrand disease is an autosomal-dominant bleeding disorder caused by mutations affecting the GPIb–IX–V complex, resulting in a gain-of-function phenotype[80,81]. The resultant mutants bind vWF with high affinity and the paradoxical presence of a bleeding diathesis is due to clearance of the hemostatically most active large vWF multimers. Two missense mutations (Gly233→Val and Met239→Val) within the Cys209–Cys248 loop of GPIbα are associated with a gain-of-function phenotype, suggesting that the loop may function as a regulatory region that prevents the exposure of the ligand-binding site[82–84].

The molecular basis for the giant platelets observed in BSS remains elusive. GPIbα-null mice also exhibit a bleeding diathesis as well as thrombocytopenia and giant platelets[85]. In addition, this mouse model of the BSS could be rescued with transgenic expression of a human GPIbα, demonstrating a direct link between expression of the GPIb–IX–V complex and platelet morphogenesis[85]. In contrast, platelets from GPV-null mice are normal in size and express normal amounts of GPIb–IX that is functional in vWF binding[86,87]. Thus, GPV is not required for the expression or function of GPIb–IX, which is consistent with the fact that mutations in GPV have not been observed in BSS.

With the impaired expression of GPIb–IX–V in BSS platelets, response to α-thrombin is also compromised[88]. Protease-activated G-protein-coupled receptors, PAR-1 and PAR-4, have a key role in the activation of human platelets by α-thrombin. It has been revealed that the 45-kDa domain of GPIbα that contains the vWF binding sites also is the region that binds thrombin[89]. Although the mechanism by which the binding of α-thrombin to GPIb contributes to platelet activation is obscure, a recent study suggests that binding of thrombin to GPIbα accelerates the hydrolysis of PAR-1 on the platelet membrane[90]. Thus, GPIb may function as a cofactor for PAR-1 activation by thrombin. In contrast to the normal vWF binding activity, platelets from GPV-null mice may be hyper-responsive to thrombin and GPV-null mice have a shorter than normal tail bleeding time[86]. These findings suggest a role for GPV in decreasing thrombin responsiveness of platelets, with experimental removal of GPV from the platelet surface contributing to platelet stimulation by thrombin.

CD36 (Glycoprotein IV)

Structure

CD36, also known as GP IV or GP IIIb, consists of 471 amino acid residues with N- and C-terminal hydrophobic portion domains that presumably represent transmembrane domains[91–93]. N- and C-terminal regions of CD36 are palmitoylated, further suggesting that both N- and C-terminal tails are cytoplasmic, and that the protein may partition to glycolipid-enriched membrane microdomains[94]. Because

Cambridge Books Online © Cambridge University Press, 2009

of its topology, most of the CD36 molecule is thought to be oriented to the extracellular milieu, and this region contains 10 potential N-glycosylation sites that likely accounts for this molecule being resistant to proteolysis[95]. CD36 is expressed in a wide variety of cell types, including platelets, monocytes, microvascular endothelial cells, mammary gland epithelial cells, activated keratinocytes, some melanoma cells. CD36 shares structural similarities with some molecules such as SR-B1/CLA-1 (a HDL receptor), LIMP-II (a lysosomal protein) and SNMP-1 (a membrane protein expressed in olfactory neurons), and these molecules are classified as the CD36 family[96–98].

Functions

CD36 is a multifunctional glycoprotein. From the viewpoint of platelet function, it has been shown to interact with a large variety of ligands such as collagen and thrombospondin[99,100]. However, CD36-deficient platelets bind to thrombospondin normally[101]. Although platelet aggregation by type V collagen was impaired, there have been conflicting reports as to the role of CD36 on platelet adhesion to collagen under static and flow conditions[102–105]. In contrast to the other platelet membrane protein deficiencies discussed above, CD36 deficiency is not associated with a bleeding diathesis. Thus, the role of CD36 in platelet function remains unclear. Beyond its role as a platelet glycoprotein, CD36 serves as a receptor on erythrocytes for the human malaria parasite, *Plasmodium falciparum*[91,106]. In addition, recent studies have suggested that CD36 plays an important role in lipoprotein and lipid metabolism[107–110]. CD36 has also been suggested as a candidate for an insulin-resistant gene[111], which is still a subject of controversy[112,113].

Deficiency

The first case of CD36 deficiency was found in a Japanese patient showing refractoriness to HLA-matched platelet transfusions due to an anti-Nak[a] isoantibody that recognizes CD36[114–116]. Platelet CD36 deficiency is divided into two subgroups according to expression of CD36 on monocytes: type I also lacks CD36 on monocytes and presumably on all other tissues, while type II expresses CD36 on monocytes[117,118]. Platelet CD36 deficiency is present in ~3% of the Japanese population and rare in Caucasians (~0.3%), and the majority of platelet CD36 deficiency is the type II phenotype[114,116]. Three genetic abnormalities have been identified, a missense mutation causing substitution of Pro[90] with Ser in CD36, a two-base deletion and a one-base insertion[119–121]. Careful clinical characterization of CD36 deficient subjects, especially type I subjects, would provide a better understanding of the role of CD36 in vivo.

Glycoprotein VI

It has been generally accepted that integrin $\alpha_2\beta_1$ (GPIa–IIa) and GPVI are major collagen receptors on platelets, playing critical roles in adhesion and activation, respectively[122,123]. The first indication that $\alpha_2\beta_1$ is a physiological collagen receptor came from the study of a patient whose platelets demonstrated decreased expression of GPIa and a failure to interact with collagen[124]. Similarly, the critical role for GPVI was first indicated by a patient with GPVI deficiency. Recently, it has become clear that GPVI plays an important role in platelet activation in response to collagen.

Structure

Recent molecular cloning of GP VI cDNA demonstrated that this receptor is a type I transmembrane protein belonging to the immunoglobulin (Ig) superfamily[125]. GPVI contains two Ig-C2 like extracellular domains formed by disulfide bonds and a 51 amino acid cytoplasmic tail.

Function

GP VI has been implicated in platelet–collagen adhesive interactions, together with integrin $\alpha_2\beta_1$[126,127]. GP VI exists in the platelet membrane in a non-covalent association with the FcRγ subunit, and GP VI surface expression is strictly dependent on its association with FcRγ[128]. Moreover, GP VI appears to function as the collagen-binding subunit, whereas FcRγ contains tandem immune receptor tyrosine-based activation motifs (ITAM) and functions as the signalling subunit of the complex. Collagen binding to GP VI-FcRγ induces platelet activation through signalling molecules such as Syk, SLP-76, LAT and phospholipase Cγ2[129,130]. Indeed, Syk becomes tyrosine phosphorylated upon collagen-induced platelet activation and associates with GP VI/FcRγ by binding to the ITAMs of FcRγ. Murine platelets deficient in FcRγ or Syk fail to become activated in response to collagen, although they do respond to other agonists[131].

Deficiency

The involvement of GPVI as a collagen receptor was first suggested in a Japanese patient with autoimmune thrombocytopenia whose platelets were unresponsive to

Cambridge Books Online © Cambridge University Press, 2009

collagen and defective in a 62 kDa platelet membrane protein, which was later identified as GPVI[132]. Three cases of GPVI-deficient patients without thrombocytopenia have been reported, and all of them have shown a mild bleeding tendency with a slightly prolonged bleeding time[122]. However, the molecular basis for GP VI deficiency has not yet been identified. GPVI-deficient platelets do not aggregate in response to collagen or adhere on immobilized collagen, whereas they do aggregate in response to other agonists. Mice injected with an anti-GP VI monoclonal antibody show rapid disappearance of GP VI from the platelet surface, reduced platelet responsiveness to GP VI agonists, and protection from lethal thrombogenic infusions of a mixture of collagen and epinephrine[133].

Conclusions

Numerous platelet membrane glycoproteins function as adhesion and signalling receptors and play a crucial role in hemostatic plug formation and pathological thrombus formation. Gene targeting and other experimental techniques in mice as well as naturally occurring quantitative or qualitative abnormalities of these receptors in humans have provided valuable information as to their functions in vivo. In addition, receptor–ligand interactions are beginning to be characterized at the molecular level. Thus, as exemplified by $\alpha_{IIb}\beta_3$, some platelet adhesion receptors are good targets for the development of new antithrombotic drugs[134,135]. Although not discussed here, other less characterized surface membrane glycoproteins, for example CD9 (a tetraspannin) and CD47 (integrin-associated protein), may also play roles in platelet adhesion and signalling, and their further characterization is warranted.

The crystal structure of the extracellular segment of integrin $\alpha_V\beta_3$ has recently been solved[136].

Dynamics of the platelet cytoskeleton

Kurt L. Barkalow, Hervé Falet and John Hartwig

Brigham & Women's Hospital, Hematology Division, LMRC Building, Rm 301, 221 Longwood Ave., Boston, MA O2115

Introduction

Platelets play a critical role in hemostasis and coagulation. At rest, they circulate in blood as small anucleated discs, measuring 3 × 0.5 µm. Following blood vessel injury and disruption of the endothelial layer, platelets avidly interact with exposed elements of the underlying connective tissue, a reaction that is further stimulated by soluble factor release. They rapidly change from discoid shapes into active forms, first by rounding, then by generating finger-like projections called filopodia and spreading over surfaces using thin sheet-like extensions called lamellipodia. A sturdy cytoskeleton composed of actin and tubulin polymers maintains the shape of the resting and activated platelet. Actin and tubulin are dynamic polymers that can be reversibly assembled. When assembled they can be crosslinked into higher-order structures such as bundles and networks, fragmented into smaller pieces, and slide relative to one another by motor proteins. A large cast of cytoskeletal-associated proteins controls these dynamic processes. Actin filament assembly, temporally and spatially, orchestrates the extension of filopodia and lamellipodia and shape transformation.

The cytoskeleton of the resting platelet

Resting platelets are discs (Fig. 6.1(a)) whose surfaces are smooth and featureless except for small membrane invaginations that mark entrances into the open canalicular system (OCS). Cytoskeletal proteins that maintain the discoid shape represent a large fraction of the platelet proteome. Actin, present at a concentration of 0.55 mM (230 000 actin subunits/platelet[1]), represents 20% of the total cellular protein. Actin subunits (called globular actin or G-actin) reversibly assemble into polymers (filaments of actin or F-actin). In the resting platelet, 40% of the total or ∼90 000 subunits of actin are assembled into 2000–5000 filaments of 0.5 to 1 µm lengths[1,2]. Actin filaments are polarized structures, first recognized by the way they interact with the myosin head domain, which bind periodically along the length of the filament to define pointed and barbed ends[3]. The barbed end of the filament is the preferred end in the assembly reaction, having the higher affinity for actin and grows at a rate ten times faster than the pointed end[4]. The barbed end of the filament is the only end that contributes to actin assembly in cells[5]. The G:F equilibrium of the resting cell is maintained by three mechanisms. First, virtually all (95–97%) of the actin filament barbed ends in the platelet are capped by high affinity binding proteins. Platelet proteins known to constitutively cap actin filament barbed ends are CapZ[6,7] and adducin, a protein that also caps the short actin filaments in the erythrocyte membrane skeleton[8,9]. Capping prohibits actin monomer addition to the barbed ends of filaments. Secondly, actin subunits not incorporated into filaments complex to proteins that prevent their addition to the pointed ends[10]. Proteins that bind actin monomers in this fashion are thymosin-β4[11] and profilin[12,13]. Both profilin and thymosin-β4 have higher affinities for G-actin than does the pointed filament end. Lastly, Arp2/3 complexes or other pointed end binding proteins may also cap many of the pointed ends in the platelet. Despite these many control mechanisms, actin filaments rapidly turnover in cells, particularly in regions of cells engaged in movement. The dynamic status of filaments in the platelet has not been directly investigated, but treatment with cytochalasins perturbs the G: F ratio, suggesting a flux of actin monomer between the two pools. Cofilin may participate in this process by

[1] $(0.55 \times 10^{-3}) \times (7 \times 10^{-15}) \times 6.023 \times 10^{23}$.

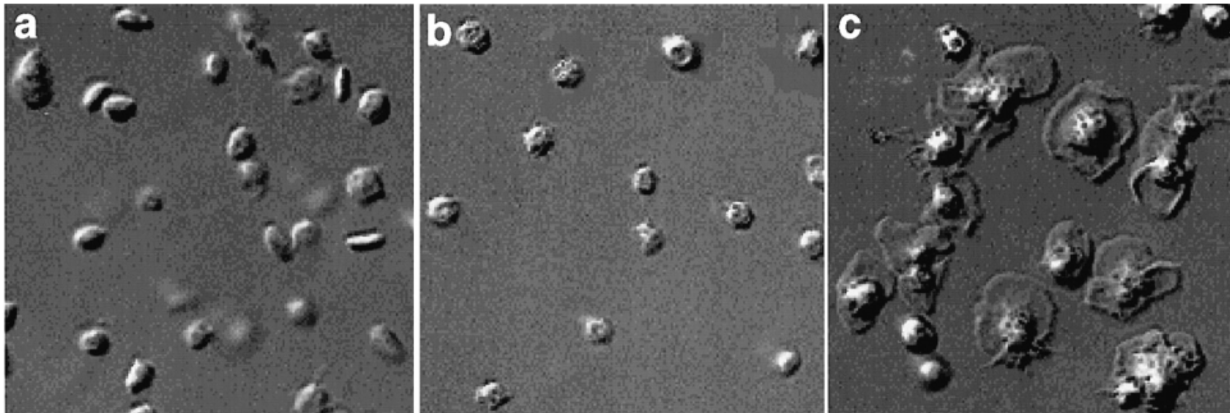

Fig. 6.1. Morphology of resting and activated platelets. Light micrographs, taken using differential interference contrast optics, showing (*a*) platelets at rest, (*b*) 10–15 s after activation of PAR-1 on platelets in suspension, and (*c*) platelets spread on glass for 10 min.

stimulating depolymerization from the pointed ends of filaments[14].

Actin filaments in the resting platelet are organized into a rigid cytoplasmic scaffold by filamin A (ABP-280), which can cross-link filaments at high angles, and by α-actinin, a protein that tends to align filaments in parallel. α-actinin is an abundant actin filament bundling protein that is often associated with adhesion sites in various cell types and has been shown to bind to the cytoplasmic tail of β1 integrins[15], suggesting a role in linking actin filaments to the membrane, in particular, at adhesion sites. Filamin A is a large homodimer whose 280 kD subunits self-associate at their carboxytermini while the amino-terminal domains contain actin binding sites, each capable of binding to a different actin filament. Filamin A also participates in actin–membrane interactions. The carboxyterminal portion of each subunit harbours a binding site for the integral membrane protein GP Ibα[16,17], a component of the von Willebrand factor receptor (vWFR) complex (GP Ib–IX–V)[18,19]. A stable link between the platelet plasma membrane and the cytoplasmic actin filaments is ensured by the complexing of $>$90% of the 25 000 copies of vWFR to filamin A[20]. The critical role of this interaction in maintaining the discoid shape has been established in studies of Bernard–Soulier Syndrome (BSS) platelets that lack the vWFR, and hence the vWFR–filamin–actin linkage. Platelets from BSS patients are abnormally large in size, fragile and circulate poorly, at least in part because their membrane skeleton (below) is weakly adhered to the underlying actin filaments.

A dense lattice of spectrin laminates the cytoplasmic side of the plasma membrane and is attached to the actin filament network of the resting platelet. Actin filament ends, derived from the filament network, selectively interact with the spectrin molecules. Capture of these ends by spectrin, which in theory should bind equally well along the length of the actin filament, may be related to the finding that many of the barbed ends in the resting platelet are capped by adducin. Adducin forms a high affinity ternary complex with spectrin and actin[21,22]. The near equivalent stoichiometry of actin filament ends (2 000–5 000), spectrin tetramers (2 000), and adducin tetramers in the resting cytoskeleton (5 000) allows for the possibility that all actin filaments which interconnect with the spectrin strands, do so via an adducin-capped barbed end. This idea is also consistent with observations that most of the actin filaments attach to the membrane skeleton by their barbed ends[1].

Traversing the pores of the spectrin network are the abundant filamin A linkages that connect vWFR to actin filaments. Actin filaments are linked at multiple points to the plasma membrane by filamin A as well as at their barbed ends by the spectrin-adducin interaction. This configuration imparts significant stability to the plasma membrane and to the discoid form of the platelet. Cleavage of these actin linkage proteins (filamin A and spectrin) by the protease calpain in aggregating platelets or during platelet storage, causes membrane blebbing and microvesicle release[23,24].

Tubulin and its associated proteins also contribute to the maintenance of the discoid shape of the resting platelet. Drugs that destabilize microtubules have been reported to cause the discoid shape in resting human platelets to be lost[25]. Approximately 40% of tubulin in a platelet is assembled into a specialized microtubule coil that lies just below the plasma membrane. This coil appears to form from a single microtubule that circumscribes the platelet periphery 8 to 12 times[26]. Microtubules do play an essential role

Cambridge Books Online © Cambridge University Press, 2009

in formation of platelets from megakaryocytes[27], although the precise details of how the microtubule coil develops to its mature form in the platelet are unknown. The microtubule-associated motors kinesin and cytoplasmic dynein are present in platelets[28]. Dynein localizes to punctate structures associated perhaps with intracellular organelles, but is surprisingly not enriched in the microtubule coil. A protein antigenically related to MAP2 has been shown to associate with the coil in resting bovine platelets[29].

The cytoskeleton of the activated platelet

Platelet shape change following receptor mediated activation proceeds through two recognizable steps (Fig. 6.1). First, the disc converts into an irregular or round shape (Fig. 6.1(*b*)). This transition requires a rise in intracellular calcium and activation of gelsolin to sever actin. Gelsolin severing in the cortex of the platelet destabilizes the highly ordered and constrained structure formed between spectrin/adducin- and filamin A-actin as discussed above[30]. With further surface contact, the platelet extends filopodia and spreads lamellae (Fig. 6.1(*c*)). Actin assembly drives these morphological changes.

Actin assembly occurs when actin monomers, stored in the cytoplasm and in complex with thymosin-β4 or profilin release and add to the barbed ends of actin filaments. Assembly of monomers into filaments is initiated by the exposure of nucleation sites which can be actin filament barbed ends or *de novo* nuclei. As discussed, proteins such as CapZ and adducin maintain >95% of the total actin filament barbed ends capped in resting platelets. Therefore, to trigger the actin assembly reaction either new barbed end nucleation sites must be generated de novo in the resting cell, or pre-existing and capped filaments must be uncapped. In platelets, both of these processes contribute in actin assembly. The changes seen in the actin cytoskeleton between resting and activated platelets are illustrated in the electron micrographs (Fig. 6.2). Detergent extraction of the resting platelet primarily shows the membrane skeleton, composed of spectrin and associated proteins as discussed above. Activation of the platelet results first in the loss of the discoid shape. The most striking cytoskeletal change during this ‘rounding’ is the appearance of short filaments in the cell cortex that derive from the severing of the preexisting cortical actin filaments. Spreading of the platelet requires actin assembly, and large lamellae become filled with branched networks of actin filaments. The template for this orthogonal filament array derives from fragmentation of actin filaments in the cortex of the

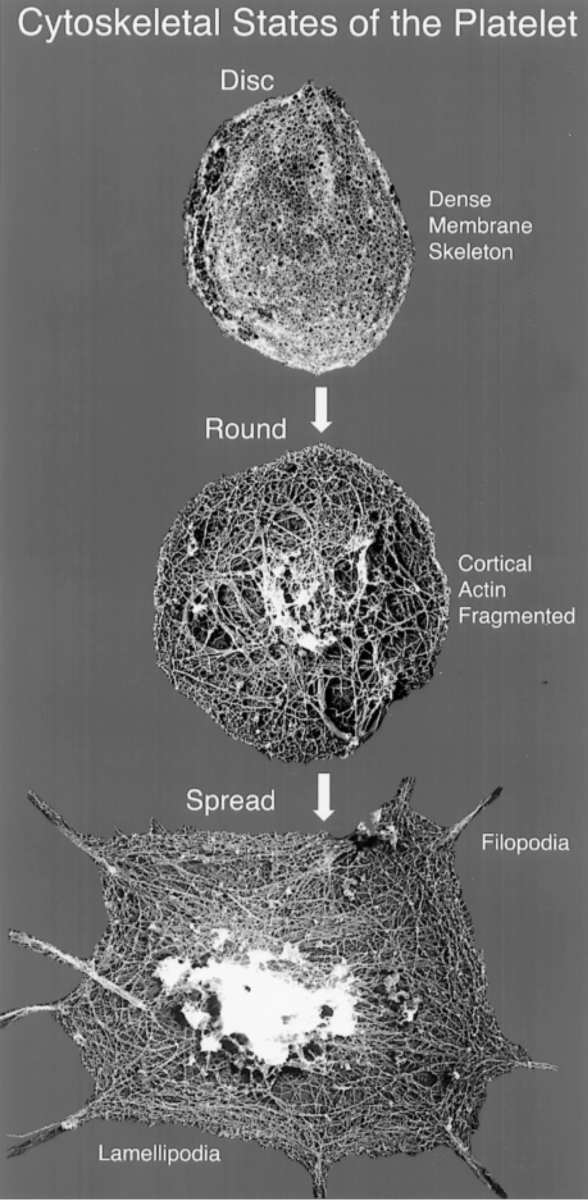

Fig. 6.2. Structure of the resting and active platelet cytoskeleton. Electron micrographs of platelet cytoskeletons at comparable stages to those shown in Fig. 6.1 (rest, round, spread). The cytoskeleton has been revealed by removing membrane with detergents. The fragmented actin filaments composing the rounded platelet cytoskeleton were captured by activating platelets in the presence of cytochalasin B, a reagent that blocks actin assembly.

Platelet shape	Actin	Actin filament ends	Main signals
Discoid	40 % of actin polymerized into filaments	CapZ and adducin cap actin filament barbed ends	$[Ca^{2+}] < 100$ nM ppl's sequestered
Round	40 % of actin polymerized into filaments	Gelsolin severs actin filaments CapZ, adducin and gelsolin are on barbed ends	PLC-mediated hydrolysis of ppl's Cytosolic calcium rises to 0.5-3 μM
Spread	80 % of actin polymerized into filaments	Gelsolin and adducin dissociate from barbed ends Arp2/3 is activated and nucleates actin assembly de novo CapZ associates with barbed ends	ppl's are synthesized: PI_4P up by 80 μM $PI_{4,5}P_2$ up by 60 μM $PI_{3,4}P_2$ up >20 fold $PI_{3,4,5}P_3$ up transiently

Fig. 6.3 (see also colour plate). The role of calcium and ppIs in the regulation of the platelet actin cytoskeleton. Platelet shape change during activation is linked with changes in the actin cytoskeleton, proteins that regulate actin filament ends and the primary signals that effect changes in filament ends. The actin filaments in the discoid resting platelet are in a mustard-yellow colour, while the capping proteins are in pink and purple. Actin monomers that add to the barbed end of filaments in the spread platelet are illustrated as blue subunits.

platelet. Gelsolin-driven severing of actin and uncapping of these filaments occur in the cortex and ultrastructural studies demonstrate that this area supports new actin assembly[31]. Furthermore, filaments, after being severed, remain in the cortex since they are still linked to the plasma membrane by filamin A, and the polyphosphoinositides that mediate uncapping of gelsolin capped filaments reside in the plasma membrane. Figure 6.3 summarizes the changes in morphology, actin content, and critical regulatory proteins and signals that occur in the active platelet forms.

Changes in the microtubule cytoskeleton coincident with platelet activation have been described. The microtubule coil is either compressed into the center of the active platelet or rearranged to a number of individual microtubules that radiate out from the cell center into the cortex, particularly into filopodia. Whether this transition requires depolymerization and/or fragmentation of the coil is not known.

Regulation of actin assembly

There are at least four potential actin filament barbed end capping proteins present in platelets that can serve as targets for signals that lead to actin filament uncapping (Figs. 6.3 and 6.4, see colour plates). Gelsolin is one of the best-studied molecules in terms of its effect on actin in vitro[32,33]. Gelsolin, a major actin filament barbed end capping protein in platelets (5 μM), is also capable of severing actin filaments. Gelsolin is activated to bind to actin in μM calcium. In the resting platelet, the cytoplasmic calcium level is $<$100 nM, and gelsolin is not associated with actin[34]. Following ligation of the thrombin receptor (PAR-1), a rise in cytoplasmic calcium activates gelsolin to bind actin; $>$90% of platelet gelsolin is complexed with actin after 5 s[34]. Association with actin begins with its binding to the side of an actin filament, followed by interdigitation into the filament to sever it. After severing, gelsolin remains on the newly formed actin filament barbed end. Gelsolin-driven severing primarily takes place in the platelet cortex, and severing of these cortical actin filaments causes platelets to lose their discoid shape. Activation of gelsolin and actin–gelsolin complex formation occur before the actin assembly reaction begins. The initial complexing of gelsolin to actin is followed by a dramatic decrease in the amount of gelsolin bound to actin, and by 90 seconds after platelet activation, ~50% of the gelsolin complexed with actin in the first seconds of platelet activation is released. Gelsolin-actin dissociation is mediated by membrane phospholipids (polyphosphoinositides, ppIs[35], and lysophosphatidic acid, LPA[36]), whose synthesis after platelet activation is stimulated by small GTPase activation. The signal transduction cascade leading to new production of ppIs is described below. Mouse platelets from transgenic

Cambridge Books Online © Cambridge University Press, 2009

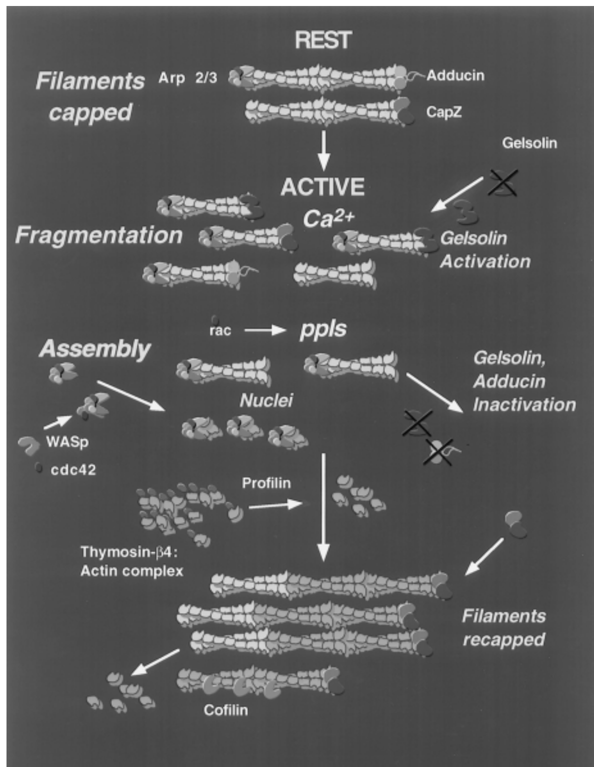

Fig. 6.4 (see also colour plate). Regulation of platelet actin assembly. The role of known platelet proteins in the actin assembly reaction is shown. In the resting platelet, adducin and CapZ cap actin filament barbed ends. Activation leads to calcium release and the activation of gelsolin. Gelsolin fragments the cortical actin filament network and this event is responsible for the loss of the discoid shape of the resting platelet, which now assumes a more rounded morphology. Polyphosphoinositides are robustly generated at the cytoplasmic surface of the platelet plasma membrane and lead to the initiation of actin assembly onto exposed barbed ends of actin filaments. PpIs both inactivate capping proteins (adducin and gelsolin) and maximally activate the Arp2/3 complex through the WASp family of proteins. Profilin and thymosin $\beta 4$, by binding to actin monomers, maintain the large actin pool that drives filament assembly. Actin filaments are subsequently buffered by CapZ, which recaps the filaments, and terminates the assembly reaction. Subsequent actin filament turnover if it occurs in platelets is stimulated by cofilin.

animals that lack gelsolin have a 50–75% reduction in their capacity to generate barbed end nucleation sites and assemble actin following platelet activation. These results demonstrate that gelsolin is directly responsible for much of the actin assembly events (exposure of actin filament barbed ends) during platelet activation.

Another important actin filament barbed end capping protein in platelets is CapZ[6,7]. Platelets have 5 μM CapZ, one third of which is associated with actin in resting platelets. With activation of platelets, more CapZ is deposited onto actin. The kinetics of CapZ association with actin closely follows the kinetics of actin assembly and binding reaches a maximum when actin assembly ceases. CapZ's association with actin, therefore, reaches a maximum after the gelsolin-actin interaction is reversed. This normal synergistic interaction of CapZ with gelsolin-generated ends is defective in gelsolin deficient platelets. Platelets from transgenic mice lacking gelsolin have more polymerized actin and consequently, the amount of CapZ associated with actin is elevated (~50% of the total being associated with the actin cytoskeleton). The amount of CapZ bound to actin following activation, however, does not change, indicating that CapZ incorporation into the actin cytoskeleton depends on the gelsolin-driven actin filament fragmentation reaction. This information shows that CapZ acts primarily as an actin assembly buffer to maintain actin filament barbed ends capped and inaccessible at rest and to terminate assembly in activated platelets by capturing exposed barbed ends. Although these experiments show that CapZ's main function is to buffer actin filament barbed ends, a small amount can be released from actin by signals generated by receptor ligation. In vitro, CapZ is released from actin filament barbed ends by polyphosphoinositides[37] and following treatment of permeabilized platelets with micelles of the polyphosphoinositides $PI_{3,4}P_2$ or $PI_{4,5}P_2$ or following PAR-1 ligation, a small amount of CapZ (~8%) releases from actin filament ends[6]. These data indicate that CapZ can be a target in signal transduction pathways.

Flightless-I, a gelsolin homologue, is also expressed in human platelets and associated with actin filaments comprising the cytoskeletons of resting and activated platelets. Flightless-I has an intriguing structure. In addition to having a domain that is homologous to the full amino acid sequence of gelsolin, it also contains an amino-terminal leucine rich repeat domain that binds other proteins[38]. Flightless-I is present at one-tenth of the concentration of CapZ or gelsolin. Therefore, although the specific details of its function have not been worked out, it may participate in cytoskeletal dynamics.

The last capping protein that has been studied in platelets is adducin. Adducin has been well described in erythrocytes where it caps the barbed end of small actin filaments composing the spectrin membrane skeleton. Platelets contain ~3 μM adducin and 80–85% of it is associated with the resting cytoskeleton. Several signalling molecules modulate adducin–actin interactions including calcium–calmodulin, phosphorylation by protein kinase C (PKC) or Rho-associated protein kinase (ROCK)[39,40], and

Cambridge Books Online © Cambridge University Press, 2009

possibly polyphosphoinositides by regulating the interaction of adducin with actin via the MARCKS domain in adducin[41,42]. Calcium–calmodulin, phosphorylation by PKC, and possibly polyphosphoinositides, are negative regulators of the adducin actin interaction, whereas phosphorylation by ROCK is a positive regulator. Unpublished data (K.L. Barkalow) suggest that α-adducin in platelets is largely associated with the actin cytoskeleton in resting platelets, but becomes soluble with platelet activation, coincident with phosphorylation by PKC. These data are consistent with a role for adducin in actin filament barbed end uncapping in early platelet activation.

De novo actin nucleation by WASp and the Arp2/3 complex

Recent evidence indicates that WASp family proteins integrate signals leading to nucleation of actin by the Arp2/3 complex[43,44]. WASp and Arp2/3 are likely to contribute to the burst of actin assembly that follows platelet activation. WASp is the protein mutated in Wiskott-Aldrich Syndrome (WAS), a rare X-linked recessive disorder characterized by eczema, severe immunodeficiency and thrombocytopenia[45]. The disease affects most hematopoietic lineages, including lymphocytes, monocytes, neutrophils and platelets. Platelets are among the most severely affected cells. Platelets from WAS patients, which lack WASp, are abnormally small, and circulating counts can be 10% of normal or lower. Other WASp family members have been identified. A gene encoding a protein highly homologous to WASp was cloned from bovine brain and was termed neural WASp (N-WASp)[46]. Unlike WASp, which is only expressed in hematopoietic cells, N-WASP is widely expressed. Subsequently, a novel protein related to WASp, WAVE/Scar, was identified, first in *Dictyostelium discoideum*, and then in vertebrates[47,48]. WASp family members interact with numerous signalling molecules known to alter the actin cytoskeleton. WASp contains an N-terminal pleckstrin-homology (PH) domain, which partially overlaps with a WASp-homology (WH) domain, WH1, found in Ena/VASP family proteins that are involved in the maintenance of cytoskeletal integrity[49]. C-terminal to this domain is a GTPase-binding domain (GBD), which binds the small GTPase Cdc42, a number of proline-rich stretches, a second WH domain, WH2, which has homology to the yeast protein verprolin, a cofilin-homology (CH) sequence and an acidic C-terminal region[50]. Overexpression of WASp in cultured cells leads to formation of actin clusters[49], and inducible recruitment of Cdc42 and WASp to a membrane receptor triggers actin polymerization that results in filopodia formation[51].

In the past few years, it became clear that WASp family proteins interact with the Arp2/3 complex to induce nucleation of actin filaments[43,44]. Arp2/3, originally found in *Acanthamoeba castellanii*, consists of two actin-related proteins, Arp2 and Arp3, and five novel proteins[52,53]. Arp2/3 nucleates actin filaments, but its activity requires WASp family proteins. Binding of Cdc42 and membrane ppIs to the WASp homologue N-WASp exposes the N-WASp C-terminus to Arp2/3 and actin monomers to mediate their association, initiate actin polymerization, and form new actin filaments in vitro[54]. It has been shown that Arp2/3 initiates the actin-based motility of intracellular parasites such as *Shigella flexneri* and *Listeria monocytogenes*[55–57]. Arp2/3 localizes to the leading edge of crawling cells such as *Xenopus laevis* keratocytes[58], suggesting that Arp2/3 is responsible for branching of actin filaments and de novo actin filament nucleation at the cell cortex that leads to cell movement.

The roles of WASp and Arp2/3 in platelet shape change and actin assembly are unclear. WASp is phosphorylated on tyrosine during platelet activation induced by collagen and a cross-linked collagen-related peptide specific for GPVI by a mechanism dependent on PI 3-kinase and actin assembly[59,60]. Arp2/3 localizes at the edge of the lamellipodia of platelets spreading on glass and redistributes to the actin cytoskeleton after platelet activation by the thrombin receptor PAR-1 and the collagen receptor GPVI (Falet, unpublished data). However, WASp-deficient platelets do not show any defect in actin assembly and shape change[60,61], and Arp2/3 redistributes normally to the actin cytoskeleton in the absence of WASp. These observations suggest that platelets differ from the other lymphoid cells affected by WASp deficiency and may recruit Arp2/3 to nucleate actin filaments in the absence of WASp by mechanisms that are yet to be discovered. Noteworthy, human platelets express WAVE/Scar, but not N-WASp[62] (Falet, unpublished data).

Signalling leading to platelet shape change

Platelet shape change and actin assembly are mediated by the production of two essential signalling molecules. First, cytosolic calcium concentrations are elevated by the release of intracellular stores, which requires the hydrolysis of plasma membrane polyphosphoinositides (ppIs) by phospholipase C (PLC), and by opening of calcium channels. The second key signal for platelet shape change is the production of ppIs downstream of the small GTPases[63].

Cambridge Books Online © Cambridge University Press, 2009

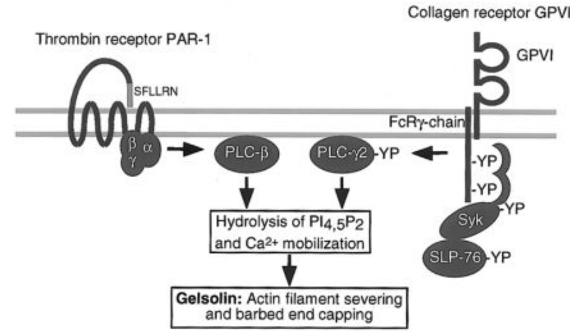
Cytosolic calcium increase

A rise in intracellular calcium results from the activation of PLC. Polyphosphoinositides (ppIs), notably phosphatidylinositol-4,5-bisphosphate (PtdIns-4,5–P_2), are cleaved by PLC into inositol-1,4,5-trisphosphate (Ins-1,4,5–P_3) and diacylglycerol. The platelet calcium increase occurs through both Ins-1,4,5–P_3 mediated release of calcium from the intracellular stores and by the entry of calcium from the external medium. The diacylglycerol produced by this reaction goes on to activate protein kinase C (PKC)[64,65]. Thrombin and collagen, two of the most potent platelet activators, use distinct receptors, and their signalling pathways lead to the activation of PLC-β and PLC-γ2, respectively (Fig. 6.5).

Thrombin is a serine protease that plays a central role in hemostasis and coagulation. Thrombin binds to the vWFR and activates at least two protease-activated receptors (PAR) on human platelets: PAR-1 and PAR-4, which both belong to the seven-transmembrane receptor family that couples trimeric G-proteins. PAR-1 was the first PAR to be cloned, and its signalling pathway is well characterized[66,67]. Cleavage of its N-terminus by thrombin leads to its activation and the cytoplasmic stimulation of PLC-β through G-proteins of the Gq family[65]. Active PLC-β hydrolyzes PtdIns-4,5–P_2 in the plasma membrane as described above. PAR-1 ligation alone is sufficient to initiate platelet activation. Peptides having the exposed N-terminal SFFLRN sequence of cleaved PAR-1 mimic most platelet responses initiated by thrombin. These peptides, called thrombin receptor activating peptides (TRAP), are widely used in the literature as selective PAR-1 activators.

The platelet collagen receptor GPVI belongs to the immunoglobulin superfamily and forms a complex with the Fc receptor γ-chain (FcRγ-chain) that contains an immunoreceptor tyrosine-based activation motif (ITAM) and the two Src-family tyrosine kinases, Fyn and Lyn[68–71]. Platelet stimulation by collagen, or a cross-linked collagen-related peptide (CRP) selective for GPVI, significantly increases the tyrosine phosphorylation of multiple signalling proteins, including FcRγ-chain, the tyrosine kinase Syk, the adaptor proteins SLP-76 and LAT, and PLC-γ2. A model has been proposed where FcRγ-chain ITAM is phosphorylated by Fyn and Lyn after GPVI ligation and binds Syk through Syk tandem Src homology 2 (SH2) domains. SLP-76 is phosphorylated by Syk and recruits PLC-γ2 to the plasma membrane, where Syk phosphorylates and activates it. In support of this model, tyrosine phosphorylation of PLC-γ2 and platelet activation induced by collagen and CRP are abolished in FcRγ-chain-, Syk- and SLP-76-deficient mice[72–75]. It has also been shown that phospho-

1. Ca^{2+} mobilization and actin filament severing



2. Production of ppIs and actin assembly

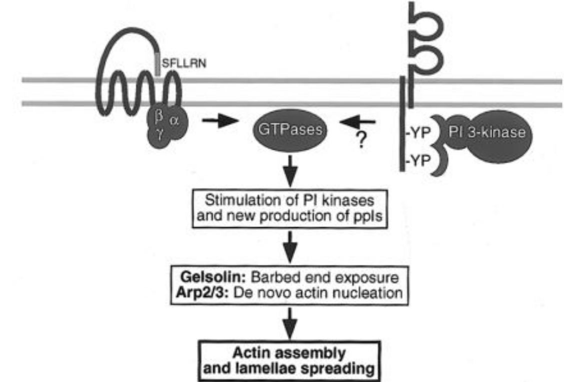


Fig. 6.5. Scheme for signal transduction from the thrombin receptor PAR-1 and the collagen receptor GPVI to platelet actin assembly and shape change. (*a*) Engagement of PAR-1 results in the GTP loading and the dissociation of Gqα from the trimeric G protein complex. Gqα-GTP activates PLC-β, leading to the hydrolysis of membrane ppIs. This mediates Ca^{2+} mobilization, resulting in the activation of gelsolin, which severs the actin filaments and caps their barbed ends. Engagement of GPVI activates the protein tyrosine kinase Syk, which phosphorylates the adaptor protein SLP-76. SLP-76 recruits PLC-γ2 to the plasma membrane, where Syk phosphorylates and activates it. This also results in Ca^{2+} mobilization and activation of gelsolin. (*b*) Subsequently, platelet activation also results in the activation of small Rho GTPases, which bind and activate PI kinases, leading to a new production of membrane ppIs. PpIs inactivate gelsolin and mediate the uncapping of the actin filament barbed ends; they also stimulate WASp family proteins, leading to the *de novo* nucleation of actin filaments by Arp2/3. Both PAR-1 and GPVI induce the actin assembly required for the formation of lamellae. Engagement of GPVI requires PI 3-kinase activation.

Cambridge Books Online © Cambridge University Press, 2009

inositide (PI) 3-kinase is involved in GPVI signalling. PI 3-kinase binds to the phosphorylated FcRγ-chain ITAM after GPVI ligation by collagen or CRP[76], and its inhibition by wortmannin or LY294002 affects the platelet responses downstream of GPVI[73,77,78]. Membrane ppIs phosphorylated in the D3 position of the inositol ring modulate PLC-γ2 activity by binding to its pleckstrin homology and/or SH2 domains[79,80]. Noteworthy, human platelets express another ITAM-containing receptor: the immunoglobulin G Fc receptor FcγRIIA. It is believed that GPVI and FcγRIIA share similar signalling pathways leading to PLC-γ2 activation and calcium mobilization[79,81].

Small GTPases and new production of membrane polyphosphoinositides

The key signal for platelet shape change is the new production of ppIs[63]. As described above, ppIs couple to multiple actin regulatory proteins. They inactivate capping proteins and are critical co-factors in the activation of WASp family proteins, which both lead to actin assembly. Synthesis of ppIs is driven by small GTPase activation of PI kinases.

Small GTPases of the Rho family have been shown to control actin assembly and architecture. The paradigm described first by Hall and collaborators, using microinjected or transfected fibroblasts, is that Cdc42 controls the formation of filopodia, Rac the extension of lamellipodia and Rho the formation of stress fibres and adhesion sites[82]. Rac binds to PI 5-kinase and stimulates its activity[83]. In permeabilized platelets, dominant negative Rac or kinase-dead PI 5-kinase block the signalling from PAR-1 to actin assembly[63]. Furthermore, a rapid and robust activation of Rac follows ligation of the thrombin receptor PAR-1 causing Rac to localize at the edge of the lamellipodia of platelets spreading on glass[84]. Activation of Rac correlates with the new production of ppIs observed after PAR-1 ligation. No redistribution to the actin cytoskeleton has been described in platelets activated in solution in non-aggregating conditions.

Small GTPases exist in two forms: an inactive GDP-bound form and an active GTP-bound form. Activation of Rho family GTPases requires guanine nucleotide exchange factors (GEF). However, the mechanisms of activation of these GTPases downstream of trimeric G-proteins are still unclear. In platelets, PAR-1 ligation leads to the dissociation of G_{12} family of trimeric G-proteins. The $G_{12}\alpha$ subunit, in other cells, has been shown to activate Rho GEFs. Other GEFs, e.g. Vav and Trio, may be important upstream mediators in the signalling to Rac and Cdc42. PI 3-kinase is also involved in the activation of Rac[85–87]. The lipid products of PI 3-kinase interact with Rac and stimulate GDP dissociation from Rac[88]. However, PI 3-kinase is not required for Rac activation, actin assembly or platelet spreading mediated by PAR-1[89]. PI 3-kinase is involved in platelet spreading over fibrinogen-coated surfaces mediated by ADP[90] and in platelet actin assembly initiated by the fibrinogen receptor, the integrin αIIbβ3[89]. PI 3-kinase plays also a critical role upstream of gelsolin for the exposure of actin filament barbed ends and the actin assembly required for the formation of lamellae mediated by the collagen receptor GPVI[73]. Unpublished data suggest that PI 3-kinase is upstream of Rac in human platelets activated by the other platelet ITAM-containing receptor FcγRIIA (Barkalow, unpublished data).

Conclusion

The platelet cytoskeleton has two main functions: (i) maintain the discoid shape of the resting platelet; and (ii) mediate a rapid shape change in response to external stimuli at sites of vascular injury. At rest, actin-binding and cross-linking proteins such as filamin A and spectrin maintain the unique architecture of the actin cytoskeleton and connect it to the plasma membrane. Capping proteins, such as CapZ and adducin, prevent the assembly of actin onto the barbed ends of the actin filaments composing the resting cytoskeleton. β4–thymosin and profilin maintain a large actin monomer pool that can be rapidly mobilized to assemble into filaments for the shape change reaction following platelet activation. Receptor ligation leads to the cytoplasmic signals, Ca^{2+} and membrane ppIs, which stimulate the activities of the regulatory proteins, gelsolin, adducin and the WASp family proteins. The interactions of these molecules generate actin nucleation sites to initiate actin filament growth by stimulating the Arp2/3 complex to form new barbed ends or by dissociating capping proteins to expose barbed ends. These intimate interactions between cytoplasmic signals and the actin cytoskeleton make the rapid shape change of the platelet possible.

Platelet organelles

Francine Rendu and Brigitte Brohard-Bohn

Centre de médecine préventive cardiovasculaire, Hôpital Broussais, Paris, France

Introduction

The blood platelet is unique in that it appears as a very simple cell with a clear cytoplasm, no nucleus, and a variety of organelles. These organelles contain various components which serve in metabolic and secretory processes. In response to a variety of stimuli, platelets liberate granule constituents in the outer medium. Yet, platelets cannot be considered a secretory cell, since they do not synthesize the secreted components. The purpose of this chapter is to describe the different platelet organelles, to analyse the role of each of them and to describe the function of the different granule constituents.

The different organelles, including few mitochondria, are dispersed randomly in the cytoplasm together with skeletal components (microtubules and actin filaments), a large amount of glycogen as a source of energy, and a complex membranous system. The latter consists of two prominent structures: the open canalicular system, which allows connections between the cytosol and the surrounding medium, and the dense tubular system (DTS), which stores important metabolic enzymes. Mitochondria and DTS are involved in metabolic processes, whereas specific granules (dense granules, alpha granules, and lysosomes) are involved in platelet secretion, the so-called 'platelet release reaction'. In other words, mitochondria and DTS work in concert to provide the metabolic energy and control the cytosolic calcium required for secretion of the different granule constituents.

Dense granules (also termed dense bodies, dense core granules, and δ-granules)

These are so-called because they are both heavy and electron dense.

Structure, size, and number

Dense granules are the smallest granules present in the platelet cytoplasm, with an average diameter of 150 nm. Typically, dense granules are characterized by the presence of an intensely opaque dense core surrounded by a clear space and a single membrane. The dense body may completely fill the whole lumen of the granule, or depending on the thin section of the electron microscope grid, it appears round, spherical, elongated or even with a round head and a tail as a tadpole. There is an average of 5–6 dense granules per platelet[1–3].

Properties

Dense granules have three major characteristics: (i) they absorb the electron beam, and hence are intrinsically dense when viewed by electron microscopy of unstained whole mount platelet preparations. Inasmuch, being highly osmophilic, they appear black after osmium staining of thin sections; (ii) they contain small non-protein molecules; (iii) they are able to accumulate various basic compounds, such as reserpine, chlorpromazine, chloroquine and mepacrine[4]. Dense granules also incorporate serotonin through a very high concentration gradient, and the amine concentration within the dense granule can be a thousand times higher than in plasma. The latter property is related to the fact that the internal pH of the dense granule is acidic (pH = 6.1), a pH maintained thanks to a proton-pumping ATPase[5]. Thus, dense granule properties are very similar to those of adrenal chromaffin granules, storing catecholamines.

Content

Compounds stored in dense granule are small molecules (Table 7.1). Dense granules contain high concentrations of

Table 7.1. Platelet dense granule constituents

Membrane	Matrix
GTP binding protein: Ral1	Adenine nucleotides: ATP, ADP
Glycoproteins GPIb[a,b], IIbIIIa[a,b]	Serotonin (5-HT)
Granulophysin (LIMP1/CD63)[c]	Calcium, magnesium
LAMP 2[c]	Pyrophosphate
Src[b]	Guanine nucleotides: GTP, GDP
P-selectin (CD62)[a,b]	Histamine

[b] Also present on plasma membrane.
[c] Also present on lysosomal membrane.

adenine nucleotides (65% of total platelet content) with over 0.6 and 0.4 M of ADP and ATP, respectively. This pool of adenine nucleotides is metabolically inert and can be distinguished from the metabolic pool in that it is not labelled by incubation of platelets with radiolabelled phosphate. They also contain 70% of the total platelet content of bivalent cations, with calcium as the predominant ion in human platelets at around 2.2 M (Table 7.1). This pool of calcium is distinct from the pool which is mobilized for platelet activation, the latter being localized in the dense tubular system. Dense granules are the storage granules for serotonin (5-hydroxytryptamine), at a concentration of 65 mM, and hence were originally called the 5-hydroxytryptamine organelles. Serotonin is the major osmiophil factor of dense granules. Within the dense core, adenine nucleotides and pyrophosphate form tight complexes with calcium and serotonin held together by intermolecular forces[6]. Consequently, the high amount of calcium, not in an ionised form but in a heavy complex, confers to denser granules their high stability. A high level of phosphorus also participates in the high dense granule stability[7].

Membrane

As for classical exocytotic vesicles, the dense granule membrane consists of phospholipids with insertion of proteins[8]. Analysis of phospholipids revealed that dense granules are rich in lysolecithin and ganglioside GM3, a property shared with chromaffin granules[9]. A small GTP-binding protein, Ral, is associated with the dense granule membrane[10], suggesting that the dense granule is equipped of transducing proteins required for the release reaction (Table 7.1). After the secretion process, the granule membrane is integrated in the platelet membrane and yields the expression of dense granule membrane proteins on the activated platelet surface. This is the case for granulophysin[11], and the tyrosine kinase src[12,13]. Noteworthy, a number of receptors which are present on either plasma membrane or other granule membrane, are also present on the dense-granule membrane. Granulophysin is identical to LIMP-1, a lysosomal integral membrane protein (see lysosome membrane section)[11]. The glycoproteins GPIb and GPIIbIIIa[14] and P-selectin[15] are also present on plasma and alpha-granule membranes.

Origin

Dense granules are formed in the megakaryocyte (MK) at an early stage of maturation[16]. In MK, they are empty sacks which are filled in with adenine nucleotides during maturation[17], and with serotonin at an intermediate stage. In mature MK, dense granules are less numerous per unit of surface than in platelets [18].

Means of study

The osmiophilic property of dense granules together with their intrinsic density allows their clear distinction from other granules by electron microscopy, either by whole mount technique[3], or by the uranaffin reaction, specific for phosphonucleotides[19]. Dense granule capacity to incorporate serotonin has been widely used to study their release during platelet activation, after preincubation of platelets with radiolabelled serotonin which is incorporated almost exclusively in the dense granule. The high density and stability of dense granules has allowed their isolation by subcellular fractionations on various types of gradients at high yields and purity[9,20,21], inasmuch as their purification could be followed by direct observation of mepacrine-labelled granules. Mepacrine has also allowed their quantitation by direct observation under a fluorescence microscope[1,2], and is now widely used in flow cytometry to monitor the yellow-green fluorescence of platelet dense granule content[22]. It can also be used to monitor the dense granule release[23] and advantageously replace the radiolabelling of dense granule serotonin.

Functions

Dense granules contain high levels of ADP and calcium, their function during the release reaction is therefore to liberate in the outer medium ‘proaggregating factors’ that will recruit other platelets to aggregate. Serotonin is also a proaggregating agent although this does not hold true in every species. In human, serotonin is a weak platelet agonist, and it most likely acts as a local vasoconstrictor at

Cambridge Books Online © Cambridge University Press, 2009

the site of injury which will in turn contribute to further aggregate platelets.

Defects in dense granules

Isolated dense granule deficiency remains rare, although its incidence may be high in some populations, as is the case for the Hermansky–Pudlak syndrome (see below) frequent in northwestern Puerto Rico. Dense granule deficiency is referred to as δ-storage pool deficiency (SPD) identifying the defective granule (δ for dense granule). Criteria for this disease include reduced dense granule number, reduced platelet content of dense granule constituents (decreased ADP and decreased serotonin), and hence defective dense granule functions[24,25]. The dense granule structure abnormality is very heterogeneous[26,27]. The clinical manifestation is characterized by a moderate bleeding from bruising and epistaxis to bleeding after surgery. The laboratory screening reveals a prolonged bleeding time and a typical platelet aggregation defect, characterized by the absence of a second wave of aggregation or rapid deaggregation in response to ADP, and no aggregation in response to low doses of collagen.

δ-SPD is often associated with pigment abnormalities. Actually, the first δ-SPD was described by Hermansky and Pudlak[28], who reported two cases presenting with hemorrhagic disorder of medium severity with a prolonged bleeding time concomitant with tyrosine-positive oculocutaneous albinism and accumulation of an unusual ceroidlike pigment in macrophages. The Hermansky–Pudlak syndrome (HPS) may be complicated by different diseases, including granulomatous colitis and inflammatory and lung diseases. The latter may be directly related to the platelet dense granule defect: because the defective platelet does not store serotonin properly, the amine is at a higher level in the plasma. In a case of HPS associated with pulmonary hypertension, administration of ketanserine, an antagonist of serotonin, reduced the pulmonary hypertension[29]. The Chediak–Higashi syndrome (CHS)[30] also falls in this category of platelet δ-SPD[31] and is associated with deficient pigmentation, the presence of large granules in leukocytes and immune deficiency. The two syndromes, HPS and CHS have been recently reviewed[32]. There is no specific treatment for δ-SPD. The use of desmopressin (1-deamino-8–D-arginine vasopressin, DDAVP) may be helpful, however, to prevent excess bleeding and to shorten the bleeding time.

The genes for each of the two syndromes HPS and CHS have recently been identified with a number of mutations identified. The HPS gene encodes a 79 kD HPS protein and the most important pathologic frameshift mutations of the gene abolish formation of functional HPS protein, suggesting that truncation of HPS proteins may have consequences at the subcellular level[33]. As with HPS, the CHS gene encodes a CHS protein, and frameshift and nonsense mutations abolish expression of CHS protein[33]. In the two syndromes, however, the above mutations were not found in every patient, and other loci in the genome and/or other factors may determine the clinical phenotype.

Alpha granules

This population of granules is much more heterogeneous than the previous one, both in terms of opacity and structure and of constituents. They represent the major granule population in size and in number[35].

Structure, size and number

Alpha granules are large organelles of 200–400 nm diameter with a single membrane. They are spherical or ovoid granules, with an electron density lower than that of dense granules and not even in the granule lumen[36]. Two major compartments can be identified: the dark nucleoid containing proteoglycans, and an electron-luscent matrix[37]. The latter can be subdivided into the nucleoid adjacent region, an intermediate zone often associated with labelling with plasmatic proteins, and a small peripheral zone characterized by the presence of tubular structures where the massive proteins, von Willebrand Factor (vWF), GPIa/multimerin, and factor V are colocalized[38,39].

Properties

The alpha-granule population has two major characteristics: (i) the complex mechanism of packaging of the protein content by both synthesis and endocytosis; and (ii) the nature and functions of the proteins stored, which are large adhesive and healing proteins. The alpha granules are typical secretory vesicles which carry proteins to the cell surface to be released: some of the released soluble intragranular proteins adhere to the platelet surface and become peripheral proteins of the plasma membrane; some are incorporated in the membrane; and some diffuse into the extracellular fluid. Thus, alpha granules concentrate plasma proteins that play a critical role in hemostasis, wound healing and cell–matrix interactions, and store them until delivery is required at a site of vessel injury.

Content

Two specific platelet proteins, i.e. β-thromboglobulin (βTG) and platelet factor 4 (PF4), are localized in the alpha-granule nucleoid together with proteoglycans (Table 7.2). The latter include a chondroitin sulfate, serglycine, an histidine rich glycoprotein (HRGP), and a family of βTG-antigen (Ag) molecules consisting of the platelet basic protein (PBP), connective tissue activating protein-III (CTAP-III) and neutrophil-activating protein-2 (NAP-2), all precursors of βTG and PF4. Proteoglycans confer to the alpha-granules a relative stability. Besides these proteoglycans, alpha-granules contain many different types of large proteins, such as adhesive proteins, coagulation factors, and cellular mitogens. Among the mitogenic factors, the specific platelet derived growth factor (PDGF) is present together with transforming growth factor β (TGFβ), epidermic growth factor (EGF), endothelial cell growth factor (ECGF), transforming growth factor-β (TGF-β), insulin-like growth factor (IGF), vascular permeability factor (VPF) or vascular endothelial growth factor (VEGF), and interleukin β. Protease inhibitors are also present in the alpha granules, among which are the platelet derived collagenase inhibitor (PDCI)[40], the protease nexin-2/amyloid beta-protein precursor (PN-2/APP), and the plasminogen activator inhibitor 1 (PAI 1) tissue factor plasminogen inhibitor (TFPI). The coagulation factors and some other proteins, such as albumin, are identical or similar to the corresponding plasma proteins. Fibrinogen, thrombospondin and fibronectin are detected only in the intermediate zone of the granule lumen.

Membrane

The major alpha-granule membrane protein was simultaneously discovered in two different groups: the platelet activated derived granule external membrane (PADGEM)[41] or the granule membrane protein 140 (GMP140)[42], is now termed P-selectin, and is the CD62 antigen. Other glycoproteins are found at the inner face of the alpha-granule membrane, including GPIIbIIIa, GPIb–IX, GPIV (CD36), the tetraspanin CD9,[43] GMP-33,[44] and osteonectin[45]. The

Cambridge Books Online © Cambridge University Press, 2009

glucose transporter GLUT-3[46], the platelet endothelial cell adhesion molecule (PECAM) and the vitronectin receptor[47] are also present on the alpha-granule membrane. As for the dense granule, the alpha-granule membrane is equipped with GTP-binding proteins (Rap1, rab4, rab6 and rab8) required for the regulatory mechanism of secretion, although the mechanisms differ for alpha and dense granule populations[48–50].

Origin

Alpha granules are formed during MK maturation. In immature MKs, small immature alpha granules are found which enlarge during MK maturation. The gradual morphological transition occurs through different types of multivesicular bodies[51]. Some of the alpha-granule proteins are synthesized by the MK (βTG, PF4, vWF, factor V), and are expressed early during MK maturation. The proteins synthesized in the MK rough-endoplasmic reticulum are sorted in the *trans*Golgi network, where they are packaged in storage vesicles. The latter pinch off from the network and are visualized in the MK. Other proteins are endocytosed from the circulating plasma pool at both MK and platelet levels, and appear later in MK maturation than synthesized proteins. Endocytosis of proteins that are found at very low concentrations in the alpha-granule, such as immunoglobulins and albumin, proceeds passively by the so-called fluid phase endocytosis. Endocytosis of proteins that are present at a concentration within the alpha granule higher than in plasma, occurs through a receptor-mediated endocytotic process. This is the case for fibrinogen that is endocytosed through the GPIIbIIIa receptor.

Means of study

The two platelet specific proteins βTG and PF4 can be monitored by immunoassays. Hence, they are useful tools to monitor both the amount and the release of alpha granules, using commercially available immunoassays. The expression of P-selectin on the activated platelet membrane is now widely used as a marker of platelet activation and is easily detected by flow cytometry using an anti P-selectin antibody.

Functions

The function of alpha-granules during platelet activation is to release ‘repairing factors’ in the outer medium in the context of wounding. Newly expressed GPIIbIIIa, and its bound ligands, fibrinogen and vWF, contribute to magnify aggregation and above all to the spreading of aggregated platelets on exposed subendothelium. In specific activation conditions, secreted platelet factor V binds to the activated platelet surface possibly on the exposed complex GPIa/multimerin, and hence serves as a receptor for factor Xa, thus favouring coagulation[52]. Thrombospondin and osteonectin, members of the secreted protein, acidic and rich in cystein (SPARC) family, form multimolecular complexes with other adhesive proteins (albumin and PDGF among others) on the extracellular matrix of the platelet surface and mediate interactions with basement membranes involved in tissue remodelling at sites of wound repair[53,54]. The P-selectin exposed on the activated platelet membrane binds its counter receptor, the P-selectin glycoprotein ligand 1 (PSGL1) present on leukocytes and endothelial cells and is thus responsible for platelet–leukocyte and platelet–endothelial cell interactions[55,56]. The βTG-Ag molecules are secreted in unactive forms of precursors of chemokines ready to control the inflammation process[57]. The two platelet proteins, PF4 and βTG, and HRGP have antiheparin activity, and would modulate FGF activity by competing with the latter on cell surface heparan sulfate proteoglycans, making FGF available[58]. Serglycin binds to PF4 and collagen and regulates the inflammatory process, inasmuch as it binds the lymphocyte adhesion molecule CD44[59]. The PN-2/ APP inhibits blood coagulation, a function of special importance in the brain, since the APP processing is altered in platelets of patients with Alzheimer disease[60]. Mitogenic factors have various roles in wound repair once liberated. For example, PDGF stimulates medial smooth muscle cell proliferation, whereas TGFβ inhibits cell proliferation; both PDGF and TGFβ stimulate collagen synthesis.

Defects in alpha granules

The referenced alpha-granule deficiency is the Gray syndrome, so called because the lack of alpha granules confers to the platelet a grey colour after May–Grunwald–Giemsa staining of a platelet smear. It is a rare congenital disorder, first described by Raccuglia[61], and characterized by a bleeding tendency associated with quantitative and qualitative platelet abnormalities. Intensity of the hemorrhagic syndrome is moderate and varies with the thrombopenia. The mean platelet volume is higher than normal, and platelet size is heterogeneous. Platelet functions are decreased in most reported cases[62–64]. The platelet life span is slightly shorter than normal despite a normal number of MK. The granule membrane is normal, hence platelets from patients with Gray syndrome exhibit many vacuoles corresponding to empty alpha granules. Typically, soluble

Cambridge Books Online © Cambridge University Press, 2009

proteins synthesized in the MK are absent, whereas endocytosed proteins are only partially reduced. This is due to a defect of packaging at the MK level where synthesized proteins are not properly targeted to their granule[65]. One characteristic of this syndrome is the frequent observation of myelofibrosis, a consequence of the protein packaging defect: if growth factors and PF4 are normally synthesized but not packaged, they are not properly targeted and are discharged in the extracellular medium through MK demarcation membranes. The disease is thus a model to investigate the protein sorting and packaging in secretory cells.

Another related disease has been described, the factor V Quebec syndrome. This syndrome is characterized by multiple abnormalities concerning alpha-granule proteins, including a quantitative deficiency in mutimerin, and qualitative defects of factor V, thrombospondin, vWF, and fibrinogen[66].

Lysosomes

The third category of granules involved in the release reaction concerns lysosomes or the λ-granules. Lysosomes are lighter than alpha granules and contain a variety of digestive enzymes active at acid pH.

Structure

The size of lysosomes is intermediate between dense granules and alpha granules, measuring 175–250 nm in diameter. They can be identified only by specific cytochemical stains as acid phosphatase or arylsulfatase reactive granules[67]. Without cytochemical stains, their electron density is very similar to that of alpha granules, although this density fills almost the entire granule. No debris has ever been identified inside platelet lysosomes, suggesting they are primary lysosomes.

Properties

The lysosome characteristic is that they contain enzymes which hydrolyse the glucidic moiety of glycoproteins, glycolipids and glycosaminoglycans, i.e. all components of extracellular matrix.

Content

These acidic granules contain almost exclusively acid hydrolases: glycosidases, acid proteases, cationic proteins with bactericidal activity (Table 7.3) which breakdown their substrates to the simplest units, i.e. amino acids, sugars and simple lipids from glycoproteins and glycolipids. The major ones, i.e. which are in sufficient amounts to be used as markers, are β-*N*-acetylglucosaminidase, β-*N*-acetylgalactosaminidase, β-glucuronidase, and β-galactosidase. Others are only present in small amounts.

Table 7.3. Platelet lysosomal constituents

Membrane	Matrix
LIMP1/CD63[a]	*Acid Proteases*
	Cathepsines D, E
LAMP1, LAMP2	Carboxypeptidases (A, B)
	Prolinecarboxypeptidase
	Collagenase
	Acid phosphatase
	Arylsulfatase
	Glycohydrolases
	Heparinase
	β-*N*-acetyl-glucosaminidase,
	β-glucuronidase, β-galactosidase,
	β-glycerophosphatase, α-D-glucosidase,
	β-D-glucosidase, α-L-fucosidase,
	β-D-fucosidase, α-L-arabinosidase,
	α-D-mannosidase,

Note:
[a] Also present on dense granule membrane (see Table 7.1)

Membrane

The lysosome membrane contains typical lysosomal associated membrane proteins (LAMPs), the first described as LIMP/CD63 and two distinct LAMP-1 and LAMP-2[68]. All are heavily glycosylated at the luminal side of the lysosome, probably representing a protective coat against the lysosomal hydrolases. The LIMP/CD63 antigen belongs to the tetraspanin family, which consists of proteins with four transmembrane domains and the two N- and C- extremities in the cytoplasm. Both LIMP/CD 63 and LAMP- 2 are also found on dense granule membrane[11,69].

Origin

Lysosomes are found in the earliest recognizable megakaryocytes. Two lysosomal enzymes can be found in immature MK in small vesicles similar to Golgi-endoplasmic reticulum lysosomes of around 70 nm. These vesicles fuse to form larger ones during MK maturation and increase in number[67].

Cambridge Books Online © Cambridge University Press, 2009

Means of study

All proteases can be monitored spectrophotometrically, with different substrates[70]. The expression of CD63 on the activated platelet surface is now monitored by flow cytometry, and as for alpha-granule P-selectin, used as a marker of platelet activation.

Functions

The typical lysosomal role of desensitisation of internalised receptors, such as described for the thrombin receptor[71], seems limited in this anucleated cell unable to resynthesise new receptors. On the other hand in activated platelets, platelet lysosomes play an important role during the release reaction, since they liberate 'clearing factors' in the outer medium. Secretion of acid hydrolases from lysosomes promotes clearing of platelet aggregates and digestion of material trapped in the platelet aggregate. Thus, lysosomes could facilitate the digestion and resolution of thrombi. Noteworthy, lysosome secretion is (i) slower than dense granule and alpha-granule secretion, and (ii) always incomplete even with high agonist concentrations. Yet, upon activation, platelets release their lysosomal content in vivo[72]. It is not unlikely, therefore, that in some pathological conditions, platelets represent an important source of hydrolytic enzymes which play a role in local degradation of the connective tissue matrix of the vascular wall leading to atherosclerosis and focal thickening of arteries.

Defects in lysosomes

So far, no defects specifically concerning platelet lysosomes have been described. Moreover, considering dense granules as a subpopulation of lysosomes[73], it is most likely that any defect of this category will concern dense granules rather than lysosomes.

Conclusions

From this review, it appears that the best characterized platelet granules are the dense and alpha granules. The typical density and properties of dense granules have allowed their easy distinction from other granules. The complexity of the alpha granule has emphasized their major role in hemostasis. For several years, serotonin has been used as the only marker for the release reaction: platelets were incubated with radiolabelled serotonin which was rapidly and exclusively concentrated in the dense granules, and its liberation outside the activated platelet was easily measured. For a more complete screening of the three granule populations, PF4 and βTG, on the one hand, and acid phosphatases, on the other hand, have more rarely been used to measure content and release of alpha granules and lysosomes, respectively. Nowadays, flow cytometry has been substituted as a measure of secreted compounds in the external milieu and is used to analyse activated membranes which have incorporated granule membrane markers. Flow cytometry does not allow, however, the measure of the intact platelet granules, except for the mepacrine-labelled dense granules. Finally, although dense granules are classified in the category of lysosome-related organelles[73], and the different granule membranes share common molecules, the three types of granules have different roles to play during hemostasis and secrete different amount of constituents depending on the conditions of platelet activation.

Platelet receptors for thrombin

Lawrence F. Brass[1], Marina Molino[2], Peter J. O'Brien[1] and Mark Kahn[1]

[1]Departments of Medicine and Pharmacology, and the Center for Experimental Therapeutics at the University of Pennsylvania, Philadelphia, USA and the [2]Istituto di Ricerche Farmacologiche Mario Negri, Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy

Introduction

Thrombin is one of the most potent agonists that platelets will encounter in vivo, but unlike most of the others it is a protease. For years after thrombin was shown to be a platelet activator as well as an effector in the clotting cascade, the precise mechanism by which it activates platelets remained obscure. Binding studies demonstrated high affinity interactions with several sites on the platelet surface, including glycoprotein (GP) Ibα, but efforts to establish that any of these constituted a receptor in the signalling sense were not entirely successful. Substrates on the platelet surface for proteolytic cleavage by thrombin were also identified, including GP V, but cleavage of these sites did not appear to be required for platelet activation by thrombin. Before discussing the receptors that have been identified, it is worth considering what some of the criteria might be for establishing a protein as a true signalling receptor for thrombin. Such criteria would include (i) demonstrating its presence on the platelet surface, (ii) showing that it was a substrate for thrombin or closely associated with a substrate for thrombin, (iii) demonstrating an association of the candidate receptor with mediators or effectors for intracellular signalling cascades, (iv) showing that expression of the candidate receptor could render a cell that was otherwise unresponsive to thrombin capable of responding, and (v) showing that blocking, dismantling or otherwise removing the candidate receptor would reduce platelet responses to thrombin.

Clues to the identity of receptors that might meet these criteria were obtained in the late 1980s when several laboratories independently demonstrated that thrombin responses in human platelets were at least partially mediated by heterotrimeric G proteins. However, credit for the first identification of thrombin-responsive G protein coupled receptors goes to the Coughlin[1] and Pouyssegur[2] laboratories for their descriptions of protease-activated receptor-1 or PAR1. To date, PAR family members are the only receptors that have been described that meet all of the above criteria for mediating thrombin responses in platelets. However, it is not yet clear (as of late 2000) whether PAR family members are necessarily the only thrombin receptors on platelets or whether other proteins on the platelet surface play a role as well, either by initiating signalling themselves or by facilitating the activation of PARs.

The intention of this chapter is to review current information about the molecular basis for platelet activation by thrombin, with a particular emphasis on PAR family members. The first section will briefly describe the effects of thrombin on platelets. The second will summarize current knowledge about the four known members of the PAR family, particularly those expressed on human and mouse platelets. The third section will address the biology of PAR family members in platelets, while the final section will return to the potential role of other platelet receptors for thrombin. The reader is referred to chapters elsewhere in this volume dealing with related aspects of platelet biology.

Platelet responses to thrombin

Platelets are activated at sites of vascular injury by the combined effects of a number of molecules, including thrombin, collagen, von Willebrand factor, ADP, thromboxane A_2 and epinephrine. The relative contribution of each of these varies during the evolution of the hemostatic plug. Initially, newly exposed collagen fibrils and von Willebrand factor play the primary role, but as the first monolayer of adherent platelets forms, recruitment of non-adherent platelets

by locally generated thrombin, secreted ADP and released TxA_2 takes on increasing importance. Thrombin is generated from prothrombin because of the exposure of tissue factor, the activation of factors VII and IX, and the conversion of factor X to Xa to form the prothrombinase complex. Thrombin is able to activate platelets at concentrations as low as 0.1 nM (approximately 0.01 units per ml). Hallmarks of the platelet response to thrombin include reorganization of the actin cytoskeleton, secretion of the contents of the platelet's storage granules, exposure of fibrinogen receptors on the integrin $\alpha_{IIb}\beta_3$, and platelet aggregation. Underlying these responses is the activation of signalling pathways whose known effectors include phospholipase C, phospholipase A_2, and PI 3-kinase. Phospholipase C hydrolyses membrane phosphatidylinositol-4,5,-bisphosphate (PIP_2) to form 1,4,5–IP_3 and diacylglycerol, which in turn raise the cytosolic free Ca^{2+} concentration and activate protein kinase C isoforms. PLA_2 mobilizes arachidonic acid from platelet membranes, making it available as a substrate for COX-1 and conversion to TxA_2, itself a potent platelet agonist. Although other platelet agonists can also cause phosphoinositide hydrolysis, none appear to be as efficiently coupled to phospholipase C as thrombin. Within seconds of the addition of thrombin, the cytosolic Ca^{2+} concentration increases tenfold to approximately 1 μM, triggering downstream Ca^{2+}-dependent events, including the activation of phospholipase A_2. Thrombin also activates the Ras superfamily members such as Rac, Rho and Rap1B, leading to rearrangement of the actin cytoskeleton and shape change. Finally, thrombin, like ADP and epinephrine, is able to inhibit adenylyl cyclase activity in platelets, relieving the tonic inhibitory state caused by elevated cAMP levels in circulating platelets. Since small changes in 'basal' cAMP levels can have a large effect on the magnitude of platelet responses to agonists, suppression of cAMP formation plays an important role in platelet activation by thrombin.

Most, if not all, of these responses to thrombin are thought to be mediated by G proteins. Mammalian G proteins are commonly denoted according to the identity of their α subunit. G_α binds GTP in the on state and GDP in the off state. Human platelets express members of the G_q, G_{12}, and G_s family of G proteins, and at least four members of the G_i family, G_{i1}, G_{i2}, G_{i3} and G_z. Biochemical and gene deletion studies suggest that G_q is the primary link to phospholipase Cβ activation in platelets[3], with an incompletely defined contribution from G_i family members. As in other cells, G_s and the three G_i family members, respectively, stimulate and inhibit adenylyl cyclase activity in platelets, and, in the case of the G_i family members probably do other things as well. The G_{12} family members in platelets (G_{12} and G_{13}) are believed to regulate the actin cytoskeleton and, therefore, shape change[4,5]. Of these G proteins, there is indirect evidence that thrombin signalling involves G_q, G_i and G_{12} family members, although recent evidence suggests that thrombin's ability to inhibit cAMP formation is largely mediated by secreted ADP[6], despite the fact that PAR1 can couple to G_i family members in reconstitution systems[7].

Biology of the PAR family of receptors

Four PAR family members have been identified to date. Three (PAR1, PAR3 and PAR4) are thrombin receptors. The fourth, PAR2, is activated by serine proteases other than thrombin (Table 8.1). Each of these is composed of a single polypeptide with an extracellular N-terminus, an intracellular C-terminus and seven membrane-spanning domains – a basic structure that is common to nearly all of the known G protein coupled receptors (Fig. 8.1). PAR1 was initially identified using a cloning strategy with RNA derived from thrombin-responsive cells and of the four current family members it is still the one about which there is the most known[1,2]. It is also the one that established the activation paradigm that in general terms applies to the other three family members[1]. In each case, receptor activation occurs when the appropriate protease binds to the extended N-terminus of the receptor, cleaving it and exposing a new N-terminus that serves as a tethered ligand for the receptor. The binding site for the tethered ligand is presumed to be formed by the extracellular loops of the 'body' of the receptor. Because the ligand is not free to diffuse away from the receptor, it is thought to present a high effective local concentration at the receptor and, perhaps, maintain signalling longer than would otherwise occur. As is the case for other G protein coupled receptors, contact between PAR ligands and the receptor is thought to initiate signalling because of an induced conformational change in the receptor that is transmitted across the plane of the plasma membrane to promote exchange of GTP for GDP on associated G proteins. In the case of PAR family members, the activation paradigm that was initially established for PAR1 includes the ability to respond to peptides based upon the sequence of the tethered ligand. The one exception to the rule is PAR3 for which no activating peptide agonist has yet been reported.

In contrast to PAR1, PAR2 was cloned serendipitously and only subsequently found to be activated by trypsin[8–10], tryptase[15–17]. PAR3 was identified as a second thrombin receptor after gene ablation studies showed that platelets from mice lacking PAR1 were still responsive to throm-

[c] Structure/activity relationships have been explored in some detail for short peptides (up to 14 amino acids) that activate PAR1 and PAR2[28,99–106], and more recently for PAR4[21,51,60,107]. To date, no peptide activators of PAR3 have been described[108].

[d] Optimal activation of PAR2 by factor VIIa appears to require co-expression of tissue factor (TF) and the presence of factor X[16]. Under these conditions the concentration of factor VIIa that is required to elicit signalling through PAR2 drops to 8 pM (EC50). This basic phenomenon was observed in several mammalian cell lines, human umbilical vein endothelial cells and injected *Xenopus laevis* oocytes (see references below), although not in baby hamster kidney (BHK) cells[109]. It does not require the cytoplasmic domain of tissue factor[16,110]. Tryptase is able to cleave and activate PAR2, but with a potency less than trypsin. Trypsin[8–14]. Tryptase[11–14]. bin[18]. It is a major regulator of thrombin responses in rodent platelets[19], but little else is known about it. When overexpressed, human PAR3 can respond to thrombin by a mechanism that was initially thought to resemble PAR1. However, there are as yet no well-studied examples of signalling by PAR3 in human tissues and recent evidence suggests that on murine platelets PAR3 serves solely to facilitate cleavage of PAR4 by thrombin[20]. The fourth family member, PAR4, was identified by database searches using conserved domains of the other three family members[21,22]. PAR4 is expressed on human and mouse platelets and presumably accounts for the continued ability of platelets from PAR3 knockout mice to respond to thrombin[21,22].

Thus, the four PAR family members have some features in common, but there are differences among them as well. As noted above, three of the receptors can be activated by thrombin. Two of these, PAR1 and PAR3, have similar dose–response curves when studied in expression systems. The third, PAR4, requires 10–100-fold higher concentrations of thrombin, apparently because it lacks the hirudin-like sequences that can interact with thrombin's anion-binding exosite and facilitate receptor cleavage[20–23]. This distinction is important for understanding the role of PAR4 in human and mouse platelets and will be discussed further later in this chapter.

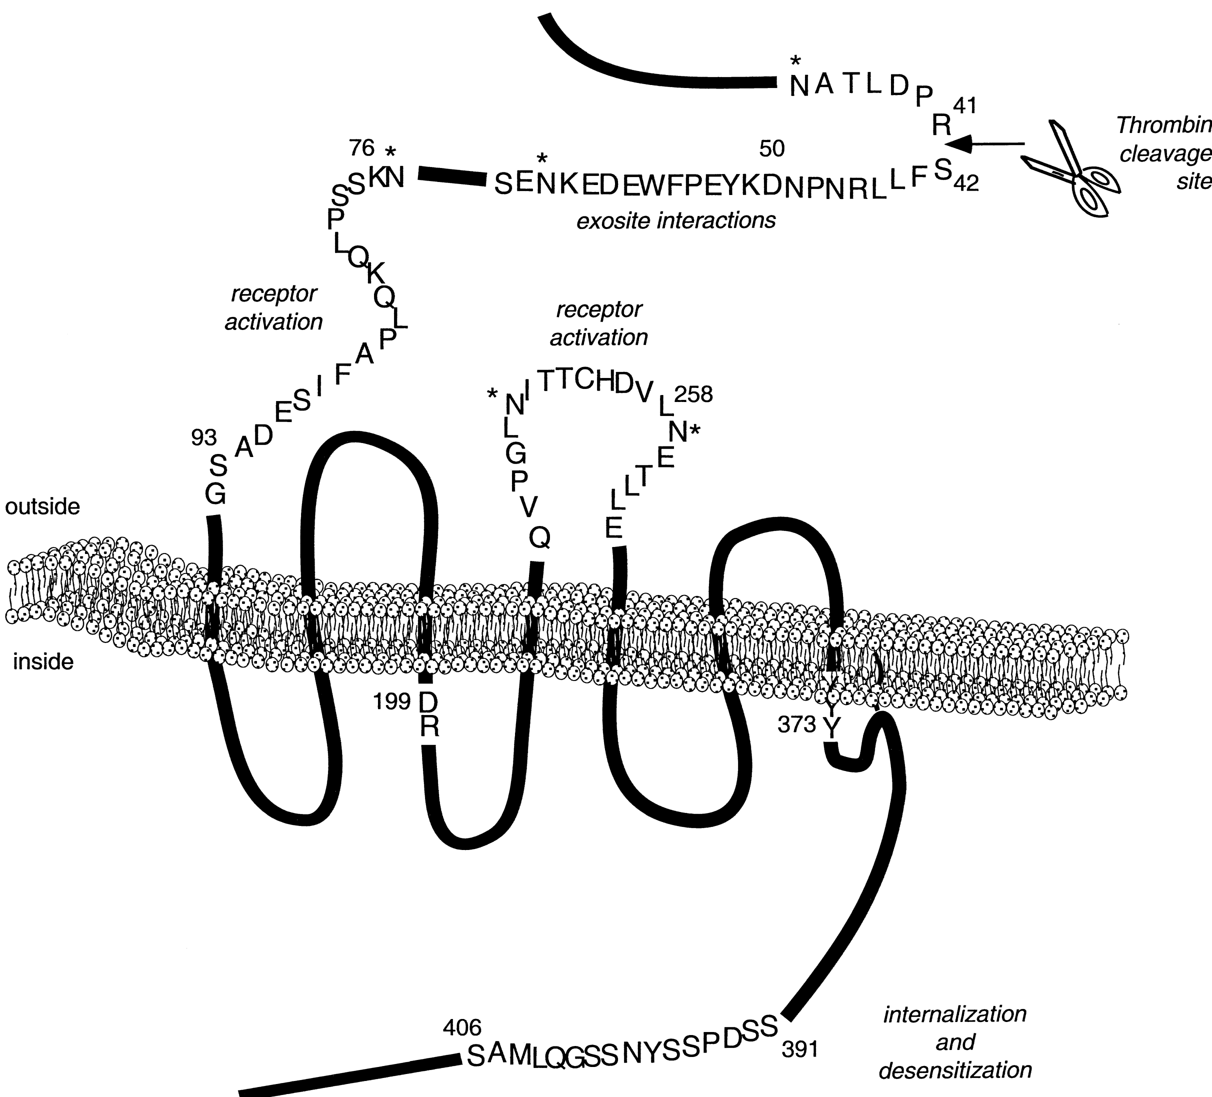

Fig. 8.1. Structure and features of PAR1. Cartoon of human PAR1 highlighting domains thought to be involved in receptor activation and interactions with thrombin. Additional details and references are included in the text. Potential sites for N-linked glycosylation are marked with an asterisk. L258P, D199R/R200D and Y371A/Y372A/Y373A are some of the known induced mutations that will inactivate PAR1. There are (as yet) no known naturally occurring PAR1 mutants that result in receptor inactivation.

Genetics and tissue distribution

The genes encoding all four PAR family members have a similar structure with a single intron interrupting the sequence encoding the receptor N-terminus. Their genetic loci are conserved across species, suggesting a common ancestral origin[24]. In humans PAR1, PAR2, and PAR3 are tightly clustered at chromosome 5q13, while PAR4 is located separately at 19p12[22,24]. In mice PAR1, PAR2 and PAR3 are in a cluster that maps to 13d2. Murine PAR4 is located at 8b3[24]. If genes for additional PAR family members exist, they have yet to be identified. Information about the tissue distribution of the four PAR family members is most complete for PAR1 and PAR2 since antibodies for these receptors are widely available. PAR1 and PAR2 are found in a variety of tissues and cell lines, and have been described in several species and during embryonic development (recently reviewed in[25], see also reference[26]). The patterns of expression of PAR3 and PAR4 are less well characterized, and rely primarily upon analyses of mRNA expression. While the message for PAR3 appears to

Cambridge Books Online © Cambridge University Press, 2009

be widely distributed in human tissues, murine PAR3 mRNA is highly expressed only in megakaryocytes, bone marrow, and spleen[19]. Human PAR4 mRNA is abundant in gastrointestinal tissues including the liver, small intestine, and pancreas, as well as in megakaryocytes, lung, placenta, thyroid, and prostate tissues[21,22]. Whether the receptor is actually expressed in those tissues remains to be demonstrated.

Identification of the ligand binding domain

Characterization of the ligand binding domain for PAR tethered ligand domains is most complete for PAR1 and PAR2. These receptors are approximately 30% identical to each other with near-identity of sequence within the second extracellular loop (ECL2), a region implicated in ligand docking[9,27,28]. The first studies of the PAR1 ligand binding domain used antibodies to inhibit activation of the receptor by thrombin and the peptide agonists, SFLLRN. Two different polyclonal antibodies were used, one raised against the entire receptor N-terminus, the other raised against a 20-residue peptide spanning the thrombin cleavage site[29,30]. The latter antibody prevented PAR1 activation by thrombin, but not by SFLLRN. The former blocked PAR1 activation by both, suggesting that it might target the ligand binding site. Follow-up studies showed that the antiserum raised against the entire N-terminus contains antibodies to the membrane-proximal region (residues 83–94), implicating this domain in ligand binding[30] (Fig. 8.1).

In subsequent studies, the ligand binding domain was mapped using chimeras between human and *Xenopus* PAR1[31,32]. Those studies also highlighted a region of the N-terminus near the first transmembrane domain, as well as the second extracellular loop. Selected point mutations suggested that a residue in the membrane-proximal amino terminal exodomain (Phe 87) and a residue in ECL2 (Glu 260) are sufficient to confer selectivity for the PAR1 agonist peptides. The interaction of ECL2 with the SFLLRN ligand peptide was determined to occur between Glu260 and Arg46 in the tethered ligand domain, and to a lesser extent Phe87 in the membrane-proximal amino terminal exodomain. Nanievicz and coworkers[33] also found that insertion of eight residues of *Xenopus* ECL2 into human PAR1 produces a constitutively active receptor. In a similar approach, Lerner et al.[27] created chimeric gain-of-function receptors to determine which receptor domains specify agonist selectivity. Again, the results suggest that ECL2 confers most of the agonist selectivity. An additional interaction between the amino-terminal exodomain and the third extracellular loop (ECL3) was also demonstrated. Taken together, the chimera studies suggest that the extracellular domains of protease-activated receptors interact to form a ligand binding site that is critical for signalling.

Inactivation and replacement of PAR family members

Once activated by a protease, PAR family members need to be turned off to prevent indefinite signalling. Since cleaved receptors are unable to respond to proteases a second time, cleaved receptors also need to be replaced in order to permit a second round of responses to the protease. How this is accomplished varies among the family members and can be different in different types of cells. Several common mechanisms for terminating signalling through other G protein coupled receptors also apply to PAR family members. These include receptor desensitization, which uncouples receptors from their G proteins; receptor endocytosis, which removes cleaved receptors from the cell surface; and receptor downregulation, which leads to a reduction in total receptor number[34]. In some cases, proteolysis of the tethered ligand domain may also play a role[35].

Indirect evidence for the role of receptor phosphorylation in PAR1 signal termination was first obtained in studies of megakaryoblastic cell lines when it was shown that the recovery of signalling through receptors that had been activated by peptide agonists could be retarded by adding inhibitors of serine/threonine phosphatases[36]. Proof that phosphorylation of PAR1 actually occurs was obtained by Van Obberghen-Schilling and coworkers using an epitope-tagged PAR1 construct expressed in CCL39 cells[37,38]. Ishii et al.[39] later showed that coexpression of PAR1 with the kinase, GRK-3 (βARK-2), in *Xenopus laevis* oocytes selectively inhibits PAR1 signalling. This was later demonstrated in vivo, when transgenic mice overexpressing GRK-3 were shown to have significantly attenuated thrombin signalling[40]. Truncation of the C-terminus of PAR1 at residue 397 or replacement of all of the serine and threonine residues with alanine renders PAR1 insensitive to GRK-3 regulation (see Fig. 8.1 and[39]). These alanine mutants and truncated receptors signal more robustly than their wild type counterparts, as might be predicted if phosphorylation were linked to receptor inactivation[39,41,42]. Finally, GRK family members may not be the only kinases capable of phosphorylating PAR1. Ido et al. have recently identified a 33 kDa kinase capable of phosphorylating the C-terminus of PAR1 fused to GST[43]. As yet, little is known about the role of this kinase in regulating PAR1 signalling in cells that normally express the receptor.

The carboxyl tail of PAR1 also participates in receptor

Cambridge Books Online © Cambridge University Press, 2009

shutoff through its role in agonist-induced receptor internalization and trafficking[44–46] (Fig. 8.1). For many G protein coupled receptors, internalization can contribute to receptor resensitization. PAR family members are an exception to this rule since once cleaved, they cannot be activated a second time by a protease. Information about the internalization and trafficking of PAR1 and, to a lesser extent, PAR2 has been obtained by several groups of investigators[34,44,47–49]. In most types of cells, PAR1 and PAR2 are rapidly internalized after agonist stimulation. In megakaryoblastic cell lines, ~85% of PAR1 is sequestered into coated pits and then endosomes within one minute of activation[47]. In endothelial cells, fibroblasts, and epithelial cells, the internalization of PARs is not as complete, with rapid internalization of at most ~60% of cell surface receptors. Most of the internalized receptors are transferred to lysosomes, but the sorting is not completely efficient and in megakaryoblastic cell lines in particular as much as 40% of the cleaved receptors are recycled back to the cell surface[47]. The physiological relevance of this recycling is unknown. It does not appear to occur on platelets.

PARs and platelets

Given all of this information about protease-activated receptors, how does it all fit together for platelets and can the known members of the PAR family account for everything that is known about platelet responses to thrombin? Are there additional receptors on the platelet surface that contribute either directly or indirectly to the initiation of platelet activation by thrombin? These are the questions that will be considered in the last two sections of this chapter. On the face of it, the answers to these questions seem straightforward. It was shown nearly 10 years ago that human platelets express PAR1 and that the addition of PAR1 agonist peptides such as SFLLRN would mimic thrombin's ability to cause platelet aggregation and secretion[1]. There were hints from studies with PAR1 blocking antibodies and with platelets from some non-primate species that a second thrombin receptor might also be present, but definitive evidence for this came much later with the knockout of PAR1 in mice[18] and the identification of PAR3[19] and PAR4[21,22]. Of the three known thrombin-responsive members of the PAR family, human platelets clearly express PAR1 and PAR4. Agonist peptides for either will activate human platelets[1,21]. PAR3 has been detected on human platelets and endothelial cells[50], but so far there is no evidence that it contributes to thrombin responses in either. Not only is there no known agonist peptide that activates human PAR3, but simultaneous inhibition of PAR1 and PAR4 with blocking antibodies or a small molecule antagonist (in the case of PAR1) completely abolishes human platelet responses to thrombin[51]. This would not, of course, rule out the possibility that PAR3 facilitates activation of human PAR4 as it does in mice. However, human PAR3 appears to signal more readily in response to thrombin than does mouse PAR3, so the failure to detect a signal attributable to PAR3 in platelets and endothelial cells is harder to explain (discussed further in references[52,53]).

Thus, the picture has emerged that thrombin responses in human platelets are largely, if not entirely, mediated by PAR1 and PAR4 (Fig. 8.2). Cleavage of human PAR4 requires a higher concentration of thrombin than does cleavage of PAR1 and it is likely that PAR1 is the predominant signalling receptor at low thrombin concentrations. Recent evidence suggests that PAR4 not only kicks in at higher thrombin concentrations, but also produces a more sustained signal[54,55]. The potential physiological significance of this remains to be established in human platelets, although it may account for the results from a number of studies that suggested that PAR1 agonist peptides do not have quite the same range of effects on platelets as does thrombin (e.g. references[56–59]). It has recently been shown that human PAR4 is incapable of inhibiting cAMP formation by adenylyl cyclase, which suggests that it is not coupled to the G_i family members that are present in human platelets[60]. On the other hand, as already noted, it also appears that human PAR1, which is capable of inhibiting adenylyl cyclase in reconstitution systems, may not do so in intact human platelets. Therefore, the significance of this difference between PAR1 and PAR4 also needs to be examined further. Otherwise, current evidence suggests that PAR1 and PAR4 are both coupled to G_{12} to cause shape change, while G_q and possibly G_i activate phospholipase Cβ. The link from G_i to phospholipase C is suggested by old data which showed that in platelets permeabilized with saponin and in megakaryoblastic cell lines that express PAR1, thrombin-induced phosphoinositide hydrolysis is at least partially sensitive to pertussis toxin[61,62]. Pertussis toxin ADP-ribosylates and uncouples the α subunits of all of the G_i family members in human platelets except for G_z. Since platelets (unlike most cells) are impermeable to pertussis toxin, entry can only be gained by using agents such as saponin which create gaps in the platelet plasma membrane by sequestering cholesterol – and at the same time perturbing the membrane to the point where the outcome of the experiment may be affected.

Mice are different

Mouse platelets also express two PAR family members, but they are PAR3 and PAR4, rather than PAR1 and PAR4. The

Cambridge Books Online © Cambridge University Press, 2009

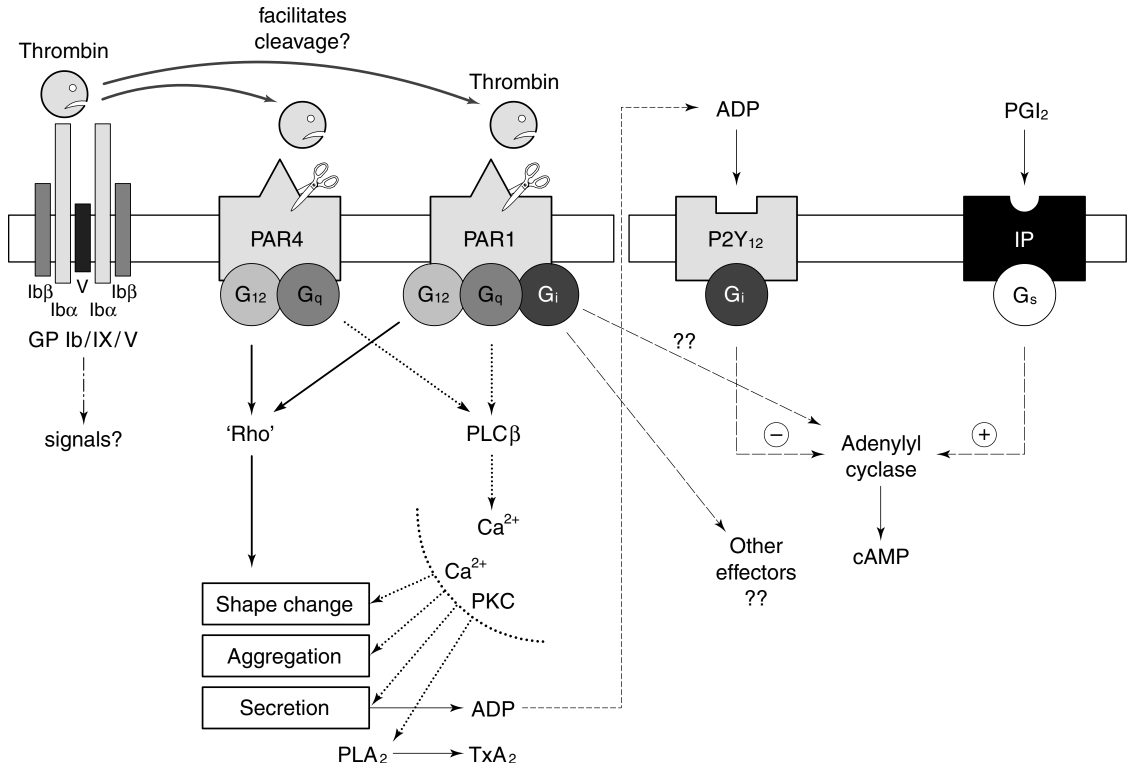

Fig. 8.2. Thrombin signalling in human platelets. Human platelets express PAR1 and PAR4. and, in addition, have a high affinity binding site for thrombin on the GP Ib/IX/V complex. They may also express PAR3, although the functional significance of any PAR3 on human platelets (unlike mouse platelets) is unclear. GP V is a substrate for thrombin. Thrombin can cleave and activate PAR1 and PAR4. The binding site on GP Ibα may facilitate this process. Once receptor activation has occurred, heterotrimeric G proteins serve as mediators to couple the receptors to intracellular effectors, leading to shape change, aggregation and secretion.

PAR1 knockout made it clear that the failure of mouse platelets to respond to PAR1 agonist peptides was due to the absence of PAR1 from mouse platelets. The subsequent identification of PAR3 and PAR4, and the knockout of PAR3 has led to the model that although murine platelets express both of the these receptors, signalling is due solely to PAR4[20] (Fig. 8.3). The role of PAR3 on murine platelets appears to be to facilitate the cleavage of PAR4 at low thrombin concentrations. This is necessary because the N-terminus of PAR4 lacks a domain that can interact with the anion-binding exosite on thrombin. This exosite-interacting is present on PAR1, but not on PAR4 (Fig. 8.1). On the face of it, this seems an awkward arrangement, since it implies that on mouse platelets thrombin binds first to PAR3, cleaves it (without generating a signal), and then cleaves a physically proximate PAR4. Supporting this conclusion is the PAR3 knockout, which shifts the dose/response curve for platelet activation by thrombin to higher concentrations, and the inability of mouse PAR3 to signal efficiently in expression systems[20,21]. If the model is correct, then platelets from mice lacking PAR4, but not lacking PAR3, should be unresponsive to thrombin. Evidence that this is the case has just been reported[113].

Expression levels and the location of thrombin receptors on platelets

In resting human platelets, PAR1, like many other platelet surface proteins, seems to be distributed in two compartments. The first is on the exposed platelet plasma membrane. The second is on the surface connecting membrane system, which evaginates and supplies additional membrane for the platelet surface when platelets are activated and change shape. Based on binding studies with a monoclonal antibody specific for human PAR1, there are approximately 2000 copies of PAR1 on the surface of resting platelets, plus an additional 40% more in the surface connecting system which is externalized when platelets are activated and change shape[63–65]. There is no information on PAR4. Notably, the number of copies of PAR1 detected

Cambridge Books Online © Cambridge University Press, 2009

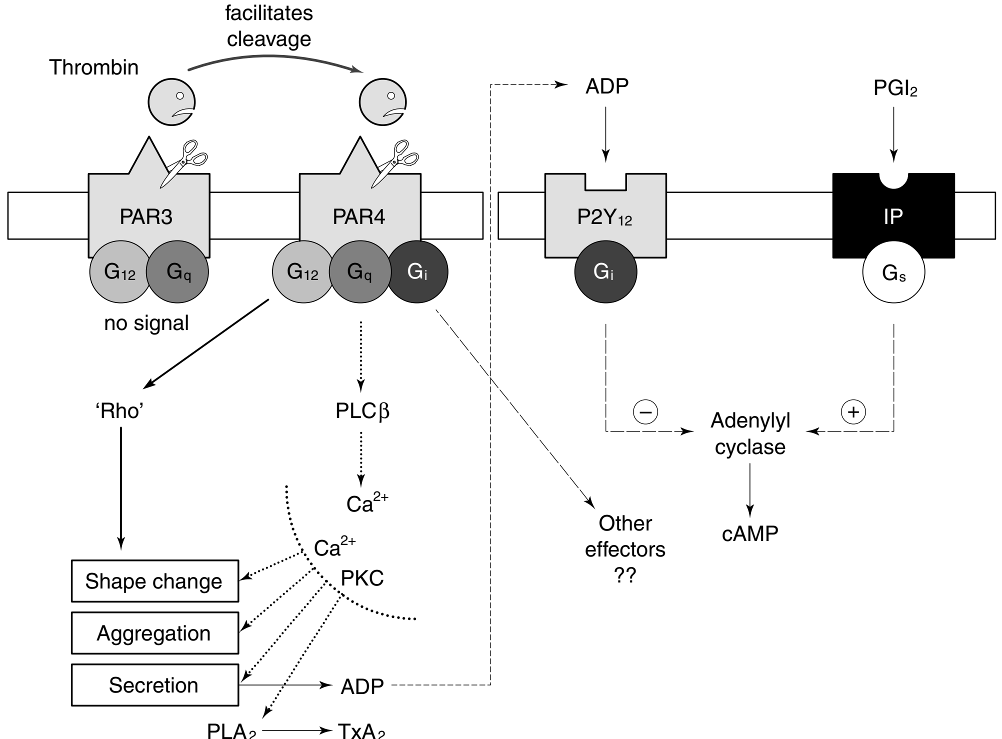

Fig. 8.3. Thrombin signalling in mouse platelets. Mouse platelets express PAR3 and PAR4, but not PAR1. Present evidence suggests that the PAR3 facilitates cleavage of PAR4 at low thrombin concentrations, but does not itself cause signalling.

in the antibody binding studies (a few thousand), fits reasonably well with the number of moderate affinity ^{125}I-thrombin binding sites identified by Harmon and Jamieson[66,67] prior to the cloning of PAR1. It is likely that PAR1 and PAR4 are clustered in membrane microdomains such as rafts, but to our knowledge, this issue has not been directly addressed. There is also no information yet available about the level of expression and distribution of PAR3 and PAR4 on mouse platelets. Indirect evidence from over-expression studies[68] and from studies on endothelial cells[52] suggests that PAR family members can be sufficiently close to each other to allow transactivation of PAR1 or PAR2 by cleaved PAR1. That supports the concept that PAR3 and PAR4 can reside close enough to each other for thrombin bound to murine PAR3 to be able to cleave PAR4 – as does the mounting evidence that other G protein coupled receptors can physically associate with one another. However, this remains to be directly established.

Cleavage and recycling of thrombin receptors on human platelets

Here again, most of the available information is from studies on PAR1. Cleavage of PAR1 can be detected fairly easily as a loss of binding sites for monoclonal antibodies whose epitopes include the cleavage site and therefore, are lost when the receptor is cleaved by thrombin[69]. Cleavage can also be detected with assays for the released N-terminal fragment[70,71]. The results obtained through both approaches suggest that thrombin rapidly cleaves most, if not all, of the copies of PAR1 that are present on resting platelets, as well as those that become exposed as the platelets activate. Rapidly in this case means within seconds following the addition of even moderate thrombin concentrations. The cleaved fragment can be recovered quantitatively in the fluid phase, suggesting that none of it is retained on the platelet surface.

Once cleaved by thrombin, PAR1 on human platelets appears to be subject to three possible fates. Most of it remains on the surface in a cleaved state, but some is internalized and some is shed into membrane microvesicles[65]. This is different from other cells that express PAR1, such as

Cambridge Books Online © Cambridge University Press, 2009

fibroblasts or endothelial cells. As was described earlier in this chapter, activated PAR1 on cells other than platelets is rapidly internalized into an endosomal compartment and then either recycled or (more commonly) delivered to lysosomes where it is degraded. Replacement occurs by the movement of intact receptors to the cell surface, either directly or after temporary storage in an intracellular reserve pool. So far, there is no information about the fate of activated PAR4 in platelets. Since platelets do not normally encounter thrombin more than once, it is not entirely surprising that they lack the necessary cellular machinery to fully remove and replace cleaved thrombin receptors.

Interactions of platelet protease-activated receptors with proteases other than thrombin

An extensive literature exists on the interaction of PAR family members with proteases other than thrombin (reviewed in reference[53]). Much of it concerns PAR1. Summarizing, the results suggest that proteases that uniquely cleave PAR1 at the same site as thrombin will expose the tethered ligand domain and can cause receptor activation. Proteases that cleave elsewhere in the N-terminus potentially remove the tethered ligand domain, rendering the receptor unresponsive to thrombin, although not necessarily unresponsive to an agonist peptide. Trypsin, factor Xa and granzyme A have been shown to be able to cleave and activate PAR1, although not necessarily with the same rapid kinetics as thrombin (see Table 8.1). Their physiological relevance for platelets is not yet clear. Examples of proteases that can disable signalling through PAR1 include plasmin and two neutrophil proteases, cathepsin G and elastase (see Table 8.1). These proteases might be expected to accumulate at sites of vascular thrombosis or inflammation, placing them at sites where they could influence PAR1 cleavage by thrombin. Whether this occurs in vivo still remains to be established. The site of PAR1 cleavage by cathepsin G lies between residues Phe55 and Trp56[72]. Cathepsin G can also inactivate PAR3[73]. The paradoxical ability of cathepsin G to cause human platelet activation is apparently explained by activation of PAR4[74].

Other potential thrombin receptors on platelets

Long before the identification of PAR1, evidence was obtained by the Jamieson laboratory that the extracellular domain of GP Ibα contains a high affinity binding site for thrombin[66,75]. Binding studies with radioiodinated thrombin suggested that this site had a K_D of approximately 0.1 nM and a B_{max} of 50–100 sites per platelet[66,75]. Although the apparent discrepancy between this number of sites and the much larger number of copies of GP Ibα (15 000–25 000 per platelet) has never been fully explained, the suggestion was made that GP Ib might be not only a thrombin binding site, but also a participant in thrombin-initiated platelet activation. This suggestion has persisted despite falling out of fashion for a period. Recent studies have revived the issue. GP Ib is a heterodimer composed of an α and a β subunit that are disulfide linked. It forms a complex with two other proteins, GP IX and GP V in a 2: 2: 1 (Ib: IX: V) ratio that serves a well-established role as a binding site for von Willebrand factor and as an anchor for the platelet cytoskeleton (reviewed in reference[76] and elsewhere in this volume). There is a binding site for thrombin located at approximately residues 268–287 on GP Ibα which is thought to interact with domains other than the active site[77]. Interestingly, when taken as a whole, the molecular weight of the entire GP Ib/IX/V complex (all five proteins) approaches that predicted by target size analysis of the thrombin binding site on platelets[67].

In addition to serving as a thrombin and vWF binding site, recent studies show that GP Ib/IX/V can initiate signalling in platelets and in heterologous systems (e.g. references[78–81]. Platelets from patients with the Bernard–Soulier syndrome lack GP Ib/IX/V and have a reduced response to thrombin – but they also have an aberrant morphology (reviewed in reference[76]). Deletion of the sialic acid rich 'glycocalicin' domain of GP Ibα removes the highest affinity thrombin binding site and blockade of the binding site with antibodies or lectins has been shown to decrease platelet responses to thrombin, particularly at low thrombin concentrations[75,82–84]. Dormann et al.[85] have recently provided evidence that the binding of thrombin to GP Ib is needed for platelets to fully express procoagulant activity and suggested that the lack of binding to GP Ibα may be one reason for the discrepancies between platelet responses to thrombin and SFLLRN, particularly with regard to the development of procoagulant activity (see for example references[56–59]). The existence of PAR4 is obviously another.

What is not clear from the evidence discussed so far is the mechanism by which thrombin binding to GP Ib might affect platelet responses to thrombin. There are at least two theoretical mechanisms. Thrombin, like von Willebrand factor, could initiate signalling through the cytoplasmic domains of GP Ib/IX/V. Alternatively, the binding of thrombin to GP Ibα could facilitate the cleavage of a PAR family member on human platelets, much as the binding of thrombin to PAR3 is thought to facilitate cleavage of PAR4

Cambridge Books Online © Cambridge University Press, 2009

on mouse platelets at low thrombin concentrations (Figs. 8.2 and 8.3). There is not yet enough evidence to firmly establish either of these possibilities. However, a recent study by De Candia et al.[84] shows that blockade of the interaction between thrombin and GP Ib impairs the cleavage of PAR1 on human platelets. The effect was an approximately fivefold reduction in the kcat/Km for PAR1 hydrolysis detected as the loss of the cleavage-sensitive binding site for a PAR1-directed monoclonal antibody. Furthermore, a report by Ramakrishnan et al.[86] suggests that cleavage of GP V by thrombin (a phenomenon first reported many years ago[87]) may release a suppressive effect on thrombin-induced platelet activation. Thus, although it is very clear that PAR1 and PAR4 provide the primary response elements for thrombin on human platelets, it remains possible that interactions with one or more members of the GP Ib/IX/V complex may facilitate cleavage/activation of PAR1 or otherwise regulate platelet activation by thrombin.

Conclusion: things are fitting together, but some pieces may still be missing

At this point it is fair to say that a lot has been learned about the molecular basis for thrombin responses in platelets, but some interesting issues remain to be resolved. There seems to be little question that the PAR family members expressed on human and mouse platelets are the primary receptors for thrombin. The precise contribution of the GP Ib/IX/V complex (discussed in the previous section) still remains to be settled and may not be resolved by studies on mouse platelets because of differences between mouse and human GP Ib. The mechanisms that limit the duration of signalling through thrombin receptors are arguably particularly important in preventing overly robust platelet activation at sites where it is not warranted. The role of receptor phosphorylation and uncoupling in that process still remains to be resolved, particularly since cleaved receptors tend to remain on the platelet surface and not be internalized. It has recently been shown that there are polymorphisms in the human PAR1 gene which may be associated with an increased risk of venous thrombosis[88], but not myocardial infarcts[89]. A polymorphism in the second extracellular loop of PAR2 has been shown to affect PAR2 activation by trypsin[90]. This issue needs further study, as does the reported ability of the released N-terminus of PAR1 to activate platelets[91,92]. In addition, there still remain a number of unsettled issues about signalling from these receptors. Precisely which G proteins are coupled to PAR1 and PAR4, and why does it appear that neither receptor is able to inhibit adenylyl cyclase via G_i in intact platelets? Are there signalling mechanisms involved in platelet responses to thrombin that do not immediately involve phospholipase C, adenylyl cyclase, PI 3-kinase and other known direct effectors of G protein α and $\beta\gamma$ subunits? Finally, are there additional thrombin-binding molecules on the surface of platelets that either signal directly in response to thrombin or modify the responses of known receptors to activation by thrombin? Although much is now known, a complete understanding of platelet activation by thrombin is still some time away.

Platelet receptors: ADP

Christian Gachet and Jean-Pierre Cazenave

Institut National de la Santé et de la Recherche Médicale U.311, Etablissement Français du Sang-Alsace, Strasbourg, France

Introduction

Adenine nucleotides interact with P2 receptors, which are widely distributed in many different cell types including endothelial, smooth muscle, epithelial and blood cells, mastocytes and neurons and regulate a broad range of physiological processes. These receptors are divided into two main groups: the G protein coupled or 'metabotropic' superfamily termed P2Y and the ligand gated ion channel or 'ionotropic' superfamily termed P2X[1]. ADP was identified 40 years ago as a factor derived from red blood cells which influenced platelet adhesiveness[2,3] and induced platelet aggregation[4,5] and it rapidly became recognized as one of the most important mediators of hemostasis and thrombosis[6,7]. Evidence that ADP plays a crucial role in formation of the hemostatic plug and the pathogenesis of arterial thrombosis has accumulated during the last decades: ADP is present at near molar concentrations in platelet dense granules and is released when platelets are stimulated by other agents such as thrombin or collagen, thus reinforcing their aggregation[8,9]; inhibitors of ADP-induced platelet aggregation are effective antithrombotic drugs[10,11]; ADP removing enzymes display antithrombotic properties in animal models[12,13]; patients with defects of ADP receptors or lacking ADP in their platelet granules suffer from a bleeding diathesis[14]. Hence ADP receptors are potential pharmacological targets for antithrombotic drugs. Molecular identification of the platelet P2 receptors over the last 5 years has now made it possible to separately assign the known effects of ADP and ATP to the three cloned P2 receptors found on platelets, namely $P2Y_1$, $P2Y_{12}$ and $P2X_1$.

Effects of ADP on platelets

Signal transduction of a weak platelet agonist

Addition of exogenous ADP to washed human platelets results in shape change, reversible aggregation at physiological concentrations of ionized calcium in the external medium and finally desensitization[15,16]. Two types of aggregation response can be distinguished in vitro: primary aggregation which is reversible and does not involve the release reaction and secondary aggregation which is irreversible and associated with granule release and formation of thromboxane A_2 (TXA_2). The factors responsible for the ADP-induced secretory reaction of human platelets have been studied extensively[17] and it is now current knowledge that low concentrations of Ca^{2+} (μM range) support release from platelets stimulated with ADP in a stirred suspension, thus inducing extensive secondary aggregation[18]. Hence the ADP-induced aggregation observed in citrated platelet-rich plasma or in artificial media containing no Ca^{2+} is artefactual and does not correspond to the physiological response of platelets to ADP. The reason for the occurrence of this aggregation is presently unknown, although it might be related to the ADP receptor density (see p. 134). Transduction of the ADP signal involves a transient rise in free cytoplasmic calcium, due to mobilization of internal stores and secondary store-mediated influx and a concomitant inhibition of adenylyl cyclase[19,20]. ADP also induces an extremely rapid influx of calcium from the extracellular medium, which has been attributed to ligand gated calcium channels[21]. The demonstration that platelets from knockout mice lacking the Gαq subunit of the Gq protein do not aggregate in response to ADP[22] indicated that the phospholipase Cβ (PLCβ) pathway is necessary to raise intracellular calcium following ADP stimulation and that this is essential to platelet

aggregation. Along with the identification of the $P2Y_1$ receptor coupled to Gq, this finding closed a long debate on whether the ADP-related rise in intracellular calcium was due to inositol (1,4,5) trisphosphate (IP_3) formation or not[23]. On the other hand, the inhibition of adenylyl cyclase is a key feature of ADP-induced platelet activation but displays no direct causal relationship to aggregation[20]. Moreover, this effect of ADP is observable only when adenylyl cyclase has been prestimulated by prostaglandins or other activators. The demonstration that ADP stimulates a G protein identified as Gi_2 in human platelet membranes[24,25], provided the first evidence that at least one of the putative ADP receptors might belong to the G protein-coupled superfamily. Thus, ADP triggers at least two main biochemical pathways in platelets, a Gq/PLC mediated rise in intracellular calcium and a Gi_2 mediated inhibition of adenylyl cyclase, which suggests the involvement of two distinct G protein-coupled receptors.

ADP is a necessary cofactor for platelet activation

Although itself a weak aggregating agent, ADP is a necessary cofactor for normal activation of platelets by other agonists such as thrombin or collagen, which induce its secretion from the dense granules. In addition, low concentrations of ADP potentiate or amplify the effects of all and even weak agonists like serotonin[15], adrenaline[26] or chemokines[27,28]. A selective role of ADP as an important cofactor of phosphoinositide 3-kinase (PI 3–K) activation has been proposed on the basis of results in platelets stimulated by PAR-1 thrombin receptor activating peptides[29] and might explain the well-known stabilization by ADP of platelet aggregates induced by thrombin[30–32]. Similarly, ADP has been implicated as an important cofactor of platelet activation through cross-linking of the FcγRIIa receptor or by sera from patients with heparin-induced thrombocytopenia[33] where PI 3–K activation is pivotal. It has been shown that the Gi-coupled pathway of ADP is critically involved in synergism, with agonists triggering tyrosine kinase activities which lead to PLCγ2 activation[34]. The same phenomenon is observed when platelets are activated through the collagen receptor GPVI (Nieswandt et al., unpublished data). Thus, concomitant signalling through Gi and either Gq or tyrosine kinases, depending on the primary agonist, could be envisaged as a general mechanism by which ADP contributes to efficient platelet activation and aggregation[35].

Molecular identity of the platelet ADP receptors

The $P2Y_1$ receptor is an ADP receptor

A platelet ADP receptor was first defined on the basis of pharmacological data as the receptor responsible for ADP-induced aggregation, intracellular calcium increases and adenylyl cyclase inhibition at which ATP was believed to be a competitive antagonist. This receptor was termed $P2_T$, where T denotes thrombocytes, and was presumed to be lineage specific[36]. Initial attempts to clone such a receptor from megakaryoblastic cell line libraries were unsuccessful. However, several P2 purinoceptors were cloned in HEL cells, in particular the $P2Y_1$ receptor which was the first P2 purinoceptor to be cloned, originally from a chick brain cDNA library[37–39]. The human $P2Y_1$ receptor contains 373 amino acid residues, has the classical structure of a G-protein coupled receptor and is widely distributed in many tissues including heart, blood vessels, smooth muscle cells, connective and neural tissues, testis, prostate and ovary[1]. $P2Y_1$ mRNA was detected in megakaryoblastic cell lines (HEL, MEG-01, Dami, CHRF-288 and K562) and human platelets[40]. A milestone was passed when, after its stable expression in Jurkat cells, the human $P2Y_1$ receptor proved to be an ADP receptor at which triphosphate nucleotides were competitive antagonists. Partial agonistic responses to triphosphate nucleotides were, in fact, due to degradation of the commercial reagents into diphosphate nucleotides[40]. These studies were extended to platelets and brain capillary endothelial cells expressing the $P2Y_1$ receptor and it was shown that the agonistic effects of purified triphosphate nucleotides were due to enzymatic transformation into the diphosphate analogues by ectonucleotidases present at the surface of the cells[41]. Such results supported the hypothesis that the $P2Y_1$ receptor could be the elusive $P2_T$ receptor.

Evidence for another platelet ADP receptor

The fact that the selective $P2Y_1$ antagonists, adenosine-2′,5′-diphosphate (A2P5P), adenosine-3′,5′-diphosphate (A3P5P) and adenosine-3′,5′-phosphosulphonate (A3P5PS) inhibited ADP-induced platelet aggregation also supported a key role of the $P2Y_1$ receptor. But the fact that these antagonists had no effect on ADP-induced adenylyl cyclase inhibition led to the firm conviction that another receptor must mediate this effect of ADP on platelets. Several groups published simultaneously studies using these antagonists, all showing that the $P2Y_1$ receptor is indeed necessary although not sufficient to induce full platelet aggregation in response to ADP[42–44]. Conversely, work with inhibitors like the thieno-

Cambridge Books Online © Cambridge University Press, 2009

pyridines ticlopidine and clopidogrel or the ATP analogue 2-propylthio-β,γ-difluoromethyleneATP (AR-C66096MX) further confirmed the existence of a separate receptor responsible for the inhibition of cAMP production by ADP[44–49]. Additional evidence came from the demonstration that the $P2Y_1$ receptor was normal, at the genetic and pharmacological levels, in a patient with congenital impairment of platelet responses to ADP[50]. Finally, definite proof of the existence of a second ADP receptor distinct from $P2Y_1$ and coupled to adenylyl cyclase inhibition was provided by the generation of $P2Y_1$ receptor knockout mice, in which platelet shape change and aggregation to usual concentrations of ADP were completely abolished, whereas the ability of ADP to inhibit cAMP formation was maintained[51,52]. It is worthy of note that a first hypothesis of two distinct ADP receptors mediating platelet shape change and aggregation, on the one hand, and inhibition of adenylyl cyclase, on the other, had already been proposed by MacFarlane in 1983 on the basis of pharmacological studies[53].

Identification of the $P2Y_{12}$ receptor

This second platelet ADP receptor, suggested to be of the P2Y type since ADP is known to activate the heterotrimeric G protein Gi_2 in human platelet membranes[24], was expected to exhibit a pharmacological profile identical to that of $P2Y_1$ but with subtle differences in the selectivity of certain ligands[23]. Depending on the authors, this elusive receptor was termed P2cyc[46,51], $P2T_{AC}$[45] or $P2Y_{ADP}$[48]. It was finally cloned from human and rat platelet cDNA libraries using an expression cloning strategy in *Xenopus* oocytes designed to detect Gi-linked receptors through their coupling to cotransfected inward-rectifying K^+ channels[54]. Sequence analysis led to the identification of a new P2Y receptor designated $P2Y_{12}$. This receptor displayed the expected pharmacological characteristics of the Gi-coupled platelet ADP receptor. In particular, Chinese Hamster Ovary (CHO) cells expressing the human $P2Y_{12}$ receptor displayed ADP-mediated inhibition of cAMP formation and this effect was reversed by selective antagonists such as 2MeSAMP or C1330–7[54] and blocked by pertussis toxin, while $P2Y_1$ antagonists were ineffective. An interesting point is that this receptor contains four extracellular cysteines and the thiol reagent *p*-chloromercuriphenylsulfonic acid (*p*CMBS), known to block the ADP-induced inhibition of cAMP production in platelets[53], has been shown to inhibit ADP-induced $P2Y_{12}$ activation in *Xenopus* oocytes[54]. This effect of thiol reagents was one of the key arguments in favour of two separate ADP receptors on platelets and it is satisfying to obtain a molecular explanation. It has also been suggested that clopidogrel acts on the $P2Y_{12}$ receptor through a thiol metabolite, which could covalently modify its cysteine residues[55]. Finally, $P2Y_{12}$ appears to be mutated in a patient known to have a congenital defect of platelet aggregation to ADP related to the Gi-linked pathway (see below). The tissue distribution of this novel G protein-coupled receptor seems to be restricted to platelets and subregions of the brain including the amygdala, caudate nucleus, corpus callosum, hippocampus, substantia nigra and thalamus[54]. The $P2Y_1$ and the $P2Y_{12}$ genes are both located on chromosome 3q24–25, together with the gene coding for the UDP-glucose receptor. In terms of homology, $P2Y_{12}$ is more closely related to the latter receptor (44% identical) than to $P2Y_1$ (19% identical). The relatively poor homology with other P2 receptors probably explains why homology cloning failed to identify the Gi-coupled ADP receptor (Fig. 9.1). The same sequence has been reported for an orphan receptor SP1999, of which ADP was found to be the cognate ligand[56], having an identical tissue distribution.

Early and later concordant binding studies numbered about 400 to 1200 binding sites per platelet for 2MeSADP[53,57–60] of which approximately one-third corresponds to the $P2Y_1$ receptor and two-thirds correspond to the $P2Y_{12}$ receptor as deduced from measurements in the presence of $P2Y_{12}$ antagonists or inhibitors[44,46] and further confirmed using [^{33}P]MRS 2179 as a selective $P2Y_1$ radioligand[61].

The $P2X_1$ receptor

In addition to the G protein-coupled $P2Y_1$ and $P2Y_{12}$ receptors, platelets also express the $P2X_1$ receptor, which has been shown to be responsible for the fast calcium entry induced by ADP[62]. P2X receptors are ATP-gated ion channels which mediate rapid (within 10 ms) and selective permeability to cations. The human $P2X_1$ receptor is composed of 399 amino acids with two transmembrane domains, intracellular amino and carboxyl termini and a large extracellular loop with ten conserved cysteine residues[1]. Homomeric or heteromeric association of at least three P2X subunits is required for the formation of a pore. These receptors are broadly expressed mainly on excitable cells like smooth muscle cells, neurons and glial cells. PCR amplification demonstrated the presence of $P2X_1$ transcripts in platelets and megakaryoblastic cell lines, while the selective $P2X_1$ agonist $\alpha\beta$MeATP was found to trigger a calcium influx into fura-2 loaded human platelets[63]. Other immunological and biochemical studies have since confirmed the existence of a functional $P2X_1$ purinoceptor on blood platelets[64–66].

Pharmacology of the platelet ADP receptors

Agonists

The order of potency for agonists is 2MeSADP ≫ ADP = ADPαS > ADPβS at the $P2Y_1$ receptor and 2MeSADP ≫ ADP = ADPβS at the $P2Y_{12}$ receptor, at which ADPαS is an antagonist. Structure–activity studies have been extensively reviewed[16,23]. ATP has been found to have low intrinsic activity at the $P2Y_1$ receptor[67] and its action might in this case depend on the level of receptor expression. At low levels of expression, ATP would act as an antagonist and this is the case for platelets, while at higher receptor densities (transfected cells, selective tissues) it might behave as a partial agonist. The physiological significance of this behaviour is at present unclear. Concerning $P2X_1$, ATP is the 'standard' agonist and αβMeATP is a selective agonist[1]. It is not completely clear whether ADP is a true agonist of $P2X_1$ or whether the reported effects of ADP are due to contamination of the commercial sources with ATP[68]. An emerging idea is that the $P2X_1$ receptor could be activated by some diadenosine polyphosphates (Ap_nAs), and adenosine polyphospho guanosines (Ap_nGs) which are released from the dense granules of stimulated platelets[69]. These molecules have been shown to be vasoconstrictors or vasodilators depending on the local environment, and a direct effect on platelets is not excluded.

Antagonists

Selective antagonists which allow discrimination between the $P2Y_1$ and $P2Y_{12}$ receptors now exist (Table 9.1 and Fig. 9.2). A3P5PS, A2P5P and A3P5P inhibit platelet aggregation to ADP by competitively antagonizing the intracellular calcium rise induced by this agonist. These adenosine analogues are selective $P2Y_1$ receptor antagonists[70] and have no effect on adenylyl cyclase inhibition[42–44]. More efficient $P2Y_1$ antagonists such as *N*⁶-methyl-2′-deoxyadenosine-3′,5′-bisphosphate (MRS 2179) have been synthesized and shown to be antiplatelet agents[61,71,72]. However, MRS 2179 has been reported to be an antagonist of the $P2X_1$ receptor in vitro[73]. New compounds like (N)-methanocarba-*N*⁶-methyl-2-chloro-2′-deoxyadenosine-3′,5′-bisphosphate (MRS 2279) seem to be more selective and are strong antagonists of ADP-induced platelet aggregation[74,75]. Competitive antagonists of $P2Y_{12}$ also exist. Apart from 2MeSAMP and ADPαS, these are ATP analogues of the AR-C series like 2-propylthio-β,γ-difluoromethylene ATP (AR-C66096MX), 2-propylthio-β,γ-dichloromethylene ATP (AR-C67085MX) and *N*⁶-(2-methylthioethyl)-2-(3,3,3-trifluoropropylthio)-β,γ-dichloromethylene ATP (AR-C69931MX)[11]. They strongly inhibit ADP-induced platelet activation in vitro without interfering with shape change or calcium mobilisation. Other compounds such as C1330–7 have been reported to directly antagonize $P2Y_{12}$ but their structures have not yet been revealed[54].

Ticlopidine and clopidogrel

The thienopyridine compounds ticlopidine and clopidogrel were the first $P2Y_{12}$ inhibitors to be used clinically as antithrombotic drugs[10]. In contrast to the AR-C analogues, they are inactive in vitro and have to be metabolized in the liver to acquire their antiaggregatory properties. These compounds selectively and irreversibly antagonize ADP-induced inhibition of PGE_1-activated adenylyl cyclase[76,77], binding of GTPγS to platelet membrane[78], tyrosine phosphorylation of several proteins[79] and dephosphorylation of the vasodilator-stimulated phosphoprotein VASP[80]. Conversely, they do not modify other effects of ADP on platelets like shape change, calcium movements or phosphorylation of the proteins involved in these processes. Ticlopidine and clopidogrel induce a dose-dependent reduction in the number of 2MeSADP binding sites on platelets[57–59,81]. However, under conditions where the 2MeSADP binding sites are maximally reduced (by up to 70% reduction) and ADP-induced inhibition of adenylyl cyclase is completely blocked by thienopyridine treatment, ADP can still promote platelet shape change, rise in intra-

cellular calcium and transient residual aggregation through activation of the $P2Y_1$ receptor, which is insensitive to thienopyridines[46,57,59]. Hence these drugs are selective $P2Y_{12}$ inhibitors. It is worthy of note that, at the maximum ex vivo effect of clopidogrel, attainable only in animals, none of the AR-C compounds have any additional effect on ADP-induced platelet aggregation, thus demonstrating that the two unrelated molecules act at the same receptor and that clopidogrel is able to fully inhibit all the receptors (Léon et al., unpublished data). The short-lived active metabolite of clopidogrel has been isolated and found to be a thiol derivative of the parent molecule. As mentioned above, it is believed to bind covalently to the $P2Y_{12}$ receptor[55]. A new antiplatelet agent (CS747) apparently identical to clopidogrel was reported recently[82] and is a thienopyridine which is totally inactive in vitro and has to be metabolized to be effective in vivo or ex vivo. One of its metabolites (R-99224) has been shown to display in vitro activity[82,83].

Congenital defects of platelet ADP receptors

Initially, two unrelated patients were described whose platelets, when exposed to ADP, changed shape normally but underwent no or only very slight, rapidly reversible aggregation and did not exhibit the normal inhibition of PGE_1-stimulated adenylyl cyclase[84,85]. Binding studies revealed a strong reduction in the number of binding sites as compared to control platelets[59,85]. There was also an abnormal pattern of protein phosphorylation upon activation by ADP or low concentrations of other agonists[86]. Thus, the clinical profile and platelet functions of these patients were the same as when thienopyridines are administered to humans or animals, suggesting them to have a $P2Y_{12}$ deficiency. This was confirmed in one patient who displays a heterozygous defect of the $P2Y_{12}$ receptor gene consisting of a dinucleotide deletion near the amino-terminal end of TM5, at amino acid 240, resulting in a 28-residue frame shift and a premature stop codon. Although they have one wild type and one mutant allele at least in the coding region, for reasons still not fully understood[54] the patient's platelets only produce RNA for the mutant receptor. Whether all the patients so far described share the same mutation will require further studies. The $P2Y_{12}$ receptor defect is inherited as an autosomal recessive trait and all the patients so far described were born from consanguineous parents. Finally, patients with secretion deficiencies but normal granule stores and TXA_2 production have been shown to have fewer ADP receptors than healthy individuals, and some of these patients are heterozygotes for the defect in $P2Y_{12}$[60,87].

A $P2Y_1$ receptor-deficient patient has been reported in abstract form[88] but has not yet been confirmed. Finally, a dominant negative mutation in the $P2X_1$ receptor consisting of a deletion of one leucine residue within a stretch of four in the second transmembrane domain (AA 351–354) has been reported in a patient with a severe bleeding disorder[89]. However, further studies will be needed to confirm these data and assess the supposedly important role of $P2X_1$ in hemostasis.

Respective roles of the $P2Y_1$, $P2Y_{12}$ and $P2X_1$ receptors in platelet functions (Fig. 9.3)

Coactivation of both $P2Y_1$ and $P2Y_{12}$ is necessary for normal ADP-induced platelet aggregation, since inhibition of either receptor is sufficient to block it. Inhibition of the $P2Y_1$ responses by selective antagonists or by gene targeting, which results in the abolition of intracellular calcium mobilization, can be bypassed by stimulating the Gq pathway with serotonin, which alone is not able to promote aggregation[43,44,51,52,90]. Similarly, inhibition of the $P2Y_{12}$ responses by clopidogrel or antagonists or its blockade in patients described above can be bypassed by adrenaline which activates Gi[46,50,90]. In this latter case, lowering cAMP is not the key signal since incubation with SQ22536, a direct inhibitor of the cyclase, of platelets from clopidogrel treated animals, did not restore ADP-induced aggregation[91]. Similarly, SQ22536 does not induce aggregation of platelets stimulated by serotonin[92]. These results show that a signalling event downstream from Gi is required for full activation of the αIIbβ3 integrin and subsequent aggregation. Nevertheless, lowering cAMP levels results in reduction of calcium removal from the cytosol, as has been evidenced in a patient with a probable $P2Y_{12}$ defect[50] and in control platelets using AR-C69931MX[93,94].

The $P2Y_1$ receptor is necessary to trigger response and is responsible for shape change and transient platelet aggregation

Adrenaline does not restore aggregation in the presence of $P2Y_1$ selective antagonists, which demonstrates that the $P2Y_1$ receptor is absolutely necessary for ADP-induced platelet aggregation[42]. This has been confirmed in $P2Y_1$ knockout mice[51,52] and likewise in studies of the well-known refractoriness of platelets to ADP[15]. The refractory state was found to be entirely due to desensitization of the $P2Y_1$ receptor, with a resultant loss of shape change and aggregation[95]. Shape change is an important event in

Cambridge Books Online © Cambridge University Press, 2009

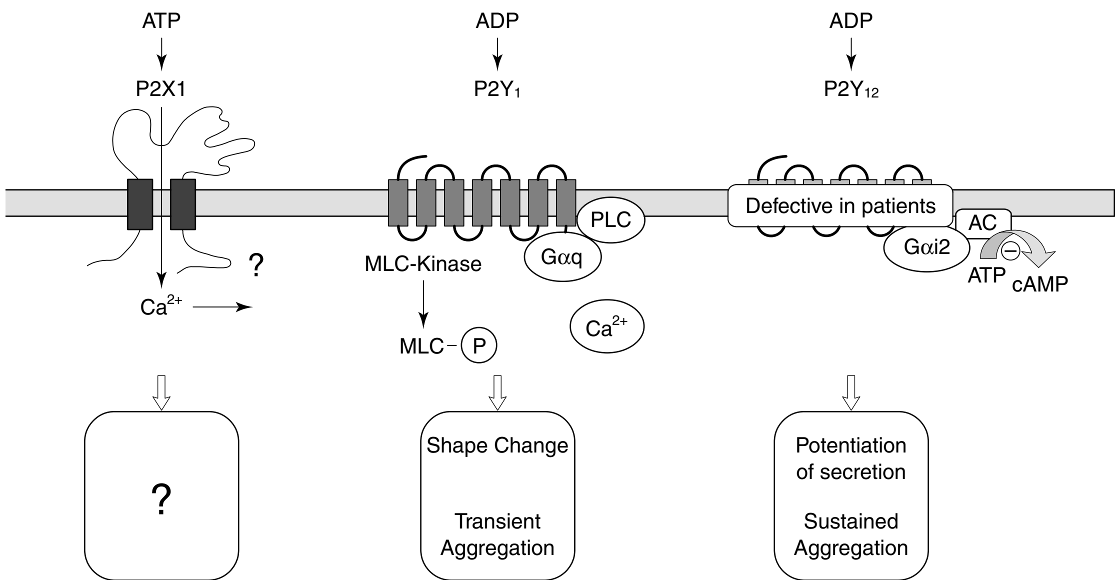

Fig. 9.3. Current view of the interplay between the platelet P2 receptors. Two G protein-coupled receptors are involved in ADP-induced platelet aggregation: the $P2Y_1$ receptor responsible for intracellular calcium mobilization, shape change and transient aggregation and the $P2Y_{12}$ receptor coupled to adenylyl cyclase inhibition, responsible for the amplification of platelet aggregation and the potentiation of platelet secretion. The latter is the molecular target of the ADP specific antiplatelet drugs thienopyridines and AR-C compounds and is defective in patients with a bleeding diathesis. Both receptors are required for normal platelet aggregation in response to ADP. Finally, a $P2X_1$ receptor is present in platelets. Responsible for rapid calcium influx, it could synergize with the $P2Y_1$ receptor. Its role in platelet activation is not yet well established.

platelet activation and is dependent on two separate biochemical pathways: a Gq-linked release of calcium from internal stores and a G12/G13-linked Rho-kinase activation[96–98]. Whether the $P2Y_1$ receptor is coupled to both pathways or only to the Gq pathway is not yet clear[98–100], but whatever its coupling, this receptor initiates platelet aggregation in response to ADP and its role is not limited to shape change. In PRP, where the concentration of fibrinogen is high (2–4 mg/ml in humans) or in washed platelet suspensions supplemented with appropriate amounts of fibrinogen, the $P2Y_1$ receptor on its own can trigger a clear, although transient, aggregation response[46] (and unpublished data). These observations better fit the aggregation profile of $P2Y_{12}$ defective patients, where a small but distinct aggregation response is obtained in PRP[84,85]. Interestingly, overexpression of $P2Y_1$ in transgenic mice results in a larger amplitude of ADP-induced platelet aggregation, even in the presence of $P2Y_{12}$ blocking agents[101]. Strikingly, ADP induces a much stronger release reaction in these murine platelets, suggesting receptor density to be the key for strong stimulation of the PLCβ and/or PLA_2 pathways.

The $P2Y_{12}$ receptor serves to amplify and complete the responses

The $P2Y_1$ receptor is nevertheless not sufficient for a full platelet response and the $P2Y_{12}$ receptor is responsible for completion and amplification of the aggregation induced by ADP and other agonists[42,45–47,49]. This receptor plays a specific role in full activation of the αIIbβ3 integrin by ADP, as has emerged from studies of patients with ADP receptor deficiencies[14]. $P2Y_{12}$ also mediates the stabilization of platelet aggregates through activation of a PI 3–K pathway downstream of Gi activation[29] and potentiation of platelet secretion[60,87]. In addition, the $P2Y_{12}$ receptor can mediate partial aggregation without shape change in platelets from $P2Y_1$ knockout mice when ADP is added at a high concentration (100 μM)[51,99], suggesting that αIIbβ3 activation can occur in the absence of $P2Y_1$ and any detectable calcium signal. The $P2Y_{12}$ receptor is also responsible for the ability of ADP to restore collagen-induced aggregation in Gαq deficient mouse platelets[99]. In general terms, it would seem that the $P2Y_{12}$ receptor is involved in all cases where ADP acts as a costimulus in the presence of low concentrations of other agonists such as thromboxane A_2, thrombin, chemokines or IgGs, while the $P2Y_1$ receptor has a specific

Cambridge Books Online © Cambridge University Press, 2009

role in early platelet activation. These respective roles of $P2Y_1$ in the early steps of aggregation and $P2Y_{12}$ in the amplification and stabilization of aggregates have been confirmed in several recent studies[93,102]. The relative contributions of the two receptors to the morphological changes induced in platelets by ADP or agonists causing ADP release have been explored in $P2Y_{12}$-deficient patients, in subjects receiving clopidogrel and in control platelets treated with selective antagonists[103,104]. It is clear from this work that $P2Y_{12}$ is involved in the constitution of stable macroaggregates through full activation of the αIIbβ3 integrin, while $P2Y_1$ is involved in the centralization of platelet granules induced by ADP and the formation of filopodia in platelets activated with low concentrations of agonists like TXA_2 or thrombin.

A role for the $P2X_1$ receptor?

One characteristic of the $P2X_1$ receptor is to become very quickly desensitized rendering difficult studies of its function in platelet activation in vitro. $P2X_1$ receptor knockout mice have been generated and display male infertility due to reduced vas deferens contraction[105], but so far no obvious defect of hemostasis. Studies of their platelet functions should help to define a role of the $P2X_1$ receptor in hemostasis and/or thrombosis. However, many investigators have, as yet, failed to find any such functional activity[45,63,106]. It has been suggested that the $P2X_1$ receptor could be implicated in shape change when care is taken to avoid desensitization by using a high concentration of apyrase at all steps of platelet handling[107]. $P2X_1$ has also been reported to synergize the ADP-induced calcium response of the $P2Y_1$ receptor, particularly under conditions where cAMP levels have been raised, which could be relevant to the in vivo situation when platelets are in contact with the vessel wall, where prostacyclin and NO are generated[94].

The platelet ADP receptors as targets for antithrombotic drugs

Since the $P2Y_1$ and $P2Y_{12}$ receptors have distinct roles in platelet activation and aggregation, they might also play separate roles in thrombosis. $P2Y_{12}$ has long been recognized as an attractive target for antithrombotic drugs. Thus, ticlopidine and clopidogrel are already commercially available, while some AR-C compounds are under evaluation in clinical trials, and both families of molecules have been shown to be efficient in animal models of thrombosis[10,11]. Ticlopidine was discovered in 1972 and already marketed in 1978, even though its precise mechanism of action was not understood. However, its selectivity as an ADP inhibitor was very quickly recognized and helped to elucidate the role of ADP in arterial thrombosis[7,108]. Clopidogrel was developed in 1986 and has been on the market since 1997[10]. This compound proved to be effective in reducing the risk of ischemic stroke, myocardial infarction or vascular death in large-scale clinical trials[10]. The AR-C compounds have proved effective in various animal models of arterial thrombosis. These compounds have already been tested in man and AR-C69931MX is in phase II clinical trials for the treatment of coronary syndromes[11]. In general terms, the pharmacological properties of the thienopyridines and AR-C analogues point to a major contribution of the $P2Y_{12}$ receptor to thrombotic states and further studies will probably lead to the discovery of new antagonists of this key target. On the other hand, the finding that $P2Y_1$-deficient mice display increased resistance to thromboembolism would suggest that this receptor could also be a target for new antiplatelet drugs[51,52]. When thromboembolism was induced by infusion of a mixture of collagen and adrenaline, $P2Y_1$ knockout mice displayed lower mortality and platelet consumption than control animals. In similar experiments, using tissue factor to promote thrombin dependent thromboembolism, $P2Y_1$-deficient mice again exhibited higher thromboresistance and significantly reduced in vivo thrombin generation[72]. Moreover, administration to mice of the $P2Y_1$-antagonist MRS 2179 resulted in prolongation of the bleeding time, inhibition of ex vivo platelet aggregation in response to ADP and resistance to thromboembolism induced by collagen and adrenaline or by tissue factor[61,72]. These results demonstrate that $P2Y_1$ represents a potential target for antithrombotic therapy.

Conclusion

ADP was identified in the 1960s as a factor influencing platelet adhesion and inducing platelet aggregation and rapidly came to be recognized as one of the most important mediators of hemostasis and thrombosis. Over the last 5 years, the platelet ADP receptors have been identified and characterized and selective P2 receptor antagonists are now under investigation as potential antithrombotic agents. Whether such $P2Y_{12}$ and $P2Y_1$ antagonists will prove useful for the antiplatelet therapy of vascular diseases should emerge in the near future.

Platelet receptors: prostanoids

Roberta Vezza and Garret A. FitzGerald

Center for Experimental Therapeutics, University of Pennsylvania, Philadelphia, USA

Introduction

Prostanoids, consisting of thromboxane (Tx) and prostaglandins (PGs), are oxygenated metabolites of the polyunsaturated, essential fatty acid, arachidonic acid. Prostaglandin G/H synthase, also called cyclooxygenase (COX), catalyses the rate-limiting step in the synthesis of prostanoids. It is a bifunctional enzyme, causing biotransformation of arachidonic acid to the cyclic endoperoxides, PGG_2 to PGH_2, via sequential cyclooxygenase and peroxidase activities. Prostanoids are produced in response to diverse physical and chemical stimuli and exert their actions by binding to G protein-coupled receptors (GPCRs) which are located on the surface of the same or nearby cells. Prostanoid receptors specific for TxA_2, prostacyclin (PGI_2), PGE_2, PGD_2, and $PGF_{2\alpha}$ are termed TP, IP, EP, DP, and FP, respectively[1]. As discussed later, isoforms of some of these receptors have been identified. Each receptor binds its cognate ligand with a Kd value of 1.3–40 nM. Most prostanoids cross-react with receptors other than their own, with affinities usually more than two orders of magnitude below this range. There are also some compounds that act potently on two different receptors. For example, iloprost activates not only the IP, but also the EP1, and PGE_1 displaces the binding of ^{3}H-iloprost more potently than other IP agonists, indicating that PGE_1 binds not only to EP isoforms, but also to the IP[2]. Prostanoids play an important role in platelet physiology. The major arachidonic acid metabolite in platelets is TxA_2. TxA_2 is also synthesized by other cells, including macrophages, monocytes, and lung parenchyma[3]. In platelets, TxA_2 is produced in response to activation by conventional agonists, such as thrombin and ADP, but TxA_2 is also a platelet activator itself. PGI_2 and PGD_2, in contrast, are antiaggregatory. PGI_2 is mainly synthesized by arterial endothelial and smooth muscle cells[1]. PGD_2 is the major arachidonic acid metabolite in the brain, and is also synthesized by mast cells and spleen[4]. In the vasculature, PGD_2 can be synthesized by isomerization of PGH_2 catalysed by plasma albumin[5]. Thus, PGD_2 provides a negative feedback mechanism for regulation of platelet activation, at least in vitro. PGE_2 is synthesized mainly by endothelial cells of the microvasculature and by venous homogenates[1,6] and exerts a proaggregatory activity when combined with other stimuli, although it is not able to induce platelet aggregation by itself[7,8].

The overall homology amongst prostanoid receptors is not high, ranging approximately from 20 to 30%, although homology among receptor homologues from different species is considerably higher (79–89% between human and mouse receptors)[2]. Prostanoid receptors possess features common to other rhodopsin-type receptors, such as two cysteines in the first and second extracellular loop, consensus sequences for *N*-glycosylation of asparagine (Asn–X–Ser/Thr) in the amino-terminal extracellular portion, and serine and threonine residues in the putative cytoplasmic domain. In addition to features common to other GPCRs, particular motifs specifically conserved among the prostanoid receptors are found in several regions, such as the seventh transmembrane domain, the second extracellular loop, and the third transmembrane domain[9]. Here we review recent studies on prostanoid receptors with particular relevance to platelet function.

Thromboxane A_2 receptor (TP)

Structure

TxA_2 receptors are abundant on platelets, vascular and airway smooth muscle cells and mediate platelet aggregation and vaso- and bronchial constriction[1]. Radioligand binding studies have been performed using several ago-

nists and antagonists, and results using the agonist ^{125}I-BOP, a compound with high affinity for the receptor, are shown in Table 10.1[10,13].

Northern blot analysis of various mouse tissues shows presence of TP message also in immune-related organs, such as thymus and spleen[9]. PGH_2 and TxA_2 share the same pharmacological properties and activate the same receptor in platelets[14]. The platelet TxA_2 receptor is often referred to as TxA_2/PGH_2 receptor. For the sake of simplicity, we will refer to this receptor as the TP. In addition to PGH_2 and TxA_2, some isoprostanes have also been shown to act as ligands of the TP in platelets and in the vasculature in vivo[15].

Pharmacological and radioligand binding studies have identified the presence of two forms of the receptor for TxA_2 in platelets[3,16]. Platelet aggregation and secretion are mediated by receptors with low affinity for the agonist I-BOP and which bind irreversibly the antagonist GR32191 (Fig. 10.1); platelet shape change is mediated by receptors with high affinity for I-BOP which bind GR32191 in a reversible fashion (Fig. 10.1)[3,16,17].

The platelet TP was purified using ligand affinity chromatography[18]. Then, a megakaryocytic cell line (MEG01 cells) and placenta cDNA libraries were screened with a probe corresponding to the partial aminoacid sequence. The deduced aminoacid sequences of the clone obtained from placenta and of the partial clone obtained from MEG01 cells were identical[19]. Since placenta is a highly vascularized tissue, this finding suggested that the platelet receptor and the vascular receptor are identical. Thus, the platelet TP is also called 'placental isoform'. According to a more recent nomenclature, this TP isoform is called TPα.

Cambridge Books Online © Cambridge University Press, 2009

TPα has also been cloned from other megakaryocytic cell lines, such as HEL[20] and K562 cells[21] and it has been confirmed that this isoform has a deduced sequence identical to that reported for the human placental TP, consisting of 343 amino acids (Fig. 10.2). Screening of a human umbilical endothelial cell library led to the cloning of a second TP isoform, TPβ[22]. Endothelial cells express both TPα and TPβ, as detected by RT-PCR[23]. TPα and TPβ are alternative splice variants of the same gene (Fig. 10.3). The alternative splicing occurs in the carboxy terminal region after the seventh transmembrane domain. Thus, TPα and TPβ differ only in the carboxy terminal tail, which is 15 amino acids long in TPα and 79 in TPβ.

Platelets express the message for both TPα and TPβ[24] although only TPα could be detected using isoform-specific antibodies[25]. The latter study also demonstrated that the platelet TP with low ligand binding affinity that mediates platelet aggregation and secretion is the cloned isoform TPα. On the other hand, the nature of the high affinity binding site responsible for platelet shape change remains to be fully elucidated.

The TP has seven transmembrane domains (Fig. 10.4) and, similarly to other rhodopsin-type receptors, has two asparagine residues in the amino terminus (Asn^4 and Asn^{16}) that are glycosylated[19]. Glycosylation of the receptor explains the difference in molecular mass of the purified TPα (57kDa) from its calculated molecular weight of 37kDa[26]. In addition, there are two cysteine residues in the first (Cys^{105}) and in the second (Cys^{183}) extracellular loop that form a disulfide bond, important for the maintenance of the receptor structure and ligand binding. Indeed, substitution of these residues with serines eliminates TPα binding[27]. Cys^{102} is important for ligand binding and signalling properties, while Cys^{223} and Thr^{221} seem to be important in eliciting normal signalling properties, although mutation of these sites does not affect ligand binding[27]. Other mutagenesis experiments have revealed that the first transmembrane domain and, in particular, a combination of Leu^{37} with either Ala^{36} or Gly^{40}, is necessary for high affinity ligand binding[28]. Other amino acids important for optimal ligand binding are located in the seventh transmembrane domain and, curiously, substitution of Trp^{299} with Leu allows preferential agonist binding and loss of antagonist binding[29]. Other mutations seem to affect the signalling or desensitization characteristics of the TPs, rather than ligand binding properties. In particular, substitution of the hydrophobic amino acid Phe^{138} in the second intracellular loop with a more polar amino acid, such as tyrosine or aspartic acid, reduces the ability of TPs to induce activation of phospholipase C (PLC)[30]. Truncation of the last 22 amino acids of the carboxy terminal tail of the mouse TP also decreases the ability to activate PLC by roughly 50%[31].

The human TxA_2 receptor gene, mapped to chromosome band 19p13.3, is present as a single copy, spans over 15 kilobases and contains 3 exons divided by 2 introns[9,32] (Fig. 10.3). The first intron occurs in the 5′ untranslated region, and the second at the end of the sixth transmembrane domain. The alternative splicing that generates TPα and TPβ occurs at the level of the third exon. Analysis of the promoter region of the TxA_2 receptor gene revealed the presence of protein kinase C (PKC) responsive elements. Activation of PKC and induction of AP-2 or an AP-2 like DNA binding factor may be responsible for transcriptional up-regulation of TPs during megakaryocytic differentiation[33]. This finding also suggests that circulating humoral factors, such as thrombin, released during myocardial infarction, activate PKC in megakaryocytes, thus stimulating the formation and release of platelets with an increased number of TxA_2 receptors[33].

Polymorphism at the TP gene locus has been recently described in rabbits and might explain differences in vascular responses to TxA_2[34]. In humans, two single nucleotide polymorphisms in the TP gene have been described: one leads to an Arg to Leu mutation at position 60[35] and is associated with bleeding disorder (see later); the other is a synonymous substitution that has been associated with bronchial asthma in adult Japanese subjects[36].

Mice differ from humans in having only one TP isoform, that consists of 341 amino acids and, thus, is similar in length to the human TPα[37]. Mice lacking the TxA_2 receptor have been generated[38]. Bleeding time is prolonged in TP deficient mice; their platelets fail to aggregate to TP agonists and have a delayed aggregation response to collagen. Contrary to the situation in humans, activation of the mouse TP does not play a significant role in ADP-induced aggregation, since ADP-induced aggregation is normal in $TP^{-/-}$ mice. In addition, vascular responses (shock syndrome associated with systemic platelet aggregation, pulmonary thrombosis, coronary spasm, and cardiovascular collapse and sudden death) to arachidonic acid and TP agonists are absent in TP deficient mice. This study confirms that most of the known functions of TxA_2 can be accounted for by the single known *Tp* gene locus in mice.

Transgenic mice overexpressing TPβ in the vasculature have been recently generated[39]. These mice do not show abnormalities in their vasculature, and blood pressure and heart rate are normal. Mating between TPβ-overexpressing females and wild type males led to intrauterine growth retardation[39] which is commonly associated with maternal diabetes or cigarette smoking in humans, both conditions associated with increased TxA_2 biosynthesis[40,41].

Notes:
See text for further details. IP: inositol phosphate; cAMP: cyclic AMP; AC: adenylate cyclase; ↓: decrease; ↑: increase; ? indicates either conflicting data reported by different groups, or an absence of data.

Signal transduction

Stimulation of platelets with TP agonists causes shape change, aggregation, and secretion of granule contents. These phenomena are accompanied by an increase in intracellular calcium, activation of PLC with consequent release of inositol phosphates and diacylglycerol, activation of PKC and phosphorylation of pleckstrin (also called P47), stimulation of myosin light chain kinase (MLCK) and phosphorylation of MLC, activation of phospholipase A_2 (PLA_2), and exposure of GPIIb/IIIa binding sites[3]. It is worth noting that while shape change and the increase in intracellular calcium occur independently of other platelet agonists, ADP and epinephrine are important for the occurrence of platelet aggregation following stimulation with TxA_2 analogues[42].

The effects of TxA_2 are mediated through the activation of pertussis toxin-insensitive G protein(s) (Table 10.2). Several studies have demonstrated coupling of platelet TxA_2 receptors with members of the $G\alpha_q$ family[43–45]: this may result in PLCβ activation and phosphatidyl inositol metabolism[46].

The platelet TxA_2 receptor also copurifies with an unidentified G protein of 85 kDa[44,47] that could represent the newly described G protein, $G\alpha_h$. We have shown that TPα can activate PLC in transfected cells not only through $G\alpha_q$, but also through $G\alpha_h$[48]. Arg^{60} in the first intracellular loop is important in mediating activation of PLCβ by both TPα and TPβ. It is worth noting that an arginine or another basic amino acid is present in the first intracellular loop of all of the prostanoid receptors at analogous positions[9]. Mutation of Arg^{60} impairs also adenylate cyclase stimulation by TPα, but not adenylate cylase inhibition by TPβ. These findings suggest that adenylate cyclase inhibition might be involved in some of the TxA_2-induced platelet responses, such as shape change and activation of PLA_2, which are normal in patients carrying an Arg^{60} to Leu mutation[35]. On the contrary, platelets from patients with this mutation do not aggregate in response to TxA_2 analogues, due to a defective activation of PLC[35,49].

Cambridge Books Online © Cambridge University Press, 2009

In transfected cells, TPα has been shown to mediate an increase in inositol phosphate when coexpressed not only with Gα_q, but also with other members of the Gα_q family, such as Gα_{11}, Gα_{14}, Gα_{16} and its murine counterpart, Gα_{15}[46]. The coupling of TPα with Gα_{16} is particularly interesting, since the expression of this G protein is restricted to hematopoietic cells.

Platelet TPs also couple with Gα_{12} and Gα_{13}[45]. Coupling of the TP with these G proteins may be responsible for platelet alkalinization[50], which is one of the early events in plaletet activation[51]. Another study[20] showed that the affinity status of TPα transfected into COS-7 cells can be altered by coexpression of Gα_q and Gα_{13}, but not Gα_{12}, although Gα_{12} was able to potentiate the effects of Gα_{13}. These authors hypothesize that the high and low affinity TPs responsible for platelet shape change and aggregation, respectively, and identified by radioligand studies[3,16], are not separate entities, and that the affinity status can be altered by coupling with different G proteins.

The coupling of TxA_2 receptor with Gα_i, with consequent inhibition of adenylate cyclase, is controversial. Several studies could not detect coupling of TP with Gα_i[20,43,45,52] while Ushikubi et al.[53] demonstrated reconstitution of platelet TP with Gα_{i2} in phospholipid vesicles and inhibition of iloprost-induced cyclic AMP increase in intact platelets.

Coupling of the platelet TP with Gα_s and activation of adenylate cyclase has not been demonstrated in platelets, although homologous desensitization of the TP subtype linked to PLC is accompanied by an increased sensitivity of adenylate cyclase to stimuli[54] (see later). In addition, stimulation of TPα with relatively high doses of the agonist activates adenylate cyclase in transfected CHO cells, while TPβ inhibits this enzyme[24].

Activation of adenylate cyclase by TPα, but not TPβ, has been demonstrated also in TP-null endothelial cells transfected with either TPα or TPβ. Stimulation of these cells and of wild type endothelial cells with the TP agonist, I-BOP, results in inhibition of angiogenesis, possibly mediated by increased apoptosis[23]. In addition, adenylate cyclase inhibitors and activators enhance and reduce, respectively, the apoptotic response induced by TPβ stimulation, while they do not affect TPα mediated apoptosis. Thus, no association between cyclic AMP changes and apoptosis could be established and it is suggested that stimulation of each TP isoform may inhibit angiogenesis and induce apoptosis *via* different downstream pathways[23].

Regulation

Since TxA_2 plays an amplifying role in platelet activation, one would expect that the response to this agonist would be tightly regulated. One of the mechanisms that regulates TxA_2 activity is the desensitization of the TP[3,55]. Initial uncoupling between receptor and G protein (desensitization) occurs with a $t_{1/2}$ of approximately 2 min, while prolonged exposure to the agonist results in progressive loss of binding sites from the cell surface (down-regulation). Both homologous and heterologous desensitization in platelets has been described[54]. Desensitization of the platelet TP subtype which activates PLC is accompanied by an increased sensitivity of adenylate cyclase[54], but not guanylate cyclase[56], to stimuli. Sensitization of adenylate cyclase in TP desensitized platelets might be important in disease conditions associated with increased TxA_2 production, in which the TP is desensitized[57]. In these patients, TP desensitization and enhanced sensitivity of adenylate cyclase might serve as compensatory mechanisms to limit the occurrence of thrombotic events. In addition, adenylate cyclase sensitization in TP desensitized platelets might have pharmacological implications. We have demonstrated that Tx synthase inhibitors, which redirect arachidonic acid metabolism toward the synthesis of antiaggregatory PGD_2 in platelets[5], have a more potent antiaggregatory activity in TP desensitized platelets than in control platelets[58]. This can be of relevance for the treatment of thrombotic disorders in which an in vivo desensitization of the platelet TP occurs.

In recent years, the mechanisms leading to desensitization and down-regulation of TPα and TPβ have been studied in overexpression systems.

The carboxy terminal tail of TPα and, especially, of TPβ, contains several serines and threonines that could be potential targets for phosphorylation. Phosphorylation is likely to be intrinsic to the process of desensitization, since it can lead to uncoupling with G proteins. Conflicting data have been reported concerning the role of PKC in TP desensitization. TPα and TPβ, when overexpressed in HEK293 cells, can be phosphorylated by exposure to the TP agonist, U46619, but neither PKC nor cyclic AMP-dependent protein kinase (also called protein kinase A, or PKA) seem to be responsible for this phosphorylation[59]. Nonetheless, both PKC and PKA are able to phosphorylate TPα and TPβ in vitro[60]. A study that used transfected CHO cells showed that both TPα and TPβ undergo homologous desensitization and that TPβ, but not TPα, could be desensitized by treatment of the cells with the PKC activator, PMA; activation of PKA did not have major effects on desensitization of either isoforms[61]. Thus, this study suggests that PKC-mediated

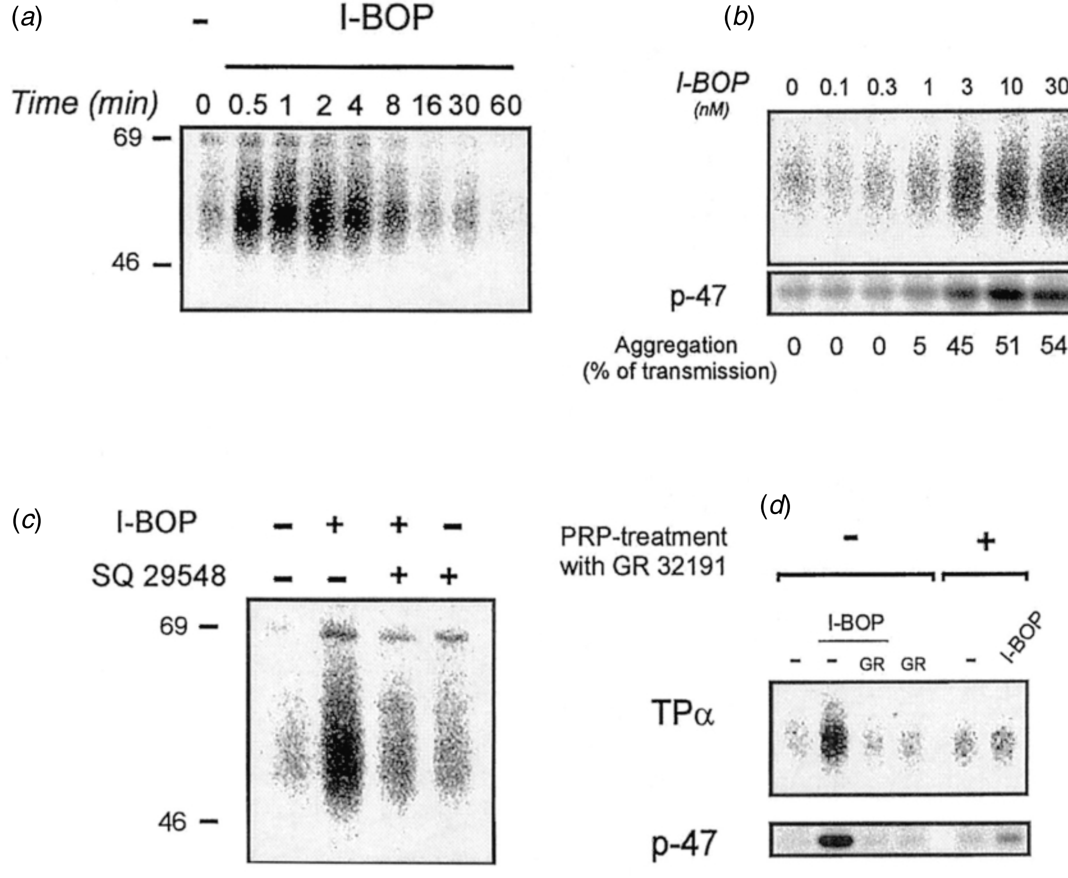

Fig. 10.5. I-BOP-induced TPα phosphorylation. [^{32}P]-labelled platelets (0.4×10^9/ml, 0.4 ml) were incubated under different conditions. Samples were immunoprecipitated using an anti TPα antibody and further subjected to SDS-PAGE. Radioactive signals were analysed using a Fuji imaging analyser. (*a*) Kinetic of TPα phosphorylation. Platelets were incubated with 10 nM I-BOP under nonstirring conditions for increasing periods of times. Results are representative of two experiments. (*b*) Dose-dependent phosphorylation of TPα was performed in the presence of I-BOP (0.1–30 nM). Corresponding aggregation is expressed as percentage of light transmission. Pleckstrin (or p-47) phosphorylation was identified after autoradiography of SDS–PAGE electrophoresis of 20 μl of total platelet lysates. These results are representative of three similar experiments. (*c*) Platelets were incubated in the presence or absence of 10 μM of SQ 29548 for 1 min at 37 °C prior to the addition of 10 nM I-BOP for 2 min. Data are representative of 3–5 experiments. (*d*) Effect of blocking low affinity binding sites of TP on TPα phosphorylation using GR 32191. Platelet-rich plasma was treated in the presence or absence of 1 μM of GR 32191 for 1 h at room temperature prior to platelet washing and labelling. Washed platelets were further incubated with 10 nM I-BOP. Platelets derived from platelet-rich plasma untreated with GR 32191 were further incubated in the presence or absence of 0.1 μM GR 32191 prior to the addition of I-BOP. P-47 phosphorylation was performed as described for (*b*). These data are representative of two similar experiments.
Reproduced from Habib et al., 1999[25].

phosphorylation plays a role in TPβ, but not TPα, desensitization. On the contrary, PKA activation following IP stimulation causes phosphorylation of TPα, but not TPβ, at Ser^{329}; this phosphorylation is accompanied by inhibition of TPα signalling[62]. Mutagenic analysis of the mouse TP revealed that PKC-mediated phosphorylation of serines located in the C-terminal tail (Ser^{321}, Ser^{322}, and Ser^{328}) is important in causing desensitization of this receptor, although the same studies suggest that PKC-induced desensitization of TP is complex and might involve mechanisms distinct from direct phosphorylation of the receptor protein[31,63]. TP phosphorylation has also been studied in human platelets, where only TPα could be detected by isoform-specific antibodies[25] (Fig. 10.5). TPα is phoshorylated in platelets following stimulation with TP agonists, arachidonic acid, collagen, thrombin, and calcium ionophore. Both homologous and

Cambridge Books Online © Cambridge University Press, 2009

heterologous phosphorylation can be blocked by PKC inhibitors[25], again suggesting the importance of PKC-mediated phosphorylation in TP regulation, at least in some experimental conditions. It is worth noting that the platelet TP is phosphorylated mainly in a PKC-dependent manner[25], while the same receptor isoform (TPα), when overexpressed in HEK293 cells, is phosphorylated independently of this enzyme[59]. This raises the possibility that heterologous expression systems may not accurately mimic the regulation of receptors in their native milieu.

Cyclic GMP-dependent protein kinase (PKG) is able to phosphorylate TPα and TPβ, independent of receptor activation. This phosphorylation, which occurs in the C terminal tail, might be important in inhibiting TP-mediated signal transduction and might explain the inhibitory activity of nitric oxide, which activates PKG, on platelet activation[64].

While phosphorylation plays a role in desensitization, down-regulation and loss of binding sites from the cell surface occurs through internalization of the receptor, following desensitization. It has been recently shown that TPα does not internalize, while TPβ does, with a plateau of ~40% after ~2–3 hours of stimulation ($t_{1/2}$~45 min). Agonist-induced internalization of TPβ might be the consequence of G protein coupled receptor kinase (GRK)-mediated phosphorylation (although this remains to be established), that might occur in the sequence between amino acids 355 and 362. Phosphorylation would increase the affinity for arrestin binding, thereby targeting the receptor for clathrin-coated pit-mediated endocytosis[65].

Another mechanism by which TPs can be regulated is at the level of gene expression. This regulation might occur in megakaryocytes, leading to production of platelets with an increased number of TPs, and also in platelets themselves. In fact, although anucleate, platelets are capable of regulated protein synthesis. It has been shown that platelets contain mRNA for Bcl-3, a member of the IκB-α family of regulatory proteins. Upon stimulation with thrombin, the message for Bcl-3 is translated and Bcl-3 protein accumulates over time. Bcl-3 synthesis in platelets is abolished by treatment with inhibitors of translation, but not with inhibitors of transcription, indicating that the Bcl-3 mRNA serves as a template for protein synthesis. Other proteins beside Bcl-3 can be synthesized upon platelet stimulation, and engagement of GPIIb/IIIa is important for initiating transcriptional events[66].

Although the mechanism is not elucidated, the PKC activator, PMA (see above and[60,67]) and testosterone[68] induce TP expression in HEL cells, a megakaryocyte-like cell line. Testosterone also increases human platelet TP density and the aggregatory response to TP agonists ex vivo[3,69]. Testosterone has been suggested as a risk factor of thrombotic disease in young athletes who abuse anabolic steroids[70].

TP antagonists have been developed and used in clinical trials for the prevention of restenosis following percutaneous transluminal coronary angioplasty (PTCA). The tested compounds did not show a significant advantage when compared to aspirin. However, the trial design included periprocedural aspirin, which suppresses the increment in PGI_2 biosynthesis induced by angioplasty[71]. Studies in mice suggest that this is of functional importance in limiting the response to injury[72] and preservation of PGI_2 biosynthesis is a potentially critical discriminant between TP antagonists and aspirin. Given the new knowledge on TPs, COX-1, and COX-2[73], the efficacy of TP antagonists in retarding atherogenesis[74], and the existence of more advanced imaging systems, it seems worthwhile to reconsider the utility of TP antagonists in cardiovascular disease.

Prostacyclin receptor (IP)

Structure

The IP is expressed by platelets, megakaryocytes, smooth muscle cells and tissues such as aorta, heart, lung, and kidney[75–77]. PGI_2 mediates inhibition of platelet aggregation and smooth muscle cell relaxation. Thus, PGI_2 antagonizes the actions of TxA_2[9] and an imbalance of these prostanoids is thought to be involved in a variety of cardiovascular disorders, such as cerebral thrombosis and ischemic heart disease[78].

The human IP has been cloned from a lung cDNA library[75,76] and a megakaryocytic leukemia cell line cDNA library[79]. It encodes a protein of 386 amino acids (Fig. 10.2) with an estimated molecular weight of 41 kDa. The IP appears to be glycosylated[80] and isoprenylated[81]. *N*-linked glycosylation at Asn[7] and especially at Asn[78] is important for proper membrane localization, ligand binding properties, and signal transduction of the IP as demonstrated by mutagenesis experiments[82].

In some studies, the cloned IP displays both a high and a low affinity binding of the ligand, [^{3}H]-iloprost[76,80], although the reason for this is presently unknown. Using ^{3}H-PGE_1 as a ligand for the IP, a low and a high affinity binding site have been detected also in human platelets[83].

Similar to the gene for the TP and DP, the gene for the human IP contains three exons separated by two introns. The first intron occurs in the 5′ untranslated region and the second at the end of the sixth transmembrane domain[84].

Cambridge Books Online © Cambridge University Press, 2009

The IP gene spans over 7 kilobases and is located on chromosome 19[84].

IP expression in megakaryocytes and in megakaryocytic cell lines is increased upon treatment with phorbol ester (which is known to induce megakaryocytic maturation), thrombopoietin (which is a potent promoter of megakaryocytopoiesis), and cytokines involved in megakaryocyte maturation or proliferation, such as interleukin-3, interleukin-6, and granulocyte–macrophage colony-stimulation factor (GM-CSF)[77]. Also proinflammatory cytokines, such as interleukin-1 and tumour necrosis factor-α upregulate IP expression, suggesting regulation of the IP gene during megakaryocyte maturation and differentiation and in inflammatory states[77].

The importance of PGI_2 as an antithrombotic agent has been demonstrated by the targeted disruption of the IP gene in mice[85]. These mice are viable, fertile, normotensive, and their heart rate, blood pressure and bleeding are normal under basal conditions, indicating that PGI_2 is not involved in the regulation of these parameters under normal circumstances. However, IP knock-out mice have an increased susceptibility to thrombosis and their response to the inflammatory stimulus, carragenan, is reduced to that observed in indomethacin-treated wild-type mice[85].

Signal transduction

Several studies have demonstrated coupling of the IP with adenylate cyclase *via* $G\alpha_s$, with a consequent increase of intracellular cyclic AMP levels[1] (Table 10.2). The increase in cyclic AMP is sufficient to inhibit platelet aggregation induced by all of the platelet agonists. Although an increase of cyclic AMP above the basal level inhibits platelet aggregation, a decrease in cyclic AMP does not favour aggregation. This has been demonstrated by using adenylate cyclase inhibitors: these compounds are not able to induce platelet aggregation, nor to potentiate aggregation induced by subthreshold concentrations of different agonists[86]. The increase in cyclic AMP leads to activation of PKA and phosphorylation of different substrates[86]. It has been recently shown that activation of platelet PKA by PGI_2 leads to phosphorylation of a G protein associated with the TxA_2 receptor, $G\alpha_{13}$. This raises the possibility that $G\alpha_{13}$ phosphorylation may be one of the mechanisms by which cyclic AMP inhibits TxA_2-induced platelet activation[87].

In addition to increasing cyclic AMP, the recombinant and the native IP also increase inositol phosphate production and intracellular calcium levels in certain cell types, but not in platelets[80,81,88,89]. This response appears to be mediated through activation of PLC via a member of the Gq family, since it is cholera and pertussis toxin insensitive[26] (Table 10.2). The EC_{50}s for cyclic AMP and inositol phosphate production in HEK293 cells stably transfected with the IP are 0.1 and 43 nM, respectively[80], although this disparity in the EC_{50} values is not evident in cells that express the receptor endogenously[88,89].

Regulation

The IP undergoes homologous desensitization followed by down-regulation. In human platelets, loss of binding sites is due to internalization of the receptor and is time and concentration dependent[90]. Platelets with internalized IPs are less responsive to the antiaggregatory effect of PGI_2[90], although the internalized receptors are not degraded and can recycle to the platelet surface within 3 hours[91]. Desensitization of the IP might be due to phosphorylation, although contrasting data have been reported in fibroblasts endogenously expressing the IP, and in transfected cells. Exposure of IP-transfected cells to a PGI_2 analogue results in a rapid, PKC-dependent, receptor phosphorylation, which is maximal within 5 minutes[80]. Ser^{328} in the carboxy-terminal tail appears to be the locus of PKC-mediated phosphorylation[92], and phosphorylation correlates with receptor desensitization. An IP mutant in which Ser^{328} is replaced by alanine does not undergo phosphorylation and is not desensitized by prior exposure of the cells to the PGI_2 analogue, iloprost[92]. It is interesting to note that the $S^{328}A$ mutant couples normally to adenylate cyclase, but not to PLC[92]. While PKC-mediated phosphorylation is important for IP desensitization in an overexpression system, this enzyme does not play a role in IP desensitization in fibroblasts naturally expressing the IP[93]. In addition, the time course of receptor desensitization in fibroblasts is much slower (1–7 hours) than in overexpressing cells and correlates with receptor internalization. Removal of the agonist after treatment of fibroblasts with iloprost for 6 hours allows recycling of the receptor to the cell surface, while more prolonged stimulation of the IP (16 hours) causes receptor degradation and *de novo* synthesis becomes a prerequisite of resensitization[93]. IP internalization following desensitization has been studied also in overexpressing cells (Fig. 10.6, see colour plate): contrary to desensitization, internalization is independent of PKC in this cellular system, and proceeds in part via a dynamin-dependent clathrin-coated vesicular endocytotic pathway[94].

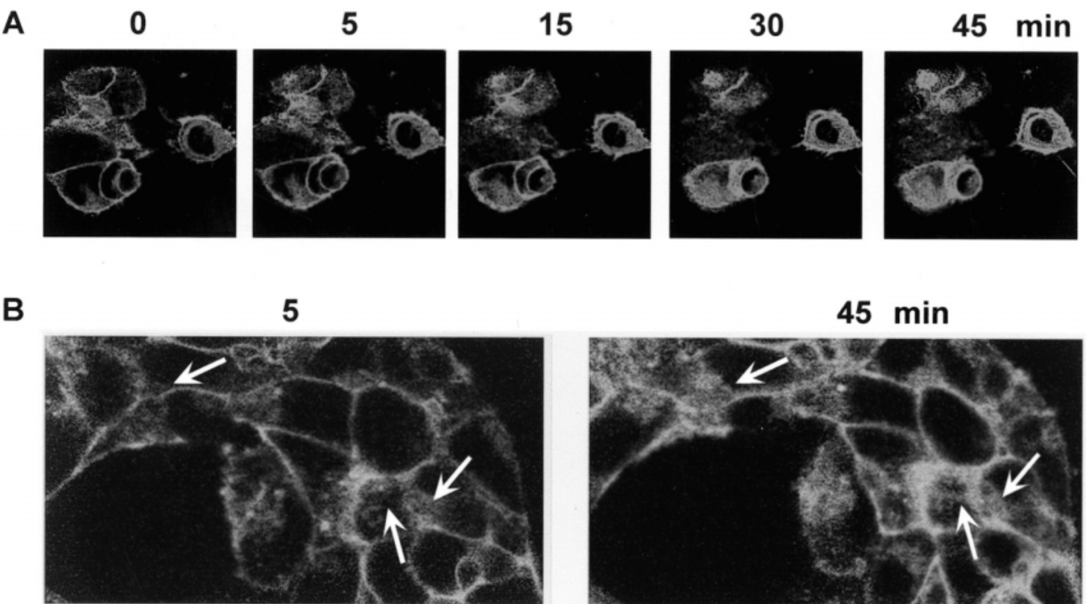

Fig. 10.6 (see also colour plate). Confocal imaging of hemagglutinine (HA) tagged human IP fused to green fluorescent protein (GFP) (HAhIP–GFP) cells in real time. (*a*) HAhIP–GFP cells were treated with 1 μM iloprost and images acquired at the indicated times. (*b*) HAhIP–GFP (green) cells were preloaded with rhodamine-conjugated transferrin (red) and images acquired at 5 and 45 min after treatment with 1 μM iloprost. Areas of co-localization (yellow) are indicated by the arrows. Data are from one experiment that was repeated with similar results. Reproduced from Smyth et al., 2000[94].

Prostaglandin E_2 receptors (EPs)

Structure

Receptors for PGE_2 are differentially expressed. Among the EPs, EP3 and EP4 are the most widely expressed, and their mRNAs have been found in almost all tissues examined. In contrast, EP1 expression is restricted to several organs, such as kidney, lung, and stomach. The EP2 is the least abundant, although its expression can be up-regulated[1,9].

The four EPs, EP1, EP2, EP3, and EP4, have been cloned from different species, including humans[9] (Fig. 10.2). The EP3 has been cloned from the erythroleukemia cell line, HEL[95], supporting earlier pharmacological studies that indicated that the platelet EP belongs to the EP3 subtype[96]. Splice variants of the EP3 have been identified in several species, including humans[97–99] (Fig. 10.7). EP3-Ia and EP3-Ib differ only in their 3' untranslated region and thus have identical open reading frames[97]. RT-PCR analysis showed that human platelets and HEL cells express several subtypes of the EP3, such as EP3-Ib, EP3-II, EP3-III, and EP3-IV, but not EP3-VI. In addition, human platelets express the EP4, but not the EP2 (both these isoforms are coupled to stimulation of adenylate cyclase), in contrast to HEL cells, that express EP2 but not EP4[100]. The expression of the EP1 was not assessed in this study. Mouse platelets express the EP3 and low levels of the EP2 and the EP4, while they do not express the EP1[101].

EP3-I	IRYHTNNYASSSTSLPCQCSSTLMWSDHLER
EP3-II	VANAVSSCSNDGQKGQPISLSNEIIQTEA
EP3-III	EEFWGN
EP3-IV	MRKRRLREQEEFWGN

Fig. 10.7. Sequence of the carboxy terminal tails of the four splice variants of the human EP3 subtype according to Kotani et al., 1995[97].

The different isoforms of the human EP3 derive from alternative splicing of the same gene[102]. The structure of the EP3 gene is very complex. It spans over more than 80 kilobases and is composed of 10 exons separated by 9 introns. Splicing occurs at the level of the carboxy terminal tail, which derives from the last portion of exon 2 or combinations of exons 3–10[102]. The EP3 isoforms are identical for the first 359 amino acids, while the C tail varies in length[97,98] (Fig. 10.2 and Fig. 10.7).

Mutagenic analysis of the second extracellular loop of the rabbit EP3 showed that this loop plays an important role in receptor–ligand interactions, but not in the signalling properties of the receptor[103]. The same study shows that mutation of Cys^{204} (which is analogous to Cys^{183} in the

Cambridge Books Online © Cambridge University Press, 2009

TP) does not cause any change in receptor binding or signalling properties: thus, a putative bridge involving Cys[204] does not seem to be important in the EP3, contrary to the situation for the TP[27].

Mice lacking the EP3 receptor have been recently generated[104]. These animals have an impaired febrile response, i.e. do not develop fever in response to endogenous (PGE_2) or exogenous (lipopolysaccharide or interleukin-1β) pyrogenes[104]. In addition, *EP3*$^{-/-}$ mice are resistant to thrombosis induced by systemic[101] or local[8] administration of arachidonic acid, although contrasting data have been reported concerning the bleeding time[8,101]. These results show that PGE_2 *via* the EP3 plays a key role in hemostasis and acute thromboembolism, at least in those models in which thrombus formation is mediated by prostanoids[101]. Thus, PGE_2 may be generated in vivo at concentrations that are in the proaggregatory range (see later). Low levels of PGE_2 appear to be necessary to augment the hemostatic effect of TxA_2, which is known to be important in hemostasis and thromboembolism in vivo[38].

Signal transduction

PGE_2 has a biphasic effect on human platelets. Low concentrations of PGE_2 (5–500 nM), although not able to induce platelet aggregation in themselves, potentiate aggregation induced by subthreshold concentrations of different agonists (collagen, ADP, thrombin, thromboxane analogues); higher and supra-physiological concentrations of PGE_2 (50–100 μM) inhibit platelet aggregation[7,8,105].

The antiaggregatory effect of high doses of PGE_2 (>50 μM) is due to increased cyclic AMP levels and is mainly the consequence of cross-activation of the IP[8]. A small contribution of the Gs-coupled EP2 and EP4 receptors in the antiaggregatory activity of PGE_2 has also been suggested[101].

The molecular mechanisms explaining the proaggregatory effect of low doses of PGE_2 are less clear. For example, it has been shown that PGE_2 induces an increase in calcium movements in human[106] and mouse platelets[101], although a calcium signal might be the consequence of cross activation of the TP[8]. We have demonstrated that proaggregatory doses of PGE_2 have a priming effect on PKC in human platelets[7]. Studies on human[107] and mouse platelets[8] have shown inhibition of adenylate cyclase by proaggregatory doses of PGE_2 (see later). Others have shown that, in human platelets, PGE_2 can either stimulate or inhibit adenylate cyclase; this may be due to the stimulation of EP4 and EP3, respectively. PGE_2 would bind to EP3 with higher affinity than to EP4 and, as a consequence, the overall effect would be an inhibition of adenylate cyclase[108]. Also the EP3 cloned from HEL and expressed in COS-1 cells has been shown to inhibit adenylate cyclase[95]. However, the results of this study are confounded by the presence of endogenous EPs in COS-1 cells that activate adenylate cyclase. In HEL cells, PGE_2 also causes an increase of intracellular calcium and, in turn, activation of phospholipase D, although it is not clear which EP is responsible for this effect[109].

Recent studies using platelets from mice deficient in EP1, EP2, EP3, or EP4 have clarified that the EP3 is the subtype responsible for the proaggregatory activity of low concentrations of PGE_2[8,101]. The proaggregatory effect of PGE_2 (100 nM) is observed in *EP1*$^{-/-}$, *EP2*$^{-/-}$ and in *EP4*$^{-/-}$ platelets, but not in *EP3*$^{-/-}$ platelets. The study of Fabre et al. suggests that PGE_2 potentiates platelet aggregation in mice by decreasing cyclic AMP levels, previously increased by antiaggregatory mediators, such as adenosine[8].

In vitro studies have shown that different EP3 isoforms differ in their ability to inhibit adenylate cyclase (Table 10.2). For example, the mouse EP3α has a marked constitutive activity, i.e. is able to activate $G\alpha_i$ and, in turn, inhibit adenylate cyclase, even in the absence of agonists, while EP3β does not display constitutive activity[110]. The level of complexity is increased even further in the bovine EP3. Four alternative splice variants of the bovine EP3 have been cloned, and termed EP3A, EP3B, EP3C, and EP3D. EP3A and EP3D, as shown for EP3 isoforms from different species, inhibit adenylate cyclase through $G\alpha_i$. Paradoxically, EP3D also activates adenylate cyclase through $G\alpha_s$ and activates PLC through a pertussis-insensitive G protein. Although EP3A also activates PLC, this most likely occurs *via* the $\beta\gamma$ subunit of $G\alpha_i$, since this effect is pertussis toxin sensitive. EP3B and EP3C only activate adenylate cyclase by coupling with $G\alpha_s$[111]. The human EP3-I inhibits adenylate cyclase and stimulates phosphoinositide turnover; EP3-II is functionally identical to the bovine EP3D, since it couples with Gi, Gs, and Gq; EP3-III inhibits adenylate cyclase; and EP3-IV is able to both inhibit and stimulate adenylate cyclase[97], although stimulation of adenylate cyclase by any of the EP3 isoforms has not been observed by another group[112]. EP3-II, EP3-III, and EP3-IV have also been shown to increase intracellular calcium in a pertussis-toxin insensitive manner[112] (Table 10.2). The human EP3-III and EP3-IV show constitutive activity toward inhibition of adenylate cyclase, while EP3-I and EP3-II inhibit adenylate cylase only in an agonist-dependent manner[113].

Regulation

Desensitization and down-regulation of EP3 isoforms have been studied following overexpression of the mouse EP3α

Cambridge Books Online © Cambridge University Press, 2009

and EP3β in CHO cells. Exposure of EP3α overexpressing cells to PGE_2 causes desensitization and downregulation of the receptor. Long-term exposure of the cells to PGE_2 causes internalization of EP3α and loss of the receptor from the cell surface: 50% of the binding sites are lost after 5 h, while up to 80% of the binding sites are lost within 24 h. In sharp contrast, EP3β does not undergo desensitization nor down-regulation. The difference between the ability of EP3α and EP3β to undergo regulation might be due to the different amino acid composition and hydrophobicity of their carboxy terminal tails. The C tail of EP3β may be incorporated into the membrane, due to its high hydrophobicity, while that of EP3α is likely to be cytoplasmic, more accessible to receptor kinases and, as a consequence, phosphorylation and desensitization. In addition, the higher number of serines and threonines and the presence of one tyrosine residue in the C tail of EP3α, but not of EP3β, can contribute to the differential regulation of these two EP3 isoforms[114]. A differential pattern of desensitization has been observed also for the human EP3 isoforms. EP3-II down-regulation occurs within 3 hours and persists up to 12 hours, while isoforms EP3-III and EP3-IV undergo a more rapid down-regulation (within ½ hour) which reverts to control level by 3 hours[112].

Prostaglandin D_2 receptor (DP)

Structure

The DP is, among the prostanoid receptors, the most restricted in its expression. It is present on human, but not mouse platelets[101], neutrophils, non-chromaffin cells from adrenal medulla, smooth muscle cells from several tissues, and nervous tissue. The DP is usually expressed in association with other prostanoid receptors and PGD_2 itself behaves as an agonist toward the TP and the FP. Mouse[115] and human[116] DP have been recently cloned. Northern blot analysis has shown that DP expression is restricted to few tissues. In mice, the DP is expressed in ileum and very weakly in lung, stomach and uterus[115], while in humans the DP is expressed in retina and in the small intestine[116]. The human DP consists of 359 amino acids (Fig. 10.2) with a calculated molecular mass of 40 kDa. There are three potential glycosylation sites in the *N*-terminus and in the first and third extracellular loops, potential PKC phosphorylation sites in the first and second cytoplasmic loops, and other potential phosphorylation sites in the C-terminal tail[115,116]. The DP gene contains an open reading frame consisting of two exons separated by an intron at a position homologous to that of the TP[115,116].

A DP-deficient mouse has been recently described[117]. Although no platelet abnormalities have been reported, it is interesting to note here that $DP^{-/-}$ mice are less susceptible to allergic asthma. Ovalbumin challenge in wild-type mice results in increased acetylcholine sensitivity, lymphocyte accumulation and increased concentration of T_H2 cytokines in the lungs. These responses were significantly lower in $DP^{-/-}$ mice, indicating that DP deficiency is manifested locally at the site of challenge[117].

Signal transduction

PGD_2 inhibits platelet aggregation in a species-specific manner, since human platelets, but not platelets from most laboratory animals, respond to PGD_2. PGD_2 also causes vasodilation and is important in the central nervous system, where it has been shown to induce sleep, hyperalgesia, regulation of body temperature and odor responses[1,9,118]. PGD_2 is abundantly released by mast cells, and plays a role during immunologic reactions.

The DP activates adenylate cyclase through Gs (Table 10.2), and the consequent increase of cyclic AMP is responsible for inhibition of platelet aggregation[1]. Although the cloned DP expressed in HEK293 cells can induce an increase of intracellular calcium upon stimulation, this response is not due to PLC activation, since no increase of inositol phosphates could be detected[115,116]. Rather, it appears that the calcium increase might be a consequence of the increased cyclic AMP, although the mechanism is presently unknown[116].

Regulation

DP regulation has not been studied in great detail. Although one could imagine that this receptor, like other GPCRs, undergoes desensitization and down-regulation, and that phosphorylation might play a role in receptor regulation, these events have not been studied in DP-expressing cells. There is one report that indirectly demonstrates regulation of the DP by phosphorylation and dephosphorylation. Binding of $^3H\text{-}PGD_2$ to membranes of the mastocytoma cell line, P-815, is increased upon treatment with phosphatase inhibitors (NaF and molybdate) and decreased upon treatment with phosphatases. In addition, the binding activity could be partially restored by treatment with molybdate[119], suggesting that reversible phosphorylation of the receptor might occur as a result of the action of unidentified protein kinase(s) and phosphatase(s) present in the membranes.

Cambridge Books Online © Cambridge University Press, 2009

Summary

Prostaglandins play important roles in platelet pathophysiology. TxA_2 is a potent platelet activating agent, while PGI_2 and PGD_2 are antiaggregatory. PGE_2 does not aggregate platelets by itself, but potentiates aggregation induced by other stimuli, while $PGF_{2\alpha}$ does not have any effect on platelet function, at least at physiological concentrations. It seems likely that the diverse actions of the different prostanoids are important in platelet homeostasis. Receptors specific for each prostanoid have been cloned and splice variants for the TP and the EP have been found. The functions of these receptors have been highlighted by the generation of knock out and transgenic mice.

Understanding prostanoid receptor function and regulation might result in improvement of therapeutic strategies to regulate platelet activation.

Platelet receptors: collagen

Pia R-M. Siljander and Richard W. Farndale

University of Cambridge, Department of Biochemistry, Cardiovascular Biology Section, Cambridge, UK

Introduction

Platelet–collagen interaction is fundamental to both normal haemostasis and pathological thrombotic incidents. In recent years the complexity of platelet collagen receptors and their interplay has become better understood. However, further work is needed before the specific recognition sequences in collagens for each receptor are identified and the events leading from initial contact to primary adhesion and full-blown platelet activation become mapped. To achieve this will require knowledge of the relevant collagen receptors themselves, the signalling pathways they activate and the vascular collagens with which they interact. It is also becoming clear that accessory molecules on the platelet surface, together with adhesive proteins that bind both collagen and the platelet, can each modulate the interaction without being direct collagen receptors themselves. Finally, we envisage that the importance of employing experimental conditions which more accurately reflect the platelet–collagen interaction in vivo will become more widely recognised. Thus, the presentation of collagen in triple-helical conformation, as polymeric fibres rather than monomers, immobilized on a surface rather than in suspension, and finally under shear conditions which represent blood flow, will have a strong impact on the final understanding of collagen as an adhesive substrate and a platelet agonist. We aim here to pool current awareness of the various aspects of the platelet-collagen interaction introduced above. For recent reviews, see[1–8,*1,*2].

Early work, using tissue extracts in turbidimetric aggregometry, established the importance of collagen as a platelet agonist[9–11]. This method provides limited insight into the different adhesive and activatory properties of collagen, as it measures solely the upregulation of the fibrinogen receptor, αIIbβ3, to which secondary stimuli contribute together with primary signals from collagen. However, such studies demonstrated that both triple-helical conformation and higher-order structure in collagens are necessary to support platelet aggregation[12–15]. Subsequent work, using platelet adhesion to immobilized cyanogen bromide fragments of collagens I and III, located adhesive and activatory sites at several different positions within the tropocollagen molecule, and established a set of recognition sites essential for primary platelet adhesion[16–19]. From this basis, candidate sequences were identified and triple-helical peptides synthesized[20–22] and used to locate the site of interaction in collagen with the first collagen receptors identified, such as $\alpha2\beta1$[23–28]. To date, little equivalent information is available for the other well-characterized platelet collagen receptors, CD36 and Glycoprotein (Gp) VI (see pp. 162–163).

The future elucidation of the detail of the platelet–collagen interaction will involve peptide-binding studies, purification and cloning of receptors, knockout technology and understanding how the several receptors coordinate platelet adhesion and signalling.

Collagens of the vascular system

Nine of the different human collagens identified so far[21–*3], types I, III–VI, VIII and XII–XIV, have been located in the vasculature, where the fibrillar collagens I, III and V are the major species, and the network-forming collagen type IV occurs in the subendothelial basement membrane[29,30]. Collagens form 20–40% of total protein in aorta and other arteries[31]. Furthermore, a developing atherosclerotic plaque becomes enriched in both type I and type III collagens[32]. Vessel wall collagens provide an important primary stimulus for platelet adhesion and activation upon exposure to blood flow by injury or disease. Although collagens I and III are revealed mainly when injury reaches the media

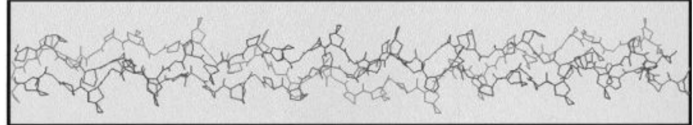
or adventitia, in some vessels they also occur in the subendothelium[33,34]. Not surprisingly, these collagens, including type IV, are reported to have the highest platelet reactivity (although XIII and XIV have yet to be evaluated), each able to induce adhesion and aggregation under both static and flow conditions[1,35,36]. In contrast, collagen V, which is important in the organisation of composite fibres with other collagens, has been reported to support only static platelet adhesion[35].

Collagens are defined by their common primary structure, a sequence of repeating G–X–X′ triplets, where G is glycine, X is often proline (P) and X′, hydroxyproline (O). The sequence GPO represents about 10% of the fibrous collagens I and III. Collagen I consists of two α_1(I)-chains and one α_2(I)-chain, whereas collagen III is a disulfide-bonded homotrimer of α_1(III)-chains. Each of the α-chains forms a left-handed helix, of which a G–X–X′ triplet represents one turn, and together they comprise a right-handed superhelix (polyproline helix II), forming the tropocollagen molecule. The small amino acid G occupies the axial position of the triple-helix, while X and X′ face the external milieu[37–40]. Each chain in collagens I and III possesses a triple-helical domain of ~1000 amino acids (length 300 nm, diameter 1.5 nm) with short non-helical N- and C-terminal telopeptide extensions. In non-fibrillar collagens, the triple-helical parts may be flanked by other domains, such as an A-domain fold like that of von Willebrand factor (vWf)[41].

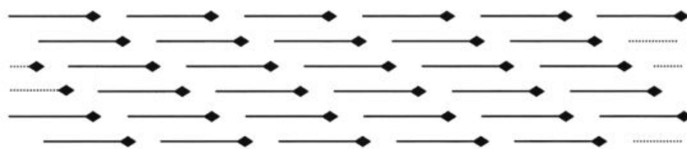
The preservation of collagen's native conformation depends strongly on its source and method of isolation[42]. As a structural component of tissue, existing generally in complex with other poorly soluble molecules, collagen has often been isolated using proteases. While the triple-helical domains resist digestion except by specific collagenases[43,44], the telopeptides are susceptible to proteolysis, e.g. by pepsin. Thus, 'native' fibres have often been prepared using proteolytically modified collagen monomers. However, the initiation of collagen fibril formation is seriously impaired by the removal of telopeptides[45–49], as they contain those lysine and hydroxylysine residues which become covalently cross-linked to stabilise the fibril[48].

Native collagen fibres are formed by arrangement of tropocollagen molecules side-by-side and end-to-end in a quarter-staggered array[50] (Fig. 11.1, see colour plate). The polymeric organization of collagen fibrils can be seen as a typical striated (670 ± 30 Å) structure in transmission electron microscopy. In vivo collagen fibres can be hybrids of different collagen types, e.g. I with V or III, and connective tissue components such as proteoglycans associate with the fibres, affecting their fibril formation and binding properties[51]. It should be noted that many matrix components, e.g. laminin and plasma proteins (vWf, fibronectin, thrombospondin) can also bind both collagen and platelets. This complexity obscures the understanding of the primary platelet–collagen interaction.

Triple-helical collagen monomer



Monomers assemble to form fibril



Native collagen fibre

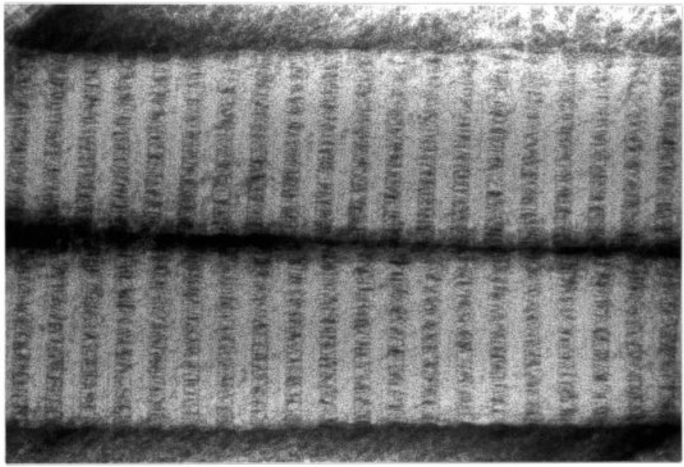


Fig. 11.1 (see also colour plate). Illustrates the hierarchical structure of collagen: the monomer is represented using the crystal coordinates of $[GPO]_{12}$, obtained from 2clg.pdb with its individual alpha chains shown in different colours, and the proline and hydroxyproline residues protruding into the external medium. The tropocollagen monomers assemble head-to-tail in a quarter-staggered array into fibrils, and their organization into fibres is clearly visualized by transmission electron microscopy. ◆ indicates the N-terminus of the tropocollagen molecule. (Transmission electron microscopy, courtesy of M. Hess, University of Helsinki.)

Understanding of the molecular structure of collagen, from simple linear sequences to the correct spatial presentation of an array of receptor-specific ligands, of different collagen species and their capacity to associate with other

Cambridge Books Online © Cambridge University Press, 2009

molecules, are each essential for the resolution of the platelet–collagen interaction. New data in this rapidly developing area drives the evolution of the simple two-site, two-step concept[3,18,52,53] towards a multisite, co-operative adhesive and signalling model (see pp. 165–168).

Importance of platelet–collagen interaction in haemostasis and thrombosis

Evidence for a role for collagen in the haemostatic response has hitherto been indirect. A very few patients affected by bleeding disorders were found to be defective in the expression of the platelet collagen receptors, or to express autoantibodies against them[54–62]. Some of these anomalies have been transient[63]. In each case, however, platelets were either refractory to stimulation by collagen, or lacked the capacity to adhere to collagen. The absence of specific tools to antagonize collagen receptors in vivo has hindered direct proof of their importance. Defective collagen synthesis is also known to impair haemostasis[64–66].

The platelet–collagen interaction has been shown to be a cornerstone for deposition of platelets in human atheromatous coronary artery explants[32]. It is increasingly accepted that collagen exposed during rupture or fissure of atherosclerotic plaque leads to platelet adhesion and activation. Exposure of subendothelial collagens in the vessel wall cannot be avoided during bypass grafting or angioplasty, and is considered to precipitate acute thrombotic episodes that accompany both procedures[67]. As antiplatelet therapy at the time of angioplasty prolongs vessel patency, it seems plausible that activation of platelets by agonists including collagen may stimulate the release or generation of mitogens and chemotactic substances, such as PDGF or thrombin, that may provoke restenosis[68].

Activation of platelets contributes to thrombotic events either through direct thrombus formation or through the procoagulant response. Two linked, silent polymorphisms in the $\alpha2$ gene (C807T and G873A) correlate with the expression of the collagen receptor $\alpha2\beta1$ on the platelet surface[69], which varies by a factor of about 4[70,71]. The 807T/873A (high receptor expression) polymorphism has been associated with increased risk of stroke and myocardial infarction[72–76], strongly supporting the proposed importance of collagen receptors in the sequelae of atherosclerosis[77]. Conversely, low $\alpha2\beta1$ density, correlating with 807C, has been linked to bleeding tendency[78]. Other reports show no such correlation, which may depend on the exact study population and the clinical endpoint being investigated[79–81,*4–*7]. The A1648G (HPA-5) polymorphism correlated with increased risk of cardiovascular events in otherwise low-risk groups[82], whereas the SIT(a) C2531T dimorphism of the $\alpha2$ gene leads to impaired response to collagen[83]. A recent study suggested that GpVI-depletion in mice provided protection against lethal thromboembolism[84]. Opinion is moving in favour of platelet collagen receptors as important mediators of thrombosis, and therefore as targets for antithrombotic therapy[4].

Platelet receptors for collagen

At present, only two receptors are both sequenced and understood in some functional detail, namely integrin α2b1 and GpVI. In addition, the sequence of two other receptors, perhaps of lesser significance, is known: CD36, and the p65 collagen I receptor. Binding motifs within collagen are being elucidated at present for $\alpha2\beta1$, for GpVI and for a less well-characterized receptor, specific for collagen III (Table 11.1).

Several other platelet proteins, such as cC1qR, have been proposed as collagen receptors[5,6,*8]. Many of these, including type III collagen-binding protein (TIIICBP) and p65, await independent verification. Collagen receptor function may involve regulatory membrane receptors or other accessory molecules, and examples of these are described below. It should be noted that the collagen-binding tyrosine kinase receptors, the discoidin domain receptors, DDR1 and DDR2[85], have not been located on platelets.

The integrin $\alpha2\beta1$ (Gp Ia/IIa, CD49b/CD29, VLA_2)

In addition to other $\beta1$ integrins ($\alpha5\beta1$ and $\alpha6\beta1$, the receptors for fibronectin and laminin, respectively) platelets express $\alpha2\beta1$[86], which is also the major collagen receptor in many other cell types[87]. In contrast to the single $\alpha2$ isoform, several different $\beta1$ gene products exist, and the A isoform predominates in platelets, although the C-isoform has been located by RT-PCR[88]. The reported receptor densities for $\alpha2\beta1$ vary between individuals from about 800 to 3500 copies per platelet[70,71,89]. $\alpha2\beta1$-deficient patients[54,63] have significant bleeding problems, and their platelets display impaired spreading upon adhesion to collagen[55]. So far, no $\alpha2$ knockout mice have been reported, but $\beta1$ knockouts exhibit early embryonic lethality[*9]. As yet, other collagen-binding integrins, $\alpha1\beta1$, $\alpha10\beta1$ and $\alpha11\beta1$, have not been located on platelets. In other cells, $\alpha2\beta1$ can also bind the physiological ligands, laminin, E-cadherin and echovirus-1[90–93], but the selectivity of $\alpha2\beta1$ for particular ligands is poorly understood. Integrins are α/β heterodimers, and subunit association, through electrostatic interac-

tion between their transmembrane regions, is necessary for both cell-surface expression and for competence to bind ligands. The general structure of integrins has recently been reviewed[87].

The $\alpha2$ subunit inserted (I-) domain, which is homologous with the A-domains of vWf, is the site of interaction of $\alpha2\beta1$ with collagen. The integrin α subunit has been modelled as a seven bladed β-propeller[94,*10], and the I-domain is located above blades 2 and 3. Collagen binding centres upon a divalent cation co-ordinated within the metal ion-dependent adhesion site (MIDAS) in the I-domain. Mg^{2+} is the physiological ion, though in vitro, several others, notably Mn^{2+}, may augment the adhesive process[87]. Lately, Ni^{2+} has also been reported to enhance collagen-induced platelet activation[95]. However, the role of divalent cations is not restricted to the MIDAS. $\alpha2\beta1$ requires micromolar Ca^{2+} to bind collagen[96], possibly, like αIIb$\beta3$[97,98], to stabilize the association between subunits. The $\alpha2$-subunit contains three Ca^{2+}-binding sites, each with characteristic DXXXDXXXD motif. Recently, these structures were suggested to resemble β-hairpin loops rather than EF-hands[99]. Expression of partial $\alpha2$ constructs suggests that the first Ca^{2+}-binding loop (in blade 4 of the putative β-propeller) may enhance the binding competence of the integrin[100]. In contrast, millimolar Ca^{2+} levels inhibit $\alpha2\beta1$ function[101]. As the large Ca^{2+} ion will not fit into the $\alpha2$ I-domain MIDAS[102], it is plausible that an inhibitory Ca^{2+}-binding site resides in the β-subunit of the integrin. Other $\alpha2\beta1$-associated Ca^{2+}-binding molecules may also contribute to Ca^{2+}-dependent effects. In summary, the divalent cation-dependence is derived from three different sites within the integrin. Finally, it is of interest that $\alpha2\beta1$ has been reported to exhibit cation-independent binding of echovirus-1 and snake venom rhodocytin[103,104].

The major collagen motif binding to the $\alpha2$ I-domain MIDAS is the sequence GFOGER[27], residues 502 to 507 of the $\alpha1$(I) chain. This sequence, as a triple-helical synthetic peptide, has been co-crystallized with recombinant I-domain, allowing the first structural analysis of an integrin–ligand complex[102]. Site-directed mutagenesis[91,105,106] and the use of inhibitory monoclonal antibodies[93,107] previously identified sequences close to the MIDAS crucial for collagen binding. The co-crystal structure confirms direct co-ordination of the MIDAS cation by the GFOGER glutamate residue (recently reviewed[108]), and also provides evidence for two conformations of the I-domain, possibly representing either inside-out (affinity regulation) or outside-in signalling (see Fig. 11.2, see colour plate). Only two strands of the triple-helix interact with the I-domain in the crystal structure[102] and thus, homotrimeric peptides containing the equivalent sequence from $\alpha2$(I), GPOGES, are incapable of binding $\alpha2\beta1$ (authors unpublished data). A similar sequence, GLOGER, has also been located within collagen I as an $\alpha2\beta1$-recognition motif, along with a lower-affinity motif, GASGER[28]. However, GFOGER-containing peptides can inhibit platelet adhesion to immobilized collagen I, suggesting that other sequences are of lower affinity[27]. In collagen IV, GFOGER is the major site of interaction with $\alpha2\beta1$, although other higher affinity sequences are present for $\alpha1\beta1$[27,109], another major collagen-binding integrin not found in platelets. Previous reports identified the sequence DGEA, close to GFOGER in the collagen I $\alpha1$ chain, as an $\alpha2\beta1$-recognition motif for platelets[110]. These data have not been confirmed, and triple-helical peptides containing DGEA do not support $\alpha2\beta1$ or platelet binding[26]. Despite this, DGEA is reported to inhibit adhesion of other cell types[111–113].

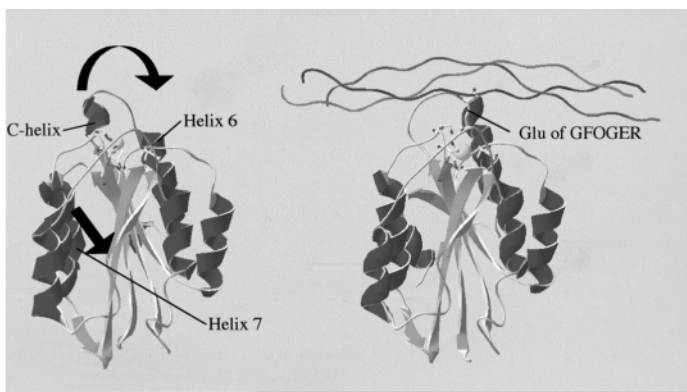

Fig. 11.2 (see also colour plate). Shows the differing conformation of the free integrin $\alpha 2$ I-domain compared with that bound by collagen. As indicated by the black arrows, the resting I-domain moves upon ligation by the collagen- like peptide. The C-helix unwinds and is added to the top of helix 6. Helix 7 moves axially towards the base of the I-domain. The I-domain construct contains a truncated helix 7, the native form of which, in the active conformation, would protrude from the I-domain and alter its relationship with the rest of the $\alpha 2$ subunit. The metal ion in the MIDAS is shown as a yellow sphere. Crystal coordinates, free I domain, 1aox,.pdb; peptide-I-domain complex, 1dzi.pdb. (Molecular graphics courtesy of Dr D. Tuckwell, University of Manchester.)

Glycoprotein VI

GpVI (p62) has recently been cloned and expressed by several groups[114–119]. It is most closely related to the immunoglobulin superfamily natural killer receptor, 1NKR, and to Fcα-R. Thus far, GpVI has been located only on platelets and late megakaryocytes[*11]. GpVI was identified as a collagen receptor in a few Japanese patients with a mild bleeding problem whose platelets proved refractory to collagen[56,57,59,61]. An autoantibody against a 62 kDa protein lacking in a patient's platelets, aggregates heterologous platelets[120]. GpVI has two Ig folds, each stabilized by a single disulfide bond. Heavy glycosylation of a mucin-like region adjacent to the transmembrane domain is proposed to account for the apparent 62–65 kDa mass of the receptor on SDS–PAGE[114]. In megakaryoblastic cells, three alternative splice variants of GpVI have been described, two of which bind CRP and associate with Fc-receptor γ-chain[118]. GpVI-2 lacks 18 amino acids from the mucin-rich stem, whereas GpVI-3 lacks a functional transmembrane domain. These variant forms were not found in platelets. The cytoplasmic domain of GpVI contains a proline-rich region reminiscent of SH3 domain-binding motifs, suggesting a possible mode of signal transduction.

GpVI expression level is currently unknown, although convulxin, a snake venom protein from *Crotalus durissus terrificus* and a known ligand of GpVI, has around 300 high-affinity binding sites in platelets[121]. A subsequent study suggested about 1200 high-affinity sites for convulxin, about 15% of which could be inhibited by a synthetic triple-helical peptide, known as collagen-related peptide or CRP[122]. Crosslinked CRP contains repeating GPO motifs and is a potent GpVI-specific agonist[25,123] which has proved valuable in elucidating signalling (see pp. 165–167). Another 'mini-collagen', a triple-helical peptide containing a proposed $\alpha 2\beta 1$-recognition sequence from collagen IV, also contained eight repeating GPO motifs[24].

GpVI is currently considered to be the main collagen signalling receptor[124], mediating collagen-induced platelet activation and aggregation[125,*12,*13]. Stationary adhesion experiments, demonstrating cation-independent attachment to fibrillar collagen, probably reflect adhesion to GpVI[18,126]. However, in contrast to stationary adhesion[25], the use of CRP under conditions of blood flow showed that GpVI was incapable of mediating platelet attachment even at low shear rates[127]. A study using citrate-anticoagulated GpVI-deficient blood showed that biphasic platelet deposition was impaired at the level of aggregate formation, but not initial surface coverage[128]. Thus, it seems that receptors such as $\alpha 2\beta 1$ or TIIICBP are responsible for the initial platelet adhesion, and other receptors, such as GpVI, subsequently induce activation (see pp. 165–167), summarized currently as the two-site, two-step model of platelet–collagen interaction.

CD36 (GpIV, GpIIIb)

CD36 is a highly expressed receptor for both collagen and thrombospondin in platelets[129]. Its specificity for collagen over thrombospondin depends on phosphorylation of amino acids within residues 87–99 of its ectodomain[130]. CD36 is a scavenger receptor in macrophages, binding fatty acids and oxidized low-density lipoproteins, so having a possible role in atherogenesis, and in endothelial cells it binds malaria-infected red cells. The single isoform of CD36 was recently proposed to have two transmembrane domains with short cytoplasmic tails[131] (although this is subject to debate). CD36 is thought to associate with src-family tyrosine kinases[132] and with αIIbβ3[133]. Crosslinking of CD36 using antibodies causes platelet aggregation[134], dependent on FcγRIIa. The role of CD36 as a platelet collagen receptor is controversial, since most studies show that CD36-deficient platelets (Nak^a – phenotype, present in 3% of the Japanese population) support normal collagen-induced aggregation[135,136], adhesion

Cambridge Books Online © Cambridge University Press, 2009

under both static and flow conditions[35,137] and finally, have undisturbed signal transduction[138]. However, some studies revealed impaired platelet aggregation and adhesion to collagen type V[35,136], and impaired response to collagen type I[139,140]. These results were corroborated using polyclonal and monoclonal antibodies against CD36, demonstrating a role for CD36 in the early (2–5 min) phases of platelet-collagen interaction in flowing blood in the absence of Mg^{2+}, using native type I collagen fibrils as a substrate[141–143].

Other collagen receptors

65, 68/72 (TIIICBP) and 47 kDa receptors

Most of the findings concerning other collagen receptors in platelets[5] remain as single unconfirmed observations. However, analysis of two of these candidates has been carried further.

A collagen III-specific receptor was originally recognized using a synthetic linear octapeptide of sequence KPGEPGPK[144]. This peptide associated with two different proteins, 68 and 72 kDa, in ligand blotting after SDS–PAGE. A related peptide, KOGEOGPK, inhibited both platelet interaction with type III collagen or subendothelium under static and flow conditions[145] and activation of αIIbβ3[144]. Recently, the same peptide was used as an affinity ligand for p72, (TIIICBP) which has not yet been sequenced[*14]. The peptides described are linear, and when assembled in triple-helical conformation they did not support platelet adhesion under flow or static conditions[146].

The collagen I-specific 65 kDa receptor was first isolated using affinity chromatography with the single stranded α-chain from chick-skin type I collagen[147]. Oligonucleotide probes were designed from the CNBr-fragment sequence of the purified receptor. cDNA of p65 was cloned and sequenced from a human bone marrow library, and it lacks homology with any known receptor[148]. The 65 kDa receptor co-precipitated with the serine/threonine protein phosphatase 1, and was able to mediate phosphoinositide hydrolysis and calcium mobilisation[5].

Another collagen type III-specific platelet receptor, p47, was isolated using affinity chromatography as for the p65 protein, confirming that different collagens possess specific platelet recognition motifs[149]. However, the relationship of these two receptors with the other established receptors, as well as their place in the sequential adhesion of platelets to collagen, is not yet known.

p85

Like $\alpha2\beta1$ and GpVI, an 85 kDa protein was identified as a possible collagen receptor in platelets from a patient with a bleeding disorder and impaired responses to collagen. p85 could be discriminated from CD36 using mAbs, though not by electrophoresis[150]. No further data has been produced on p85.

cC1q-receptor

A complement receptor, cC1q-R, expressed at 4000 copies per platelet, has been suggested to be a collagen receptor[151]. Its defined ligand is the collagen-like, triple-helical tail of C1q[152]. cC1q-R is now accepted as a form of calreticulin[153], associating with the cell-surface through either a transmembrane domain or a KDEL sequence. Polymeric C1q has been reported to cause platelet aggregation, P-selectin expression and procoagulant activity[154]. Both C1q and anti-cC1q-R antibodies inhibited collagen-induced platelet aggregation, but not adhesion of platelets to collagen. cC1q-R remains to be confirmed as either a true collagen receptor, or as a modulator of other associated receptors.

Affinity regulation of receptors and accessory molecules

The affinity of $\alpha2\beta1$ and specificity of CD36 have been shown to alter after platelet activation. Several associated proteins either mediate inside-out signalling or co-operate with $\alpha2\beta1$. For GpVI, in contrast, a requirement only for the Fc receptor γ-chain has been demonstrated. This section addresses affinity regulation and the role of possible accessory proteins both outside and within the platelet.

Affinity regulation of $\alpha2\beta1$

The conformational shift (see Fig. 11.2) in $\alpha2\beta1$ integrin I-domain revealed upon ligand binding[102] may correlate with alteration in $\alpha2\beta1$ affinity which occurs with activating mAbs and divalent cations such as Mn^{2+}[87]. On the other hand, inside-out signalling has long been known to cause conformational changes and to promote soluble fibrinogen binding by αIIbβ3 (see Chapters 4 and 22)[155]. Such changes expose new binding sites, ligand- and receptor-induced binding sites (LIBS and RIBS) on αIIbβ3. For CD36, the dephosphorylation of its extracellular domain is claimed to switch ligand-specificity from collagen to thrombospondin[130].

Recently, it was suggested that the affinity of $\alpha2\beta1$ for collagen is also controlled by inside-out signalling[71,156,*15].

Cambridge Books Online © Cambridge University Press, 2009

Platelets do not bind soluble monomeric collagen, which must first be polymerised into fibrils. Pre-activation of platelets with ADP, thrombin, CRP or certain mAbs facilitated binding of soluble collagen[71,157], generating two states of affinity depending on the activating agonist, which was blocked by PGI_2[157] or inhibitors of intracellular signalling pathways[156]. Low-affinity ligand-binding was induced by ADP regardless of concentration, whereas thrombin or CRP could generate high-affinity interaction of soluble collagen with $\alpha 2\beta 1$. These results fit the observations of activation-dependent binding of platelets to collagen via $\alpha 2\beta 1$ under flow[158], in which an activatory mAb for $\alpha 2\beta 1$ was shown to slow platelets down, while inhibitory mAbs increased the velocity of the platelets over a collagen surface. Changes in binding affinity may determine substrate selectivity of $\alpha 2\beta 1$[86]. Although currently the regulation of affinity modulation is uncharacterized, the $\alpha 2$-domain has been shown to exert negative regulation[159], and the NPXY motif in the $\beta 1$-cytoplasmic domain is thought to be critical for inside-out signalling[160]. Finally, there is increasing evidence for associated intracellular molecules that may mediate these conformational changes, whereas the cysteine-rich protein disulfide isomerase-like domain in the $\beta 1$-subunit may regulate covalent changes in conformations from the outside (see p. 164, next section).

Protein disulphide isomerase

On activation, platelets express protein disulphide isomerase (PDI) activity on their surface[161] and into the external medium[162]. PDI, a 62 kDa protein, is normally considered an ER enzyme and chaperone, responsible for correct disulfide bonding and folding of nascent proteins. In this context, it also serves as the β-subunit of 4-prolylhydroxylase, binding collagen monomers to allow their hydroxylation[163]. PDI is not known to bind mature collagen, however.

PDI expressed on the platelet surface, perhaps secured by its KDEL sequence, appears to regulate the interaction of platelet glycoproteins and their ligands, and in vitro evidence suggests that it may also interact with other accessory molecules, such as calreticulin/cC1q-R[164]. PDI activity has been implicated in the function of GpIbα[165], in the association of thrombospondin with PDGF secreted from platelet α-granules[166], and in the regulation of the fibrinogen receptor, αIIb$\beta 3$, where it is believed to mediate reorganization of the disulfide bridges in the Cys-rich stem of the integrin β-subunit[167,168]. This region has marked sequence homology with the active site of PDI, suggesting that intrinsic PDI activity, and thiol re-arrangement, may be a general property of integrin β-subunits[169,170].

Thiol re-arrangement[171] and cell-surface PDI[172] have been shown to be important in the $\alpha 2\beta 1$-mediated interaction of platelets with collagen. Use of receptor-specific triple-helical peptides allows $\alpha 2\beta 1$ to be discriminated from GpVI in this context, showing the role of PDI to be integrin-specific (authors' unpublished data). No evidence exists thus far for a role for Ca^{2+} in regulating PDI activity, as may be the case in the ER. These data suggest that conversion between the high and low affinity states of $\alpha 2\beta 1$ could be catalysed by PDI activity.

Integrin-associated protein (CD47)

As its name implies, IAP associates with both αIIb$\beta 3$ and $\alpha 2\beta 1$ on the platelet surface[173,174]. This 52 kDa protein has a single Ig-like fold and five transmembrane domains. CD47 binds thrombospondin, and one model proposes that it co-operates with an integrin to deliver a signal to the cell interior, for example, by acting as an ion channel. A specific sequence (known as 4N1K) from thrombospondin binds CD47, inhibiting adenylate cyclase through G_i[175]. 4N1K has been reported to exhibit synergism with soluble collagen in activating platelets, an effect absent in CD47 knockout mice[174].

Fc receptors

Platelets express both the low-affinity IgG receptor, FcγRIIA, and the Fc-receptor γ-chain. Whilst signalling caused by crosslinking FcγRIIA has much in common with collagen-induced signalling[176,177], there is little evidence for direct involvement of FcγRIIA. However, FcγRIIA has been found to associate with GpIb/IX/V[178], and so could possibly mediate indirect signals from collagen through the vWf/collagen axis.

The structurally-distinct FcR γ-chain, in marked contrast, is essential for signal transduction from GpVI by collagen or CRP[179]. The association of GpVI with FcR γ-chain, occurring through an arginine–aspartate salt bridge within the plasma membrane[114] in resting and stimulated platelets[180–182], is essential for its expression[117,119]. FcR γ-chain is thought to represent the key internal apparatus for transmitting signals onwards from GpVI to the platelet interior, although it also associates with GpIb/IX/V[183]. FcR γ-chain is a disulfide-bridged dimer, with short external domains. Its cytoplasmic tail (42 amino acids) contains an immunoreceptor tyrosine activation motif (ITAM), a site which on phosphorylation recruits signalling proteins.

Cambridge Books Online © Cambridge University Press, 2009

Calreticulin

Intracellular forms of calreticulin may interact with a consensus sequence, KXGFFKR, in the integrin α-subunit cytoplasmic tail[184]. Calreticulin interacts with both αIIbβ3 in platelets and with $\alpha 2\beta 1$ in other cells, regulating their function and signalling[185–187]. The high-affinity form of $\alpha 2\beta 1$ was shown to interact with calreticulin in phorbol ester-treated Jurkat cells, where anticalreticulin antibodies reversed cell adhesion to collagen I[188].

PECAM-1 (CD31)

The platelet and endothelial cell adhesion molecule, PECAM-1, a member of the Ig superfamily, can bind and activate protein tyrosine phosphatases through its immunoreceptor tyrosine inhibitory motif (ITIM)[189,*17,*18,*19]. Platelet PECAM-1 is phosphorylated on tyrosine residues by c-src family kinases, and co-immunoprecipitates with them after activation by several ligands including collagen[190]. Recently, PECAM-1 was reported to inhibit the response of platelets to collagen[191,*20,*21]. In other cells, PECAM-1 oligomerisation induces integrin-mediated spreading[192].

CD9

The tetraspanin, CD9, associates with $\alpha 2\beta 1$ and other $\beta 1$ integrins on vascular smooth muscle cells, where it is believed to modulate collagen matrix reorganisation[193]. CD9 is expressed in platelets, where it complexes with glycoproteins, including αIIbβ3 and CD36[194–196]. Anti-CD9 antibodies stimulate platelet tyrosine kinase activity[197].

Venoms, etc.

The evolution of specific inhibitory or activatory proteins in snake venoms or the saliva of leeches and blood-sucking insects underscores the importance of the platelet-collagen interaction in haemostasis. These proteins may target either the receptors on platelets or collagen itself. Typically, they belong to either of two categories, which characterise their mode of action: the C-type lectin family, or the metalloproteinase-disintegrins. However, as these venoms often contain mixtures of active proteins or because the proteins have dual effects, experimental results may be contradictory and should be interpreted with care. These natural modulators may help us to understand the relevance of individual receptors and, crucially, may indicate important antithrombotic targets. We will mention briefly a few examples of functional significance[198–200].

As there is no readily available monoclonal antibody targeting GpVI, the multimeric protein, convulxin, from *Crotalus durissus terrificus,* has been used, like the CRP peptide, to specifically activate platelets. Many of the platelet activation events induced by very low convulxin concentrations, i.e. aggregation, Ca^{2+} signalling and tyrosine phosphorylation[201], resemble closely those induced by collagen fibres. Convulxin competes with CRP for one of its two binding sites on platelets[122] and although it has also been suspected to bind $\alpha 2\beta 1$[121], no receptor other than GpVI has been proven.

Although jararhagin and jaracetin from *Bothrops jararaca* were originally found to activate the vWf A1-domain, promoting vWf binding to GpIb/IX/V, because they blocked $\alpha 2\beta 1$-collagen binding through both the disintegrin and metalloproteinase domains, they were soon implemented in studying the platelet-collagen interaction[202]. Proteolysis of the $\beta 1$-subunit of the integrin was shown to mediate this inhibitory effect, together with direct binding to the $\alpha 2$-subunit[203,204]. A positively charged cyclic RKK peptide, based on the metalloproteinase domain, bound strongly to acidic amino acid sidechains near the $\alpha 2$–I domain MIDAS and inhibited collagen binding[205,206].

Other snake venom proteins claimed to be $\alpha 2\beta 1$-specific include alternagin (*Bothrops alternatus*)[207], trimucytin (*Trimeresurus mucrosquamatus*)[208] and rhodocytin/aggretin (*Calloselasma rhodostoma*)[209,210], and the two latter induce platelet aggregation. However, trimucytin was recently suggested to work through GpVI[211]. Interestingly, the use of rhodocytin supported the concept that $\alpha 2\beta 1$ can signal in platelets[212]. However, the specificity of these venom proteins for $\alpha 2\beta 1$ has been questioned. Neither soluble recombinant $\alpha 2\beta 1$ nor the wild-type integrin bound to rhodocytin. Instead, within the same venom, a 27 kDa antagonist of collagen-induced aggregation was identified as rhodocetin, a specific ligand for $\alpha 2\beta 1$[213,214]. The ability of proteins (pallidipin, moubatin and Tick Adhesion Inhibitor) from different species to perturb platelet–collagen interaction has been discussed elsewhere[1].

Finally, some venom proteins bind directly to collagen and thus hamper its interaction with either platelet $\alpha 2$ I-domain or vWf A-domain. Such proteins include catrocollastatin (*Crotalus atrox*)[215], LAPP (leech antiplatelet protein) and calin (*Hirudo medicinalis*)[216].

Signalling through collagen receptors

Collagen, like thrombin, is a strong platelet agonist, causing several separate activation events (arachidonate

Cambridge Books Online © Cambridge University Press, 2009

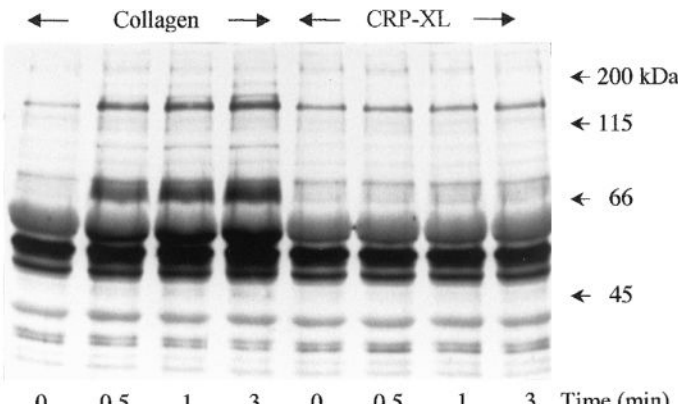

Fig. 11.3. Shows the response of GpVI-deficient platelets in suspension to collagen fibres and to CRP, over the indicated times. While CRP has no discernible effect on protein tyrosine phosphorylation (detected in Western blots), collagen caused a marked increase in protein phosphotyrosine, although it did not aggregate platelets. Thus, GpVI is both sufficient and necessary for full platelet aggregation, but collagen-induced signals are also mediated by other receptors. (Courtesy of T. Ichinohe and M. Okuma, Kyoto; collaborative data with the authors.)

release, morphological changes, secretion, aggregation and procoagulant activity). Pathways as diverse as G-protein linked signalling and tyrosine kinase activity converge upon intracellular calcium (Chapter 17) to elicit each of these defined signalling endpoints, which involve the interplay of a profusion of signalling molecules including cyclic nucleotides (Chapter 20), ADP (Chapter 9), H_20_2[217] and eicosanoids such as PGI_2 and TxA_2 (Chapter 15).

Immobilized collagens, in the context of the blood vessel wall, provide unique means for activation when compared with soluble ligands. They offer to the platelet a surface to spread upon, and by virtue of the highly organized structure of the collagen fibre, they present a repetitive array of receptor-recognition motifs. Thus, several novel concepts arise: receptor clustering may cause signals to propagate simply from the increased local concentration of receptors and their associated signalling proteins at the inner surface of the platelet plasma membrane. This increased receptor avidity has long been associated with integrin function in other cells. Further, the structure of collagen may support spatial and temporal association of dissimilar receptor populations, for example $\alpha 2\beta 1$ with GpVI, or either of these with CD36. The different protein species associated with the intracellular domains of these various receptors will support great diversity of signalling from collagen, but renders the dissection of particular signalling pathways highly complex.

The use of specific ligands, CRP and convulxin, demonstrates that GpVI ligation and/or clustering is sufficient for platelet activation. Early studies involving GpVI-deficient platelets indicate its essential role in platelet aggregation by collagen[56,57]. Some signals, however, as shown by protein tyrosine phosphorylation (see Fig. 11.3) including the specific activation of the intracellular kinase c-src[218] and the up-regulation of αIIbβ3 for fibrinogen binding[124], can arise through other collagen receptors, whose identity is hotly debated. The collagen fibre offers binding motifs to such receptors, and it is increasingly accepted that these contribute, especially under physiological blood flow[143], to the platelet deposition and activation process[219,220]. A key task remaining is to determine the degree of overlap of these two functions, and which other receptors participate.

Second messenger pathways stimulated by collagen

The cytoplasmic domains of platelet collagen receptors identified to date lack catalytic activity. Platelet activation therefore depends upon associated signalling molecules, especially tyrosine kinases, leading to the activation of phospholipase Cγ2[221,222]. This pathway results in the activation of protein kinase C together with elevation of cytosolic calcium (see Chapter 17), which is central to the platelet activation process.

Platelet activation involves controlled modulation of cyclic nucleotide levels (Chapter 20). Early work showed that collagen lowered cyclic AMP levels in platelets[223], a process blocked by pertussis toxin treatment[224], implicating G_i function[225]. Inhibition of adenylate cyclase by type I collagen fibres was independent of ADP or TxA_2 production[223,226], and the GpVI-specific CRP was inactive[21]. The peptide KPGEPGPK, from collagen III, has been implicated in cyclic AMP metabolism, suggesting a role for the TIIICBP[148], but the receptors responsible have not been formally identified. Collagen also stimulates guanylate cyclase activity, and cyclic GMP, like cyclic AMP, is an inhibitor of platelet activation (see Chapter 20). This paradoxical action may reside in the capacity of collagen to stimulate αIIbβ3-independent NO synthesis[227], which in turn stimulates soluble guanylate cyclase. It might thus represent a termination signal, restricting the extent of collagen-stimulated platelet activation and deposition at sites of vascular damage. Recently, the p65 type I collagen receptor was implicated in NO production[228].

GpVI signalling

Truncation of the cytosolic tail of GpVI in a rat leukemia cell line abrogated convulxin-stimulated signalling but not

Cambridge Books Online © Cambridge University Press, 2009

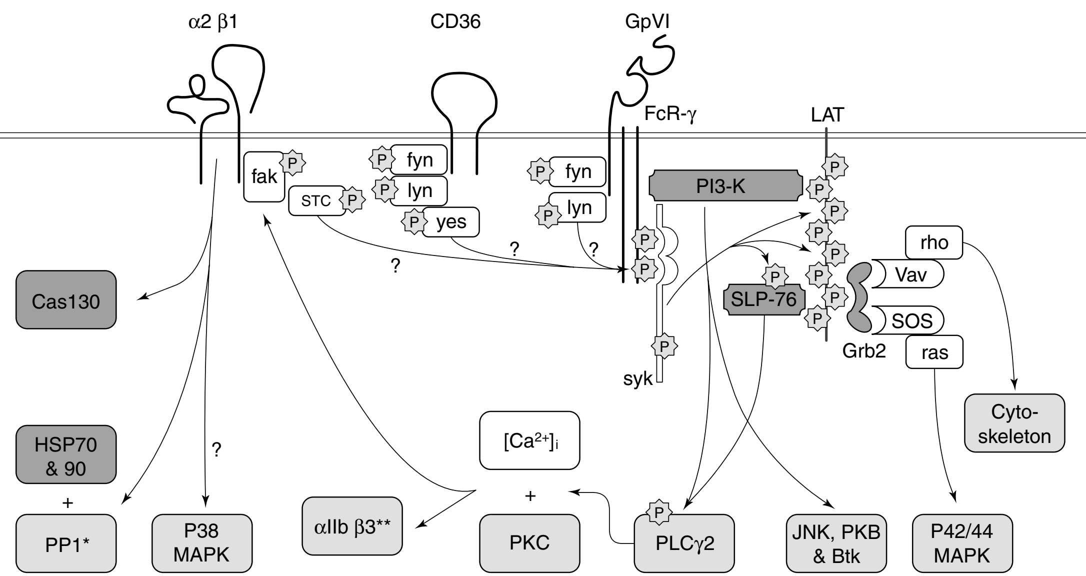

Fig. 11.4 (see also colour plate). Depicts proposed signalling pathways from the major collagen receptors, $\alpha 2\beta 1$, CD36 and GpVI. Phosphorylation events are shown using blue arrows, and other signalling pathways in black. Question marks indicate possible signalling pathways, lacking specific detail at present. Signalling molecules are defined in the text. Tyrosine kinases are coded *beige*, serine/threonine kinases *pink*, adapter proteins in *orange*. Tyrosine phosphorylation is indicated by stars on the relevant proteins. Other collagen receptors and possible signals arising from the GpIb/IX/V axis are omitted for clarity.

expression of GpVI, which depends on its association with the FcR γ-chain[119]. During the activation process, the ITAM motif of FcR γ becomes phosphorylated[181,*19], an event required for only one of the FcR γ-chains[180]. The GpVI/FcR γ-chain-associated src-family kinases fyn or lyn[229] have been proposed to mediate this event in both human[230] and mouse platelets[231].

A crucial question, yet to be answered, is how the activation of these kinases occurs, to allow phosphorylation of FcR γ-chain. The polyproline motif in the cytosolic tail of GpVI may bind these kinases through their SH3 domains. Other less direct possibilities exist, as fyn and lyn also associate with CD36[132], which might be engaged together with GpVI during the early phases of interaction with the collagen fibre[142,219]. However, since CD36-deficient platelets respond fully to collagen, $\alpha 2\beta 1$ is a more plausible candidate for a coreceptor: a recent report suggested that rhodocytin promotes the dissociation from $\alpha 2\beta 1$ and activation of c-src, and its subsequent binding and phosphorylation of p130cas[104].

Knowledge of platelet activation downstream from GpVI has developed rapidly, modelled on signalling pathways in T-cells[125]. The hematopoetic cell-specific tyrosine kinase, p72syk (spleen tyrosine kinase), is activated in response to collagen[218,232,233], and is essential for collagen- and CRP-induced signal transduction[179]. The phosphorylated ITAM of FcR γ-chain recruits p72syk, which is believed to phosphorylate the scaffold protein, LAT (linker for activation of T-cells), a prominent substrate for tyrosine kinases in collagen- and especially CRP-stimulated platelets, and SLP-76 (SH2 domain-containing leukocyte protein of 76 kDa)[234,*22]. Signalling complexes can assemble on SLP-76 and LAT[235], so relaying signals to different apparatus including protein tyrosine phosphatases[236] within the platelet. Thus, PI-3-kinase (phosphatidylinositol 3-kinase) becomes recruited to the cell membrane by association with both LAT and FcR-γ chain[237], where it generates 3-phosphoinositides which may lead to the activation of PKB/Akt[238,239]. PI-3-kinase[240] and SLP-76 acting in concert[241] lead to PLC $\gamma 2$ becoming phosphorylated and activated, causing phosphoinositide turnover, Ca^{2+} signalling and PKC (protein kinase C) activation. Btk (Bruton's tyrosine kinase) and its homologue tec, activated by collagen[242], have also been implicated in mediating PLC $\gamma 2$ activation[243]. Guanine nucleotide exchange factors such as Vav1 and Sos (son of sevenless), recruited to signalling complexes via the adapter protein, Grb2 (growth factor receptor-bound2), activate small GTP-binding proteins and so initiate cytoskeletal change[244,245] or activate MAP kinases (mitogen-activated protein kinases). The role of adaptor proteins has been reviewed recently[246]. Fig. 11.4, see colour plate, summarizes the present incomplete understanding of these events.

$\alpha 2\beta 1$ signalling

Although $\alpha 2\beta 1$ is an essential signalling receptor in other cells[247], regulating, for example, smooth muscle cell phenotype[248], signalling by $\alpha 2\beta 1$ in platelets is debated. The two-site two-step model implies tight binding of $\alpha 2\beta 1$ to collagen as a pre-requisite for the weaker interaction with GpVI. Thus, blockade of $\alpha 2\beta 1$ may indirectly inhibit signals from GpVI (or other receptors). On the other hand, $\alpha 2\beta 1$-generated signals may be masked by those from GpVI. Ligands that bind or crosslink $\alpha 2\beta 1$ cause neither aggregation of platelets in suspension nor discernible protein tyrosine phosphorylation[123], although blockade of $\alpha 2\beta 1$ by specific mAbs attenuated signalling from collagen[249]. Signals from $\alpha 2\beta 1$ appear to be more subtle than those from GpVI. However, platelet adhesion through $\alpha 2\beta 1$ to collagenous substrates induced phosphorylation of the focal adhesion kinase, p125fak, under either static or flow conditions[250,251], but a cross-linked triple-helical peptide specific for $\alpha 2\beta 1$ caused no discernible tyrosine phosphorylation of p125fak when applied to platelets in suspension[252]. It is plausible therefore that signals attributed to $\alpha 2\beta 1$ derive from the cytoskeletal re-organisation supported by immobilised ligands. Thus, the adhesive process itself amplified responses to GpVI ligands, although the basis for this remains to be resolved.

In two further studies assessing $\alpha 2\beta 1$ signalling in adherent platelets by TxA_2 generation and $\alpha IIb\beta 3$ activation, Mg^{2+}-dependent adhesion to monomeric collagen induced PAC-1 binding, but not TxA_2 generation[219,220]. Interestingly, TxA_2 generation stimulated by fibrillar collagen in the presence of Mg^{2+} was 3–4 times lower than in its absence, perhaps implying an inhibitory role for $\alpha 2\beta 1$.

Previously, phosphatase inhibitors have been shown to influence various aspects of collagen-induced platelet activation, from spreading to $\alpha IIb\beta 3$ upregulation. Under flow conditions, $\alpha 2\beta 1$ occupancy has been implicated in the activation of the serine/threonine phosphatase, PP1, which dissociates from its complex with heat shock protein (hsp) 90 and hsp70, an event correlating with dephosphorylation of several platelet proteins[253]. There is further evidence for phosphatase association with $\beta 1$ from other cells: PP2A associated with $\beta 1$ integrins in stem cells[254], and okadaic acid inhibited adhesion to collagen through $\alpha 2\beta 1$ in Jurkat cells[186].

The collagen-induced procoagulant response[255] is regulated by a balance between phosphorylation and dephosphorylation[256,257]. GpVI was shown to be an essential receptor[258], although incapable of eliciting procoagulant activity from platelets in suspension[259]. In contrast, the response was enhanced and partly dependent on $\alpha 2\beta 1$ in platelets adherent to collagen. Furthermore, inhibition of p38 MAP kinase reduced platelet blebbing, an event leading to procoagulant microvesiculation[259]. Previous work has shown a specific role for p38 MAP kinase in collagen-induced aggregation[260], and in other cells, p38 is thought to be activated by $\alpha 2\beta 1$ occupancy[261].

The limited evidence for direct signalling via $\alpha 2\beta 1$ may be explained if essential conformational changes in $\alpha 2\beta 1$ occur in adherent but not suspended platelets. $\alpha 2\beta 1$ signalling may also be dependent on accessory molecules. $\alpha 2\beta 1$ associates with co-receptors in other cell types, and in platelets $\alpha 2\beta 1$ has been suggested to co-exist with GpVI[262]. In platelets and other cells, $\beta 1$ integrins, CD36, GpIb/IX/V, activated lyn and uPAR also occur in cholesterol-rich membrane microdomains (although caveolin, often found in such structures, is absent)[263–265], which may prove to be sites for cooperative interaction between collagen receptors. Finally abnormal gangliosides from tumour cells or athero sclerotic plaques have been shown to enhance $\alpha 2\beta 1$ function[266,267].

Models for platelet–collagen interaction

Recent evidence has allowed the concept of the platelet–collagen interaction to develop from a two-site two-step process[52] into a multisite multistep model[8,145], implying that no single adhesion or activation receptor is responsible, but rather several receptors act in concert. This is reflected in the mild nature of bleeding disorders associated with single receptor deficiencies compared with those having several coinciding defects[63,268]. This also explains why collagen receptor polymorphisms may be difficult to associate with multifactorial diseases such as coronary thrombosis or stroke (see p. 160).

The detailed role of the various collagen receptors is beginning to emerge. Under high shear rate flow conditions, both the vWf–Ib/IX/V axis[269–271] and $\alpha 2\beta 1$ seem to be essential[78,143,272], although recent knock-out mouse data does not support this[*9]. The affinity of $\alpha 2\beta 1$ increases through adhesion-dependent platelet activation, and under those conditions, $\alpha 2\beta 1$ may elicit typical signalling reactions. GpVI, the major signalling receptor, unable to engage under flow conditions itself[146], may induce the high-affinity state of $\alpha 2\beta 1$[156]. CD36 is involved in very early platelet adhesion, but other receptors can compensate for its absence. Recently, TIIICBP was also shown to interact under high shear rate conditions as an early contact receptor with signalling capacity[145], and a similar pre-$\alpha 2\beta 1$-binding receptor was proposed for collagen type I[273].

The model in Fig. 11.5 suggests that as the platelet slows after vWf-Ib engagement, initial direct contact with colla-

Cambridge Books Online © Cambridge University Press, 2009

gen is by receptors such as TIIICBP or $\alpha2\beta1$, which are responsible for arrest of the platelet on the sub-endothelial collagen surface. This allows GpVI to be cross-linked to an extent that will support full-blown platelet activation and may also activate src-family kinases important for signal transmission through the GpVI-FcR γ-chain pathway. The resulting signals, or possibly even those from contact receptors, also transform $\alpha2\beta1$ into a high-affinity conformation. This final anchorage may then generate additional signal transduction, important for certain platelet responses such as procoagulant activity. The model does not take into account the various accessory co-receptors or molecules which may orchestrate and fine tune both platelet adhesion and activation.

Closing remarks

The complexity of platelet collagen receptor populations is matched by that of collagen, so to elucidate their interplay requires carefully defined experiment. Thus, flow studies using physiological cation concentrations and collagens in immobilized native form are required before a full understanding can emerge. Many discrepancies in the literature arise from the use of functionally dissimilar collagen preparations as platelet agonists.

The field is rapidly advancing. Since writing this chapter, novel collagen species have been described, and new studies on the comparative significance of receptors under flow have appeared. A better understanding is developing of collagen-induced signalling and the role of receptor polymorphisms in disease. Very recent references, marked in the text thus *, can be found at the end of the reference list.

Platelet receptors: von Willebrand factor

Jerry Ware and Zaverio M. Ruggeri

Division of Experimental Hemostasis and Thrombosis
Departments of Molecular and Experimental Medicine and of Vascular Biology
The Scripps Research Institute, La Jolla, CA, USA

Historical perspective and overview

For most bleeding disorders, the symptoms and clinical recognition of the disease occurred long before the biochemical characterization of the disease. A case in point is the description of von Willebrand disease by the Finnish physician Erik von Willebrand (ca. 1926) and the description of the Bernard–Soulier syndrome by French physicians, Jean Bernard and Jean-Pierre Soulier (ca. 1948). In both cases, decades would past before the molecular basis of the disease would define roles for von Willebrand factor (vWF) and the platelet receptor, glycoprotein (GP) Ib–IX–V, in hemostasis and thrombosis. Two-dimensional gel electrophoresis would associate an absent platelet glycoprotein in patients with the Bernard–Soulier syndrome[1]; while the molecular identity of vWF would not be unequivocally established until the gene was characterized and shown to be a distinct protein circulating in a complex with blood coagulation factor VIII[2–4].

The current models of platelet adhesion to the extracellular matrix involve a number of different ligands and platelet receptors coordinated in a synergistic response to correct a vascular lesion. Nevertheless, vWF and its platelet receptors represent a major component in this response and become the exclusive ligand and receptor interaction under blood flow conditions typically found in arterioles and small arteries. Thus, under certain conditions vWF-dependent thrombus formation is part of the synergistic response, yet under specific rheological conditions it becomes the sole ligand capable of initiating platelet deposition and thrombus growth.

The molecular mechanisms by which vWF participates in hemostasis can be viewed as an initial tethering of platelets to a reactive surface via the platelet GP Ib–IX–V receptor (Fig. 12.1). Through this transient and reversible interaction with vWF, platelets can become activated increasing the binding competency of the platelet integrin receptor GP IIb–IIIa ($\alpha_{IIb}\beta_3$). The combination of vWF interacting with both GP Ib–IX–V and $\alpha_{IIb}\beta_3$ results in stable and irreversible platelet attachment to the surface. Subsequently, the process can be repeated with the newly formed layer of platelets behaving as a reactive surface recruiting additional platelets and leading to thrombus growth. In this regard, the initial platelet adhesion and subsequent aggregation can both be viewed from a similar mechanistic standpoint, that is, both require platelet attachment to a reactive surface.

Although GP Ib–IX–V represents the primary adhesive platelet receptor for vWF, the role of $\alpha_{IIb}\beta_3$ in the sequence of events leading to thrombus formation should not be forgotten. A detailed description of $\alpha_{IIb}\beta_3$ can be found in Chapter 12, as it is the sole platelet receptor for fibrinogen. This chapter will focus on the structure and biological properties of the GP Ib–IX–V complex but will reference $\alpha_{IIb}\beta_3$ as it pertains to vWF-dependent thrombus formation (p. 183).

Structure

Table 12.1 summarizes the alternative nomenclature used for the subunits and genes encoding the GP Ib–IX–V complex. Most commonly, the subunits are referred to as GP Ib, GP IX and GP V (Fig. 12.1). The GP Ib molecule is actually composed of two disulfide-linked subunits, α and β (GP Ibα and GP Ibβ), both the products of separate genes. GP Ibα is the structurally and functionally dominant subunit of the complex (M_r, 145 000) and associates with

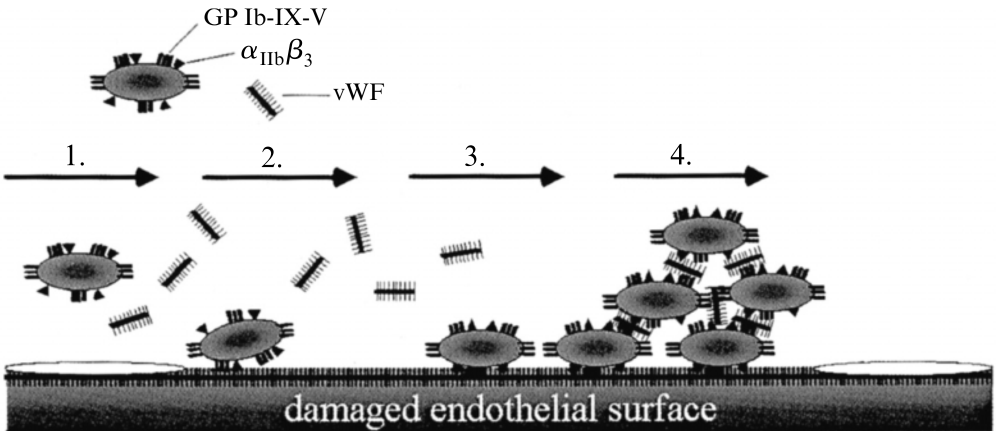

Fig. 12.1. Temporal events in vWF-dependent thrombus formation. In a regulated series of events, platelets will adhere to damaged endothelium and form a platelet thrombus. Depicted are a series of steps (1 to 4) representing a simplistic interpretation of the processes necessary to capture a platelet from flowing blood and build the platelet thrombus. (Step 1) A circulating platelet is traveling (left to right) and contains surface-expressed GP Ib–IX–V and GP IIb–IIIa ($\alpha_{IIb}\beta_3$) receptors. (Step 2) Via a transient and reversible interaction between platelet GP Ib–IX–V and von Willebrand factor (vWF), platelets will tether and move along the thrombogenic surface until the platelet undergoes activation. (Step 3) Upon activation the ligand binding competency of the $\alpha_{IIb}\beta_3$ receptor is increased leading to irreversible platelet adhesion. (Step 4) A subsequent repeat of steps 1–3 leads to the additional recruitment of platelets with the net effect of a growing thrombus on the thrombogenic surface. This figure illustrates the exclusive role of vWF and its receptors under flow conditions typically found in vessels with high shear rate, such as small arteries and arterioles. Under conditions when the blood flow rate is slower, vWF-dependent thrombus formation becomes part of a synergistic effort involving additional platelet receptors and ligands.

Table 12.1. Platelet von Willebrand factor receptors

GP receptor complex	Subunit composition	CD nomenclature	Genbank acc. number	HUGO[a] nomenclature	Chromosome location
GP Ib–IX–V	GP Ibα	CD42b	M22403	GP1BA	17pter–p12
	GP Ibβ	CD42c	Z23091	GP1BB	22q11.21–q11.23
	GP IX	CD42a	U07983	GP9	3q21
	GP V	CD42d	M80478	GP5	3q29
GP IIb–IIIa	GP IIb (αIIb)	CD41b	J02764,M34480	ITGA2B	17q21.32
	GP IIIa (β3)	CD61	J02703	ITGB3	17q21.32

Note:
[1] Human gene nomenclature http://www.gene.ucl.ac.uk/nomenclature]

GP Ibβ (M_r, 22000) and GP IX (M_r, 17000) in a 1: 1: 1 stoichiometry. GP V (M_r, 82000) associates with the GP Ib–IX complex in a 1:2 ratio (GP V: GP Ib–IX). The primary sequence of each of the four subunits has been quite revealing for identification of distinct domains, yet most characterizations of the complex have focused on GP Ibα since it contains binding sites for both vWF and α-thrombin (Fig. 12.2).

An amino-terminal 45 kDa domain of GP Ibα can be generated through limited tryptic digestion and retains vWF and α-thrombin binding properties[5–7]. A striking feature of the GP Ibα 45-kDa domain is the presence of seven leucine-rich repeats, which are found in a large number of seemingly unrelated proteins[8]. A single repeat is composed of 24 residues with leucines commonly found at positions 2, 5, 7, 12, 16, 21 and 24. Members of the leucine-rich repeat family have roles in signal transduction either as membrane receptors or as cytoplasmic signalling molecules[9]. The presence of a single leucine repeat in GP IX and GP Ibβ along with multiple repeats in GP V suggests the leucine-rich repeats may be critical for assembly and surface expression of the intact complex[10], a concept supported by mutations within the repeats of GP Ibα and GP IX which result in the Bernard–Soulier phenotype[11].

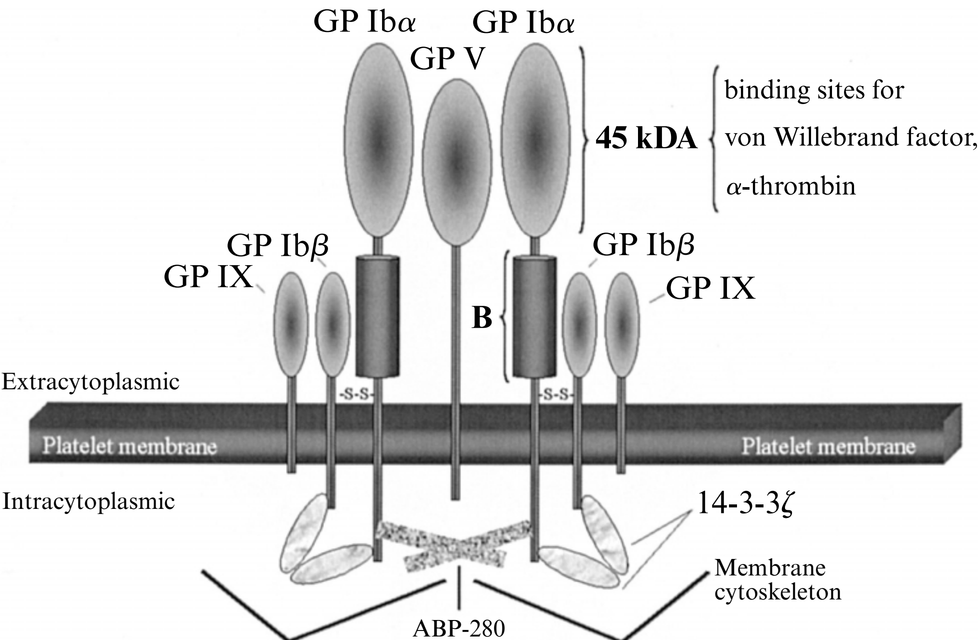

Fig. 12.2. The platelet GP Ib–IX–V complex. The GP Ib–IX–V complex exists on the platelet surface with a suggested stoichiometry of 2:2:2:1 (GP Ibα:GP Ibβ:GP IX:GPV). The α-subunit of GP Ib (GP Ibα) contains the ligand binding sites for vWF and α-thrombin within an amino-terminal 45 kDa domain. In addition, GP Ibα contains a large macroglycopeptide domain (*b*) that supports surface exposure of the α-subunit. Cytoplasmic interactions with the complex include ABP-280 (filamin) within the platelet membrane cytoskeleton and the 14-3-3ζ isoform of phospholipase A2. The three-dimensional structure of the complex or isolated domains of the complex have not been determined but the illustrated subunit sizes do correspond with their molecular weight contribution to the complex. The depicted diagram should be considered a conceptual cartoon of the GP Ib–IX–V complex.

The 45 kDa domain of GP Ibα can be functionally recapitulated via domain-specific expression of a secreted soluble receptor fragment[7,12]. This work has led to the identification of a series of negatively charged amino acids within the linear sequence of GP Ibα that are critical for vWF binding. Three tyrosine residues whose modification via a post-translational sulfation event also contribute to the negative charge of the linear sequence and are critical for binding to vWF[13,14].

The extracellular sequences of GP IX and GP Ibβ are similar to each other and are considerably smaller than GP Ibα. The lack of ligand binding sites within the extracellular sequences of either subunit seems to suggest their primary role in the complex is to support efficient intracellular assembly of the complex and translocation to the plasma membrane[15]. Each subunit of the GP Ib–IX–V complex has a single transmembrane domain. Recently, the cytoplasmic tails of GP Ibα and GP Ibβ have become areas of active research with the identification of a binding site for platelet phospholipase A2 (ζ-isoform of the 14–3–3 protein)[16,17]; filamin (actin-binding protein 280) binds the cytoplasmic tail of GP Ibα[18] and the biologic relevance of these interactions will be discussed below (p. 184).

A number of polymorphisms have been identified within the subunits of the GP Ib–IX–V complex. Most of the polymorphisms are associated with GP Ibα reflecting the more intense analysis and larger size of the GP Ibα gene. Most striking are the molecular weight variants visible by PAGE analysis which result from multiple replications of a 13-residue motif within the heavily glycosylated extracellular domain[19,20] (Fig. 12.2). A polymorphic amino acid, residue 145, within the 45 kDa domain of GP Ibα forms the basis for an alloantigen associated with platelet transfusion refractoriness[21,22].

Gene structure and expression

All four genes of the GP Ib–IX–V complex have a relatively simple organization with the majority of protein-encoding sequences present within a single exon. Detailed analysis for the promoters of GP Ibα and GP IX have been

Cambridge Books Online © Cambridge University Press, 2009

performed and have identified essential GATA-1 and Ets cis-acting elements within the core promoter of each gene[23,24]. These results have been confirmed in GATA-1 deficient mice which have a sevenfold reduction in GP Ibα gene expression and have supported the hypothesis that GATA and Ets binding sites are major regulatory elements for megakaryocytic-specific gene expression[25,26]. Also relevant to the expression of GP Ibα is a polymorphic Kozak sequence which can alter the levels of expressed GP Ib–IX–V complex. Circulating platelets with genetically predetermined levels of GP Ib–IX–V may influence an individual's susceptibility for the development of cardiovascular disease although population studies will be necessary to convincingly establish a correlation[27–29].

The expressed gene products of GP Ibα, GP Ibβ and GP IX assemble within the endoplasmic reticulum prior to being transported to the Golgi and the cell surface[30]. The role of GP Ibβ and GP IX in this process is to direct GP Ibα away from lysosomal degradation pathway and protect it from proteolysis[30]. This observation provides a mechanistic basis for how mutations within either the GP Ibβ or GP IX genes can abrogate the functional surface expression of the GP Ibα subunit. Of note, GP V is not a required component for assembly and expression of a GP Ib–IX complex[15], but may regulate the ability of a GP Ib–IX or GP Ib–IX–V complex to bind vWF[31,32]. The absence of mouse GP V within the murine GP Ib–IX–V complex does not result in a murine Bernard–Soulier syndrome, nor have mutations within the human GP V gene been associated with the Bernard–Soulier phenotype[33,34]. Thus, the physiologic relevance of GP V expression is not obvious and remains to be established. However, as a known thrombin substrate, GP V may contribute in the platelet response to thrombin[33,35].

A source of great confusion is the possibility of GP Ib–IX–V gene expression in cells of nonhematopoietic lineage. In particular, several reports from the same laboratory have identified an expressed GP Ib–IX complex on cultured endothelial cells[36–39], but these studies have not proposed an in vivo consequence of expression at these nonhematopoietic sites. However, the in vitro expression of GP Ib–IX by cultured endothelial cells is not without controversy, as others have reported an inability to identify a GP Ib–IX complex on cultured endothelial cells[40]. Moreover, in vivo studies of murine endothelial cells have failed to identify an endothelial GP Ib–IX–V complex[41]. What is clear is vWF can bind to endothelial cells via the integrin receptor, $\alpha_v\beta_3$ (40), or by electrostatic charges presented by glycosaminoglycans on the endothelial cell surface[42].

Congenital deficiencies

The Bernard–Soulier syndrome

Although rare, this congenital disease may be severe with life-threatening bleeding episodes occurring from early childhood[11]. The bleeding is caused by an absent or dysfunctional GP Ib–IX–V complex and is clinically characterized by an inability of platelets to agglutinate in the presence of ristocetin and macrothrombocytopenia. The Bernard–Soulier syndrome is inherited as an autosomal recessive trait and is associated with a growing database of heterogeneous mutations within GP Ibα, GP Ibβ and GP IX [http://www.bernard–soulier.org/]. Overall, the published studies have supported a concept that the syndrome parallels congenital abnormalities in other multisubunit receptor complexes, to the extent that a single subunit prevents assembly and surface expression of the entire complex. A mouse model of the Bernard–Soulier syndrome recapitulates all of the known characteristics of the human syndrome[43]. There is a limited number of missense mutations which do not abrogate the surface expression of the complex but still result in a dysfunctional GP Ib–IX–V receptor. How these variant complexes generate macrothrombocytopenia is still unclear, but is assumed to be related to the expression of a structurally abnormal GP Ib–IX–V complex.

Platelet-type von Willebrand disease

Nature has provided two bleeding disorders resulting in an altered affinity between vWF and platelet GP Ib–IX–V. The disease states, platelet type von Willebrand disease and type 2B von Willebrand disease, are abnormalities within the receptor or the ligand, respectively. Both result from missense mutations resulting in variant proteins capable of supporting an in vivo interaction between plasma vWF and platelets. In both cases, there is sufficient affinity to promote intravascular clumping, thrombocytopenia and a resulting bleeding disorder. These disorders have been model examples of mechanisms that regulate the interaction of vWF with GP Ib–IX–V. To date, two different mutations have been described that result in platelet-type von Willebrand disease and both reside within a limited region of GP Ibα[44]. It remains to be established which amino acids of vWF or GP Ibα are in direct contact with each other, but current hypotheses suggest that the phenotype in type 2B von Willebrand disease is due to amino acid substitutions which expose an otherwise cryptic binding site within the domain of vWF binding to GP Ib–IX–V[45]. A similar model for platelet-type von Willebrand disease would be that

Cambridge Books Online © Cambridge University Press, 2009

alterations in the receptor are able to interact with a normally cryptic binding site within the ligand. Both platelet-type von Willebrand disease and type 2B von Willebrand disease are two excellent experimental models to understand the physiologic events that regulate the interaction of platelets with vWF.

Biologic function

Ligand binding – vWF

To mediate platelet adhesion and aggregation during thrombus formation platelets must form stable bonds with components of the extracellular matrix (adhesion) or with other platelets (aggregation). For both adhesion and aggregation to occur, the platelet must adhere to a reactive surface and resist the force of flowing blood that would move the platelet further through the bloodstream[46]. To achieve this biological function platelets have two receptors recognizing vWF, the GP Ib–IX–V complex and the integrin $\alpha_{IIb}\beta_3$[47,48]. In the case of vWF binding to platelet receptors a model has emerged in which the GP Ib–IX–V complex and $\alpha_{IIb}\beta_3$ synergistically function in a temporal sequence of events[49]. A transient tethering of platelets to a thrombogenic surface requires the GP Ib–IX–V complex and results in reversible adhesion[50]. During this transient interaction the $\alpha_{IIb}\beta_3$ receptor may become activated resulting in the stable arrest of the platelet from flowing blood[46,51]. The same process can be repeated to capture flowing platelets onto the surface created by the already adherent platelets. The net result is a thrombus formed by platelet aggregates. Fibrinogen contributes to the stabilization of the forming thrombus, even under conditions where vWF was responsible for the initiation of platelet recruitment[46,52].

A number of experimental models have been developed to analyse the interaction of vWF with platelets. Historically, the use of the antibiotic ristocetin or the snake venom protein, botrocetin[53], have been widely used with stirred platelets in the aggregometer. In the stirred aggregometer, soluble vWF supports platelet–platelet interactions mediated exclusively through GP Ib–IX–V and not dependent upon the $\alpha_{IIb}\beta_3$ receptor. Alternatively, an agonist independent method of platelet aggregation can be demonstrated with soluble vWF and platelets in conditions generating high shear stress, but this event occurs only during high-shear and requires platelet activation and engagement of $\alpha_{IIb}\beta_3$[54]. In contrast, recently developed in vitro models of thrombus formation in flowing blood have documented surface-bound vWF as the exclusive ligand when flow conditions mimic those commonly found in arterioles or small arteries. The vWF-dependent mechanisms that support platelet tethering and irreversible platelet attachment in the presence of flow, can also function in the absence of flow[48]. However, in vivo this latter process is part of a synergistic response involving a number of different collagen platelet receptors and $\alpha_{IIb}\beta_3$ binding to fibrinogen. Thus, under these parameters the contribution of vWF is less obvious. Relative to future work, it is imperative that conclusions be referenced to the specific experimental assay, as the choice of modulator, chemical or mechanical, influences the relevance of the conclusion to in vivo platelet function.

Ligand binding – thrombin

Thrombin binding to GP Ib is well documented although the relevance of this binding and its contribution to the thrombin activation of platelets is more controversial. The identification of GP Ib as a thrombin binding site on the platelet surface predates the characterization of the platelet protease-activated receptors (PAR-1 and PAR-4)[55,56]. Originally characterized as the high-affinity platelet binding receptor for thrombin[57], later studies have shed doubt as to whether GP Ib should be considered the high-affinity thrombin binding site on platelets[58] and whether other factors, such as temperature, platelet–platelet interactions, internalization of the receptor or the inclusion of GP V into the complex can contribute to the formation of a high affinity binding site[33,59]. Regardless of these controversies, the 45 kDa amino-terminal domain of GP Ibα does contain a discrete linear amino acid sequence with homologies to other thrombin binding proteins, such as hirudin and the PARs, functioning as a distinct thrombin binding site[14,60,61]. A number of different reagents recognizing this linear sequence, such as monoclonal antibodies and the snake lectin echicetin, block thrombin binding to GP Ib and have provided the definitive proof of the receptor's thrombin binding properties[6].

A fundamental difference in thrombin binding to GP Ib vs. binding to the platelet PARs, is that GP Ib is not cleaved by the bound thrombin, whereas thrombin binding to PARs is associated with proteolytic cleavage and platelet activation (see Chapter 8). The PARs are important for thrombin-induced platelet activation, but a role for GP Ib is suggested in the initial stages of hemostasis when sub-optimal levels of thrombin are present[61]. Thrombin binding to GP Ib may also generate a procoagulant environment on the platelet surface as suggested by studies documenting the ability of monoclonal antibodies which block thrombin binding to GP Ib, to also inhibit annexin V

Cambridge Books Online © Cambridge University Press, 2009

binding to the platelet, one characteristic of a procoagulant membrane[62]. Thus, thrombin binding to GP Ib may generate an outer platelet membrane surface with procoagulant activity where prothrombin is cleaved by factor Xa to thrombin. Again, the molecular mechanisms are unresolved, but these observations are intriguing and may provide some hint for the physiologic relevance of thrombin binding to the GP Ib–IX–V complex.

Cytoplasmic interactions

The cytoplasmic domains on the α- and β-subunits of GP Ib associate with a number of intracytoplasmic molecules and presumably contribute to some undefined signalling pathways leading to integrin activation. One candidate element is a member of the 14–3–3 family of protein, specifically the ζ-isoform, 14–3–3ζ[63]. A binding site for 14–3–3ζ is located in the carboxyl-terminus of GP Ibα and the binding is regulated by phosphorylation of GP Ibα at serine[609 64]. The expression of a GP Ib–IX lacking the 14–3–3ζ binding site within GP Ibα reduces $\alpha_{IIb}\beta_3$ activation, a result confirmed by a 14–3–3ζ dominant-negative mutant's ability to inhibit vWF-induced integrin activation[65,66]. GP Ibβ also contributes to the binding of 14–3–3ζ and this binding is regulated by protein kinase A[17,67]. Binding sites on both GP Ibα and GP Ibβ may reflect the fact that dimeric 14–3–3ζ interacts with both subunits of GP Ib[67]. A model for the importance of 14–3–3ζ binding to GP Ib is based on the release of 14–3–3ζ from GP Ib which coincides with the ability of platelets to aggregate in the shear aggregometer. Moreover, blocking 14–3–3ζ release from the tail of GP Ib is associated with the inhibition of aggregation[67]. Thus, signalling through the cytoplasmic tail of GP Ib seems plausible given the candidate interactions with known signalling molecules, but the downstream effectors that ultimately affect integrin activation have not been identified.

A second critical interaction site within the GP Ibα cytoplasmic tail is a region binding to filamin (also called actin binding protein or ABP-280). This interaction cross-links GP Ib–IX–V to actin filaments within the plasma membrane cytoskeleton. The interaction of GP Ib–IX–V with the membrane skeleton may have an important role in regulating vWF/GP Ib–IX–V interaction. Recent studies have demonstrated that pretreating platelets with cytochalasin D enhances shear-induced platelet aggregation and reduces the threshold required for platelet aggregation[68,69]. Moreover, Chinese hamster ovary cells with surface-expressed mutant complexes have also demonstrated the linkage between the GP Ibα and filamin is critical for the cytochalasin effect on GP Ib–IX–V mediated aggregation[68].

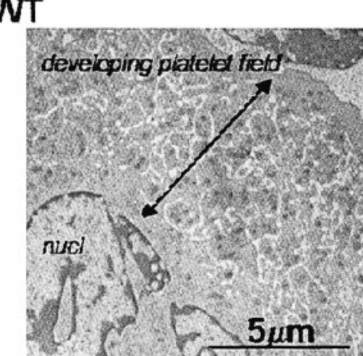
Platelets and inflammation of the endothelium

The platelet–subendothelial interaction via vWF is well established. However, recent studies have demonstrated a role for platelet GP Ibα in platelet–endothelium interaction in veins[42]. In normal conditions platelets do not interact with the endothelium. However, during inflammation platelets can adhere to the activated endothelial surface. Studies have suggested GP Ibα may be a counterreceptor for P-selectin and potentially mediate platelet rolling on the stimulated endothelium[70]. In vivo studies have documented rolling platelets on activated endothelium via a process that is dependent upon platelet GP Ibα and vWF[42]. The physiological relevance of this interaction is that it could cause platelet activation, which in turn generates a wide variety of platelet responses and potentially leads to venous thrombosis. Additional studies may help clarify the physiologic impact of platelet GP Ibα interactions with the intact endothelial surface.

Megakaryocytopoiesis

Beyond its direct participation in platelet adhesive functions, the GP Ib–IX–V complex also participates in megakaryocytopoiesis and platelet morphogenesis. The congenital absence of GP Ib–IX–V produces a 'giant' platelet phenotype. A mouse model of the Bernard–Soulier syndrome has provided proof of principle with a direct link between the absent receptor and impaired megakaryocytopoiesis[43]. The results demonstrate that in the absence of a GP Ib–IX–V complex the mature megakaryocyte fails to develop a normal demarcation membrane system or display developing platelet fields in the cytoplasm (Fig. 12.3). A disordered membrane system in the absence of GP Ib–IX–V alters the normal platelet release from the megakaryocyte and results in a mild thrombocytopenia with 'giant' platelets, or macrothrombocytopenia. The molecular basis for the abnormal megakaryocytopoiesis may be linked to the cytoplasmic interactions between the GP Ibα subunit and components of the platelet membrane cytoskeleton, but may also be influenced by extracytoplasmic components of the complex as antibodies to GP Ib–IX can alter proplatelet formation in vitro[71]. Moreover, there is in vitro evidence that the expression of GP Ib–IX–V in heterologous cells can affect cell proliferation and by analogy might also regulate megakaryocyte growth[72]. Future studies will have to define the molecular basis of the aberrant megakaryocyte morphology and the subsequent impairment of normal platelet release from the mature megakaryocyte.

Cambridge Books Online © Cambridge University Press, 2009



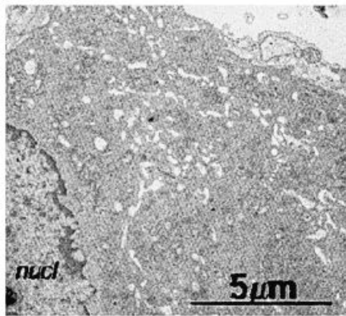


Fig. 12.3. Transmission electron microscopy of megakaryocytes devoid of platelet GP Ibα. Bone marrow from mouse femurs was isolated and prepped for transmission electron microscropy. Shown is a portion of mature megakaryocyte cytoplasm from a normal mouse (WT) and a GP Ibα-deficient mouse (GP Ibα^{null}). Nuclear material is shown (*nucl*) along with a developing platelet field and demarcation membrane system in the normal megakaryocyte cytoplasm. GP Ibα-deficient animals have mature megakaryocytes devoid of a normal developing platelet field and display a vacuolated or disordered demarcation membrane system ultimately leading to the characteristic macrothrombocytopenia of the Bernard–Soulier syndrome[43]. Conclusions

Several broad areas of work on the GP Ib–IX–V complex have the potential to provide some exciting results in the new millennium. First, will be a dissection of the molecular mechanisms whereby the complex participates in platelet activation. We have outlined studies highlighting the potential regulatory mechanisms that control vWF binding and, as such, generate both stimulatory and inhibitory intracellular platelet signals. Understanding these mechanisms may provide novel methods for manipulating platelet function in vivo. Secondly, will be further analysis on the role of the GP Ib–IX–V complex in megakaryocytopoiesis. The mechanisms that control platelet release from the mature megakaryocyte are still poorly defined. The observation that lack of a GP Ib–IX–V complex alters normal platelet release provides a starting point to use animal models to further define the mechanisms controlling this process. Thirdly, will be studies determining the three-dimensional structure of components of the GP Ib–IX–V complex. The crystal structure of the vWF domain interacting with GP Ib–IX–V has been solved, so the next logical step will be a determination of the receptor's structure or the determination of a receptor/ligand complex. Finally, the development of antithrombotics inhibiting the vWF/GP Ib–IX–V axis may have some surprising benefits over the currently used therapies. Conceptually, targeting a receptor functioning in the initial platelet response may provide a highly controlled inhibition of arterial thrombus formation with a reduced risk for spontaneous venous bleeding. When completed, these outlined studies will provide a highly detailed molecular map initiated by those astute observations of Erik von Willebrand, Jean Bernard and Jean-Pierre Soulier.

Platelet receptors: fibrinogen

Edward F. Plow, Thomas A. Haas and Tatiana V. Byzova

Joseph J. Jacobs Center for Thrombosis and Vascular Biology

Department of Molecular Cardiology, Cleveland Clinic Foundation, Ohio, USA

Introduction and historic perspectives

Scientists have always been intrigued by the highly visible reactions. Hence, platelet aggregation and fibrin deposition, the key events in one of the most visually dramatic of biological reactions, thrombus formation, have been the subject of intensive scrutiny for many decades. Evidence for an interplay between these key components of the thrombus had already begun to evolve in the early 1960s[1–3]. Platelets in plasma derived from patients with afibrinogenemia failed to aggregate or aggregated poorly when stimulated with ADP or epinephrine, but a robust aggregation response occurred upon addition of fibrinogen to the plasma. These observations also were documented in artificially defibrinated and reconstituted plasma[4]. In the 1970s, as investigators became adept at isolating functional platelets, the role of fibrinogen in platelet aggregation was corroborated; and the requirements for an agonist, a divalent cation and fibrinogen to support the aggregation response was documented[5–7]. By the late 1970s, formal studies, utilizing approaches developed to examine hormone–receptor interactions, to measure the direct interaction of fibrinogen with platelets, were under way[6,8,9]. Thus, in the early 1980s, results from multiple laboratories had documented that platelets expressed fibrinogen receptors, capable of binding this plasma protein in a specific and saturable manner[10–15]. Furthermore, an important functional response, platelet aggregation, could be ascribed to the binding of fibrinogen to the platelet surface.

The identity of the surface molecule mediating fibrinogen binding to platelets emerged soon thereafter although its history began much earlier. In the early 1900s the Swiss physician, Glanzmann, had described a group of patients with a bleeding syndrome whose platelets failed to aggregate[16]. Nurden and Caen[17,18] were among the first to use gel electrophoresis to analyse the membrane proteins of platelets from patients defective in function and Phillips and Agin[19] demonstrated that two protein bands were missing from the membranes of platelets from patients with Glanzmann's thrombasthenia. Based upon their electrophoretic mobilities, these bands were II and III, and ultimately GPIIb and GPIIIa[20]. The failure of thrombasthenic platelets to bind fibrinogen[8,21,22], the ability of monoclonal antibodies to the GPIIb–IIIa complex to block fibrinogen binding to platelets and induce a thrombasthenic-like state[23], and the ability of isolated GPIIb–IIIa to bind fibrinogen[24–26] completed the circuit: platelet membrane glycoprotein GPIIb–IIIa served as a fibrinogen receptor on platelets and occupancy of this receptor was necessary for platelet aggregation.

Since the 1980s, the interaction of fibrinogen with platelets has remained the topic of extensive investigations. In 1980–2001, the number of citations dealing with fibrinogen and platelets totalled more than 3600 (PubMed search). The impetus for this extensive interest in this interaction comes from many directions. First, the capacity of platelets to aggregate is a central function of these cells. While we now appreciate that GPIIb–IIIa serves as a receptor for other adhesive proteins[27], and these interactions are of clear importance in platelet adhesion and aggregation, fibrinogen recognition plays a pivotal role in hemostatic and thrombotic responses of platelets. Secondly, the interaction of fibrinogen with GPIIb–IIIa served as a prototype for the analyses of other ligand interactions with platelets and for adhesive ligand interactions with receptors on many other cell types. By the mid-1980s, it was apparent that GPIIb–IIIa was a member of a growing family of structurally, immunochemically and functionally related heterodimeric adhesion receptors[28–30], which we now term the integrins[31,32]. In integrin nomenclature, GPIIb–IIIa is αIIbβ3, and this designation will be used

throughout. The ready availability of large quantities of platelets and, consequently, the capacity to isolate relatively large quantities of αIIbβ3 provided insights into integrin structure and function[33,34] that have been broadly applicable. Many of the paradigms regarding integrins, including their roles as signalling receptors, evolved from studies of αIIbβ3[35–38]. Thirdly, interference with fibrinogen binding to αIIbβ3 and its functional consequence, platelet aggregation, became the target of an intense and ultimately successful therapeutic strategy for development of antithrombotic agents to treat acute coronary syndromes and prevent the complications of cardiovascular interventions. Three such GPIIb–IIIa antagonists have been approved by the FDA in the United States, and well over 100 000 patients have been treated with these drugs[39–41].

This chapter considers the fibrinogen receptors on platelets. Therefore, predicated on the historical synopsis above, the major emphasis will be on the interaction of fibrinogen with αIIbβ3. Relevant related chapters in this volume include the contributions by Tomiyama et al. on platelet membrane proteins (Chapter 5), Ware and Ruggeri on von Willebrand factor receptors (Chapter 12) and Phillips on GPIIb–IIIa antagonists (Chapter 63). However, αIIbβ3 is not the sole mediator of fibrinogen binding to the platelet surface. Two other integrins expressed by platelets, αvβ3 and α5β1, can interact with fibrinogen. In addition, still other mechanisms exist for fibrin(ogen) to interact with the platelet surface. These αIIbβ3-independent interactions will also be considered briefly.

Platelet fibrinogen receptors: αIIbβ3

Structure of αIIbβ3

This brief consideration of the structure of αIIbβ3 emphasizes the properties that are relevant to its function as a fibrinogen receptor. Detailed reviews of the structure of αIIbβ3 can be found in the following citations[42–46] as well as in other chapters in the volume. The cellular distribution of αIIbβ3 is restricted primarily to platelets and megakaryocytes. Certain tumour cells also have been reported to express authentic αIIbβ3[47,48]. On the platelet surface, it is present at ~40 000 – 80 000 copies per cell[49,50]. This number approximates the number of fibrinogen binding sites on the surface of normal platelets[8], and it is generally accepted that each αIIbβ3 can function as a fibrinogen receptor. In addition, an intracellular pool of αIIbβ3 exists within the membranes of platelet α-granules and can become expressed at the platelet surface in association with the secretory reaction[51,52]. Thus, platelet stimulation leading to secretion can increase the number of functional fibrinogen receptors by about 30–50%[53]. Rapid shuttling of αIIbβ3 between the cell surface and an intracellular pool has been observed, and may be involved in the import of fibrinogen into α-granules[54]. Platelets from patients with Glanzmann's thrombasthenia lack functional αIIbβ3 and have reduced levels of fibrinogen within their α-granules[55]. This observation, together with the inability of human megakaryocytes to synthesize fibrinogen, as well as more direct experimental evidence indicating that platelets and megakaryocytes can internalize extracellular proteins[56–58], suggests that αIIbβ3 is involved in the transport of fibrinogen into platelet and/or megakaryocyte α-granules. Thus, α-granules contain both the ligand, fibrinogen, and the receptor, αIIbβ3; and there is evidence to suggest that these may, in part, be exported to the platelet surface as a preformed complex, capable of mediating platelet aggregation[59].

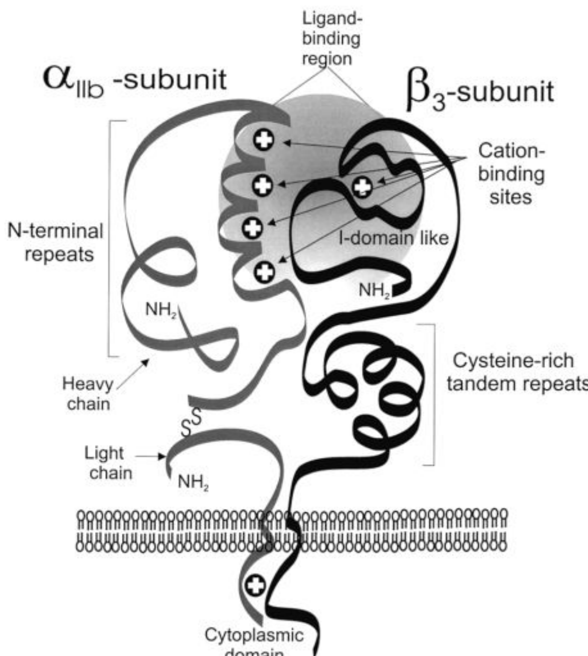

Fig. 13.1. Schematic model of integrin αIIbβ3 (adapted from ref. 40).

A schematic model of αIIbβ3 is displayed in Fig. 13.1. αIIbβ3 is a typical member of the integrin family of adhesion receptors[31,60]. As such, it is a non-covalent heterodimer composed of an alpha subunit (αIIb, GPIIb) and a beta subunit (β3,GPIIIa). Calcium is necessary to maintain αIIbβ3 as a heterodimer[61–65], explaining one of the roles of divalent cations in fibrinogen binding to this receptor. Each subunit is oriented with its N-terminus in the extracellular environment and its C-terminus within the platelet cytosol,

i.e. a Type I membrane protein orientation. Each subunit is composed of a short cytoplasmic 'tail', a single transmembrane domain, and a large and glycolysated extracellular region. Based upon their electrophoretic mobility on polyacrylamide gel electrophoresis in sodium dodecylsulfate, the estimated molecular weight of αIIb is ~130 kDa and of β3 is ~95 kDa[20,66]. Mature αIIb is composed of 1108 amino acids[67,68]. Upon reduction, it separates into a heavy chain of 115 kDa and a light chain of 25 kDa. The heavy chain is entirely extracellular while the light chain contains the cytoplasmic tail and the membrane spanning region. The N-terminal aspect of the αIIb heavy chain consists of seven homologous repeating segments of ~50 amino acids, which are predicted to fold into a β-propeller-like structure[69], such as found in G-proteins. Also present in the mid-region of the αIIb heavy chain are four putative cation binding motifs of 12 amino acids, which have the spacing of oxygenated amino acids to resemble EF-hand-like structures[68], Ca^{2+} binding motifs such as is found in calmodulin. Cations are required for the binding of adhesive ligands to αIIbβ3[8,13] and are also necessary to maintain the non-covalent association between its subunits[61,62,65]. The cytoplasmic tail of αIIb is very short (21 amino acids) and contains a high-affinity cation binding site at its C-terminus[70]. Recent structural analyses by NMR suggest that this cytoplasmic tail may be composed of a short α-helix in its membrane proximal region followed by a bend which allows the C-terminus to interact with the helical region[71]. The mature β3 subunit is 762 amino acids long, and about 90% of this sequence is extracellular. A dominant feature of this subunit is a long disulfide loop, which links its N-terminal aspects to its mid-section[34,72]. The mid-segment of β3 (~90–400) and other integrin beta subunits may fold into an I-domain-like structure composed of 5–6 α-helices and a similar number of β-strands[43,73–76]. I (also referred to as A) domains are found in several integrin alpha subunits (not in αIIb) as well as several other proteins[43,77,78]. They contain a unique cation binding motif, a metal ion-dependent adhesion site (MIDAS) motif, in which non-contiguous amino acids coordinate the cation[43,73,77,79]. It is likely that the β3 subunit also contains a MIDAS motif. Not only the mid-segment but also the remainder of the C-terminus of the extracellular domain is highly conserved among integrin beta subunits. This region is composed of four cysteine-rich tandem repeats of about 40 amino acids, which renders this region resistant to proteolysis[74.80]. A single transmembrane segment is followed by a cytoplasmic tail of fewer than 50 amino acids. Within this tail are tyrosine[81,82] and threonine[83,84] phosphorylation sites and a NPLY sequence[85], which imparts a tight β-turn to the tail[86]. The extracellular regions of the αIIb and β3 subunits interact to form the extracellular domain which mediates the binding of fibrinogen and other ligands to the receptor. In addition, the cytoplasmic tails of the αIIb and β3 subunits also appear to interact with each other to form a cytoplasmic domain[70,87,88], which regulates αIIbβ3 activation, signalling and interaction of the receptor with the platelet cytoskeleton and with the signalling machinery of the cell.

Multiple approaches have been implemented to identify regions and sequences within αIIbβ3 that are involved in ligand recognition. These have included various crosslinking approaches using intact fibrinogen[89,90] as well as its recognition peptides[91–93]; identification of point mutations that inactivate the function of αIIbβ3 in thrombasthenic patients[94–100]; site-directed mutagenesis of single residues or small segments of the molecule[80,101]; and expression and functional characterization of recombinant fragments of the receptor[102,103] and its subunits[104–106]. All approaches have yielded valuable information regarding the structure–functional relationships for ligand recognition by αIIbβ3. However, an overall understanding of where and how fibrinogen binds to αIIbβ3 remains uncertain, and high resolution structures by NMR or crystallography appear to be necessary for ultimate clarification. To provide a brief synopsis of the existing information, both subunits appear to contain contact sites for ligand[107,108], and their complex is necessary for high affinity binding of fibrinogen[26,64]. The ligand binding site appears to reside in the N-terminal half of the αIIbβ3 complex. Within the αIIb subunit, the N-terminal region, residues 1–400, imparts the specificity to αIIbβ3 that distinguishes it from its sister receptor, αvβ3[109], which shares the same β3 subunit. This region contains the seven N-terminal repeats, which form the putative β-propeller, and the four EF-hand-like cation binding domains[46] (see Fig. 13.1). Various point mutations that inactivate ligand binding to integrins cluster on spatially contiguous segments of the blades of the β-propeller[69,101,110,111]. Expression of the four EF-hand-like motifs leads to a recombinant fragment with fibrinogen and cation binding properties[104], but this segment does not establish the specificity of the receptor for fibrinogen[112]. The fibrinogen γ-chain peptide also cross-links within this region[93], and peptides from within the region exhibit fibrinogen binding properties[113,114]. Within the β3 subunit, the mid-segment extending from residues 95–400 is strongly implicated in the ligand binding function of the receptor (although certain antibodies reactive with the more N-terminal aspects of the receptor can also be function blocking[115,116]). This region corresponds to the putative I-domain in the β3 subunit and contains the predicted MIDAS motif[43]. Several naturally occurring and site-directed mutations that inactivate αIIbβ3 reside within this

Cambridge Books Online © Cambridge University Press, 2009

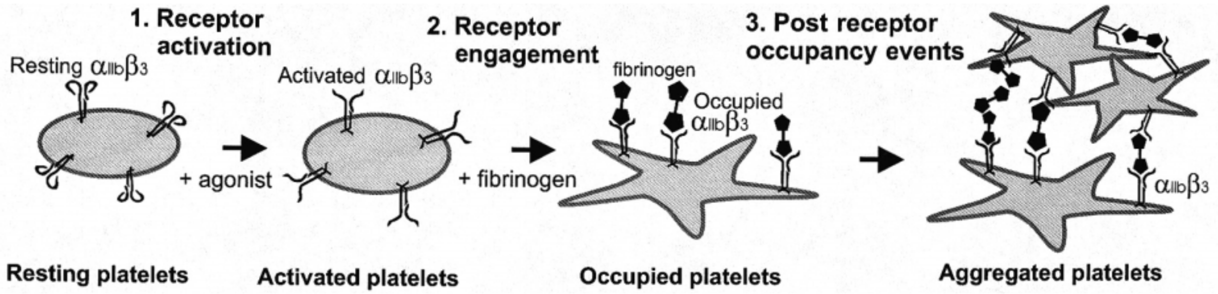

Fig. 13.2. Sequential events associated with fibrinogen binding to αIIbβ3 on platelets.

mid-segment. RGD peptides cross-link within the region of both αIIbβ3[117]and αvβ3[118]. This region also contains sequences which determine the ligand specificity of other integrins[119] and mediate recognition of monoclonal antibodies that alter the function, both activating and inhibitory, of their integrins[120], including ones to αIIbβ3[121]. Peptides containing key residues of the MIDAS domain can bind both cation and ligand in a mutually exclusive manner[122], and mutation of the cation coordinating residues within the MIDAS inhibit ligand binding[80]. Fibrinogen and RGD peptides also can bind to recombinant fragments from this β3 mid-segment[105,106]. While most attention has been focused on these two regions of the αIIb and β3 subunits, regions outside these segments can also influence receptor function. Mutations within other sites within the extracellular domain of αIIbβ3[123] and within each of the cytoplasmic tails can alter the activation states of the receptor, rendering it constitutively active or incapable of activation[124–128].

Interaction of fibrinogen with αIIbβ3: a multistep reaction

From early studies of fibrinogen binding to platelets, it became apparent that the interaction could be dissected into a series of distinct steps[13,129–131]. These steps are identified as: (i) receptor activation or induction, the process by which αIIbβ3 is transformed into a competent fibrinogen receptor; (ii) fibrinogen engagement, the reversible interaction of fibrinogen with αIIbβ3; and (iii) the postreceptor occupancy events, including the transition of fibrinogen from a reversibly to an irreversibly bound state and the intracellular signalling events initiated by αIIbβ3 occupancy. These steps are discussed separately below.

Receptor activation

Circulating platelets express αIIbβ3 at high density on their surface and are exposed to the μM concentrations of fibrinogen in blood, well in excess of the affinity of their interaction, yet the receptor does not become saturated or even minimally occupied by ligand. The reaction between fibrinogen and αIIbβ3 is tightly controlled, perhaps one of the most remarkable examples of such tight receptor regulation. This regulation is dependent upon the capacity of αIIbβ3 to transit from a resting state in which it recognizes fibrinogen with very low affinity to an activated state in which it functions as a competent receptor for the ligand. This transition must be very rapid to limit blood loss at sites of vascular injury. Thus, the first step in the sequence of events leading to engagement of αIIbβ3 by fibrinogen is receptor activation (see Fig. 13.2). This transition of αIIbβ3 from a resting to an activated state is induced by stimulation of platelets with any one of several physiological agonists. Platelet agonists that support this transition include ADP, epinephrine, thrombin, vWF, collagen, and certain arachidonic acid metabolites. Certain of these agonists (ADP, vWF and thromboxanes) are produced and released from the platelets themselves, thereby perpetuating or accelerating the activation process. Others (collagen and vWF) are the matrix proteins which mediate the initial adhesion of platelets to sites of vascular damage and, thereby, can trigger thrombus formation at these sites. While these agonists are quite distinct from one another in structure, they share the capacity to interact with receptors on the platelet surface that are capable of transducing intracellular signalling events within the cell. These ligands and their receptors are the subjects of Chapters 8–12 in this volume. Ultimately, these intracellular signalling events converge on the cytoplasmic domain of αIIbβ3 and elicit activation of the receptor. The process by which these intracellular signals are transmitted from within the cell to activate the ligand binding site within the extracellular domain is referred to as inside-out signalling[37,132]. The most proximal and specific event that activates at the cytoplasmic tails of αIIbβ3 remains to be clearly defined and could entail the association of an activator or the

Cambridge Books Online © Cambridge University Press, 2009

dissociation of an inhibitor from the cytoplasmic tails of the receptor[133]. Yeast two-hybrid screening approaches using the cytoplasmic tail of either αIIb or β3 as a bait have identified several candidate regulatory molecules[134–136] but the physiological role of any of these remains uncertain at this time. Changes in the linkages of αIIbβ3 to the platelet cytoskeleton have been strongly implicated as a possible regulator of receptor activation[86,137,138]. Phosphorylation events are common mechanisms for receptor activation. Both threonine[83,84] and tyrosine[81,82] phosphorylations occur in the cytoplasmic tail of the β3 subunit; however, these modifications appear to occur as a consequence of fibrinogen binding to αIIbβ3 and are viewed as being more involved in the transmission of outside-in signalling events rather than in receptor activation[81].

Within the context of αIIbβ3 *per se*, there are two potential mechanisms for enhancing its ligand recognition capabilities. These processes are referred to avidity or affinity modulation. Avidity modulation depends upon the clustering of receptors within the membrane so as to increase their local concentration and, thereby, drive the recognition of multivalent ligands, such as fibrinogen. Accordingly, redistribution of αIIbβ3 on the platelet membrane would be the controlling event for activation of its fibrinogen binding capacity. Redistribution of αIIbβ3 has been demonstrated by electron microscopy on the surface of adherent and spreading platelets[139–142]; and clustering of αIIbβ3 by artificial means can result in fibrinogen binding to the receptor[143]. Moreover, avidity modulation appears to be an important mechanism for integrin activation, particularly for members of the β2 subfamily[144]. Nevertheless, most data indicate that affinity modulation is the major mechanism for conversion of αIIbβ3 to a competent fibrinogen receptor. Affinity modulation depends upon an intrinsic change in the individual receptors to enhance their affinity for ligand. In the case of αIIbβ3, this is achieved by the transmission of a conformational change, initiated within the cytoplasmic domain of the receptor, across the platelet membrane to the ligand recognition site in the extracellular domain to render it competent to bind fibrinogen. Several experimental lines of evidence have been developed to demonstrate that αIIbβ3 can exist in different conformational states and can bind a soluble, monovalent ligand, indicative of affinity modulation[145,146]. Furthermore, αIIbβ3 can be isolated in a resting state[147–150], and its ligand binding function can be activated under conditions where receptor density remains constant. Nevertheless, combinations of avidity and affinity modulations may both contribute to fibrinogen binding[143].

Fibrinogen engagement

The binding of fibrinogen to activated αIIbβ3 on platelets is divalent cation-dependent and is optimally supported by millimolar calcium or magnesium concentrations[8,13]. Initially, this interaction fulfills the characteristics of true equilibrium binding. It is fully reversible and can be described by simple on and off rate constants and a dissociation constant[129,151]. The K_d of the interaction is ~300 nmol/l[8,13]. The number of fibrinogen molecules bound per platelet mirrors the number of αIIbβ3 molecules on the cell surface. Thus, 40 000 to 80 000 fibrinogen molecules are bound per platelet, and the number can exceed 100 000 if secretion has occurred to expose the granule pool of αIIbβ3[53]. However, the number of fibrinogen molecules that must be bound per platelet to support platelet aggregation is considerably less. Optimal therapy with GPIIb–IIIa antagonists seeks to attain greater than 80% inhibition of receptor occupancy, which suggests that fibrinogen binding to 20% of the available receptors is sufficient to sustain limited thrombus formation[41,152]. By virtue of its dimeric structure and the spacing of its recognition sites at distant positions in the molecule (see Fig. 14.3, fibrinogen reversibly bound to αIIbβ3 can bridge between adjacent platelets and support aggregation[153,154]. Other adhesive proteins, such as fibronectin, even though dimeric or multimeric, do not express their αIIbβ3 recognition sites in an appropriate orientation to bridge between platelets[155] and, therefore, do not support aggregation. However, the evidence that single fibrinogen molecules actually bridge between platelets linking them together in a thrombus is less than compelling. For example, fibrinogen can be bound to αIIbβ3 at high density but still fails to support aggregation[156,157]. Such observations suggest that postreceptor occupancy events are necessary to elicit an aggregation response.

Postreceptor occupancy events

The postreceptor occupancy events refer to a complex series of reactions that occur following the initial reversible binding of fibrinogen to αIIbβ3. As noted above, these events may control consequences of fibrinogen binding to the receptor as fundamental as platelet aggregation itself. The first of these postreceptor occupancy events to be identified was the transition of fibrinogen from a reversibly to an irreversibly bound state, i.e. the bound fibrinogen becomes essentially non-dissociable[13,129,130,158]. Reagents that interfere with the initial binding of fibrinogen to αIIbβ3, such as EDTA or metabolic inhibitors, fail to dissociate the ligand from the platelet[159]. Changes in the access of bound fibrinogen to proteases and to certain antibodies also occur as a consequence of the stabilization reaction[160].

Cambridge Books Online © Cambridge University Press, 2009

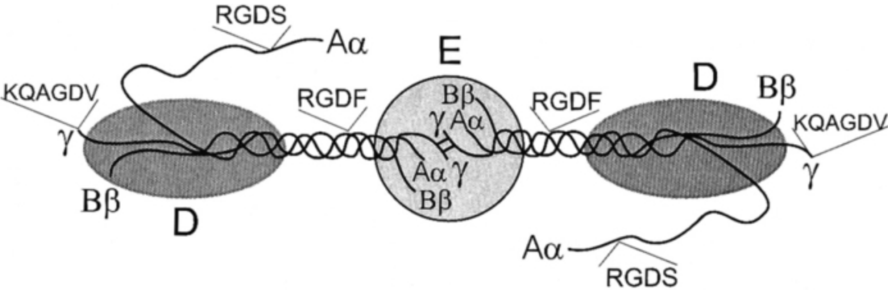

Fig. 13.3. Schematic model of fibrinogen depicting its D and E domainal organization and its constituent chains. The sequences defining the recognition specificity of αIIbβ3 on platelets are: KQAGDV at the C-terminus (406–411) of the γ-chain, RGDS at Aα572–575 and RGDF at Aα95–98.

The functional consequence of this transition is the stabilization of platelet aggregates such that they become poorly dissociable[13]. Two prevailing mechanisms have been evoked to explain the basis for irreversible fibrinogen binding. One possibility is that irreversibly bound fibrinogen remains associated with the platelet surface. For example, fibrinogen may bind to αIIbβ3 initially via its γ-chain sequence, but then may develop additional contacts, such as via the RGD or still other sequences, with the receptor, or the ligand–receptor complex becomes associated with the cytoskeleton, which stabilizes the interaction. There is support for this latter possibility[161]. The second possibility is that the bound fibrinogen becomes internalized into a distinct compartment within the platelet. Internalization of ligands bound to αIIbβ3 has been demonstrated by multiple approaches[54,162] and provides a ready explanation for the observed changes in the accessibility of bound fibrinogen to antibody and protease probes. Combinations of both mechanisms also may be operational.

A second category of postreceptor occupancy events is the induction of the LIBS and RIBS epitopes, acronyms for ligand induced binding sites and receptor induced binding sites[163]. These are epitopes recognized by monoclonal antibodies that react preferentially with the occupied receptor (LIBS) or the bound ligand (RIBS). LIBS antibodies that recognize αIIbβ3 react poorly with the resting or activated receptor, but are expressed by αIIbβ3 when it is occupied by fibrinogen and other ligands[164–168]. There are multiple LIBS within αIIbβ3, and the epitopes reside in both the αIIb and β3 subunits[169]. Certain, but not all of the LIBS, are induced by the γ-chain and RGD ligand peptides. Still other LIBS antibodies react weakly but sufficiently with resting αIIbβ3 to induce activation of the receptor[167]. Other LIBS alter functional responses of occupied αIIbβ3, including its mediation of clot retraction[165]. Antibodies with LIBS recognition properties can occur naturally and can lead to thrombocytopenia when GPIIb–IIIa antagonists are administered to some individuals[170]. RIBS are epitopes that are induced in the ligand upon its binding to the receptor[163,171–173]. Thus, there are specific monoclonal antibodies that react with fibrinogen when it is bound to αIIbβ3 but not when it is in free solution. Fibrinogen–RIBS can be induced by other modifications of the molecule, such as its deposition on surfaces or its proteolytic degradation[171,173]. Together, the induction of LIBS and RIBS indicate the dynamic nature of the postreceptor occupancy events with the induction of multiple and long-range conformational changes in both fibrinogen and αIIbβ3[174].

Additional postreceptor occupancy events include the induction of an extensive array of outside-in signalling responses. Rapid phosphorylation and activation of specific tyrosine and serine/threonine kinases, activation of specific phosphatases, recruitment of adaptor proteins, cytoskeletal rearrangements, phospholipase activation and hydrolysis of phosphoinositides are among the responses that are elicited upon fibrinogen binding to αIIbβ3[38,175,176]. Some of these outside-in signals are evoked directly by receptor occupancy, but many depend upon aggregation of the platelets. The characterization of these outside-in signalling events in platelets has provided valuable insights into the nature and regulation of integrin signalling in general. Moreover, these down-stream signalling events appear to contribute to platelet function as well. One obvious justification of this statement is mechanism of clot retraction. This contraction stabilizes the thrombus and renders it more resistant to lysis. The force for clot retraction depends upon the rearrangement of the actin cytoskeleton, which presumably 'pulls' on the cytoplasmic domain of αIIbβ3 and, thereby, on the fibrin bound to the receptor. This contractile pull on fibrin between platelets results in retraction of the thrombus. However, clot retraction is mechanistically much more complicated. Since platelets from patients with Glanzmann's thrombasthenia

Cambridge Books Online © Cambridge University Press, 2009

do not support clot retraction[177], αIIbβ3 is required for this response. Nevertheless, there is evidence that sites within fibrinogen, in addition to those known to mediate its binding to αIIbβ3, are required for clot retraction[178]. The possibility that other fibrin(ogen) receptors may participate in clot retraction is suggested from the capacity of other cell types which lack αIIbβ3 to mediate this response[179,180]. Additional evidence of the importance of these downstream events in platelet functions comes from studies of transgenic mice expressing αIIbβ3 in which the two tyrosine residues that are targets for phosphorylation in the β3 cytoplasmic tail were mutated to phenylalanines. Although this phosphorylation is detected as a postreceptor occupancy event dependent upon platelet aggregation, the aggregation response of the transgenic mouse platelets shows abnormalities[181].

Recognition of fibrinogen by αIIbβ3

Soon after the initial characterization of fibrinogen binding to αIIbβ3, efforts were initiated to identify the sites within the ligand that were recognized by the receptor. This endeavour represented a major challenge as fibrinogen is a molecule of 340 kDa and is composed of three pairs of polypeptide chains (see Fig. 13.3). Classical biochemical strategies, including proteolytic and chemical degradation and synthetic peptide approaches, were applied[153,182–185]. Ultimately, two synthetic peptides corresponding to two discrete amino acid sequences were obtained which defined the recognition specificity of αIIbβ3 for fibrinogen as well as for other adhesive ligands of the receptor[186]. The first of these peptide sets corresponds to the extreme C-terminus of the constituent γ-chain of fibrinogen[153,183], and KQAGDV was the minimal active sequence[187]. This sequence, often referred to as the γ-chain peptide, is relatively specific for αIIbβ3 and reacts considerably less well with other platelet integrin fibrinogen receptors, αvβ3 and α5β1. The second peptide, referred to as the RGD peptide, has Arg–Gly–Asp–X as its minimal sequence. RGD sequences reside at two sets of sites in the Aα-chain of fibrinogen. RGD sequences also are present within and mediate the interaction of several of the other adhesive ligands for αIIbβ3[188,189] and define the recognition specificity of several other integrins for their ligands, including αvβ3 and α5β1[190,191]. While both sequences were identified through a systematic dissection of fibrinogen, the adhesive properties of the RGD peptide had been previously identified within fibronectin[192] and had been shown to inhibit binding of this ligand[188] as well as fibrinogen and vonWillebrand factor to αIIbβ3[184]. Both peptide sets are effective inhibitors of fibrinogen binding to αIIbβ3 and platelet aggregation, and both bind directly to αIIbβ3[187,193]. This latter characteristic distinguishes these recognition peptides from other peptides derived from fibrinogen, which also inhibit platelet aggregation but do so by binding to fibrinogen[194,195]. However, of the RGD and the γ-chain sequences, it is only the latter that is essential for fibrinogen binding to αIIbβ3. Mutation of the γ-chain sequence, but not the RGD sequences, blocks fibrinogen binding to αIIbβ3 in vitro[196,197] and in vivo[198]. Secondary roles of the RGD or other sequences in mediating or stabilizing fibrinogen-αIIbβ3 interactions have been suggested, but unequivocal evidence for such a role has not been developed. Current evidence suggests that the inhibitory activity of RGD peptides may be mediated by an allosteric mechanism, i.e. they bind to αIIbβ3 and alter the conformation of the receptor such that recognition of the γ-chain sequence is blunted[199]. Among the evidence to support this interpretation are data indicating the RGD and γ-chain peptides can bind to distinct sites in αIIbβ3[106]. Nevertheless, RGD peptides have proven to be extremely valuable in defining the recognition specificity of αIIbβ3 and other integrins and in the development of GPIIb–IIIa antagonists. Several of the oral antagonists under development and the FDA approved parenteral drug, tirofiban, have used the RGD sequence as a starting point in their design[200–202].

Other platelet fibrinogen receptors

Other integrins

Fibrinogen is known to be a ligand for two members of the integrin family in addition to αIIbβ3, which are expressed on platelets. α5β1 is classically referred to as the fibronectin receptor[203–205]. About 1000 to 4000 copies of α5β1 are expressed per platelet[206]. On resting platelets, under conditions where αIIbβ3 does not contribute to binding, a low level of fibrinogen binding can be detected, which is inhibited by antibodies to α5β1[207]. This receptor recognizes the RGD sequence in the C-terminal region of the Aα chain, and its affinity for fibrinogen appears to be similar to that of αIIbβ3[207]. A role of α5β1 in adhesion of unactivated platelets to fibrin(ogen) can be envisioned but has not been demonstrated.

αvβ3, classically referred to as the vitronectin receptor[208], also binds fibrinogen employing a RGD recognition specificity[28,209–211]. αvβ3 may recognize the RGD sequence in the C-terminal aspects of the Aα chain[212,213] or a sequence unrelated to RGD[214,215]. This receptor interacts poorly with the C-terminal γ-chain sequence[213]. Thus, its

Cambridge Books Online © Cambridge University Press, 2009

recognition specificity for fibrinogen is related to but distinct from αIIbβ3. Also distinct is the divalent cation requirements for fibrinogen binding. Calcium suppresses fibrinogen binding to αvβ3 but not to αIIbβ3[216,217]. αvβ3 is present on platelets but only at a low copy number; estimates range from 200 to 500 copies of αvβ3 per platelet[210,218]. In patients with Glanzmann's thrombasthenia, the defect may reside in the αIIb or the β3 genes. In the latter case, αvβ3 is not expressed on platelets or other cells. The hemostatic abnormalities in these two classes of thrombasthenics are similar suggesting that αvβ3 plays a limited physiological role. This receptor may play a much more prominent role in pathogenesis. In tumour growth, metastasis and angiogenesis, αvβ3 is believed to play a central function[219–221]. Fibrin[222] and platelets[223] play crucial roles in tumorigenesis, and recognition of fibrin by αvβ3 may be involved in mediating their interactions with tumour cells. The importance of αvβ3 on platelets is more likely to depend upon its recognition of ligands that are not recognized by αIIbβ3. Osteopontin appears to represent such a ligand[224].

Still other fibrinogen receptors?

Thrombospondin I (TSP-I) is a major platelet α-granule protein[225,226]. Upon secretion, a portion of the released TSP-1 associates with the platelet surface[226–228]. Several candidate TSP-1 receptors have been identified on platelets including αIIbβ3[228], αvβ3[211,229], CD36 (GPIV)[230–232] and surface glycoaminoglycans[233]. Relevant to this chapter is the fact that TSP-I binds fibrinogen with high (nM^{-1}) affinity[234,235]. Thus, fibrinogen could bridge between TSP-1 molecules bound to adjacent platelets and mediate their aggregation[236].

While fibrinogen has provided a convenient ligand for analysis of binding functions, fibrin may be the more physiologically relevant ligand for the platelet. Fibrin and fibrinogen are not only structurally but also conformationally distinct. However, the insolubility and heterogeneity of fibrin has made detailed analyses of its interaction with platelets difficult. Nevertheless, some studies have been published and have suggested that fibrin interacts with αIIbβ3 with high affinity[237–239]. Fibrin may interact with additional sites in αIIbβ3 other than fibrinogen[240]. There also is evidence for αIIbβ3-independent interactions of fibrin with platelets[241]. For example, polymerizing fibrin can interact with thrombasthenic platelets[242]. Such observations suggest potentially unique interaction of fibrin(ogen) derivatives with platelets. The importance of these alternative mechanisms of interaction of fibrin(ogen) with platelets is conjectural at this time.

Platelet signalling: GTP-binding proteins

Jan-Willem N. Akkerman

Laboratory for Thrombosis and Haemostasis, Department of Haematology, University Medical Center Utrecht, The Netherlands

Introduction

To respond to extracellular signals, platelets possess different types of surface receptors for stimulatory and inhibitory ligands. Surface receptors can be classified in three groups each possessing a specific property by which information is relayed through the plasma membrane. These are: (i) G-protein linked receptors, (ii) enzyme linked receptors and, (iii) ion channel-linked receptors. G-protein linked receptors are seven transmembrane receptors that relay the stimulus to high molecular weight, heterotrimeric GTP-binding regulatory proteins (G-proteins in short) consisting of three polypeptides, an α-, a β- and a γ-subunit. Enzyme linked receptors have a single transmembrane domain and contain a cytosolic tail with an intrinsic enzyme activity or that associates directly with an enzyme. They start signalling cascades that involve a second class of GTP-binding proteins which are low molecular weight, monomeric GTPases (small GTPases in short). Ion channel linked receptors respond directly to ligand binding by opening a channel pore resulting in single channel currents.

Both G-proteins and small GTPases are members of the superfamily of GTPases. They function as molecular switches between a GTP-bound 'on-state' and a GDP-bound 'off-state'. Hence, they are important elements in the initiation and termination of signal transduction. In addition, they serve in amplification of signals helping to convert a weak extracellular stimulus into a strong intracellular signal. The fact that one G-protein might be connected to several receptors or couple to more than one downstream effector enables integration of different signals. Thus, GTP-binding proteins are key elements in the signalling cascades that initiate shape change, aggregation, secretion and contraction, or prevent this [1–5].

G-proteins and small GTPases

G-proteins

The classification 'G-protein linked receptor' is based on the property that ligand binding to these receptors starts the activation of G-proteins. These receptors are typically heptahelical receptors, consisting of seven stretches of about 22 hydrophobic residues. These regions are thought to form transmembrane α-helices with a loop between helices 5 and 6 facing the cytosol which together with the C-terminal end forms the binding site for the G-protein. G-proteins consist of an α-, a β- and a γ subunit with mol.weights 39–52 kDa, 35–36 kDa and 5–8 kDa, respectively. The $\beta\gamma$ subunit splits only in the presence of detergents and under physiological conditions forms a functional monomer[1]. The α subunit contains a GTPase domain with the GTP-binding pocket as well as sites for binding of receptors, effectors and $\beta\gamma$ complexes. The C-terminus and parts of the α5 helix are sites for interaction with the receptor and thus determine receptor specificity[1]. In the absence of ligands both GDP-α and $\beta\gamma$ are bound to the receptor, α binding being greatly facilitated by $\beta\gamma$ (Fig. 14.1(*a*)). Ligand binding induces a conformational change in the receptor that moves the C-terminal α-helix of the α-subunit. This causes dissociation of bound GDP which is easily replaced by GTP as this is present in excess. The GTP-α-subunit is activated and dissociates from the receptor and from the $\beta\gamma$-complex. Each subunit can then activate their target effector. The intrinsic GTPase activity within the α-subunit restores the GDP-bound state, enabling the α-subunit to reassociate with the $\beta\gamma$-complex and the cycle is closed. GTP hydrolysis is under control of regulators of G-protein signalling. The system has an important feed back mechanism since the release of active G-protein triggers a decrease in ligand affinity of the receptor. Thus, initi-

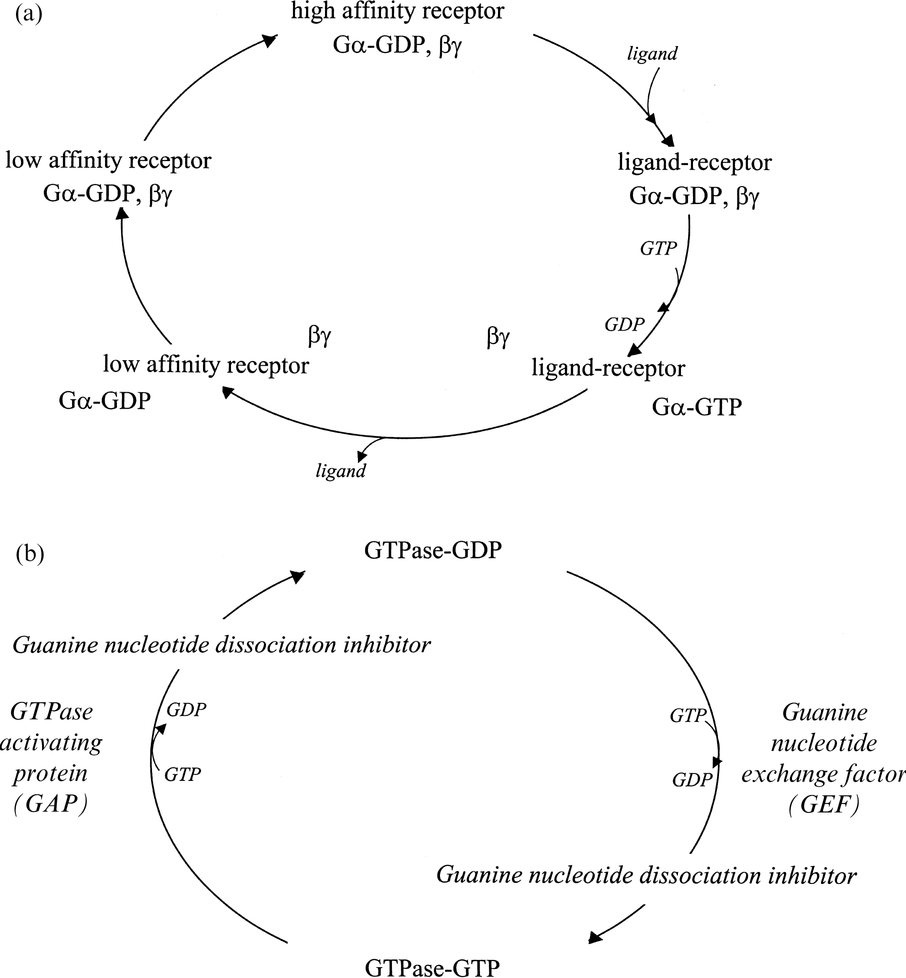

Fig. 14.1. Activation and deactivation of GTP-binding proteins. (*a*) G-proteins; (*b*) small GTPases.

ation of downstream signalling by active G-protein is accompanied by termination of receptor activation unless the ligand concentration is sufficiently high to start a new activation signal[1,4].

GTP is bound in a cleft with the purine located near the cleft entrance and the phosphate buried within the protein[6]. This core, also called 'G-domain', is almost identical for all G-proteins. The activation of Gα-subunits by GTP implies that the protein senses a relatively small change in the active site: the presence or absence of a γ-phosphate. This sensor resides upon the key residues Thr and Gly in a special region in the G-domain (G-2 region also called switch 1). GTP binding results in movement of the G-2 and adjacent G-3 (switch II) domains, which activates the Gα subunit[6]. Popular tools to activate G-proteins are AlF_4^-, which mimicks the GTP-induced movement of the G-2 and G-3 regions, and GTPγS or GMP-P(NH)P, which are resistant to hydrolysis. On the other hand, GDPβS interferes with GTP binding, inducing persistent inactivation.

More than 20 different α-subunits have been identified. Diversity is lower for β-subunits (about 5) and γ-subunits (about 10) and although in theory this would lead to numerous combinations, only a limited number of $\beta\gamma$-complexes exist. Specificity in β for binding to a γ-subunit lies in the so called WD domains. Conversely, a stretch of 14 amino acids in the middle of γ determines specificity for β-binding.

G-proteins are divided according to amino acid similarity in four classes: the α_s-, α_i-, α_q- and α_{12}-classes. The α-subunits can be phosphorylated on Ser, Thr or Tyr residues, the latter by pp60 Src, which changes the interaction with other regulatory proteins.

Cambridge Books Online © Cambridge University Press, 2009

G_s contains the α_s-subunit and stimulates adenylyl cyclase leading to the formation of cAMP. Two products of alternative splicing are known, a short α_s (45 kDa) and a long α_s (52 kDa). A tool to investigate the role of G_s is cholera toxin, which catalyses NAD-dependent ADP-ribosylation of Arg 187/188 (Arg 201/202 in splice variants) of $G_s\alpha$ subunit inducing persistent activation due to impaired GTP-hydrolysis.

G_i contains the α_i-subunit (40 kDa) and is the physiological counterpart of G_s as it inhibits adenylyl cyclase thereby abolishing cAMP formation. There are at least three isoforms (G_i α_1, α_2, α_3), with additional diversity in downstream signalling. Pertussis toxin catalyses NAD-dependent ADP-ribosylation of a Cys residue close to the C-terminus of $G_i\alpha$ (and of $G_o\alpha$ and $G_t\alpha$ which are absent in platelets), which blocks receptor binding to the α-subunit and inhibits signalling through this G-protein. Also NEM is an inhibitor of G_i proteins. On the other hand, G_i is activated by mastoparan and mastoparan analogue Mas7[7]. A special member of this class is G_z (41 kDa). Expression studies show interaction with Rap1GAP, the GTPase that inactivates the small GTPase Rap1[8].

G_q is in fact a class of different, pertussis toxin-insensitive G-proteins consisting of α_q (42 kDa), which activates phospholipase $C\beta_2$, and α_{15} (in mice platelets)/α_{16} (in human platelets; 43.5 kDa[9]), which appears specific for haematopoietic cells. $G_{16}\alpha$ antisense expressed in HEL cells leaves signalling sequences induced by thrombin and platelet activating factor intact, but changes growth factor signalling[10].

G_{12} is also a class of multiple G-proteins such as those consisting of α_{12} (44 kDa) and α_{13} (43 kDa[11]). These G-proteins signal to a special class of small GTPases that control actin polymerization.

Binding to membranes is an important prerequisite for G-protein function. The α_i-subunits are cotranslationally modified by myristoylation at N-terminal glycine, which is an irreversible process that facilitates $\beta\gamma$ binding. In contrast, α_s and α_q are not myristoylated. The α_s is post-translationally modified by palmitoylation at Cys 3 which is a reversible process enabling an α subunit to switch between a palmitoylated, active state and a depalmitoylated, inactive state. The $\beta\gamma$ subunits are independent activators of multiple signalling pathways. The prenylgroup at the C-terminus in γ mediates the binding of $\beta\gamma$ to the membrane. The binding to GDP-α blocks the signalling properties of $\beta\gamma$. The $\beta\gamma$ complexes bind to α-subunits, receptors, adenylyl cyclases, phospholipase C_β, calmodulin, cytosolic phospholipase A_2, phosphatidylinositol 3-kinase (PtdIns 3-kinase), among others.

Small GTPases

Small GTPases take part in the signalling cascades initiated by enzyme linked receptors. In addition, they serve in many other aspects of cell function, e.g. vesicle transport and cytoskeleton assembly. These monomeric, 20–30 kDa molecular weight proteins, have a similar GTP–GDP dependent on/off system to the trimeric G-proteins, but the activation cycle is under strict control of proteins that facilitate GTP binding or enhance its hydrolysis (figure 14.1(*b*)). GTP binding is catalysed by guanine nucleotide exchange factors or GEFs, most of them being specific for a single type of small GTPase. GTP-binding induces a conformational change in the so-called switch 1 and switch 2 regions, the former mediating the interaction with downstream effectors. Small GTPases contain an intrinsic GTPase activity but its velocity is low. Hence, GTP hydrolysis is catalysed by GTPase activating proteins or GAPs. Further control of the GTPase cycle comes from guanine nucleotide dissociation inhibitors or GDIs, which inhibit the release of GDP or GTP from the GTPase. In addition, adapter proteins that lack enzymatic activity assist in docking of exchange factors and GTPases. All small GTPases are posttranslationally modified by limited hydrolysis at the C-terminus, followed by isoprenylation and carboxymethylation. The prenyl moiety is farnecyl for GTPases ending with Ser, Met or Gln, or geranylgeranyl for those ending with Leu. This reaction is essential for membrane binding and proper function.

Those small GTPases that transduce signals from enzyme linked receptors are anchored to the activated receptors following ligand induced receptor dimerization, which triggers autophosphorylation of specific domains, mostly Tyr residues. These become the docking sites for adapter proteins with Src-homology (SH) domains by which they couple to the receptor dimer (SH2 domains) and to a specific GEF (SH3 domains). The result is GDP-GTP exchange of the small GTPase and activation. In a next step, downstream signalling is initiated by activating a target kinase or by docking to the exchange factor of a next effector.

The small GTPases are subdivided in the families of the Ras-like proteins, Rho-like proteins, Rab proteins, Arf proteins, Ran proteins and Rad proteins. A simplified functional classification is that Ras members function in the regulation of cell growth, Rho members in control of the actin cytoskeleton, the Rab- and Arf-members in vesicle fusion and transport and the Ran members in transport across the nuclear membrane. The function of Rad proteins is still elusive.

The Ras subfamily (21–30 kDa) consists of 17 proteins

Cambridge Books Online © Cambridge University Press, 2009

including H-Ras, R-Ras, K-Ras, Rap, and Ral among others. Ras-like GTPases are post-translationally modified by prenylation by a farnecyl protein transferase, which couples a farnecylisoprenoid moiety to a Cys residue in a C-terminal CAAX motif. This enables coupling to the membrane which is essential for Ras function[12]. RasGEFs include Sos, which couples receptor tyrosine kinases to Ras and is an exchange factor. GAPs for Ras are p120GAP and NF1. A major effector of Ras-GTP is the Ser/Thr kinase Raf, which in turn activates the ERK1/2 kinases (also called p42/44 MAPkinases). A second effector of Ras is PtdIns 3-kinase, which generates PtdIns 3,4,5 P_3. This is a first step in downstream signalling to protein kinase B[13], which is an anti-apoptotic kinase, and to protein kinase C, a key factor in platelet aggregation and secretion. Different Ras members differ in their capacity to initiate the different downstream pathways. Many other Ras effectors have now been described including Rlf, which is a GEF for Ral, protein kinase Cζ and JNK, a member of the MAPkinase family.

Rap1 (21 kDa) and Ras share about 50% homology, but their effector domains are virtually identical[14,15]. Rap1 is present as Rap1A and Rap1B, differing only in 9 out of 184 aminoacids. Both are postranslationally modified at the C-terminus by a geranylgeranyl moiety that mediates membrane attachment. Exchange factors for Rap1 include CalDAG-GEF, regulated by Ca^{2+}/diacylglycerol and Epac, regulated by cAMP[16]. SPA-1 is a Rap-GAP. Interestingly, transient overexpression of SPA-1 in cell lines inhibits Rap1 activation as well as adhesion to a fibronectin-coated surface suggesting that Rap might function in signalling through integrins[17].

Rho-like GTPases (20–30 kDa) are about 30% homologous to Ras[18,19]. Several subtypes have been identified, e.g. Rho A/B/C, Rac 1/2/3, Cdc42 and G25K[19]. The Rho members are involved in the formation of stress fibres and the assembly of focal adhesions. Rac members function in the formation of lamellipodia, membrane ruffles and focal contacts and Cdc42 is important for formation of filopodia and focal contacts.

GTP–GDP exchange is regulated by RhoGEFs that are characterized by a common Dbl-m homology (DH) domain. This encodes the catalytic activity and a pleckstrin homology (PH) domain, which mediates membrane attachment[18]. About 20 RhoGAPs have been identified. Rho-like GTPases bind to membranes via geranylgeranyl lipid modification, but in the inactive state Rho's are found in the cytosol bound to Rho GDIs. The exoenzyme C3 transferase, which is an ADP-ribosyltransferase from *Clostridium botulinum* inactivates Rho A, Rho B and Rho C. A more general inhibitor of Rho-members is *C. difficile*. Effector activation by Rho-like GTPases generally involves disruption of an intramolecular autoinhibitory bond that exposes functional domains within the effector molecule. Examples are Rho-kinase, an effector of Rho, and Wiskott–Aldrich syndrome protein, an effector of Cdc42. Inhibition of Rho-kinase by the pharmacological inhibitor Y-27632 blocks formation of stress fibres, illustrating the role of Rho proteins in the regulation of actomyosin assembly and contraction.

An important effector of Rac-GTP is PtdIns 4–P5-kinase, which triggers the release of capping proteins and actin nucleation and polymerization. A second effector is WAVE, which also contributes to these processes[18].

Major effectors of Cdc42 are Wiskott Aldrich syndrome protein and the SerThr kinase PAK. WASP is expressed in haematopoietic cells and has a more ubiquitously expressed homologue called N-WASP. N-WASP, together with PAK, controls actin nucleation and filament stabilization, respectively.

An interesting group of effectors of Rac/Cdc42 are Mlks which act as MAPkinase kinase kinase (MEKKs). These enzymes activate the MAPkinase family members JNK and p38MAPkinase[18].

Rab GTPases function in the regulation of vesicular traffic. Upon GDP–GTP exchange, these proteins facilitate the binding of a transport vesicle to its proper acceptor organelle and initiate vesicle fusion. Arf proteins are activated by Golgi-bound enzymes and start the formation of transport vesicles.

G-proteins in platelets and megakaryocytes

G-proteins as integrators of signal transduction

Table 14.1 lists the major G-proteins in human platelets. The diversity in signalling properties mainly reflects the differences in the α subunit. However, also $\beta\gamma$ complexes can signal to downstream enzymes or ion channels but it is often uncertain from which trimeric complexes they originate. There are clear examples of G-proteins that are activated by different receptors, illustrating their role in integration of different extracellular signals. There appears to be less diversity in downstream effectors but as more information on isozyme distribution becomes available, a further complexity in downstream signalling will become apparent[20–24].

The stimulatory G-protein of adenylyl cyclase Gs

A major inhibitor of platelet functions is cAMP and its control by activating and inhibitory signalling cascades is a

Abbreviations used: (+) and (−) indicate activation and inhibition, respectively.

nice illustration of the action of G-proteins (Fig. 14.2). The G-protein G_s (for stimulatory) is activated by binding of PGI_2 (prostacyclin) and a number of other inhibitory prostaglandins to their respective receptors. Adenosine activates the A_{2A} adenosine receptor, which also activates G_s. Under normal conditions epinephrine activates platelets via the α_{2A}-adrenergic receptor but when this receptor is blocked a second property becomes apparent which is the result of binding to β_2-adrenergic receptors and activation of G_s. The result of G_s activation is activation of adenylyl cyclase, accumulation of cAMP and inhibition of numerous signalling steps involved in platelet activation mainly via protein kinase A.

Analysis by RT-PCR of platelet mRNA reveals a short and a long form (called $G_s\alpha$-S and $G_s\alpha$-L, respectively). The two forms differ in 45 base pairs and are products of alternative splicing. In addition, each form is present without and with a C-A-G triplet. The triplet results in a consensus sequence (Ser–X-Lys) for a phosphorylation site for the Ser/Thr kinase protein kinase C, making these variants targets for control of cAMP formation by this kinase[25]. In accordance with its role in supporting surface receptors, $G_s\alpha$ is pre-

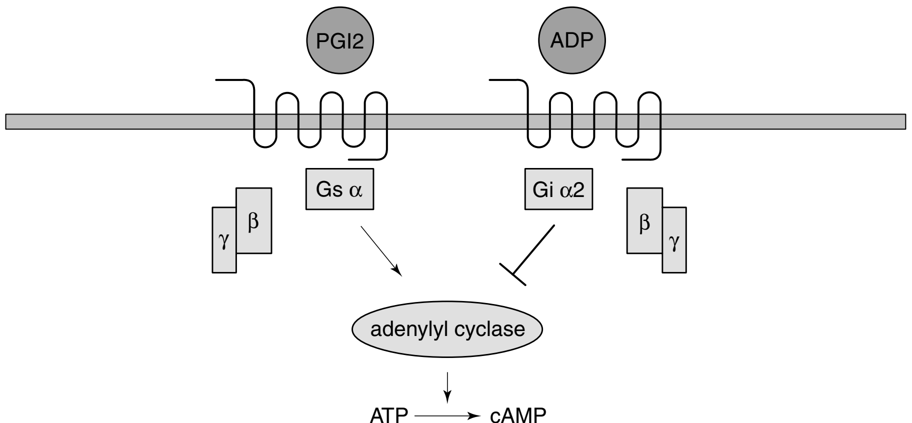

Fig. 14.2. Regulation of adenylyl cyclase by G-proteins. Prostacylcin (PGI_2) and ADP activate the IP-receptor, and the $P2T_{AC}$-receptor respectively. In turn, this activates G_s and G_i, the stimulatory and inhibitory G-protein for adenylyl cyclase. The result is production of cAMP or its inhibition.

dominant in plasma membranes, but also found in dense tubular membranes and in dense granules. Possibly it is part of a SNAP receptor complex which is known to contain G-protein subunits and assists in vesicle targeting and fusion[26]. In PGI_2-treated platelets $G_s\alpha$ physically associates with the Major Histocompatability Complex, MHC-1[27].

$G_s\alpha$ mRNA and protein are already expressed in the megakaryoblastic cell line MEG-01, which represents an early stage in megakaryocytopoiesis[28]. Stimulation with cholera toxin or the PGI_2 analog iloprost raises cAMP in MEG-01 by 2–4 fold. Co-stimulation with thrombin upregulates the PGI_2-induced cAMP formation, a property that is abolished by protein kinase C inhibition. This is quite different from cAMP control in platelets, where thrombin suppresses cAMP formation via an inhibitory G-protein as well as via protein kinase C.

The megakaryoblastic cell lines MEG-01, DAMI and CHRF 288–11 have properties in common with normal megakaryocytes at different stages of maturation. Total $G_s\alpha$ mRNA and protein are down-regulated at increasing stages of maturation, which is accompanied by a decrease in the ratio $G_s\alpha$-S / $G_s\alpha$-L and up-regulation of cAMP formation[28,29]. This accords with the kinetic properties of $G_s\alpha$-L, which is 3–10 fold more active than the short form. Platelets show the lowest $G_s\alpha$-S/ $G_s\alpha$-L ratio (0.8), which might explain their extreme sensitivity to PGI_2.

Platelets from patients with certain psychiatric disorders show increased G_s expression[30] or abnormal G_s activation[31].

The inhibitory G-protein of adenylyl cyclase G_i

The activation of adenylyl cyclase by G_s is counterbalanced by the inhibitory G-protein G_i. Thrombin, ADP, epinephrine and platelet activating factor stimulate platelets and at the same time lower cAMP by activating G_i[32,33]. Also lysophosphatidic acid and sphingosine-1 phosphate activate receptors coupled to G_i[34]. This mechanism guarantees that activating pathways function optimally and trigger full platelet responses. In the presence of inhibitory prostaglandins adenylyl cyclase-stimulating signals must be fully neutralized by inhibitory signals generated via G_i. Inhibition by G_i is not always sufficiently strong to prevent cAMP formation[35]. Thrombin activates platelets by proteolytic cleavage of three receptor subtypes: PAR1 (human platelets), PAR3 (mice platelets) and PAR4 (human and mice platelets[36]). The PAR1 activating peptide SFLLRN induces ADP-ribosylation of $G_i\alpha$, demonstrating coupling between PAR1 and G_i. However, inhibition of PGI_2-induced cAMP formation is incomplete and full suppression requires activation of all PAR subtypes.

Mice with a deleted gene for $G_i\alpha_2$ show strongly reduced ADP aggregation with a normal shape change[37]. Also the inside out activation of integrin $\alpha_{IIb}\beta_3$ following stimulation with ADP is severely impaired. $G_i\alpha_3$ partly compensates for the loss of $G_i\alpha_2$.

ADP stimulates platelets by activating the $P2Y_1$-receptor, which mediates platelet activating signals, the $P2T_{AC}$, which couples to adenylyl cyclase, and the P2X-1, which opens a calcium channel[38]. The $P2T_{AC}$ has been recently renamed $P2Y_{12}$[39]. Studies with ligand mimetics and receptor antagonists show that both the $P2Y_1$- and $P2T_{AC}$ receptors signal to optimal platelet aggregation (Fig. 14.3). Inhibition of the $P2T_{AC}$ inhibits ADP aggregation but has little effect on shape change, suggesting that this response is independent of G_i[40]. Activated α_{2A}-adrenergic receptors can replace $P2T_{AC}$ activation in assisting a $P2Y_1$ ligand to

Cambridge Books Online © Cambridge University Press, 2009

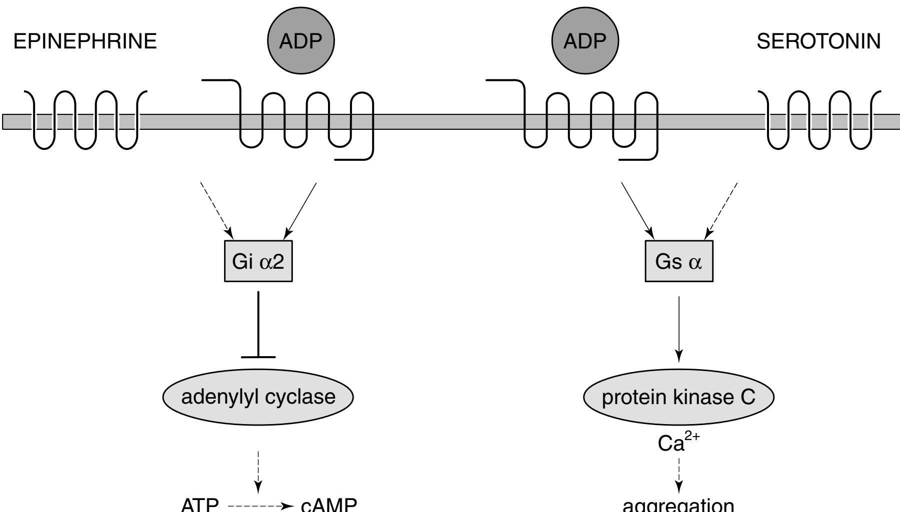

Fig. 14.3. Optimal aggregation depends on activation of both G_q and G_i. ADP induces aggregation by activating Gq via the $P2Y_1$-receptor. The result is a Ca^{2+} increase and protein kinase C activation resulting in aggregation and secretion. ADP also activates G_i (via the $P2T_{AC}$-receptor) thereby lowering cAMP and enabling optimal responses to occur. G_q activation by ligand – $P2Y_1$ complex can be replaced by ligand – $5HT_{2A}$ receptor complex; G_i activation by ligand – $P2T_{AC}$ complex can be replaced by ligand – α_{2A} adrenergic receptor complex.

fully activate the platelets. Alternatively, activation of the serotonin receptor supplements signalling through the $P2Y_1$[41]. This illustrates that activated G_i is the crucial element that lowers cAMP and enables optimal ADP-induced platelet aggregation to occur.

G_i may also take part in platelet activation by epinephrine. Activation of the α_{2A}-adrenergic receptor activates protein kinase C in a pertussis toxin sensitive manner[42]. In epinephrine-stimulated platelets pp60Src associates with $G_i\ \alpha$[43].

Inactive G_i has been found in a complex with Integrin Associated Protein (CD47), a thrombospondin receptor that forms a signalling complex with $\beta 3$ integrins. Aggregation induced via this receptor was abolished by pertussis toxin whereas GTP and AlF_4^- released G_i from the complex. This was accompanied by lowering of cAMP and reduced ligand binding to CD47[44].

Another effector of $G_i\alpha$-GTP is the Na^+/H^+ exchanger. This electron neutral pump removes protons from the cytosol in a stoichiometric exchange for extracellular Na^+ ions, thereby regulating the cytosolic pH (pH_i) and cell volume. In thrombin stimulated platelets receptor-mediated changes in pH_i are blocked following pretreatment with AlF_4^- and this inhibition is releaved by NEM. The exchanger preserves responsiveness to changes in the cytosolic proton concentration. These properties suggest an inhibitory role for G_i in receptor-mediated regulation of the Na^+/H^+ exchanger[7,45]. Another effector of G_i is SH-PTP1, a protein tyrosine phosphatase that contains two SH2 domains. Thrombin and PMA trigger phosphorylation on Ser and Tyr, thereby stimulating phosphatase activity. This coupling depends on G_i activation[46].

Platelets contain the G_i subtypes $G_i\ \alpha_2$ and $G_i\ \alpha_3$, which are 85–95% homologous at the aminoacid level[3]. $G_i\ \alpha_2$ and $G_i\ \alpha_3$ are present in the plasma membrane, dense tubular membranes and in dense granules. $G_i\ \alpha_2$ and $G_i\ \alpha_3$ are already expressed in MEG-01 and present in DAMI and CHRF 288–11. Treatment with the mastoparan analogue Mas 7 abolishes iloprost induced cAMP formation, indicating that G_i can be activated and suppresses adenylyl cyclase in these immature cells.

Decreased expression of platelet $G_i\alpha_2$ has been reported in major depression[47,48] and hypertension[49].

G_q, a key step in platelet activation

The crucial role of G_q in platelet activation is illustrated by the absent aggregation and secretion in G_q-deficient mouse platelets following stimulation by thrombin, ADP and thromboxane A_2[50]. The absent aggregation in G_q deficient platelets illustrates that activation of both G_i and G_q is required for a normal aggregation response[40,41,51–53]. Interestingly, G_q knock-out platelets show a normal shape change response following stimulation with thrombin or thromboxane A_2[54] and ADP[33]. A similar bypass of G-protein mediated signalling was found for G_i, suggesting that shape change is under control of different activation routes[54]. ADP-induced aggregation requires the concomi-

Cambridge Books Online © Cambridge University Press, 2009

tant stimulation of both G_q (via $P2Y_1$) and G_i (via $P2T_{AC}$). As described earlier, the response is preserved when the ligand for $P2Y_1$ is replaced by serotonin, illustrating that the serotonin receptor (5-HT_{2A} receptor) is also coupled to G_q. Transfection studies show that both splice variants of the thromboxane A_2 receptor, TPα and TPβ, couple to G_q[55].

G_q α is already expressed in MEG-01 and more mature megakaryoblastic cell lines. These cells respond to thrombin and platelet activating factor with a Ca^{2+} response, indicating that corresponding receptors and phospholipase $C\beta_2$ are present and functional[28].

Reduced expression of platelet G_q caused loss of responsiveness to thromboxane A_2 and an increased tendency to bleed[56]. Impaired G_q activity resulting in reduced responsiveness to thromboxane A_2 has been reported for neonatal platelets[57] and platelets from dogs[58].

G_{12} and G_{13}

The G-protein G_{12} is activated in platelets stimulated by thrombin, ADP and thromboxane A_2, indicating that this G-protein is coupled to the PAR receptors, the $P2Y_1$ receptor, and the TPα/β receptor, respectively[11,32,59]. Concurrently, $G\alpha_{12}$ is phosphorylated by protein kinase C, probably by the β,δ or ε subtype.

G_{13} is a member of the G_{12} class. $G_{13}\alpha$ is activated by thrombin, thromboxane A_2 and lysophosphatidic acid but not by ADP[32,60]. Evidence for coupling of $G_{13}\alpha$ to the TP receptor is based on copurification with the receptor, the fact that ligand binding to the receptor induces GTPγS incorporation in $G_{13}\alpha$ and the observation that the affinity of $G_{13}\alpha$ for receptor binding is changed upon ligand binding to the receptor[60]. $G_{13}\alpha$ is the target of dual phosphorylation. There is a protein kinase A mediated phosphorylation induced by prostacyclin, which results in arrest of thromboxane A_2-induced signalling[61]. A second phosphorylation is induced by protein kinase C in platelets activated by thrombin or thromboxane A_2[59].

Since stimulation with thromboxane A_2 activates G_q, G_{12} and G_{13} simultaneously, it is not easy to clarify the role of the individual G-proteins in platelet functions. Mouse platelets deficient in G_q are therefore of special interest. These cells lack thromboxane A_2-induced aggregation and secretion, but preserve a normal shape change response[50]. G_q knock-out platelets show a normal tyrosine phosphorylation of pp72 syk and pp60 c-src, suggesting that the tyrosine phosphorylation of these proteins is initiated by $G_{12/13}$. The normal shape change response is accompanied by phosphorylation of myosin-light chain, which is an important step in cytoskeleton assembly. Both shape change and myosin-light phosphorylation are abolished by inhibition of Rho-kinase, an effector of the small GTPase Rho. This suggests that $G_{12/13}$ is an upstream regulator of the Rho kinase – myosin light chain kinase pathway[54], possibly by activating the RhoGEFs p115RhoGEF and PDZRhoGEF. Lysophosphatidic acid binds to the Edg2/4/7 receptor which is coupled to G_{13} inducing Rho/Rho-kinase dependent shape change[34,62].

G_{15} / G_{16}

G_{15} (in mice platelets) / G_{16} (in human platelets) is a member of the Gq class of G-proteins and mainly expressed in haematopietic cells[9]. It is present in a short (43 kDa) and long (46 kDa) form[63]. $G_{16}\alpha$ lacks a cysteine that is the target for pertussis toxin ADP ribosylation. $G_{16}\alpha$ mRNA and protein are absent in MEG-01 cells but DAMI and CHRF-288–11 show increasing levels of expression of this subunit[28]. The appearance of $G_{16}\alpha$ mRNA and protein expression is accompanied by appearance of thromboxane A_2 induced signalling to Ca^{2+} mobilization and cAMP suppression. This raises the possibility that this G-protein couples the TP-receptor to phospholipase $C\beta_2$.

G_z

G_z is a member of the G_i family but resistant to pertussis toxin. The protein is highly expressed in platelets. $G_z\alpha$-deficient mice platelets show impaired reduction of cAMP by epinephrine, indicating that this G-protein functions in the coupling between the α_{2A}-adrenergic receptor and inhibition of adenylyl cyclase[64]. $G_z\alpha$ (41 kDa) is phosphorylated on Ser16 by p21-activated protein kinase (PAK)-1, an effector of the small GTPase Rac1. This decreases the inhibition by $\beta\gamma$ complexes and by RGSZ1, a G_z-selective GTPase-activating protein. A second phosphorylation site is Ser27, which is a target for protein kinase C[65,66]. $G_z\alpha$ is absent in MEG-01, DAMI and CHRF-288–11 cell lines, indicating that expression starts at a late stage of megakaryocyte maturation[28].

G_h

$G_h\alpha$ is a recently discovered G-protein subunit. Analysis by RT-PCR and immunoblotting reveals that $G_h\alpha$ is expressed in megakaryoblastic cell lines and platelets. Transfection studies in COS-7 show that the TPα -but not the TPβ receptor- couples to G_h, thereby taking part in thromboxane A_2 induced formation of inositolphosphate[67].

	Rab27B		α granules, plasma membrane	142

Notes:
Rab 3A absent in platelets[128].

Independent role of $\beta\gamma$ subunits

GDP-GTP replacement on α subunits triggers the dissociation of $\beta\gamma$ subunits, which act as independent signalling elements. Platelet $G_i\alpha_2$ and G_q appear major sources of free $\beta\gamma$. They contain predominantly γ5 but $\beta\gamma$ complexes from other cells equally effectively activate platelet phospholipases Cβ[68]. Targets are the phospholipases Cβ_2 and -β_{3a} in the membrane, and the -β_{3b} isoform in the cytosol[68]. The domain Glu574–Lys583 of phospholipase Cβ_2 appears to be the binding site for $\beta\gamma$[69,70]. Activation of phospholipase Cβ_2 and PtdIns 3-kinase-γ by $\beta_5\gamma_2$ has been reported[71]. In many cell types the β part is phosphorylated but in platelets this appears not to play a major role[70,72]. In rat platelets the γ_{11} isoform is present in relative excess[73].

Lysophosphatidic acid and sphingosine-1-phosphate bind to the Edg2/4/7 and Edg1/3/5 receptors respectively and are potent platelet activators. Subsequent signal induction is still poorly understood but in addition to G_q[74] and G_{12} /G_{13}[34,62] may involve G_i -derived $\beta\gamma$ subunits[75,76].

Small GTPases in platelets and megakaryocytes

Ras-like GTPases

Among the Ras-like GTPases identified in platelets so far is Ras itself. Subtype characterization is incomplete (Table 14.2). Ras is present at a concentration of about 0.5 µg/mg protein and activated in platelets stimulated with thrombin, SFLLRN peptide and thromboxane A_2[77,78]. Thus, activation pathways initiated by the PAR1 and TFα/β receptor couple to a Ras-GEF. In platelets stimulated with PMA, GDP-Ras is converted into GTP-Ras and it is therefore possible that protein kinase C functions as an activator of Ras[78]. The platelet inhibitor PGI_2 inhibits thrombin-induced Ras activation. Transfection of mutationally activated H-Ras in $\alpha_{IIb}\beta_3$ expressing CHO cells shows that the GTPase can act as a negative regulator of the integrin. Integrin inhibition was accompanied by activation of ERK1/2, which is a downstream element in the Ras pathway[79]. Also the β3-endonexin mediated activation of $\alpha_{IIb}\beta_3$ was blocked by H-Ras[80]. In contrast, R-Ras is an activator of integrins and appears to inhibit the H-Ras/Raf pathway[81]. Platelet p21rasGAP is tyrosine phosphorylated

Cambridge Books Online © Cambridge University Press, 2009

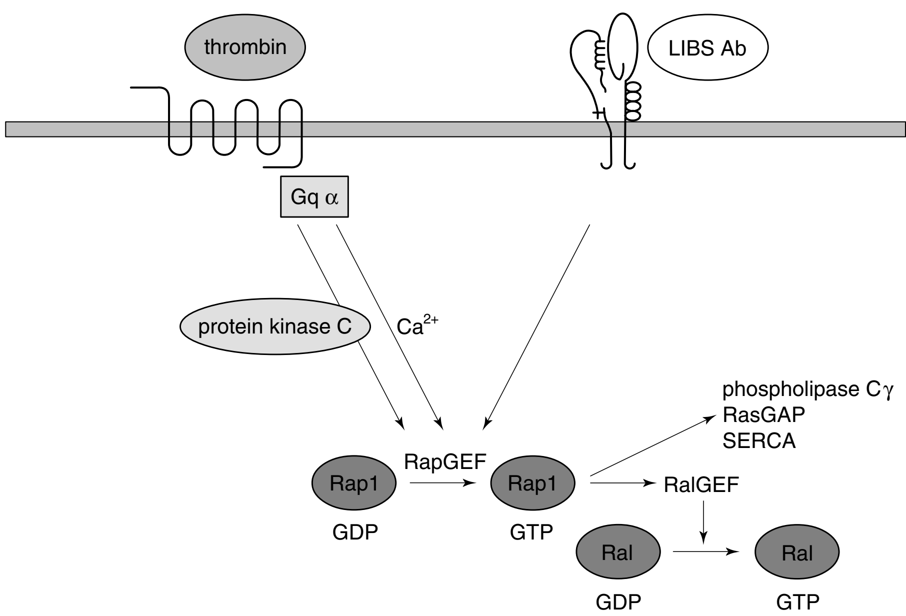

Fig. 14.4. Regulation of the GTPase Rap1. The inactive Rap1GDP is converted to active Rap1GTP by the RapGEF. Activation of Rap1 is biphasic: there is a first phase mediated by Ca^{2+} which is followed by a second phase mediated by protein kinase C. Also the monoclonal antibody LIBS-6, which activates integrin $\alpha_{IIb}\beta_3$ from the extracellular site, activates Rap1. Downstream targets of Rap1GTP are Ral, phospholipase Cγ (via RasGAP) and possibly the sarco/endoplasmatic reticulum Ca^{2+} ATPase, SERCA 3b.

and associates with the protein tyrosine kinases, Fyn, Lyn and Yes[82].

Rap1A is present in the cytosol, indicating that it lacks the posttranslational modification that enables membrane attachment[83]. In platelets Rap1A is tenfold lower than Rap1B, the latter accounting for 0.1% of protein content. In resting platelets, Rap1B is bound to membranes; upon platelet activation it translocates to the cytoskeleton[84]. Rap1B is activated in platelets stimulated by thrombin, PAR1 peptide, collagen, ADP, thromboxane A_2, platelet activating factor, low density lipoproteins and lysophosphatidic acid[85,86]. All activators raise cytosolic Ca^{2+}, which appears a crucial step in the initial phase of Rap1 activation (Fig. 14.4). This first activation phase is followed by a second phase which depends on protein kinase C and PtdIns 3-kinase[87]. Activation of integrin $\alpha_{IIb}\beta_3$ with a LIBS-6 antibody also induces Rap1 activation, indicating that the integrin signals to a Rap1GEF. Induction of platelet aggregation leads to inhibition of Rap1 activation. This downregulation correlates with Rap1 translocation to the cytoskeleton, possibly mediated by Rap1GAP, which also translocates to the cytoskeleton[88]. The contribution of Rap1GAP to Rap1 regulation appears minor, however, since upon platelet activation its activity hardly changes[89]. Two forms of Rap1GAP have been purified from platelet cytosol.

Rap1B activation is inhibited by prostacyclin but this effect appears independent of the phosphorylation induced by cAMP dependent protein kinase A. Rap1 is phosphorylated on Ser179 at the C-terminal end, which induces Rap1 translocation from plasma membranes to the cytosol[90]. Also cGMP-dependent protein kinase G phosphorylates Rap1. Thrombin equally activates Rap1 and phosphorylated Rap1[85]. Earlier work indicated that Rap1 might be involved in Ca^{2+} regulation in platelets[91,92]. Rap1 co-immunoprecipitated with the sarco/endoplasmic reticulum Ca^{2+}-ATPase isoform 3b (SERCA3b). The association was lost after protein kinase A-mediated phosphorylation of Rap1 on Ser179. The farnesylcysteine analogues farnesylthioacetic acid and N-acetyl-s-geranylgeranyl-L-cysteine inhibit methylation of prenylated and geranylgeranylated proteins respectively and decrease thrombin-induced increases in Ca^{2+} concentration[93,94]. Immunocytochemical localization shows that Rap1B in platelets and megakaryocytes is associated with the plasma membrane and the open canalicular system, as well as with α-granule membrane[95].

Phospholipase Cγ_1 is constitutively associated with the GAP for the Ras protein, p120RasGAP present in the cytosol. Thrombin triggers association of the complex to the membrane bound Rap1 thereby localizing phospholipase Cγ close to its substrates in the plasma membrane[83].

Cambridge Books Online © Cambridge University Press, 2009

Abnormalities in platelet Rap1 phosphorylation by protein kinase A have been reported in Grey Platelet Syndrome[96] and certain psychiatric disorders[97].

Platelets contain only the Rap2B isoform[98]. In contrast to Rap2A, which is farnesylated, Rap2B is geranylgeranylated similar to Rap1 proteins[99–101]. Upon platelet activation about 35% of total Rap2B translocates to the cytoskeleton in a process that critically depends on aggregation and actin polymerization. This translocation correlates with the cytoskeletal translocation of integrin $\alpha_{IIb}\beta_3$, suggesting that Rap2B functions in the regulation of fibrinogen binding and aggregation[83,84,102,103]. MEG-01 cells express Rap1A, Rap1B and Rap2B[104].

RalA and RalB have 55% sequence identity with Ras. Ral is abundantly present in human platelets[105,106] and post-translationally processed[107–109]. Ral is rapidly activated in platelets stimulated by thrombin, PAR1 peptide, platelet activating factor, thromboxane A_2[77,86]. ADP is a weak activator of Ral. The same activation is induced by Ca^{2+} ionophore, suggesting that the increase in cytosolic Ca^{2+} is a crucial step in Ral activation. In this respect, Ral activation and inhibition resembles that of Rap1B. This is the basis for the hypothesis that Rap1B is an upstream activator of the GEF for Ral[77,86] (Fig. 14.4). A Ral-GAP (34 kDa) has been found in the cytosol and particulate fraction[110].The only putative target of GTP-Ral is RLIP76, which is a GAP for Cdc42, a member of the Rho-like GTPases. If this interaction occurs in platelets, it would link the Rap1–Ral system to mechanisms that regulate cytoskeletal rearrangements. Ral is present in plasma membranes and especially dense granules[109], the latter suggesting that Ral functions in exocytosis[111]. Platelets contain RalA and RalB in approximately equal amounts[105]. Interestingly, RalA binds to phospholipase D, which has also been implicated in platelet secretion. This interaction is independent of the activity state of Ral, suggesting that Ral merely functions in targeting of PLD to the plasma membrane. MEG-01 cells express RalA[104].

Rho-like GTPases

Platelets contain Rho A, Rac1, Rac2 and Cdc42[112]. Platelet Rho is geranylgeranylated but nevertheless mainly cytosolic, possibly because a Rho-GDI prevents binding to the membrane. Thrombin stimulation induces translocation of Rho to the cytoskeleton.

Lysophosphatidic acid signals to the small GTPase Rho and regulation of actomyosin assembly[113]. This is the basis for platelet shape change induced by mildly oxidized low density lipoprotein, an important constituent of the atherosclerotic plaque[62]. *Clostridium botulinum* exoenzyme C3 ADP-ribosyl transferase[114] ribosylates Asn41 thereby preventing the interaction of the GTPase with downstream targets. This inhibitor has greatly facilitated the characterization of downstream pathways controlled by Rho. Thus, Rho inhibition abolishes activation of p85/p110 heterodimeric PtdIns 3-kinase[115]. Inhibition of Rho failed to affect inside-out signalling to integrin $\alpha_{IIb}\beta_3$ but decreased adhesion to fibrinogen and formation of vinculin-rich focal adhesions[116]. The Rho A inhibitor C3-transferase and the Rho-kinase inhibitor Y-27632 blocked lysophosphatidic acid induced myosin light chain phosphorylation, moesin phosphorylation and shape change[117]. A similar signalling pathway is initiated by sphingosine-1 phosphate, a second agonist of the lysophospholipid receptor family[118,119]. Rho signals via Rho-kinase inducing inhibition of myosin light chain phosphatase[120] (Fig. 14.5). Rho activity is regulated by a p190 RhoGAP which is associated with p120RasGAP[121]. Other GAPs of the Rho-like class are less specific for Rho and most of them have not yet been identified in platelets. Further control is carried out by Rho GDIs and at least one has been found in platelets[122]. MEG-01 cells express RhoA, Rac1, Rac2, Cdc42Hs[104].

Rac1 and Rac2 are present in platelets and translocate to the cytoskeleton upon platelet activation[122,123]. Rac activation by stimulating PAR receptors activates PtdIns 3-kinase[124]. Rac also activates PtdIns 4–P 5-kinase, resulting in formation of PtdIns 4,5 P_2 and actin filament barbed-end uncapping[123]. Another effector of Rac in platelets is γPAK, a member of the PAK65 class, which are Ser/Thr kinases involved in morphological changes. In other cells the Rac – PAK pathway signals to activation of the p38MAPkinase pathway, which in platelets signals to cytosolic phospholipase A_2 and formation of thromboxane A_2. This link is yet to be established in platelets. A RacGEF in platelets is Vav. Vav is phosphorylated in platelets stimulated with strong agonists and a target of outside-in signalling through integrins during platelet adhesion[125].

Cdc42 is geranylgeranylated and shows 50% identity with Rho and about 30% identity with the Ras-like proteins. Platelet Cdc42 is present in plasma membranes and in the cytosol[106,112]. Despite its posttranslationally modified C-terminus, it is present in the cytosol probably in a complex with a RhoGDI. Platelet stimulation with thrombin or ADP induces translocation to the cytoskeleton, which appears to occur during the second phase of a biphasic aggregation response[123]. An effector of Cdc42 is the Wiskott Aldrich syndrome protein, which is deficient in patients suffering from Wiskott Aldrich Syndrome[126,127]. These platelets have an abnormal morphology due to a defect in the actin skeleton. A Cdc42GAP is present in the cytosol and in membranes.

Cambridge Books Online © Cambridge University Press, 2009

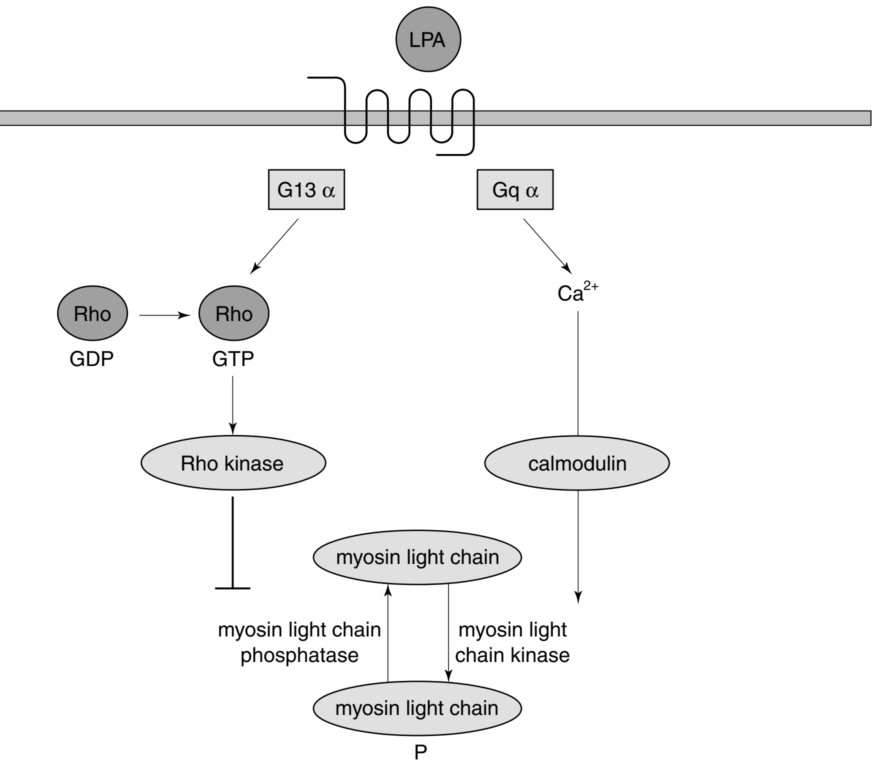

Fig. 14.5. Role of Rho in platelet shape change. Binding of lysophosphatidic acid (LPA) to its receptor activates G_{13} and G_q. G_{13} signalling involves activation of RhoGDP to RhoGTP and subsequent activation of Rho-kinase, which is an inhibitor of myosin light chain phosphatase. G_q signalling leads to a Ca^{2+} increase and together with calmodulin to activation of myosin light chain kinase. The result of both routes is phosphorylation of myosin light chain, actin–myosin interaction and cytoskeleton reorganization during shape change (adapted from[24]).

Rab GTPases

Rab proteins are involved in the docking of transport vesicles with their target compartments. They are doubly geranylgeranylated and about 30% homologous with Ras. So far seven members of this class have been found in platelets[104,128]. Rab3B is present in the cytosol whereas as Rab6 and Rab8 are found in plasma membranes and α-granules[128]. Thrombin activation of platelets leads to protein kinase C dependent phosphorylation of Rab3B, -6 and –8 and translocation of Rab6 to the cytosol[128,129]. Mice homozygous for the mutation gunmetal (gm) have prolonged bleeding, thrombocytopenia, and reduced platelet α- and δ-granule contents[130]. This is caused by a G-A substitution in Rab geranylgeranyl transferase, which catalyzes the attachment of geranylgeranyl groups to Rab. This results in a severe reduction in enzyme activity, membrane association of Rab27, and platelet formation[131]. MEG-01 cells express Rab3B, Rab6 but not Rab4[104].

Introduction

The major physiological role of platelets is in the cessation of bleeding following damage to the vasculature. Ordinarily, platelets circulate within intact blood vessels in a quiescent state, but undergo extremely rapid and powerful activation upon exposure to the subendothelial matrix leading to formation of a platelet aggregate or vascular plug. This rapid response is achieved by the stimulatory action of a range of diverse agonists including extracellular matrix proteins, e.g. collagen, and products of the coagulation cascade, e.g. thrombin. Activation is reinforced through release of agonists from platelet granules, notably ADP, and liberation of thromboxane A_2 (TxA_2), the major product of the metabolism of arachidonic acid (AA) in the platelet. The positive feedback action of ADP and TxA_2 is of direct clinical relevance. The Antiplatelet Trialists' Collaboration[1] published a summary of 20 randomized trials in 1988, concluding that antiplatelet therapy significantly reduces (by ~ 25%) the risk of cardiovascular death, non-fatal myocardial infarction and nonfatal stroke in patients with unstable angina or a past history of heart attack, transient ischemic attack, or stroke[2,3]. A follow-up report by the same group, confirmed the efficacy of platelet inhibition in a broader spectrum of pathological conditions[4]. More recently, the CAPRIE study has shown that the ADP receptor antagonist, clopidogrel, and aspirin have a similar therapeutic benefit in individuals with a history of thrombotic disease[5]. Aspirin, however, remains the drug of choice in the majority of cases primarily for reasons of cost.

The availability of AA is the rate-limiting step in the formation of TxA_2 in platelets. As will be presented in detail below, it is now well established that AA is released from membrane phospholipids in activated platelets mainly by the enzyme phospholipase A_2 (PLA_2) activity. PLA_2 hydrolyses the *sn*-2 ester of glycerophospholipids to release a free fatty acid (AA and others) and a lysophospholipid. PLA_2 would also be a very good target for development of antithrombotics. This potential is unlikely to be exploited because of the proven efficacy of aspirin as an antiplatelet agent. Aspirin is an irreversible inhibitor of platelet cyclooxygenase-1 (COX-1), and, because platelets lack a nucleus, the enzyme cannot be replenished within the lifetime of the cell. As a consequence, only a low dosage of aspirin is required to achieve full blockade of TxA_2 formation in platelets, whereas other cells can generate new enzyme within a matter of hours. This therefore restricts the major effects of the COX-1 inhibitor to the platelet. It is for these reasons that aspirin is preferred to other non-steroidal antiinflammatory agents in the prophylaxis of thrombotic-based disorders. Treatment with aspirin increases the metabolism of AA via 12-lipoxygenase and 15-lipoxygenase enzymes in platelets, but this appears to have little physiological significance as the metabolites of these two enzymes do not have a major influence on platelet activation.

Recent years have seen rapid developments in our understanding of the regulation of PLA_2 in platelets, and of the pathways that govern the metabolism of the liberated AA. In this chapter, we will describe the major forms of PLA_2 in platelets and their regulation and give only brief details on the metabolism of AA. Comprehensive reviews on the action of TxA_2 and other eicosanoids on platelet function have been published[6,7].

Metabolism of AA in platelets

AA is an essential fatty acid that is stored in the *sn*-2 position of membrane phospholipids. It is the most prevalent fatty acid in platelets, and is found in particularly high levels in phosphatidylcholine, phosphatidylethanolamine

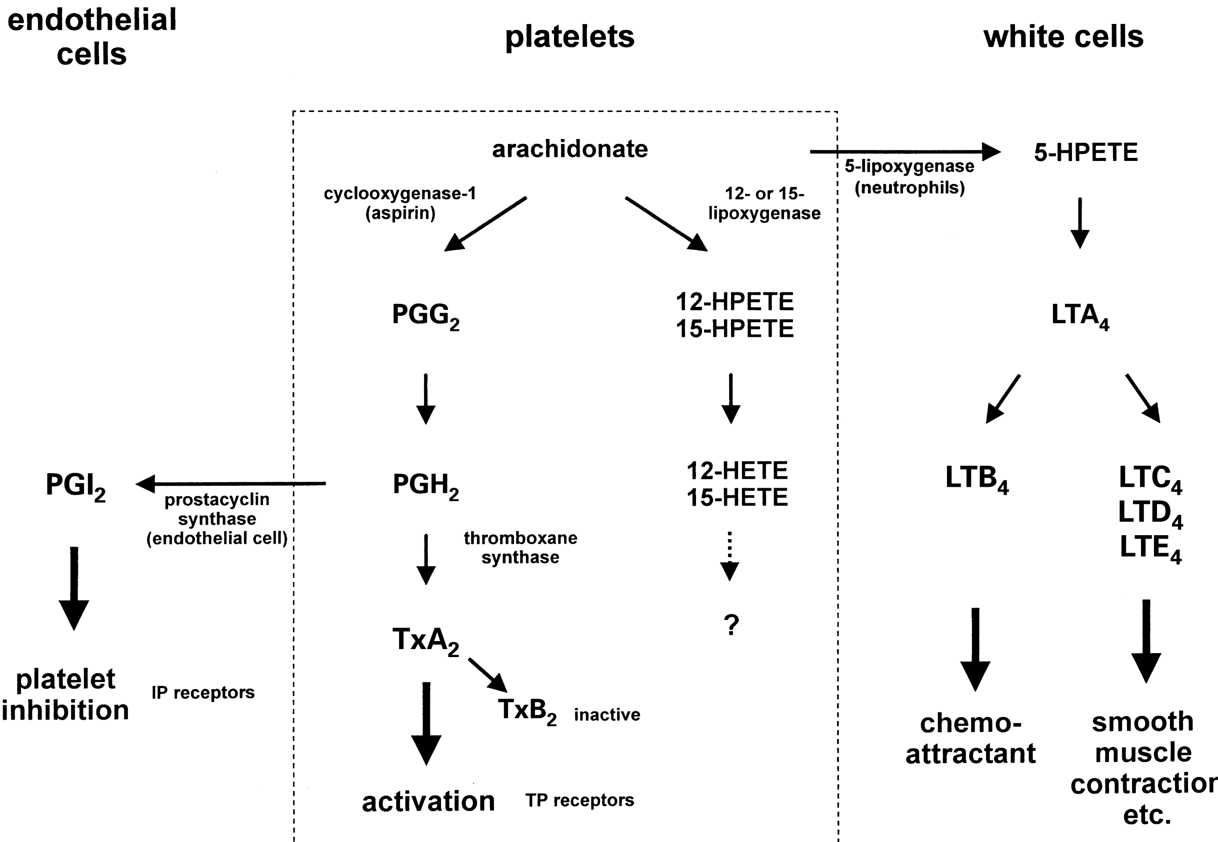

Fig. 15.1. Metabolism of AA in platelets and other cells. The metabolism of AA in platelets is shown in the dotted box. AA is converted by the action of cyclooxgenase-1 to the endoperoxides PGG_2 and PGH_2 and then to thromboxane A_2 (TxA_2), which stimulates platelet aggregation via the thromboxane receptor, TP, which is coupled to Gq-dependent activation of phospholipase C. PGH_2 is also released from the platelet and converted to the inhibitory prostaglandin, prostacyclin (PGI_2), in endothelial cells. PGI_2 inhibits platelet activation via the prostanoid receptor, IP, which is coupled to adenylyl cyclase. AA is also metabolized via 12- and 15-lipoxygenases to 12- or 15-hydroperoxyeicosatetraenoic acid (HPETE) and then to 12- or 15-hydroxyeicosatetraenoic acid. The physiological significance of this is uncertain as the products have no known functional roles in the platelet. The release of AA from platelets is available for conversion to proinflammatory leukotrienes by white cells.

and phosphatidylinositol. Phosphatidylcholine and phosphatidylethanolamine contain over 70% of the total AA in the cell. The AA-containing lipids are localized to the inner leaflet of the plasma membrane and membranes of intracellular organelles, with approximately similar levels in the two compartments. There is evidence that phosphatidylcholine and phosphatidylethanolamine, or possibly just the latter, are the major sources of AA following receptor stimulation (for discussion see[6,7]). Although AA is the predominant fatty acid in the *sn*-2 position of phospholipids, PLA_2s are able to hydrolyse phospholipids with other acyl chains. This is of particular relevance to dietary supplementation with fish oils enriched in ω-3 fatty acids, including eicosapentaenoic acid. The liberated eicosapentaenoic acid is converted to the inactive thromboxane A3, contributing to the antiplatelet effects of fish oil.

The AA that is liberated by the action of PLA_2 is available for metabolism via COX-1 or lipoxygenase pathways. COX-1 is the major AA metabolizing enzyme that is present in the platelet. In addition, platelets express 12-lipoxygenase and, in lower levels, 15-lipoxygenase, but lack the 5-lipoxygenase which is required for generation of leukotrienes (see Fig. 15.1). The major metabolite of AA in platelets is TxA_2. This is generated by the double oxygenation of AA yielding PGG_2 and then PGH_2, which, collectively, are known as the endoperoxides. PGH_2 is converted to TxA_2 by thromboxane synthase. TxA_2 is a powerful platelet agonist, inducing activation via the TP

Cambridge Books Online © Cambridge University Press, 2009

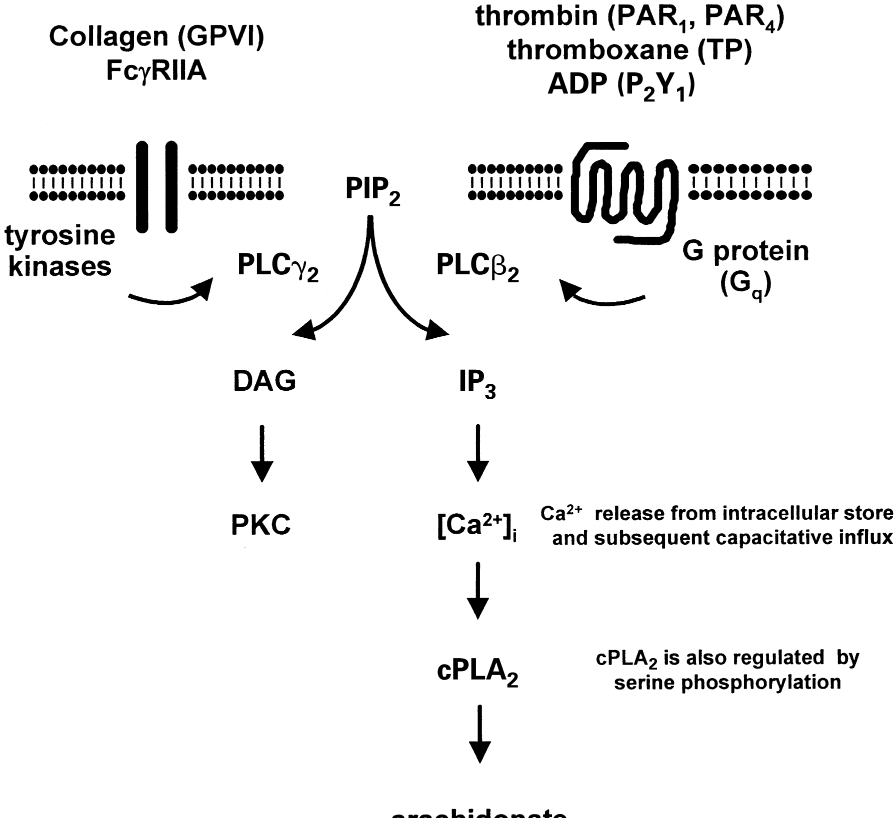

Fig. 15.2. Receptor liberation of AA in platelets. Many platelet agonists mediate activation through stimulation of phospholipase C (PLC) leading to formation of IP_3 and elevation of intracellular Ca^{2+}. These agonists can be subdivided into those which signal via tyrosine kinase-linked and G protein-coupled activation of PLCγ2 and PLCβ2, respectively. The newly generated Ca^{2+} activates $cPLA_2$-α. In addition, $cPLA_2$-α is regulated by phosphorylation on serines 505 and 727 via MAP kinases and MAP kinase-activated protein kinases (see text).

thromboxane receptor, which is coupled to activation of Gq and phospholipase C (Fig. 15.2). Because of the powerful activating effect of TxA_2, and beneficial effects resulting from conversion of released PGH_2 to prostacyclin in endothelial cells (see below), it was thought that inhibitors of thromboxane synthase would be good antiplatelet agents. These inhibitors would have the dual effect of prevention of TxA_2 generation and shunting of PGH_2 to prostacyclin in vascular endothelial cells. It has since been realized, however, that PGH_2 has reasonable activity at the TP receptor[8], making such inhibitors less effective than aspirin.

PGH_2 is also converted in much lower levels to PGD_2, PGE_2 and $PGF_2\alpha$. Platelets do not have specific receptors for PGE_2 and $PGF_2\alpha$, whereas the DP receptor for PGD_2 is present at a low level in some species. In general, the much lower levels of these three prostanoids means that they are of limited physiological significance in platelet function. The newly formed endoperoxides PGG_2/PGH_2 diffuse out of the platelet to the surrounding endothelial cell layer where they are converted to prostacyclin, one of the most powerful inhibitors of platelet activation. Prostacyclin activates IP prostanoid receptors on the platelet surface leading to elevation of cAMP. Physiologically, this helps to prevent progression of the platelet aggregate over the intact endothelium by acting as a physiological antagonist against most platelet agonists. Endothelial cells do not have thromboxane synthase and so cannot generate prostimulatory TxA_2.

The other product produced in reasonable levels in platelets following liberation of AA is 12-hydroxyperoxy-eicosatetraenoic acid (12-HPETE) (Fig. 15.1). Although HPETE has no effect on its own, it has been reported to convert the response of subthreshold concentrations of

Cambridge Books Online © Cambridge University Press, 2009

arachidonic acid to full aggregation at physiological concentrations[9]. This is mediated through potentiation of metabolism of arachidonic acid to thromboxane A_2. At higher, non physiological concentrations, HPETE inhibits platelet responses to arachidonic acid. In addition, HPETE is converted to 12-hydroxyeicosatetraenoic acid (12-HETE) which is released and metabolized to 12,20-HETE in neutrophils, where it may competitively inhibit metabolism of LTB_4[10]. Conversely, platelets convert neutrophil-derived leukotrienes into proinflammatory lipoxins[11]. There is also evidence that AA released from platelets is converted by 5-lipoxygenase to proinflammatory leukotrienes in white cells. The clinical significance of the interaction with neutrophils, however, is uncertain, but emphasizes the potential for cross-talk with other cells.

There is limited evidence to suggest that AA is a second messenger in its own right, although the physiological significance of this remains unclear. For example, AA has been shown to activate protein kinase C in the platelet cytosol independent of Ca^{2+} and phospholipids[12].

Mammalian PLA_2s

There is a diverse collection of PLA_2s in mammals, some of which are secreted whilst others remain intracellular. Secreted PLA_2s ($sPLA_2$) are Ca^{2+}-dependent, disulfide-rich, 14-18 kDa enzymes. The first mammalian $sPLA_2$ to be identified was the group IB enzyme, also known as pancreatic $sPLA_2$. This $sPLA_2$ is found at high levels in pancreatic juice, where it has a well-known function in the digestion of dietary phospholipids[13], but also at lower levels in lung, liver, spleen, kidney, and ovary where it has been proposed to play a role in cell proliferation, acute lung injury, cell migration, and endotoxic shock[14–16]. The second mammalian $sPLA_2$ to be identified was the group IIA enzyme which is expressed at high levels during inflammation[17], and is the principal bactericidal agent against Gram-positive bacteria in human tears[18].

In addition to the above roles, it is becoming clear that $sPLA_2$s are involved in a diverse set of physiological functions[14,19–21]. In the last few years, six mouse and five human $sPLA_2$s structurally related to groups IB and IIA $sPLA_2$s (mouse groups IIC, IID, IIE, IIF, V, and X, and human groups IID, IIE, IIF, V, and X) have been identified[22–27]. All of these group I/II/V/X $sPLA_2$s have similar primary structures, including identical catalytic site residues and partially overlapping sets of disulfides[28]. However, they are not closely related isoforms since the level of amino acid identity is typically 20-50% among these $sPLA_2$s. More recently, a novel human group III $sPLA_2$ was identified[29], which is structurally distinct from the group I/II/V/X $sPLA_2$s but related to the group III $sPLA_2$s found in bee and lizard venom. Very recently, a new human $sPLA_2$, group XII, was identified that is structurally distinct from all previously characterized mammalian and venom $sPLA_2$s and shares homology with known $sPLA_2$s only in short active site segments containing catalytic residues[30]. This diversity of $sPLA_2$ structures and the fact that the tissue distribution of the different $sPLA_2$s are distinct argue for a range of physiological functions for these lipolytic enzymes.

Mammalian cells also contain intracellular PLA_2s. Cytosolic PLA_2 ($cPLA_2$-α) is an 87-kDa protein that binds to membranes in a Ca^{2+}-dependent manner[31]. $cPLA_2$-α contains a C2 domain at its N-terminus which constitutes the Ca^{2+}-dependent membrane binding element[32–34]. Many of the $sPLA_2$s described above have been tested for *sn*-2 fatty acyl chain selectivity and are found to display little, if any, specificity for polyunsaturated versus saturated or monounsaturated chains[35]. In contrast, $cPLA_2$-α displays significant specificity for the *sn*-2 arachidonyl chain over the *sn*-2 oleate chain for example[35]. In response to a rise in intracellular calcium to the low micromolar range, $cPLA_2$-α transfers from the cytosol to the perinuclear region (nuclear membrane and what appears to be nearby membrane elements such as a portion of the Golgi and endoplasmic reticulum)[34,36,37]. The binding of $cPLA_2$-α to the intermediate filament protein vimentin may mediate this process[38]. Studies with $cPLA_2$-α-deficient mice provide strong evidence that $cPLA_2$-α plays a role in AA release for the biosynthesis of eicosanoids in inflammatory cells[39–42]. Two new human $cPLA_2$-α paralogs, $cPLA_2$-β and $cPLA_2$-γ, have been recently cloned based on searching genomic databases[43,44], and no physiological functions have been assigned to these enzymes.

Mammalian cells also contain an intracellular calcium-independent PLA_2 ($iPLA_2$)[45]. Studies using an $iPLA_2$ inhibitor as well as antisense technology suggest that this enzyme is involved in phospholipid remodelling in which the *sn*-2 chain of newly synthesized phospholipids is eventually replaced with a polyunsaturated fatty acyl chain[45]. $iPLA_2$ may not carry out this function in all mammalian cells[46]. $iPLA_2$ may be responsible for AA release seen in some mammalian cells undergoing apoptosis[47]. Multiple $iPLA_2$ splice variants have been identified[48] as well as a human paralog, $iPLA_2$-γ[49], but the functions of these enzymes are not known.

PLA_2s in platelets

At the time of this writing, platelets are known to contain two PLA_2s, group IIA $sPLA_2$ and $cPLA_2$-α. Kramer and

Cambridge Books Online © Cambridge University Press, 2009

coworkers discovered human group IIA $sPLA_2$ by purifying it from platelets[50]. Partial amino acid sequence obtained from the purified enzyme led to isolation of the human group IIA $sPLA_2$ genomic clone. They also showed that human group IIA $sPLA_2$ is secreted in active form following stimulation of platelets with thrombin. Whereas pancreatic-type (group IB) $sPLA_2$ is secreted as an inactive form with a propeptide and requires proteolytic activation, human group IIA does not contain a propeptide, only a signal peptide. Early studies also showed that rat and rabbit platelets contain group IIA $sPLA_2$[51–53]. Intravenous injection of ADP into rats leads to a rapid rise in plasma PLA_2 activity probably coming from activated platelets[54]. This enzyme is known to bind tightly to heparin, and after secretion from platelets may absorb onto heparan sulfate proteoglycan present on the surface of vasculature endothelial cells. Eventually, group IIA $sPLA_2$ in plasma is taken up by the liver and degraded.

$cPLA_2$-α was also purified from human platelets, leading to sufficient material for partial amino acid sequencing and cloning[55]. Bovine and rabbit platelets are also reported to contain $cPLA_2$-α[56,57]. As will be discussed in detail below, this enzyme is activated in agonist-stimulated platelets by phosphorylation and by a rise in intracellular Ca^{2+}.

Role of $cPLA_2$-α in platelet AA release

Two lines of evidence suggest that $cPLA_2$-α is responsible for much of the AA release in platelets following stimulation with the physiological agonists thrombin and collagen. The first comes from the use of a $cPLA_2$-α-specific inhibitor $AACOCF_3$[58,59]. This compound is an AA analogue in which the COOH group is replaced with a trifluoromethyl ketone group $COCF_3$. It is thought that $AACOCF_3$ forms a stable hemiketal adduct with the active site serine of $cPLA_2$-α (Ser-228) that resembles the tetrahedral intermediate that forms from the attack of this serine onto the carbonyl carbon of the substrate ester undergoing hydrolysis. $AACOCF_3$ does not inhibit $sPLA_2$s, although it does inhibit $iPLA_2$[60]. Two independent studies show that low micromolar concentrations of $AACOCF_3$ block virtually all of the AA released in human platelets stimulated with thrombin and calcium ionophore[61,62]. The control compounds $AACOCH_3$ and $AACH(OH)CF_3$, which do not inhibit $cPLA_2$-α in vitro, fail to block AA release in platelets. $AACOCF_3$ was further reported to block downstream oxygenation of AA in platelets[62], suggesting it may also act as a competitive inhibitor of oxygenating enzyme COX-1.

The second line of evidence that $cPLA_2$-α is involved in platelet AA release comes from studies of the regulation of this enzyme (described in detail below). Studies in human platelets show that $cPLA_2$-α becomes phosphorylated and activated in platelets stimulated with a variety of agonists[63,64]. This post-translational modification occurs with the same time course as AA release in platelets. $cPLA_2$-α is also phosphorylated and activated in a variety of other mammalian cells[31,65]. Although $cPLA_2$-α-deficient mice are available[39,40], studies of AA release in $cPLA_2$-α-deficient platelets have not been reported.

Regulation of $cPLA_2$-α in platelets

It has been proposed that AA liberation in platelets may be regulated by GTP-binding protein(s) and protein kinase C. Such studies were performed with platelet-membrane fractions or permeabilized platelets, and, platelet activation was performed with non physiological agonists such as PMA or fluoroaluminate[66–69]. By contrast, studies on the regulation of $cPLA_2$-α by phosphorylation and by Ca^{2+} have been reported in intact platelets activated by physiological agonists such as thrombin and collagen. Regulation of $cPLA_2$-α by phosphorylation and Ca^{2+} has also been studied in several other mammalian cells[31]. In this part, we will mainly focus our review on the regulation of $cPLA_2$-α that occurs during platelet stimulation by thrombin and collagen.

Regulation of platelet $cPLA_2$-α by Ca^{2+}

Because of the pivotal role of intracellular Ca^{2+} in the regulation of $cPLA_2$-α via its C2 domain, it follows that agonists that increase the levels of the cation also bring about the activation of $cPLA_2$-α. For the majority of agonists, the increase in Ca^{2+} is mediated through IP_3-dependent release of Ca^{2+} from intracellular stores and capacitative Ca^{2+} entry. The increase in IP_3 is brought about by G protein-coupled surface receptors, which activate phospholipase $C\beta_2$ ($PLC\beta_2$) isoforms, and tyrosine kinase-linked receptors, which activate $PLC\gamma_2$ (Fig. 15.2). Examples of G protein-coupled receptors that activate $PLC\beta_2$ downstream of Gq include the thrombin receptors, PAR_1 and PAR_4, the ADP receptor, P_2Y_1, and the thromboxane receptor, TP. Additionally, it has been proposed that the liberation of G protein $\beta\gamma$ subunits by Gi-coupled receptors such as the ADP receptor, P_2Y_1, P_2Y_2 and a_2-adrenoceptor, potentiates activation of $PLC\beta_2$ by Gq, although direct evidence for this is lacking. The major tyrosine kinase-linked receptors in human platelets are the collagen receptor GPVI and the platelet low affinity immune receptor, $Fc\gamma$RIIA. The depletion of intracellular Ca^{2+} stores by IP_3 leads to influx of Ca^{2+} by capacitative entry

Cambridge Books Online © Cambridge University Press, 2009

and a correspondingly greater increase in AA release. There is also emerging evidence for additional pathways of Ca^{2+} entry that are independent of IP_3 such as direct regulation of cation channels by tyrosine kinases[70]. There have been no studies describing the site of translocation of cPLA$_2$-α in the platelet, although it is noteworthy that studies in other cells have reported translocation to intracellular membranes[34,36,37]. It is of particular interest to investigate whether cPLA$_2$-α translocates to dense tubular membranes, the site of location of COX-1 and thromboxane synthase in platelets[71].

There is limited evidence that cPLA$_2$-α is regulated by receptors in platelets which do not elevate intracellular Ca^{2+}. The cytokine thrombopoietin potentiates platelet activation by a wide range of agonists, but has no stimulatory action on its own. Phosphorylation of cPLA$_2$-α has been proposed as the mechanism underlying the priming action of thrombopoietin[72]. This is not the only mechanism of priming, however, as thrombopoietin potentiates activation in the presence of cyclooxygenase inhibitors[73]. The physiological significance of the priming effect of the cytokine is unclear. There is limited evidence that the major platelet integrin, αIIb-β3, which is a receptor for fibrinogen and von Willebrand factor, can activate cPLA$_2$-α.

Regulation of cPLA$_2$-α by phosphorylation

Lin and coworkers at Genetic Institute in Boston were the first to provide strong evidence that cPLA$_2$-α is phosphorylated in mammalian cells in response to agonists that mobilize AA from phospholipids[74]. After this group cloned cPLA$_2$-α, they realized that the protein contains a consensus motif surrounding Ser-505 for phosphorylation by mitogen activated protein kinase family members (MAPKs). This group also provided strong evidence, but not proof, that cPLA$_2$-α is phosphorylated on Ser-505 when expressed in CHO cells. When the S505A cPLA$_2$-α mutant was expressed in CHO cells, AA release in response to Ca^{2+} ionophore and the protein kinase C activator PMA was greatly decreased compared to that produced by expression of wild-type cPLA$_2$-α. They also showed that cPLA$_2$-α phosphorylation led to a slight decrease in the electrophoretic mobility of the enzyme. This gel shift assay, which can be examined by immunoblotting methods using total protein extracted from mammalian cells, has been used by many investigators to track cPLA$_2$-α phosphorylation in response to agonists (> 300 published studies).

However, we were never completely satisfied with the gel shift assay because it does not provide site-selective cPLA$_2$-α phosphorylation data. We were able to isolate sufficient quantities of cPLA$_2$-α from a baculovirus/insect cell expression system to determine the sites of phosphorylation by protein chemical methods. We determined that cPLA$_2$-α was phosphorylated not only on Ser-505 but also on serines-437, 454, and 727[75]. This was accomplished by using combined HPLC/electrospray mass spectrometry to fully sequence the four tryptic phosphopeptides. Radiometric methods with ^{32}P were used to show that these four phosphorylations accounted for all of the cPLA$_2$-α phosphorylation in these cells. We then studied cPLA$_2$-α phosphorylation in human platelets following stimulation with the physiological agonists thrombin and collagen. Although sufficient amounts of cPLA$_2$-α from mammalian cells for mass spectrometry studies cannot be readily obtained, we were able to use ^{32}P-radiometric methods to show that the radiolabelled tryptic peptides obtained from immunoprecipitated platelet cPLA$_2$-α comigrated with authentic phosphopeptides (prepared by solid-phase peptide synthesis) on both a reverse-phase HPLC column and on a two-dimensional cellulose plate (electrophoresis followed by thin layer chromatography). By this method, we showed that cPLA$_2$-α is phosphorylated in thrombin and collagen stimulated platelets on Ser-505 and on Ser-727, and this accounted for all of the phosphorylation in these cells (Ser-437 and Ser-454 phosphorylations were not observed)[76] (Fig. 15.3). Since cPLA$_2$-α phosphorylation is stoichiometric in platelets (full gel-shift) and since the cpm incorporated at Ser-505 and Ser-727 are virtually identical, we conclude that platelet cPLA$_2$-α becomes stoichiometrically phosphorylated on both serines in response to thrombin. We also showed that cPLA$_2$-α is phosphorylated exclusively on Ser-505 and on Ser-727 in HeLa cells stimulated with activators of the stress-activated protein kinases (SAPKs, members of the MAPK family)[76]. These are the only published studies reporting the rigorous mapping of cPLA$_2$-α phosphorylation sites. Our work cast doubt on the suggestion, based only on immunoblot analysis, that cPLA$_2$-α is phosphorylated on tyrosine in HeLa cells[77].

We, along with Kramer and coworkers, showed that the p38 member of the SAPK family or a closely related kinase and not the p42/p44 MAPKs (ERK1 and 2) was responsible for cPLA$_2$-α phosphorylation in platelets[78–81]. We found that the inhibitors of p38, SB202190 and SB203580, blocked about 50% of the phosphorylation on both Ser-505 and Ser-727 in thrombin stimulated platelets. Since the Ser-727 site does not contain the critical residues for recognition by MAPKs, the inhibition data suggests that the kinase responsible for Ser-727 phosphorylation is activated by p38. The fact that cPLA$_2$-α phosphorylation is only 50% inhibited by SAPK inhibitors suggests that more than one isoform of p38 (inhibitor sensitive and insensitive

Cambridge Books Online © Cambridge University Press, 2009

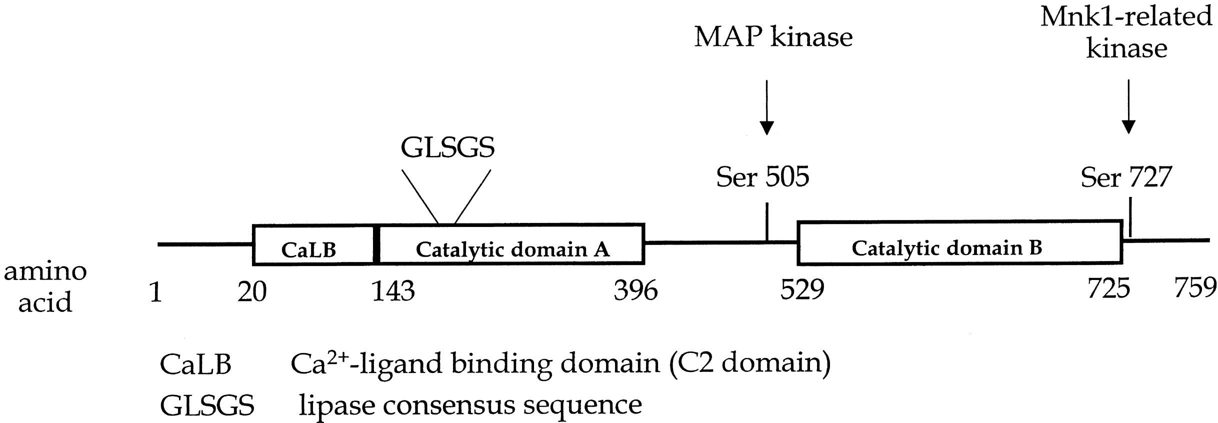

Fig. 15.3. Schematic representation of major structural domains of the cPLA$_2$-α. The catalytic domain composed of two parts of the protein (catalytic domain A and catalytic domain B), the Ca^{2+}-binding domain are indicated as well as two phosphorylation sites.

forms) may be phosphorylating cPLA$_2$-α in platelets. Since these studies, three new p38 isoforms have been cloned[82–85], bringing the current count to four gene products (SAPK2a/2b/3/4). Using recombinant SAPKs and specific antibodies, we went on to show that all four SAPKs phosphorylate cPLA$_2$-α in vitro at Ser-505[78]. All four SAPKs are present in platelets and SAPK2a/2b and four undergo activation in thrombin-stimulated platelets[78]. However, SB202190 and SB203580 inhibit SAPK2a/2b but not SAPK3/4[86]. Thus, it seems that the partial inhibition of cPLA$_2$-α phosphorylation by the SB202190/SB203580 inhibitors may be due to inhibitor sensitive and insensitive forms of SAPKs that phosphorylate cPLA$_2$-α upon thrombin addition. Alternatively, the SB202190/SB203580-insensitive phosphorylation could be mediated by other members of the MAPK family such as ERK5 or Jnk. In collagen stimulated platelets, only the SB202190/SB203580-sensitive SAPKs, SAPK2a/$_2$b, become activated, and we found that these inhibitors block all of the cPLA$_2$-α phosphorylation (Ser-505 and Ser-727) induced by collagen[78]. We then went on to show that complete blockage of cPLA$_2$-α phosphorylation leads to a shift in the AA release vs. collagen concentration dose–response curve in platelets. Threefold higher amounts of collagen are needed to elicit the same AA release response in the absence of cPLA$_2$-α phosphorylation (i.e. with SB202190/SB203580 present) as in the presence of phosphorylation[78]. We also showed that stress stimuli that activate platelet SAPKs (oxidants and osmotic shock) lead to enhanced cPLA$_2$-α phosphorylation and AA release in platelets[87], consistent with a role of SAPK-catalyzed cPLA$_2$-α phosphorylation in augmenting AA release in platelets.

Kramer et al. showed that phorbol ester activation of the p42/p44 MAPK members in platelets leads to cPLA$_2$-α phosphorylation, and we showed that such phosphorylation also occurs on Ser-505 and Ser-727[65]. It should be noted that this cPLA$_2$-α phosphorylation pathway is an induced response to the non-physiological phorbol ester agonist; as noted above, cPLA$_2$-α phosphorylation is catalysed by SAPKs in response to the physiological agonists thrombin and collagen.

Our studies with SAPK inhibitors SB202190/SB203580 led us to propose that the kinase responsible for phosphorylation of cPLA$_2$-α on Ser-727 is activated by one or more SAPKs. The identification of MAPK-activated kinases is rapidly advancing, and we decided to test all of the kinases known at the time of our study to be activated by both p42/p44 MAPKs and by SAPKs (MNK1[88,89], PRAK1[90], MSK1[91], MAPKAP-K2[89], and MAPKAP-K3[92]) for their ability to phosphorylate cPLA$_2$-α in vitro. MAPKAP-K1 ($p90^{rsk}$) is not activated by SAPK2a, but lies downstream of ERK2[86,93] and thus was not considered further. Using mass spectrometry, we proved that MNK1 phosphorylates cPLA$_2$-α in vitro uniquely at Ser-727 and that PRAK1 and MSK1 produce a radiophosphorylated tryptic peptide that co-migrates with authentic Ser-727 phosphorylated tryptic peptide on HPLC and on a two-dimensional cellulose plate[65]. MAPKAP-K2 and MAPKAP-K3, although enzymatically active, did not phosphorylate cPLA$_2$-α in vitro. Using specific antibodies, we showed that MNK1 and PRAK1, but not MSK1, are present in platelets and become activated upon thrombin addition and with the same time course as activation of SAPKs and cPLA$_2$-α phosphorylation[65]. At this point it seems clear that cPLA$_2$-α phosphorylation on Ser-727 in activated platelets is carried out by MNK1, PRAK1, or a closely related isoform.

Cambridge Books Online © Cambridge University Press, 2009

Having defined that pattern of $cPLA_2$-α phosphorylation in platelets and the family of kinases responsible for the modifications, we further examined the functional consequence of Ser-505 and Ser-727 $cPLA_2$-α phosphorylation[65]. We constructed a mammalian cell expression plasmid containing mouse $cPLA_2$-α cDNA and prepared several clones of stably transfected CHO cells, HeLa cells, and HEK293 cells (human embryonic kidney endothelial cells). Clones were also established that expressed the phosphorylation site mutants (S505A, S727A, and S505A/S727A). We studied $cPLA_2$-α phosphorylation in these cells by radiolabelling with ^{32}P-phosphate and examining the radioactive tryptic peptides derived from immunoprecipitated $cPLA_2$-α by HPLC and 2-dimensional cellulose chromatography. We found that $cPLA_2$-α was phosphorylated stoichiometrically only on Ser-505 and Ser-727 in all three cell types and that mutation of these serines to alanines abolished phosphorylation, thus confirming our phosphorylation site mapping studies.

We next quantified AA release in these clones in response to agonist stimulation[65]. Several clones expressing each type of $cPLA_2$-α were selected for study based on comparable amounts of expressed $cPLA_2$-α (based on immuno- and RNA-blots)[65]. Similar results were obtained with CHO, HeLa, and HEK293 cells[65]. Expression of wild-type $cPLA_2$-α in CHO cells leads to an increase in AA release compared to the non-transfected parental cells. Stimulation with an intermediate concentration of Ca^{2+} ionophore alone leads to more AA release than stimulation with the protein kinase C agonist PMA alone, and there is a synergistic effect when both agonists are added. These results are similar to those reported by Lin et al. for $cPLA_2$-transfected CHO cells[74]. Mutation of either Ser-505 or Ser-727 of $cPLA_2$-α significantly reduces AA release, and the double mutant fails to produce AA above the level made by non-transfected cells. When a high concentration of Ca^{2+} ionophore is used, the effect of double mutation on AA release is rescued showing that the mutant can be fully functional in these cells. These results establish that phosphorylation of $cPLA_2$-α on Ser-505 and on Ser-727 are important for efficient AA release and that high Ca^{2+} concentrations can overcome the need for $cPLA_2$-α phosphorylation. Finally, we prepared HEK293 cell double transfectants that overexpress wild-type $cPLA_2$-α and a dominant negative form of MNK1[94]. Expression of dominant negative MNK1 led to a significant reduction in AA release, but when HEK293 cells were stimulated with high Ca^{2+} ionophore concentration, no effect of dominant negative MNK1 was observed[65]. These results support our earlier studies that $cPLA_2$-α is phosphorylated by MNK1 or a closely related kinase in platelets and that phosphorylation of $cPLA_2$-α is not required for AA release in the presence of high intracellular Ca^{2+}. Our studies also underscore the need for rigorous analysis of $cPLA_2$-α phosphorylation using site-selective protein chemical techniques rather than simply relying on gel shift analysis.

In the early studies by Kramer et al. it was shown that fully phosphorylated $cPLA_2$-α partially purified from thrombin-stimulated human platelets is about two- to threefold more active than non-phosphorylated enzyme toward the hydrolysis of phospholipid vesicles in vitro[95]. Phosphorylation is unable to bring about activation of $cPLA_2$-α on its own, but increases the response to elevation of Ca^{2+}. This can be explained by the ability of Ca^{2+} to stimulate movement of $cPLA_2$-α to intracellular membranes, whereas phosphorylation increases the catalytic efficiency of the membrane-bound enzyme. In support of this, mutational studies have shown that phosphorylation of serine-505 does not play a role in translocation to intracellular membranes[37]. Thus, in combination, Ca^{2+} and phosphorylation induces a larger increase in activity than either stimulus on its own.

Evidence that group IIA $sPLA_2$ may not be involved in AA release in platelets stimulated with physiological agonists

Group IIA $sPLA_2$ has been detected in α-granules of platelets from different species including rat, rabbit and human and is secreted within a few minutes upon activation by physiological agonists[50,96,97]. The question of the possible involvement of group IIA $sPLA_2$ in AA liberation during platelet activation has been investigated by two different approaches. First, addition of a specific inhibitor for group IIA $sPLA_2$ did not inhibit AA liberation from thrombin-stimulated platelets, while specific inhibition of $cPLA_2$-α led to a strong decrease in such a liberation[61]. Secondly, it was shown that group IIA $sPLA_2$-depleted platelets aggregated as much as control platelets and produced similar amounts of TxA_2 upon agonist stimulation[97]. These data lead to the conclusion that group IIA $sPLA_2$ does not play a significant role in AA liberation upon agonist stimulation. Natural strains of mice lack group IIA $sPLA_2$[98], and it would be interesting to examine AA and TxA_2 release in platelets derived from these strains.

Since thrombosis and inflammation are two closely related processes, it is possible that once released from platelets, group IIA $sPLA_2$ could participate in eicosanoid and/or biologically active lysophospholipid formation in other inflammatory cells or from microvesicles and therefore lead to the propagation of the inflammatory

Cambridge Books Online © Cambridge University Press, 2009

process[99,100]. The addition of group IIA $sPLA_2$ on A23187-treated granulocytes, IgE/antigen-primed mast cells, TNFα-stimulated HUVEC and BRL-3A cells, leads to more prostanoids generated than that elicited by each agonist alone[101–104]. Moreover, group IIA $sPLA_2$ does contribute to AA release for eicosanoid formation in epithelial and fibroblastic cells[20]. In these cells, group IIA $sPLA_2$ seems to contribute to AA release during the late phase of eicosanoid formation, typically tens of minutes to hours after cell activation, whereas $cPLA_2$-α contributes to the early phase of AA release. In this context, it is important to note that platelets release AA and TxA_2 within a few minutes after stimulation by physiological agonists. Once secreted from platelets, group IIA $sPLA_2$ is expected to adsorb to the plasma membrane of nearby cells, rather than being diluted into the systemic circulation. This is due to its ability to bind heparan sulfate proteoglycan present at the cellular surface[20,105,106]. In fibroblastic cells, group IIA $sPLA_2$ anchored to cell surface heparan sulfate proteoglycan is internalized in a process that leads to AA release coupled to eicosanoid formation[106]. In contrast, with mast cells, such anchoring leads to group IIA $sPLA_2$ internalization for degradation[107].

The ability of exogenous added group IIA $sPLA_2$ to release AA from platelets was also studied. Addition of micromolar concentrations of exogenous enzyme to resting platelets does not induce platelet aggregation, AA liberation, or plasma membrane phospholipid hydrolysis[61,108,109]. It therefore appears that the extracellular face of the platelet plasma membrane is a poor substrate for group IIA $sPLA_2$. This is probably due to the fact that this membrane face is highly enriched in sphingomyelin and phosphatidylcholine[110,111], and that group IIA $sPLA_2$ binds extremely weakly to vesicles of zwitterionic phospholipids[112]. Phosphatidylserine is known to be transferred to the extracellular face of the plasma membranes of platelets during cell activation. However, this change in membrane composition is not sufficient to allow group IIA $sPLA_2$ to act since little or no AA is released when activated platelets are treated with exogenous addition of group IIA PLA_2[61,109]. Addition of phosphatidylserine to phosphatidylcholine vesicles leads to enhanced binding of group IIA $sPLA_2$ in vitro, but interfacial binding of enzyme remains weak unless the concentration of acidic phospholipid lipid approaches 100 mole per cent (M.H. Gelb, unpublished observations).

One possible hydrolytic action of the group IIA $sPLA_2$ is on microvesicles shed from platelets during activation by thrombin and collagen[108,113]. Such microvesicles are enriched in phosphatidylserine and phosphatidylethanolamine in the outer leaflet. Micromolar concentrations of group IIA $sPLA_2$ induced a modest phospholipid hydrolysis on such microvesicles after one-hour incubation, while a marked hydrolysis was observed in the presence of sphingomyelinase[108]. The physiological relevance of such a process remains to be established, but it is unlikely it would contribute significantly to AA liberated from platelets during thrombin or collagen stimulation. The shedding of microvesicles is a slow process, whereas AA release is complete within a few minutes[114,115]. In addition, weak agonists which are unable to induce microvesicle shedding are potent inducers of eicosanoid formation during platelet activation[115,116]. However, the possibility that physiologically relevant signaling lipids including lysophosphatidic acid and lysophosphatidylcholine are produced during group IIA $sPLA_2$-catalysed microvesicle hydrolysis needs to be considered.

In conclusion, available evidence goes against a role for group IIA $sPLA_2$ in generating AA during physiological agonist stimulation of platelets. In light of the fact that several new $sPLA_2$s have been discovered in recent years (discussed above), it will be important to explore the presence of these enzymes in platelets. It should also be mentioned that the action of an $sPLA_2$ other than the group IIA enzyme could contribute to AA release during platelet activation. It has been shown that the action of $cPLA_2$-α is needed as a prerequisite for $sPLA_2$ action in mast cells[117] and in fibroblasts[118]. This complicates the interpretation of the results that $AACOCF_3$ blocks virtually all of the AA released in activated platelets, but the results with this inhibitor show that $cPLA_2$-α plays the dominant role in liberating AA from platelet membrane phospholipids for the biosynthesis of eicosanoids.

Possible physiological functions of platelet-derived group IIA $sPLA_2$

While the synthesis and the subsequent secretion of group IIA $sPLA_2$ via the classical secretory pathway in many cell-types is regulated by proinflammatory stimuli[20,119,120] (Il-1, Il-6, TNF, LPS), in some cells group IIA $sPLA_2$ is rapidly released from storage granules following cell activation. For example, group IIA $sPLA_2$ is stored in α-granules of resting platelets and released along with other granule proteins during activation. Such a secretion is correlated with the activation state of blood platelets and with the efficiency of the release reaction, but specific regulation of group IIA $sPLA_2$ secretion compared to other granule proteins has not been reported. It is likely that platelet-derived group IIA $sPLA_2$ mainly exerts its physiological functions once secreted since no report of an action of group IIA

Table 15.1. The possible biological functions for platelet-derived group IIA $sPLA_2$

Reported properties for group IIA $sPLA_2$	Expected biological functions for platelet-derived group IIA $sPLA_2$
Binding to heparan sulfate proteoglycans	Extracellular or intracellular participation in AA production by cells other than platelets
Intracellular degradation of bacteria, extracellular hydrolysis of bacterial phospholipids	Antimicrobial effect
Binding to blood coagulation factor Xa	Anticoagulant effect
Platelet-derived microvesicle hydrolysis	Production of biologically active lipids (LPA, LPC), removal of microvesicles
LDL hydrolysis	Proatherogenic effect
Membrane hydrolysis of cells with a loss in the membrane asymmetry	Removal of apoptotic/injured/activated cells

$sPLA_2$ inside platelets has been described. Group IIA $sPLA_2$ binds tightly to heparin[20,106]. It is possible that it forms a complex with heparin inside of granules which prevents it from acting on granular membranes, but this idea remains to be investigated. It is still a question whether platelet-derived group IIA $sPLA_2$ may account for the high increase in the group IIA $sPLA_2$ level found in serum during inflammatory diseases. In the rat, in vivo platelet activation by administration of ADP was followed by a transient rise in plasma $sPLA_2$ activity[54]. However, it has been reported that other cell-types (such as inflammatory cells and liver cells) also secrete high amount of group IIA $sPLA_2$[20,121]. Group IIA $sPLA_2$ is expected to stay, at least partly, at the cellular surface after secretion (due to its proteoglycan binding properties) rather than being diluted into the systemic circulation[105,106]. High concentrations of group IIA $sPLA_2$ have been detected in local sites, such as synovial[122] and ascitic fluids[123] and in tears[18], and localization of group IIA $sPLA_2$ appears to occur during local thrombolytic events[20,108]. The possible physiological functions of the group IIA $sPLA_2$ will be reviewed mainly with the working hypothesis that it is acting locally and extracellularly after secretion from platelets (Table 15.1). However, an intracellular action of the group IIA $sPLA_2$ after binding to the cell surface and subsequent internalization has been proposed in some cells and discussed above regarding the participation of platelet-derived group IIA $sPLA_2$ in eicosanoid formation by other cells[106]. Finally, it has to be considered that group IIA $sPLA_2$ may also be secreted by other cells present at the thrombus foci and therefore act with the platelet-derived enzyme.

Anticoagulant effect of group IIA $sPLA_2$

The group IIA $sPLA_2$ has been reported to exert an anticoagulant effect and may play a negative feedback role during the initiation of thrombosis once secreted from activated platelets[124,125]. Group IIA $sPLA_2$ specifically inhibits the prothrombinase complex composed of factor Xa (FXa), factor Va (FVa), phospholipids and calcium, and this inhibitory effect is still observed in the absence of phospholipids[125,126]. Group IIA $sPLA_2$ forms a 1:1 complex with FXa and prevents the formation of the FXa/FVa complex[125]. Group IIA $sPLA_2$ contains 13 lysine and 10 arginine residues scattered over its entire surface that form cationic clusters. Several of these basic clusters lie on the surface of the molecule that contacts the lipid membrane, the so-called 'interfacial binding surface'[127]. Mutations of these basic residues led to a significant reduction of the ability of group IIA $sPLA_2$ to inhibit prothrombinase activity and to bind to FXa, and, increased salt concentrations completely abolished the binding of group IIA $sPLA_2$ to FXa, supporting an important role of electrostatic interactions[128]. High concentrations of FVa reversed the inhibitory effect of group IIA $sPLA_2$ on the prothrombinase complex, suggesting that group IIA $sPLA_2$ may compete with FVa for binding to FXa. Therefore, group IIA $sPLA_2$ is expected to act at early stages of the coagulation process by delaying the formation of a fully active prothrombinase complex, until enough FVa is generated.

Wild-type enzyme, as well as the catalytically inactive H48Q group IIA $sPLA_2$, efficiently delays the formation of thrombin measured in human platelet-rich plasma (PRP). Therefore, the anticoagulant effect of group IIA $sPLA_2$ occurs under experimental conditions close to the physiological situation and is independent of its catalytic activity,

Cambridge Books Online © Cambridge University Press, 2009

even when natural phospholipids from plasma and platelet membrane are present, supporting an inhibitory mechanism based on the interaction of group IIA $sPLA_2$ with FXa[128]. As discussed above, the levels of group IIA $sPLA_2$ in serum strongly increase from 0.35 nM up to 600 nM under various inflammatory states[121,129], and, high concentrations are expected to be found at local inflammatory/thrombolytic sites. Group IIA $sPLA_2$ inhibits the prothrombinase activity with an IC_{50} value of 80 nM, and a K_d value of 230 nM was determined for the interaction of group IIA $sPLA_2$ with FXa[128]. These values appear consistent with a potential localized and/or systemic anticoagulant role of group IIA $sPLA_2$ during various physiological or pathological states. Hydrolysis of platelet-derived microvesicles by group IIA $sPLA_2$ (described above) could lead to an anticoagulant effect since these microvesicles support the coagulation cascade in addition to the platelet membrane[113]. However, the catalytically inactive mutant showed the same efficiency as wild-type group IIA $sPLA_2$ to inhibit thrombin generation in PRP, indicating that such phospholipid hydrolysis probably does not play a major role in the anticoagulant effect of this enzyme. Finally, group IIA $sPLA_2$ has been shown to increase the generation of prostacyclin by vascular endothelial cells[103]. This eicosanoid is an efficient inhibitor of platelet activation. The occurrence of such an effect in vivo would amplify the anticoagulant effect of group IIA $sPLA_2$.

Degradation of apoptotic and injured cells by group IIA $sPLA_2$

A membrane rearrangement that could lead to increased hydrolysis by the group IIA $sPLA_2$ is the appearance of phosphatidylserine during the apoptotic process in eukaryotic cells that is correlated with the loss of the membrane asymmetry and with membrane blebbing[130]. Cells undergoing apoptosis are sensitive to the action of the group IIA $sPLA_2$[131,132]. Therefore, one possible function of group IIA $sPLA_2$ released from either platelets or other cells is to eliminate apoptotic cells or injured cells[133]. This may constitute an important role in the removal of the hemostatic clot including activated platelets and microvesicles in order to avoid establishment of a prothrombotic situation.

Role of group IIA $sPLA_2$ in atherogenesis: low density lipoprotein (LDL) hydrolysis

Atherosclerosis is a disease involving the immune system and chronic inflammation in the initiation of endothelial cell dysfunction and the development of advanced lesions[134]. In addition to endothelial cells, macrophages, T-lymphocytes and smooth muscle cells collaborate to induce such a pathological situation. The 'CD40 receptor/CD40 ligand' system, a key mediator of cell communication in the immune system, is crucial in the establishment of atherosclerotic lesions[134]. The possible involvement of blood platelets in such a process has been pointed out since the CD40 ligand is expressed on their surface upon activation, and oxidatively modified LDL (low density lipoprotein) stimulates platelets[135]. The participation of the group IIA $sPLA_2$ in atherogenesis has been recently examined since it is expressed by cells implied in this process[136,137] and detected in human atherosclerotic plaques[138]. It has been shown that group IIA $sPLA_2$ is able to hydrolyse plasma lipoproteins and in particular mildly oxidized or aged LDL leading to modified LDL with higher affinity for proteoglycans and therefore higher atherogenic properties[139,140]. The group IIA $sPLA_2$ binds to heparan sulfate proteoglycans via their glycosaminoglycan moiety and to decorin, a small proteoglycan of the collagen network in atherosclerotic plaques, via the protein core[141]. Indeed, both LDL and group IIA $sPLA_2$ are likely to be colocalized at inflammatory loci via the binding to proteoglycans present on cell membranes and on the extracellular matrix of the arterial wall. Transgenic mice overexpressing group IIA $sPLA_2$ show increased atherogenesis and altered lipoproteins, supporting a role of this enzyme in atherosclerosis[142]. However, the lipoprotein-associated PLA_2 (Lp–PLA_2) which is found predominantly on LDL is also important for the modification of the LDL[143]. The exact function of Lp–PLA_2 vs. group IIA $sPLA_2$ in the establishment of atherosclerosis has still to be further investigated.

Antimicrobial effect of group IIA $sPLA_2$

It has been established that group IIA $sPLA_2$ contributes to the antimicrobial action in response to invading microorganisms[20,144,145]. Phagocytosis and consecutive bacterial membrane degradation by polymorphonuclear leukocytes represent an essential first-line defence against invading bacteria. Group IIA $sPLA_2$ participates in intracellular bacterial digestion by associating with the surfaces of bacteria and neutrophils before phagocytosis and acting after cointernalization with ingested bacteria. Group IIA $sPLA_2$ is also able to efficiently bind and extracellularly hydrolyse the membrane of gram positive bacteria[144]. In order to achieve such phospholipid hydrolysis from gram negative bacteria, group IIA $sPLA_2$ requires the presence of the BPI (bactericidal/permeability-increasing protein) that is released by polymorphonuclear leukocytes[146]. Transgenic mice with the group IIA $sPLA_2$ gene were reported to be more resistant to *Staphyloccocus aureus* and *Escherichia*

Cambridge Books Online © Cambridge University Press, 2009

coli infection than control mice[120,147]. This antimicrobial action is likely to take place in the intestine where group IIA $sPLA_2$ is highly expressed in Paneth cells[148] and in tears[18]. During skin injury often associated with inflammation and thrombosis, it is possible that group IIA $sPLA_2$ secreted either from platelets or inflammatory cells also contribute to eliminate invasive bacteria.

Roles of phospholipase C and phospholipase D in receptor-mediated platelet activation

Mauro Torti[1] and Eduardo G. Lapetina[2]

[1]Department of Biochemistry, University of Pavia, Italy

[2]Cato Research Ltd., Westpark Corporate Center, Durham, North Carolina, USA

Introduction

For more than 30 years, the inositol phospholipids and the activities of various phospholipases have been intimately associated with fundamental aspects of the stimulation of platelets. Works of various scientific groups led to the initial discoveries in the 1970s and 1980s that related the metabolism of phospholipids to the early platelet physiological responses such as shape change, secretion, and aggregation. In many instances, these findings were used to develop signal transduction concepts in many other biological systems. The products resulting from activation of these phospholipases represent myriad second messengers with relevant biological roles. Phospholipases and their substrates and products are central to the action of many receptors, transducers, and protein kinases, as well as to the mobilization of ions. This chapter describes the roles of phospholipase C and phospholipase D in signal transduction, and it discusses how these activities interplay in a network of pathways leading to physiological responses.

Overview of phospholipase C

Phosphoinositide-specific phospholipase C (PLC) plays an essential role in receptor-mediated platelet activation. The mammalian PLCs represent a family of Ca^{2+}-dependent enzymes showing a substrate preference for phosphatidylinositol 4,5-bisphosphate (PIP_2) over phosphatidylinositol 4-phosphate (PIP) or phosphatidylinositol (PI)[1]. Hydrolysis of PIP_2 by PLC leads to the generation of two important intracellular messengers: inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 is a soluble molecule that promotes the rapid release of Ca^{2+} from internal stores. Because of PLC-mediated IP_3 formation, the cytosolic concentration of Ca^{2+} increases rapidly and transiently and causes the activation of Ca^{2+}-dependent downstream effectors such as protein kinases and proteases. For additional details on IP_3-mediated Ca^{2+} mobilization in platelets, refer to Chapter 17 in this book. DAG is a membrane-bound lipid second messenger that mediates the translocation and activation of the serine/threonine protein kinase C (PKC). The role of PKC in platelet activation by extracellular agonists is discussed in Chapter 18.

In addition to generating the intracellular second messengers IP_3 and DAG, PIP_2 hydrolysis by PLC may have other important consequences. PIP_2 also represents the preferred substrate for a different lipid-metabolizing enzyme, phosphatidylinositol 3-kinase (PI–3K). This kinase is activated in agonist-stimulated platelets and catalyses the phosphorylation of PIP_2 at the 3-position of the inositol ring to generate the second messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP_3)[2]. Therefore, PIP_2 hydrolysis by PLC reduces the substrate availability for PI-3K and, thus may affect signal transduction pathways initiated by this kinase. Moreover, PIP_2 in the plasma membrane is known to interact with profilin and gelsolin, two proteins involved in the regulation of actin polymerization. Hydrolysis of PIP_2 in agonist-stimulated platelets, for instance, liberates profilin, which, in turn, may take away monomeric actin from the sequestering protein thymosin $\beta 4$ to facilitate its polymerization into F-actin filaments[3]. Finally, hydrolysis of PIP_2 by PLC stimulates phosphoinositide turnover. Soluble IP_3 is rapidly dephosphorylated to the inactive inositol 1,4-bisphosphate by an IP_3 5-phosphatase and is then progressively converted to free inositol

by the sequential action of 4- and 1-phosphatases and used for the resynthesis of membrane inositol phospholipids.

An alternative route for IP_3 metabolism involves the transient phosphorylation by a specific 3-kinase to generate inositol 1,3,4,5-tetrakisphosphate (IP_4) before degradation by the above-mentioned phosphatases. Although IP_4 does not induce Ca^{2+} mobilization from internal stores, evidence indicates it may have different signalling functions, such as regulation of Ca^{2+} influx[4]. Moreover, a protein that binds with high affinity to IP_4 has been cloned and identified as a GTPase activating factor for the small GTP-binding proteins ras and rap1[5]. Although ras is almost undetectable in platelets, rap1b is highly expressed in these cells[6]. Therefore, IP_4 may represent an intracellular messenger playing a role in signal transduction leading to platelet activation.

DAG, the other second messenger produced by the action of PLC, is rapidly inactivated by phosphorylation to phosphatidic acid (PA) through a DAG kinase[7]. PA is a metabolic precursor for phospholipid biosynthesis, but it may also be involved in signal transduction. Although early works reported the ability of exogenous PA to induce platelet aggregation[8], its role as intracellular messenger is quite controversial. Nevertheless, deacylation of PA by a phospholipase A_2 enzyme generates lysophosphatidic acid (LPA), which has been clearly recognized as an efficient platelet agonist[9]. Because of the multitude of signalling pathways activated or modulated by the action of PLC, it is clear this enzyme plays a central role in cell activation.

Agonist-induced phospholipase C activation in platelets

Because so many effects are elicited by the action of PLC, the measurements of a wide variety of intracellular parameters can be used to monitor PLC activation in response to extracellular platelet agonists, allowing for identification of the stimuli that affect this enzyme. These parameters include direct measurement of IP_3 formation, mobilization of Ca^{2+}, accumulation of PA, and phosphorylation of pleckstrin. Measurement of IP_3, however, provides the clearest evidence for PLC activation.

Traditionally, IP_3 accumulation is evaluated upon separation by ion-exchange chromatography of soluble inositol phosphates from platelets metabolically labelled with ^3H-inositol. The main disadvantages of this technique are the low incorporation of ^3H-inositol into membrane phosphoinositides and the rather complex and time-consuming analyses of the samples. More recently, radiobinding assays for IP_3 measurement have been developed, and they are commercially available. These are simple and specific assays, but rather expensive.

Measuring the release of Ca^{2+} from internal stores is an alternative to direct IP_3 measurement: Ca^{2+} mobilization can be detected by using fluorescent, membrane-permeable indicators such as FURA 2-AM or FLUO 3-AM. When platelet stimulation is performed in the absence of extracellular calcium, the cytosolic increase of this ion exclusively reflects the IP_3-mediated release from internal stores.

In addition, the production of DAG can be used to detect agonist-induced PLC activation. DAG is rapidly phosphorylated to PA; therefore, the lipids extracted from ^{32}P-labelled platelets can be separated by thin-layer chromatography and visualized by autoradiography to measure the accumulation of PA. Similarly, separation of the total platelet proteins by electrophoresis on acrylamide gels allows the identification and quantification of the phosphorylation of pleckstrin, the 47-kDa protein substrate for DAG-activated PKC.

All these experimental approaches have been widely used to identify the platelet agonists able to promote activation of PLC. It emerged that almost all the agents able to induce platelet activation by binding to a membrane receptor were also able to stimulate the action of PLC. Among these are soluble platelet agonists that bind to seven transmembrane-domain receptors coupled to heterotrimeric GTP-binding proteins such as thrombin, PAF, vasopressin, serotonin, ADP, lysophosphatidic acid, and thromboxane A_2, as well as its stable analogue U46619[10]. The only exception is epinephrine; this molecule binds to the α_{2A}-adrenergic receptor on the platelet membrane, and as yet seems to be the only platelet agonist not able to promote PLC activation directly[11,12]. The ability of ADP to stimulate PLC in platelets has been controversial for years. Early reports documented the inability of this agonist to stimulate PIP_2 breakdown[13,14], but more recent works measuring IP_3 formation and Ca^{2+} mobilization from internal stores definitively recognize the activation of PLC in ADP-stimulated platelets[15,16]. Because all the agonists cited above bind to membrane receptors coupled to G-proteins, a role for these signal transducers in PLC activation was hypothesized quite early.

Separately from the role of signal transducers, a role for GTP-binding proteins in PLC activation in human platelets also emerged from the observations made by several investigators during the 1980s. These scientists noted that GTP and its nonhydrolysable analogue, GTP-γ-S, were able to stimulate PLC activity in isolated platelet membranes and in permeabilized platelets[17–19]. For many years, the identity of the G-protein mediating PLC activation in platelets

Cambridge Books Online © Cambridge University Press, 2009

remained unknown, and this entity was generically called Gp. Since then, incredible progress has been made, and we now have a more complete picture of the G-proteins responsible for PLC stimulation in platelets. Activation of PLC in platelets, however, is not limited to agonists acting through G-protein-coupled receptors. Some adhesive proteins, such as collagen and von Willebrand factor (vWF), are potent platelet agonists. Although collagen receptors (GP VI) and vWF receptors (GP Ib–IX–V complex) are not associated with GTP binding proteins, collagen and vWF are able to promote PLC activation[20,21]. Moreover, some plant lectins such as wheat germ agglutinin (WGA) and concanavalin A (ConA) stimulate platelets in association with PLC activation[22,23]. Even cross-linking of the low-affinity receptor for the Fc fragment of immunoglobulin G (FcγRIIA) on the platelet membrane triggers PLC activation[24]. Finally, hydrolysis of PIP_2 and formation of PA have been reported to occur as a consequence of platelet adhesion to immobilized fibrinogen[25], and a role for the fibrinogen receptor integrin $\alpha_{IIb}\beta_3$ on PLC activation has been documented based on the measurement of intracellular calcium mobilization and IP_3 formation[26,27]. Thus, the mechanism for PLC activation in platelets clearly involves multiple signalling pathways.

Because multiple signalling pathways were involved, purification, cloning, and characterization of PLC were clearly mandatory to clarify the mechanisms of agonist-induced activation of this enzyme. A number of studies using chromatographic resolution, detected the isolation of multiple forms of PLC from both platelet membrane and cytosol[28–31]. These works clearly indicate that PLC is not a single enzyme, but is present in platelets as different isoforms. Moreover, because most platelet PLC activity was found in the cytosol, it was clear that the mechanism to activate these enzymes required the translocation to the membrane, where the physiological substrates are located.

By the end of the 1980s, an incredible number of different PLC isoforms had been identified both in platelets and in nucleated cells, and the nomenclature of PLC isozymes was clearly in disarray. In 1989, after a systematic immunological analysis of most of the reported PLC isoforms, Sue Goo Rhee proposed a unified nomenclature, based on Greek letters, which is still used today[32]. According to this nomenclature, all the known PLC isoforms fall into three major classes referred to as PLCβ, PLCγ, and PLCδ.

The phospholipase C isozymes

It is now well known that each of the three major classes of PLC contains multiple subtypes sharing a high degree of sequence homology. Four different PLCβ subtypes have been identified: PLCβ1, PLCβ2, PLCβ3, and PLCβ4. Their molecular masses range from 130 to 150 kDa, and different spliced variants have been described. The PLCγ family includes two members, PLCγ1 and PLCγ2, and each has a molecular mass of about 145 kDa. The PLCδ family contains the subtypes PLCδ1, PLCδ2, PLCδ3, and PLCδ4, which are smaller than other isozymes (85–88 kDa). Therefore, at least ten different isoforms of PLC, encoded by separated genes, exist in living cells. Not all of them are expressed in human platelets, but members of each of the three classes have been described in platelets. Using specific antibodies for the four members of the PLCβ family, Nozawa's team reported the presence of PLCβ2 and PLCβ3 in a whole-platelet lysate[31]. PLCβ1 was hardly detectable, indicating that it does not represent a major PLC isozyme in these cells, and PLCβ4 was not revealed at all[31]. Immunological studies found both members of the PLCγ family (PLCγ1 and PLCγ2) to be present in human platelets[33,34]. Evidence for the presence of PLCδ isoforms was also reported[31], and subsequently identified as PLCδ1 and PLCδ3[35,36]. A quantitative immunological study of PLC isozymes separated upon fractionation of platelet extracts by high-performance liquid chromatography revealed that seven of the ten known PLC isoforms are present in platelets[35]. This study failed to detect PLCδ3 in platelets, but this isozyme was subsequently reported to be present in platelets at a concentration at least three times higher than PLCδ1[36]. Altogether, these data indicate that PLCγ2 and PLCβ2 are the predominant PLC isoforms present in platelets.

The division of the PLC isoforms into three major classes was made based on structural homology, but was later discovered also to reflect different mechanisms of enzyme activation. It is now very well known that members of the PLCβ family are selectively activated by GTP-binding proteins. All the α-subunits of the members of the Gq family of heterotrimeric GTP-binding proteins (αq, α11, α14, α15, and α16) have been found to activate PLCβ isozymes, but not PLCγ or PLCδ isozymes[37,38]. The main α-subunits of the Gq family expressed in human platelets are αq and α16; other members were not found[39,40]. The different α-subunits of the Gq family display similar potency in activating PLCβ isozymes, and therefore, they are probably interchangeable. By contrast, the members of the PLCβ family differ in their sensitivities to stimulation by α-subunits. For instance, the αq and α16 subunits activate PLCβ isoforms in the order PLCβ1 = PLCβ3 $\gg$ PLCβ2[41,42]. In light of this, we may assume that in human platelets, PLCβ3, although less abundant than PLCβ2, is probably the main target for activation through αq or α16.

In addition to being regulated by the α-subunits of the

Cambridge Books Online © Cambridge University Press, 2009

Gq family of heterotrimeric G-proteins, PLCβ isozymes are stimulated by activated $\beta\gamma$ dimers[43,44]. The activation of PLCβ isoforms by $\beta\gamma$ subunits proceeds in the order PLCβ3 > PLCβ2 > PLCβ1[45–47]. Therefore, PLCβ2, which is the most abundant PLCβ isozyme in platelets, is probably activated preferentially through a $\beta\gamma$-dependent mechanism, while PLCβ3 can be efficiently activated by the αq and α16 subunits and the $\beta\gamma$ subunits.

The members of the PLCγ family are typically activated in response to peptide growth factors and cytokines acting through membrane receptors with intrinsic tyrosine kinase activity or associated with intracellular tyrosine kinases[48]. Indeed, activation of PLCγ enzymes involves phosphorylation on tyrosine residues. In platelets, the only receptor for growth factors recognized as yet is the PDGF receptor, whose activation, however, seems to lead to platelet inhibition rather than stimulation[49]. Despite this, PLCγ isozymes are highly expressed in platelets, and the amount of PLCγ2 is almost sixfold higher than that of PLCβ2[35]. It is now very well documented that PLCγ isozymes are activated in response to a variety of agonists whose receptors are not linked to G-proteins, such as collagen, von Willebrand factor, and immunocomplexes promoting cross-linking of FcγRIIA. The mechanisms for PLCγ2 activation in platelets are discussed later in this chapter.

PLCδ isoforms are not activated either by classical G-proteins or by a tyrosine-kinase-dependent mechanism, and the modality by which these enzymes are coupled to membrane receptors is still poorly understood. Because the activity of PLCδ isozymes is more sensitive to Ca^{2+} than that of other isoforms, this class may be regulated by the cytosolic concentration of this ion[50]. Alternatively, a recently described new class of GTP-binding protein, termed Gh has been reported to bind to and activate PLCδ1[51]. Moreover, activation of purified PLCδ1 is also promoted by RhoGAP, a protein that stimulates the GTPase activity of the small G-protein rhoA[52]. Interestingly both Gh and rhoA are expressed in human platelets[53,54], but their involvement in the activation of PLCδ1 in these cells remains unclear.

Structure of phospholipase C isozymes

Analysis of the structure of the three families of PLC isozymes reveals interesting details and suggests possible strategies underlying their activation. All PLC isoforms have a modular organization and are composed of several distinct domains. At the N-terminus, all the PLC isozymes contain a pleckstrin homology (PH) domain, which is followed by four consecutive EF-hand motifs. The catalytic domain is composed of two regions, designated X and Y. In PLCδ and PLCβ, these two regions are separated by a short sequence of 50–70 aminoacids, but in PLCγ this linker region is much longer (about 400 amino acids) and is composed of two SH2-domains followed by an SH3-domain, which are all included within a second split PH domain. In all the PLC isozymes, the catalytic domain is followed by a C2 domain. Members of PLCβ present at the C-terminus a peculiar extension of about 400 amino acids. This extension is not present in other PLC isoforms. A scheme of the structure of PLC isozymes is given in Fig. 16.1. Only the three-dimensional structure for PLCδ1 has been resolved[55], and the information obtained about this isozyme is useful in predicting the organization of other isoforms.

The catalytic domain

The X and Y regions forming the catalytic domain of all the PLC isoforms are the most conserved sequences among mammalian isozymes. Structural data from PLCδ1 reveal that these two regions are organized three-dimensionally to form two halves of a catalytic unit that accommodates the substrate in a solvent-accessible cleft near the active site[55]. Co-crystallization of PLCδ1 with the product of the reaction, IP_3, reveals that all the groups of the polar head of the phosphoinositide substrate interact with the active site[55,56]. No space has been found to accommodate a possible phosphate group bound to the 3-position of the inositol ring, providing structural explanation for the known inability of PLC to hydrolyse the lipid product of PI-3K, phosphatidylinositol 3,4,5-trisphosphate[57]. The 2-hydroxyl group of IP_3 is coordinated with a Ca^{2+} ion present at the bottom of the active site, and this may represent the structural basis for the absolute calcium requirement of all mammalian PLC. A number of residues involved in the catalytic reaction have been identified by both structural and mutational analysis[55,58]. Corresponding residues are highly conserved in all the PLC isoforms, and it was reported that mutation of some of them in PLCγ1 abrogates enzyme activity[59].

The PH domain

A PH domain is present at the N-terminus of all the known mammalian PLC. It consists of a module of about 120 residues initially described in pleckstrin, the main platelet substrate for PKC, and subsequently found in more than 100 different proteins[60]. Although different PH domains share a very low sequence of similarity, these domains fold into a highly conserved three-dimensional architecture, consisting of seven antiparallel β-strands organized in a

Cambridge Books Online © Cambridge University Press, 2009

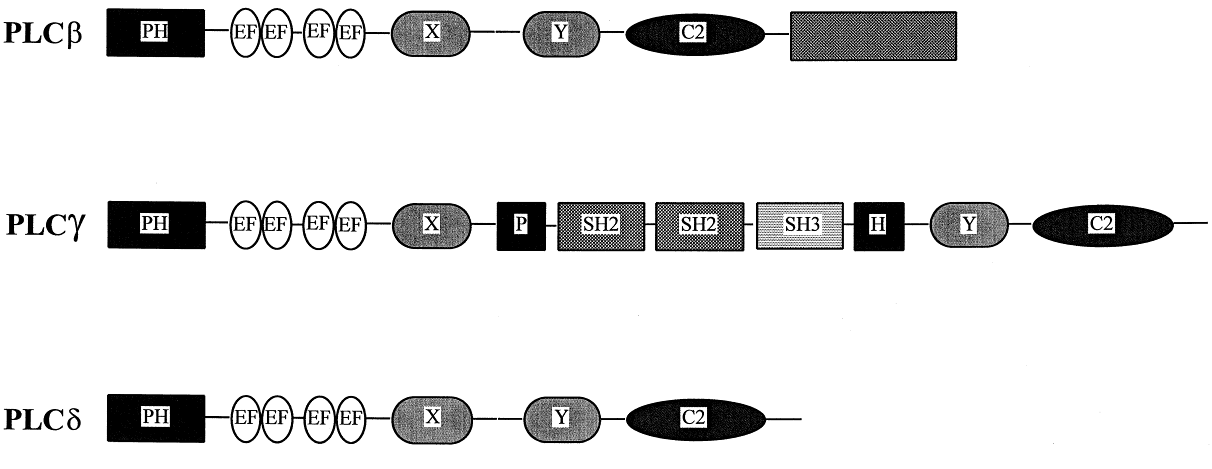

Fig.16.1. Multidomain structure of the three classes of PLC isozymes. All PLC isozymes contain an N-terminal PH domain that is involved, through different mechanisms, in membrane targeting. This domain is followed by four EF-hand motifs, which are Ca^{2+}-binding domains. The catalytic domains are named X and Y, and they are followed by a C2 domain, which is thought to act as a Ca^{2+}-dependent membrane lipid binding module. Unique to the PLCβ family of isozymes is a C-terminal tail that is involved in the binding of G-protein α-subunits. The PLCγ isozymes display an extended X/Y linker region that has essential regulatory functions and is composed of a second split PH domain, two SH2 domains, and one SH3 domain.

barrel-like structure. Because the entire PH domain is able to interact with membranes, this domain is thought to be involved in membrane targeting of proteins. As mentioned above, the evidence that most PLC activity in platelets is present in the cytosol and the finding that all PLC enzymes contain a PH domain suggest that this module may participate in the membrane translocation of PLC to allow access to phosphoinositide substrates. The crucial role of the PH domain in activation of PLC in platelets is supported by the evidence that, in these cells, pleckstrin, another PH-containing protein, can inhibit agonist-induced PIP_2 hydrolysis[61]. Although the role of PH domains in targeting proteins to the membrane is well documented, the mechanism by which this effect is achieved differs among the members of the PLC families of enzymes. In fact, the PH domains of PLCβ, PLCγ, and PLCδ display different binding specificities. The PH domain of PLCδ1, for instance, binds with high affinity to the PIP_2 of the membrane[62,63]. This interaction involves the polar head of the phospholipid, and, as expected, the PH domain of PLCδ1 can also bind to soluble IP_3. This suggests a possible mechanism for feedback regulation of PLCδ1 consisting of the displacement of the enzyme from the plasma membrane by the product of the reaction. The structural analysis of PLCδ1 PH domain allowed identification of the residues involved in PIP_2 binding and revealed that these residues are not conserved in the PH domains of members of the PLCβ and PLCγ families[64]. In fact, as expected, PH domains of these isozymes do not display affinity for PIP_2.

By contrast, the N-terminal PH domain of PLCγ has been found to bind to PIP_3, the lipid product of PI–3K[65]. The affinity of this interaction seems to be sufficient to support translocation of the protein to the membrane. Moreover, the SH2 domain of PLCγ also has been found to bind to PIP_3 with high affinity[66,67]. The level of 3-phosphorylated inositol lipids in resting cells is almost undetectable, but rapidly increases upon stimulation as a consequence of PI–3K activation. This evidence indicates that activation of PLCγ lies downstream of PI–3K activation. This is also supported by the finding that inhibitors of PI-3K, such as wortmannin, prevent activation of PLC in nucleated cells stimulated with growth factors[66,67] and in human platelets stimulated with collagen or by cross-linking of the FcγRIIA[68,69]. Moreover, in the latter case, wortmannin inhibition of PLC activation could be overcome by the addition of exogenous PIP_3[69]. The PH domain of PLCβ does not bind with suitable affinity to either PIP_2 or PIP_3[70]. In contrast, it has been shown that the PH domains of PLCβ1 and PLCβ2 interact strongly with the neutral lipid phosphatidylcholine[71]. Other PH domains, such as that of the β-adrenergic receptor kinase (βARK), bind G-protein $\beta\gamma$-subunits[72]. Such interactions could be relevant for those PLCβ isozymes that can be activated by $\beta\gamma$-dimers. Actually, the PH domain of PLCβ isozymes is able to promote the interaction of the proteins with $\beta\gamma$-dimers[73], and it is sufficient to stimulate enzyme activation[74]. Despite this, binding of $\beta\gamma$-subunits to PLCβ isozymes also involves sequences different from those found in the PH domain and located in the

Cambridge Books Online © Cambridge University Press, 2009

X/Y linker region[75,76]. Recent findings suggest that association of the PH domain of PLCβ isozymes with membrane phospholipids occurs independently of $\beta\gamma$-subunits, but facilitates lateral association of the enzyme with membrane-anchored $\beta\gamma$, leading to PLC activation[71].

The EF-hand motifs and the C2 domain

Four EF-hand motifs lying upstream of the catalytic region, and a C2 domain lying downstream, are common features of all PLC isozymes. Although their exact role in regulating PLC activity is not yet known, they appear to be involved in Ca^{2+} binding. Each of the EF-hand motifs consists of a helix–loop–helix motif similar to that found in calmodulin. Residues potentially able to interact with Ca^{2+} are present in these motifs, but direct evidence for binding of this ion has not been obtained[77]. Nevertheless, deletion of distinct portions of this region causes inactivation of both PLCδ1 and PLCγ1[78], which supports the hypothesis for an important role of the EF-hand motifs in regulating enzymatic activity.

The C2 domains are known to function as Ca^{2+}-dependent membrane lipid binding modules[79]. The C2 domain of PLCδ1 was actually found to be associated with three Ca^{2+} ions[77]. Although no binding studies have been reported as yet, it is likely that this domain is involved in membrane targeting of PLC isozymes.

The X/Y linker region

The region connecting the X and Y catalytic domains is essential for regulation of the activity of PLCγ isoforms. It contains two tyrosine residues that are phosphorylated concomitantly with enzyme activation (a third phosphorylated tyrosine is present in the C-terminal tail of PLCγ1, but is absent in PLCγ2). This region includes two SH2 and one SH3 domains, which are encompassed by a second split PH domain with unknown functions. The SH2 domains mediate protein-protein interaction by binding to tyrosine-phosphorylated proteins, and the SH3 domain specifically recognizes proline-rich sequences. It is very well known that the SH2 domains of PLCγ1 are responsible for the enzyme association with phosphorylated receptor for growth factors, and that this event represents the first step in efficient phosphorylation, membrane translocation, and activation of the enzyme[48]. In human platelets, the SH2 domains of PLCγ2 have been found to mediate the interaction with several signalling proteins[80]. In addition to tyrosine-phosphorylated proteins, the SH2 domains of PLCγ enzymes also specifically bind to PIP_3[66,67]. This interaction is thought to be essential for efficient translocation of the enzyme to the membrane. Because PLCγ isozymes are known to interact with PIP_3 also through the N-terminal PH domain, it appears clear that the lipid product of PI-3K plays a crucial role in regulating the activation of this family of enzymes[66,67]. The role of the SH3 domain of PLCγ is still poorly understood, partly because a physiological partner has not been identified. However, some evidence indicates that this domain may be involved in the translocation of PLCγ to the cytoskeleton[81].

Although very short in sequence, the X/Y linker region may also have regulatory functions in PLC isoforms different from those of PLCγ. For instance, it has been reported that proteolysis of PLCδ1 in the linker region results in the activation of the enzyme[82]. In members of the PLCβ family, the X/Y linker region may be involved in the binding of the regulatory $\beta\gamma$-subunits[76,83].

The C-terminal region

As mentioned earlier, members of the PLCβ family of enzymes are characterized by a C-terminal tail of about 400 amino acids that is absent in other PLC isoforms. Some studies indicate that this C-terminal tail is required for enzyme stimulation by Gα subunits[84,85]. Interestingly, deletion of the C-terminal tail of PLCβ2 results in an enzyme that is insensitive to stimulation by αq, but that can still be activated by $\beta\gamma$ dimers[86]. This means that the site of action of G-proteins α- and $\beta\gamma$-subunits is clearly distinct. Possible binding sites for $\beta\gamma$ on PLCβ have been localized in the X/Y linker region and in the PH domain[73–76], confirming the regulatory function of these sequences. The fact that α- and $\beta\gamma$-subunits of G-proteins activate PLCβ isozymes by binding to distinct regions may allow concomitant stimulation by both these signal transducers. Upon binding to the C-terminal tail of PLCβ, the intrinsic GTPase activity of αq increases by 100-fold. This indicates that the C-terminal tail of PLCβ acts as a GTPase activating protein (GAP) for αq[87].

Activation of phospholipase Cβ in platelets

To induce PLC activation, most of the soluble platelet agonists bind to seven transmembrane domains receptors coupled to heterotrimeric G-proteins. The only PLC isozymes regulated by G-proteins are the members of the PLCβ, and thus, these isoforms are candidates for activation by a large number of platelet agonists such as thrombin, TxA_2, and ADP. Although all four members of PLCβ family are present in platelets, the main isoforms are PLCβ2 and PLCβ3[35]. PLCβ1 is 40 times less abundant than

Cambridge Books Online © Cambridge University Press, 2009

PLCβ2, and PLCβ4 is 600 times less abundant than PLCβ2, and the amount of PLCβ2 is twice that of PLCβ3[35]. Recent evidence reports that PLCβ2 is present in platelets as two forms derived by alternative splicing, the difference being in 13 aminoacids in the C-terminal tail[88]. Platelets from a patient with a mild inherited bleeding disorder, showing reduced generation of IP_3, Ca^{2+} mobilization, and pleckstrin phosphorylation in response to different agonists, contained approximately one-third the amount of PLCβ2, suggesting a central role for this isozyme in platelet activation[35]. PLCβ isozymes are activated with different efficiency by the α-subunits of the Gq family of heterotrimeric G-proteins αq, α11, α14, α15, and α16[37,38]. Of these, only αq and α16 are expressed in human platelets[39,40]. Some studies have demonstrated that PLCβ2 is not significantly activated by αq or α16[41,42], therefore PLCβ3 is the only PLC isozyme that can be significantly activated by these α-subunits in platelets, and it also most likely represents the target of all the platelet agonists that signal through Gαq or Gα16.

The best-characterized example of the activation of PLCβ3 by these G-proteins is the agonist TxA_2 (Fig. 16.2(*a*)). Several studies based on copurification procedures, immunological evidence, and reconstitution experiments clearly demonstrated that the platelet TxA_2 receptor is coupled with αq to activate PLCβ3[39,89,90]. A possible association of the TxA_2 receptor with α16 has also been reported[91], and this may contribute to PLCβ3 activation in response to this agonist. The αq subunits are not substrates for pertussis toxin. Because PLC activation in response to TxA_2 is not affected by this toxin[92], the αq/α16-mediated activation of PLCβ3 probably accounts for the totality of PIP_2 hydrolysis promoted by TxA_2. This is consistent with the finding that inositol phosphates formation and calcium mobilization in response to TxA_2 are totally abolished in αq-deficient mice[93]. Moreover, these results implicitly question the physiological significance of a possible contribution of α16 in TxA_2-mediated PLC activation in platelets. Other G protein α-subunits such as α12 and α13 that were found to be associated with the TxA_2 receptor, do not seem to be involved in the signalling pathways leading to PLC activation[94].

Both members of the PLCβ family (PLCβ2 and PLCβ3) that are expressed in platelets at significant levels are efficiently activated by G-protein $\beta\gamma$-subunits[45–47]. In this regard, it is interesting to note that the efficiency of PLCβ3 stimulation by $\beta\gamma$ is almost twice that of PLCβ2[47]. This leads to two considerations. In platelets, PLCβ2 is probably activated mainly by $\beta\gamma$-subunits (because it is almost insensitive to α-subunits). Moreover, because the amount of PLCβ2 in platelets is almost twice that of PLCβ3, but the responsiveness of PLCβ3 to $\beta\gamma$-subunits is twice that of PLCβ2, agonists that liberate suitable $\beta\gamma$-dimers are most likely to lead to the activation of both PLCβ isozymes. Activation of PLCβ2 and PLCβ3 by $\beta\gamma$-dimers is thought to be the predominant mechanism for PLC activation in thrombin-stimulated platelets (Fig. 16.2(*b*)). It has been known for years that thrombin-induced hydrolysis of PIP_2 is inhibited by pertussis toxin[95]. The only G-protein α-subunit substrate for this toxin is αi, which is actually associated with the thrombin receptor but does not, as such, activate any PLC isozyme. However, thrombin-dependent activation of Gαi by GTP binding leads to the release of associated $\beta\gamma$-dimers that can be responsible for the pertussis toxin-sensitive activation of PLCβ2/PLCβ3. In this context, is has to be remembered that activation of PLCβ isozymes by $\beta\gamma$-dimers may not be limited to thrombin-stimulated platelets, but may potentially represent a general feature of all platelet agonists. In fact, in the absence of an exact map of association between specific α-subunits and $\beta\gamma$-dimers, we cannot exclude that PLC-activating $\beta\gamma$-dimers also may be associated with pertussis toxin-insensitive G-protein α-subunits, such as αq. In this regard, it is noteworthy that, as stated before, α-subunits of the Gq family and $\beta\gamma$-dimers activate PLCβ3 (the only isozyme sensitive to both stimulators in platelets) by binding to distinct domains, and therefore may synergistically contribute to the stimulation of this isozyme. Pretreatment of platelets with pertussis toxin inhibits, but does not totally abolish, PLC activation by thrombin, which, to a lesser extent, is still able to stimulate PIP_2 hydrolysis. This suggests the existence of a second pertussis toxin-insensitive pathway for PLC activation induced by this agonist. In addition to αi, also αq, α12, and α13 have been found to associate with the thrombin receptor in platelets[94–97]. Of these proteins, αq could mediate a pertussis toxin-insensitive activation of PLCβ3. Significantly, IP_3 formation and Ca^{2+} mobilization in response to thrombin are totally abolished in αq-deficient mice[93]. This observation suggests an essential role for αq in PLC activation by thrombin and reduces the physiological significance of the contribution of $\beta\gamma$-subunits to thrombin-dependent activation of PLCβ isozyme. However, these results clearly conflict with the concept that IP_3 formation by this agonist is produced, at least partially, by a mechanism sensitive to pertussis toxin that cannot be mediated by αq.

PLC activation in response to ADP is mediated through the binding of the agonist to P2Y1, one of the three receptors present on the platelet surface[15,16]. Despite the failure of early studies using a photoactivable GTP analogue to detect G αq among the G-proteins associated with the ADP receptors[98], it is now generally accepted that PLC activa-

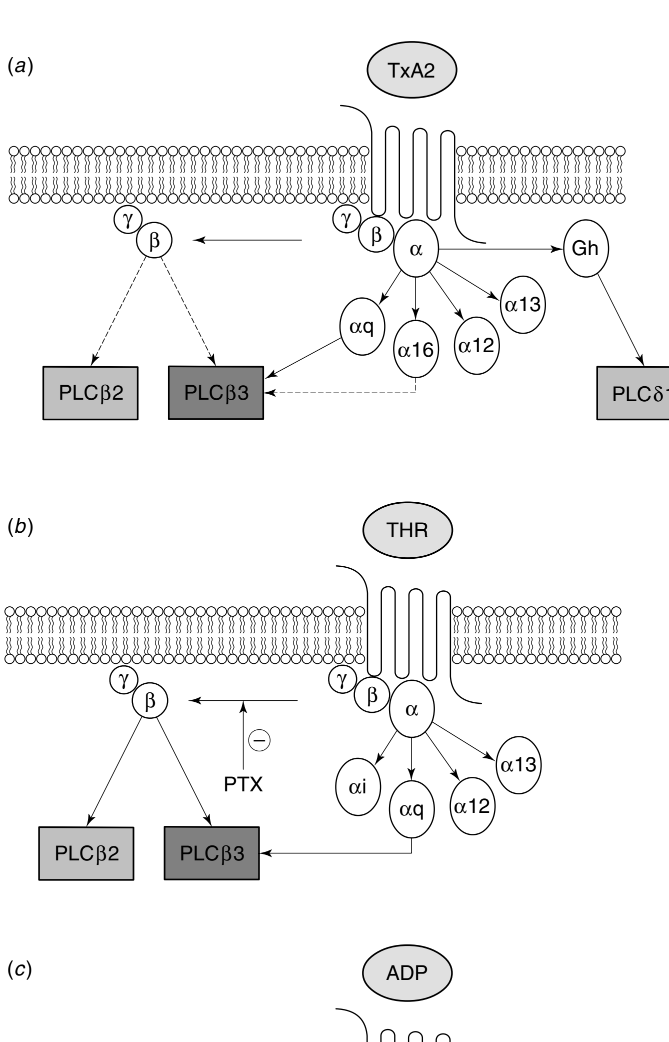

Fig. 16.2. G-protein-mediated activation of PLCβ isozymes in platelets. Although all four PLCβ isozymes are present in platelets, only PLCβ2 and PLCβ3 are expressed at significant levels[35]. PLCβ3 is efficiently activated by G-protein α-subunits, that, by contrast, are not efficient in activating PLCβ2[41,42]. G-protein $\beta\gamma$ dimers can activate both PLCβ2 and PLCβ3 with similar efficiency[45–47]. Solid lines indicate documented activating pathways, and dotted lines represent possible, although not yet confirmed mechanisms. (*a*) The platelet TxA_2 receptor is coupled to αq, α16, α12, and α13. Among these α-subunits, αq and α16 can activate PLCβ3[41,42]. Although the role of αq in PLC activation of TxA_2-stimulated platelets has been clearly documented[39,89,90,93], a direct involvement of α16 remains hypothetical. $\beta\gamma$ subunits released from activated α-subunits upon stimulation of the TxA_2 receptor can contribute to PIP_2 hydrolysis through both PLCβ2 and PLCβ3. The TxA_2 receptor is also coupled to the high molecular weight G-protein Gh[54], which has been reported to mediate activation of PLCδ1[51,54]. (*b*) The thrombin receptor is coupled to αi, αq, α12, and α13. αq has been demonstrated to be directly involved in thrombin-induced activation of PLC[93] by stimulating PLCβ3. However, PIP_2 hydrolysis induced by thrombin is inhibited by pertussis toxin[95], which catalyses the ADP-ribosylation of αi. Because αi does not activate any PLC isozyme, the pertussis toxin-sensitive activation of PLC is thought to be mediated by the action of $\beta\gamma$ dimers released from activated αi on PLCβ2 and PLCβ3. (*c*) Although many G-protein α-subunits have been found to associate with the seven transmembrane-domain ADP receptors, the only documented pathway for PLC activation involves the stimulation of PLCβ3 by αq[93]. However, an additional role for $\beta\gamma$ dimers, although not confirmed, cannot be ruled out.

tion by ADP is mediated by αq. This is based on the evidence that PLC activation by this agonist is totally abolished in αq-deficient platelets[93]. In this context, we may assume that PLCβ3 is the main PLC isozyme activated by ADP (Fig. 16.2(*c*)).

The activation of PLCβ3 may also be regulated by proteolytic cleavage of the enzyme. Stimulation of platelets with thrombin or collagen causes the degradation of PLCβ3 into a proteolytic fragment of about 100 kDa[99]. This proteolysis is also promoted by the Ca^{2+} ionophore A23187, and is prevented by calpeptin, suggesting that it is mediated by the Ca^{2+}- dependent protease, calpain. Based on immunological reactivity of the 100 kDa fragment, the site of cleavage on PLCβ3 has been tentatively localized between the Y region and the C-terminal tail. The 100-kDa proteolytic fragment of PLCβ3 is activated largely by $\beta\gamma$ subunits, unlike the intact protein[100]. Because calpain is activated by an aggregation-dependent mechanism, these observations

Cambridge Books Online © Cambridge University Press, 2009

suggest a novel strategy to amplify PLCβ3 activation, and this event may be related to irreversible aggregation.

Activation of phospholipase Cγ in platelets

Platelets express both members of the PLCγ family: PLCγ1 and PLCγ2. PLCγ2 is the most abundant protein of all the PLC isozymes in platelets, and its expression is tenfold higher than that of PLCβ2[35]. It is well accepted that PLCγ isozymes are activated by a mechanism involving the phosphorylation on PLCγ-tyrosine residues[48]. Therefore, initial studies undertaken to identify platelet agonists able to activate PLCγ focused on investigating the tyrosine phosphorylation of the two isozymes. Interestingly, tyrosine phosphorylation of PLCγ1 has never been detected in agonist-stimulated platelets, although this isozyme has been found to associate with tyrosine phosphorylated proteins[33,101–103]. One of these proteins has been identified as the GTPase-activation protein for p21ras or p120rasGAP, suggesting a link between PLCγ1 and monomeric GTP-binding proteins[33]. Although the lack of tyrosine phosphorylation of PLCγ1 raised concerns about its possible mechanism of activation in platelets, recent evidence indicates that it can be activated by some intracellular molecules, even in the absence of tyrosine phosphorylation[104]. For instance, PLCγ1 can be stimulated by arachidonic acid, which is also generated in platelets by the action of PLA_2 and by phosphatidic acid, produced by phospholipase D and by phosphorylation of PLC-released DAG. Although the exact mechanism and physiological relevance of PLCγ1 activation by these messengers in the absence of tyrosine phosphorylation remains unclear, these observations may indicate that PLCγ1 can be activated in platelets in response to different extracellular agonists.

More successful has been the investigation of tyrosine phosphorylation of PLCγ2 in stimulated platelets. This isozyme has been found to be phosphorylated in intact platelets stimulated with thrombin, collagen, von Willebrand factor, WGA, and concanavalin A, and by cross-linking of FcγRIIA[102,105–108]. The tyrosine phosphorylation of PLCγ2 in response to thrombin is very low compared with that observed in collagen- or von Willebrand factor-stimulated platelets, and the strongest phosphorylation of this isozyme is observed in concanavalin A-stimulated platelets. This evidence supports the idea that PLCγ2 may mediate PIP_2 hydrolysis in response to those agonists whose receptors are not coupled with GTP-binding proteins. Among these agonists, the most studied and best characterized example is collagen.

Collagen-induced tyrosine phosphorylation of PLCγ2 is mediated by binding to GPVI. This receptor has been recently cloned and belongs to the immunoglobulin superfamily[109,110]. It is a single transmembrane-domain glycoprotein expressed on the platelet surface in association with the Fc receptor γ-chain (FcR-γ chain), a signal-transducing unit containing an immunoreceptor tyrosine-based activation motif (ITAM) previously known as a component of several receptors for immune complexes[109–112]. The essential role of GPVI in collagen-induced PLCγ2 tyrosine phosphorylation is demonstrated by the fact that in GPVI-deficient platelets, phosphorylation of PLCγ2 by collagen is abolished[112]. Moreover, a cross-linked collagen-related triple-helical peptide (CRP) based on the repeated sequence Gly–Pro–Hyp, the snake venom protein convulxin and some monoclonal antibodies induce tyrosine phosphorylation of PLCγ2 by binding specifically to GPVI[113–115]. Tyrosine phosphorylation of PLCγ2 in response to these agonists is mediated by the tyrosine kinase Syk, as demonstrated both by studies with human platelets treated with a specific inhibitor of Syk, piceatannol, and by studies performed with platelets from Syk-deficient mice[116,117]. The signalling pathway leading to PLCγ2 tyrosine phosphorylation in collagen-stimulated platelets has been elucidated (Fig. 16.3). Collagen binding to the extracellular domain of GPVI results in the tyrosine phosphorylation of the associated FcR-γ chain, presumably within the ITAM[118]. Members of the Src family of tyrosine kinases Lyn and Fyn are probably involved in this initial step[119]. Tyrosine phosphorylated FcR-γ chain binds to the SH2 domain of the tyrosine kinase Syk leading to its activation and tyrosine phosphorylation[118]. Syk, in turn, mediates tyrosine phosphorylation of PLCγ2[116,117]. This mechanism seems to represent a general strategy for PLCγ2 phosphorylation in platelets. An ITAM is also present in the cytosolic domain of the FcγRIIA, and upon cross-linking of the receptor, is able to mediate the recruitment of Syk leading to tyrosine phosphorylation of PLCγ2[120]. Moreover, a role for FcγRIIA and the FcR-γ chain has also been proposed to be essential for PLCγ2 phosphorylation in von Willebrand factor-stimulated platelets[107,121].

The mechanism for tyrosine phosphorylation of PLCγ2, however, seems to be more complex than that depicted by the scheme illustrated above. For instance, coimmunoprecipitation experiments failed to detect a direct association between PLCγ2 and Syk, although a fusion protein containing the SH2 domains of PLCγ2 was found to precipitate Syk from a lysate of collagen-stimulated platelets[80]. This suggests that the interaction between Syk and PLCγ2 may be indirect, and that other factors may be required. In this context, a role for Bruton's tyrosine kinase (Btk) has been reported[122]. This kinase belongs to the Tec family of kinases

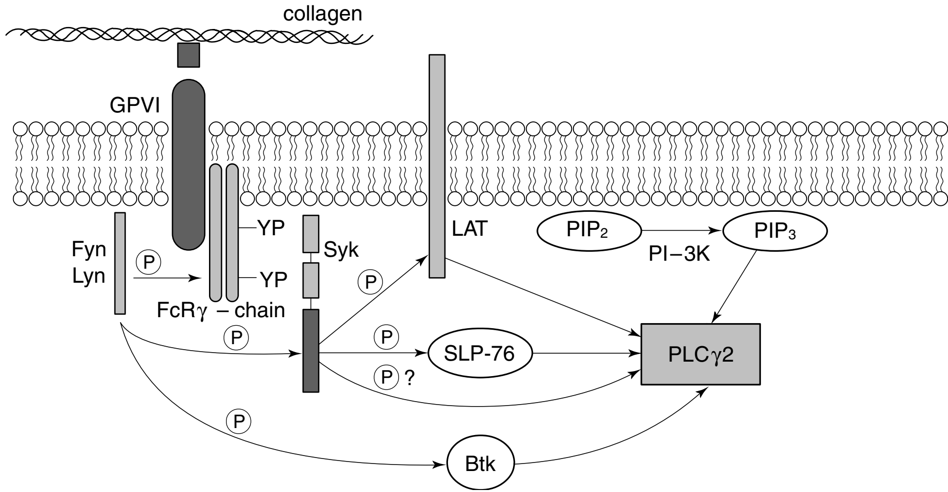

Fig. 16.3. PLCγ2 activation in collagen-stimulated platelets. Several studies performed with specific inhibitors or with selective knock-out mice have revealed that activation of PLCγ2, upon binding of collagen to the GPVI/Fc receptor γ-chain receptor on the platelet surface, requires the contribution of several signalling molecules, including the tyrosine kinases Fyn, Lyn, Syk, and Btk, the adaptor proteins LAT and SLP-76, and the lipid product of PI-3K, PIP_3. Syk and Btk may be involved in the tyrosine phosphorylation of PLCγ2, while LAT, SLP-76, and PIP_3 may participate in the translocation of PLCγ2 to the membrane. For details, see the text.

and is tyrosine phosphorylated in platelets stimulated with collagen or CRP. Btk is not expressed in platelets from patients affected with the X-linked agammaglobulinemia (XLA). Collagen stimulation of Btk-deficient XLA platelets results in an impaired tyrosine phosphorylation of PLCγ2 and Ca^{2+} mobilization[122].

In addition, two adaptor proteins, SLP-76 and LAT (linker for activation of T cells), seem also to be essential for PLCγ2 phosphorylation and activation. SLP-76 (SH2 domain-containing leukocyte protein of 76 kDa) is a 76 kDa cytosolic protein that plays an essential role in PLCγ1 activation in T-cells[48]. In human platelets, SLP-76 is tyrosine phosphorylated in response to CRP by a mechanism depending on Syk[123]. Mutant mice lacking SLP-76 show fetal hemorrhage and prenatal mortality[124]. In SLP-76-deficient platelets, collagen-induced PLCγ2 tyrosine phosphorylation is totally abolished, and Ca^{2+} mobilization is strongly attenuated. Moreover, in vitro binding studies using a GST-fusion construct containing the two SH2 domains of PLCγ2 have documented a direct interaction between PLCγ2 and SLP-76[80]. These pieces of research clearly demonstrate that SLP-76 is an important link between Syk activation and PLCγ2 regulation, although the exact role played by this adaptor protein is still unclear.

LAT is a 38 kDa transmembrane protein involved in PLCγ1 activation in T cells[48]. In human platelets, LAT is tyrosine phosphorylated in response to both CRP and thrombin, by a mechanism depending on Syk but independent from Btk or SLP-76[125]. In platelets from mice lacking LAT, tyrosine phosphorylation of PLCγ2 and accumulation of phosphatidic acid were strongly reduced[125].

Altogether, these results indicate that LAT and SLP-76 are both regulated by Syk and are required for PLCγ2 tyrosine phosphorylation and activation induced by collagen. The fact that LAT is a membrane protein may suggest that it could also participate in the mechanism for PLCγ2 translocation to the membrane, which is essential for its activation. It is known that tyrosine phosphorylation of PLCγ isozymes is required but not sufficient for activation of the enzyme in the absence of an efficient translocation to the membrane. In this context, it is very well known that the lipid products of PI-3K play a crucial role in PLCγ2 translocation and activation. Studies from nucleated cells revealed that both the PH and the SH2 domains of PLCγ bind to PIP_3 to promote membrane translocation of the enzyme[65–67]. A similar role for the lipid products of PI-3K has also been proposed in human platelets[68,69]. PI-3K inhibitors like wortmannin or Ly294002 strongly reduced PLC activation in response to CRP or upon cross-linking of the FcγRIIA. These inhibitors did not prevent tyrosine phosphorylation of PLCγ2, but abolished its translocation to the particulate fraction. This effect was overcome by the addition of exogenous PIP_3 to permeabilized platelets[69]. Although platelet PLCγ2 was found to bind directly to PIP_3, the exact role of this interaction in mediating enzyme translocation to the platelet membrane is not totally clear.

Cambridge Books Online © Cambridge University Press, 2009

Recent evidence demonstrates that, when transfected into PC12 cells, the isolated PH or SH2 domains of PLCγ2 do not undergo membrane translocation upon elevation of PIP_3[126]. On the basis of this evidence, it has been proposed that interaction mediated by these domains may not be strong enough to ensure efficient translocation, but may help hold PLCγ2 at the membrane in association with other supporting interactions. In this regard, it is interesting to note that interaction of the SH2 domains of PLCγ2 with the membrane-localized adaptor protein LAT has been reported[80]. This supports the idea that the role of LAT in regulating PLCγ2 activation is related to membrane translocation.

In conclusion, activation of PLCγ2 in collagen-stimulated platelets clearly involves multiple regulators. It is possible that the basic scheme, which strongly resembles that described in B and T cells, represents a general strategy that might also operate in platelets stimulated with von Willebrand factor or by cross-linking of FcγRIIA, where the involvement of PLCγ2 has been reported. However, although incredible progress has been made during the last 3 years in understanding how collagen activates PLC, the exact mechanism of this process is yet to be fully clarified, and some discrepancies remain to be explained. For instance, platelet activation by collagen is totally inhibited in αq-deficient mice[93], and this convincing evidence hardly fits with the model proposed above. This evidence would be consistent with the activation of PLC in collagen-stimulated platelets being totally dependent on TxA_2 production. Early works actually reported that inositol phosphate accumulation induced by collagen is strongly inhibited by aspirin[127,128]. Moreover, PLC activation by collagen is also totally inhibited by cytochalasin D, highlighting a role for the intracellular cytoskeleton[128]. However, the steps that lead GPVI-FcR-γ to activate PLCγ2 do not include any role for the endogenous TxA_2 or cytoskeleton. Moreover, PLC activation by collagen has also been found to require the production of H_2O_2[129]. Alternatively, collagen also binds to integrin $\alpha_2\beta_1$ on the platelet surface, and the contribution of this receptor in cell activation is controversial[116,130,131]. Recently, it has been shown that tyrosine phosphorylation of PLCγ2 can also be promoted upon recruitment of integrin $\alpha_2\beta_1$[116,132]. The effects elicited through this collagen receptor, but not those mediated by GPVI, are markedly suppressed by aspirin or cytochalasin D[132]. These apparent discrepancies may be related to the doses of collagen used to stimulate platelets. The GPVI-dependent pathway for PLCγ2 activation has been elucidated in studies using high doses of collagen or CRP, and other findings come from studies in which much lower doses of agonist were used. It is therefore possible that the mechanism of PLC activation by collagen may depend upon the concentration of the agonist.

Activation of phospholipase Cδ in platelets

Although PLCδ1 and PLCδ3 are present in human platelets, their concentrations are much lower than other PLC isozymes[35,36]. PLCδ1 is as yet the only PLC isozyme whose structure has been defined; however, very little is known about the mechanism of activation of this class of enzymes. Although PLCδ1 is present mainly in the cytosol of platelets, PLCδ3 is predominantly located in the membrane fraction[36], suggesting the two isozymes may be regulated differently. The possibility that PLCδ isozymes are regulated by Ca^{2+} has been proposed[50], and in this context, it is possible that PLCδ1 and PLCδ3 are also stimulated in platelets in response to those agonists able to increase the intracellular concentration of Ca^{2+}. That is, all the platelet agonists that activate other PLC isozymes and stimulate IP_3-dependent Ca^{2+} release from internal stores could be responsible for a temporary delayed activation of PLCδ members. In addition, evidence indicates that PLCδ1 in platelets can be selectively activated in response to TxA_2. This is based on the observation that PLCδ1 is stimulated by Gh, a recently identified high molecular weight (70 kDa) G-protein that also displays transglutaminase activity[51] and that is expressed in human platelets[54]. Gh has been found to associate with both isoforms of the TxA_2 receptor (TPα and TPβ)[54]. In cells cotransfected with TPα, the main TxA_2 receptor expressed on the platelet surface, and Gh, the TxA_2 analogue U46619 was able to stimulate inositol phosphate accumulation in a manner similar to that measured in cells cotransfected with TPα and αq[54]. These results indicate that Gh could efficiently link the TxA_2 receptor to PLCδ1. Whether this mechanism is physiological relevant in human platelets remains to be clarified.

Phospholipase C and the platelet cytoskeleton

One of the most important events in platelet activation by extracellular agonists is the stimulation of actin polymerization and the reorganization of the intracellular cytoskeleton. It is now very well recognized that the platelet cytoskeleton does not have an exclusively contractile function, but also represents a network connecting and regulating several signalling molecules, including PLC. For instance, it has been shown that treatment of intact platelets with cytochalasin D, which prevents actin polymerization, blocks collagen-induced PLC activation[128]. Several

Cambridge Books Online © Cambridge University Press, 2009

actin-binding proteins may be involved in the regulation of PLC, including profilin and gelsolin. Profilin isolated from platelets has been found to bind with high affinity to PIP_2 and to compete efficiently with PLC for interaction with the substrate[133]. Moreover, profilin is thought to facilitate actin polymerization by subtracting actin monomers from the sequestering protein thymosin β4[3]. This process is activated when free profilin is released upon PIP_2 hydrolysis by PLC. Therefore, PLC and profilin may influence each other reciprocally.

Gelsolin is an F-actin severing protein. In platelets, a complex composed by gelsolin and actin in a 1: 1 ratio has been found to copurify and coimmunoprecipitate with PLCγ1[134]. Upon stimulation with thrombin, the actin–gelsolin complex dissociates from PLCγ1[135]. This event occurs concomitantly with platelet aggregation and is paralleled by a threefold to fivefold increase in PLCγ1 activity[135]. Therefore, it may represent a mechanism for a delayed, aggregation-dependent activation of this enzyme.

Upon platelet activation, several lipid-metabolizing enzymes have been found to associate physically with the actin-based cytoskeleton. These include PI-3K, DAG kinase, and PLC[136]. Among the PLC isozymes, PLCβ2, PLCβ3, PLCγ1, and PLCγ2 relocalize to the cytoskeleton in thrombin-stimulated platelets. Translocation of PLCγ1 is very rapid and transient and can be prevented by inhibitors of tyrosine kinases[137]. Translocation of PLCβ2, PLCβ3, and PLCγ2 to the cytoskeleton is blocked by inhibitors of fibrinogen binding and requires platelet aggregation[138]. Although PLCβ2 and PLCβ2 progressively accumulate in the cytoskeletal fraction during platelet aggregation, the interaction of PLCβ3 with the actin filaments is quicker but more transient. Because PLCβ3 is a substrate for calpain, which is activated during platelet aggregation[99], it is conceivable that the decreased cytoskeletal levels of this protein in the late phases of platelet activation reflect its hydrolysis. Although the exact consequence of PLC isozyme's interaction with the cytoskeleton is not known, it is possible that it represents a strategy to coordinate and facilitate activation of different isozymes in different phases of platelet activation. The investigation of the mechanisms regulating different PLC isozymes, and the clarification of the cellular events promoted by the activation of selective isoforms await the availability of specific inhibitors. The compound U73122 has been widely used to block the activity of both PLCβ and PLCγ isoforms[139,140]. However, recent studies raised questions about the specificity of this compound, which was shown to also affect Ca^{2+} influx and to prevent platelet aggregation by a mechanism independent of PLC inhibition[141,142].

Overview of phospholipase D

The role of the stimulation of phospholipase D (PLD) in receptor-mediated platelet activation is not as clearly defined as that of PLC. PLD hydrolyses the phosphate diester bond of membrane glycerophospholipids to produce PA and the free alcohol corresponding to the polar group[143]. Although PLD can act on phosphatidylethanolamine and phosphatidylinositol, the classical substrate for this enzyme is phosphatidylcholine (PC), which is hydrolysed to PA and choline. No obvious role for choline as an intracellular messenger is known. This molecule is rapidly phosphorylated to phosphocholine to be reused for PC biosynthesis. In contrast, PA may act as a second messenger by itself and represent a precursor for the synthesis of the potent lipid messenger, lysophosphatidic acid. Moreover, PA produced by the action of PLD can be converted to DAG by a PA-phosphohydrolase and, therefore, can lead to activation of PKC. In this way, PLD may contribute to and extend the regulation of PKC activity in response to extracellular agonists. Several studies have shown that in agonist-stimulated cells, the accumulation of DAG is biphasic: a first, rapid and transient, production of this messenger is followed by a second, more delayed, but sustained phase. It has been proposed that the first wave of DAG production is caused by PLC-mediated hydrolysis of PIP_2, and the second phase derives from the action of PLD on PC[144,145]. The PA-phosphohydrolase and DAG kinase activities create a bidirectional connection between PA and DAG, establishing a strong link between PLD and PLC (Fig. 16.4). Moreover, the close relationship between the two classes of enzymes is strengthened by at least two additional findings. First, PIP_2, the substrate of PLC, is also an essential cofactor for PLD (see below); second, the expression of a putative PLC enzyme that specifically acts on PC rather than PIP_2 (PC-PLC) to produce DAG and phosphocholine has been described in many cells, including platelets[146,147]. Because of these interplays with PLC, measurements of the direct products of the reaction may not always represent a reliable method to evaluate PLD activation in the living cell. Production of ^{3}H-choline from ^{3}H-choline-labelled cells may also be caused by the combined action of the putative PC-PLC and of phosphocholine hydrolase. Similarly, ^{3}H-phosphocholine is not only a metabolite that accumulates upon the combined action of PLD and choline kinase, but it is also directly produced by PC-PLC. In addition, a decrease in membrane PC, which may appear indicative for PLD activation, may be caused by PC-PLC activity. Alternately, even the measurement of ^{32}P-PA production in ^{32}P-labelled cells is not indicative of PLD activation because the turnover of the primary phosphate group in membrane phospholipids is very low, and accumulation of

Cambridge Books Online © Cambridge University Press, 2009

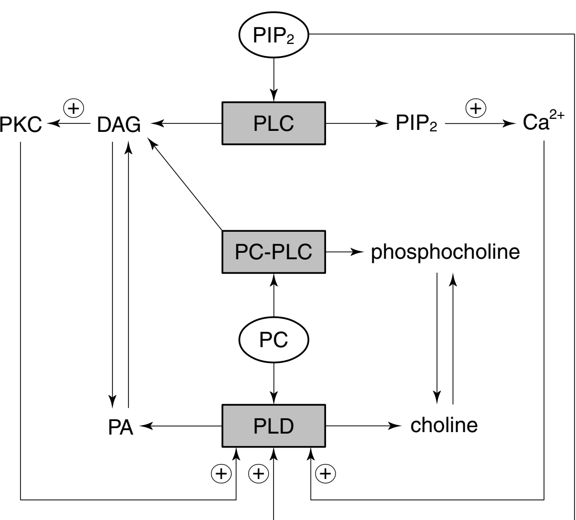

Fig. 16.4. Interplay between reactions catalysed by PLC and PLD. PC is hydrolysed by both PLD and PC-specific PLC. DAG and PA are interconverted by the action of PA-hydrolase and DAG kinase. Choline, produced by the action of PLD, is phosphorylated to phosphocholine, and phosphocholine generated by the PC-PLC is converted to choline. PIP_2 is an essential cofactor for PLD activation. DAG and IP_3, the products of PIP_2 hydrolysis by PLC, promote PKC activation and release of Ca^{2+} from intracellular stores. PKC and Ca^{2+} are known activators of PLD.

^{32}P-PA almost exclusively reveals the DAG kinase reaction on the product of PIP_2-specific PLC. The most direct and reliable approach to detect PLD activation exploits the unique ability of this enzyme to catalyze a transphosphatidylation reaction, in which the phosphatidyl group of PC is transferred not to a molecule of water, as in the normal hydrolysis reaction, but to a primary alcohol, such as ethanol or butanol. When the membrane phospholipids are labelled with ^{3}H-myristic acid or ^{3}H-palmitic acid, and cell stimulation is performed in the presence of ethanol or butanol, the accumulation of stable labelled phosphatidylethanol or phosphatidylbutanol represents unequivocal evidence for activation of PLD. The transphosphatidylation reaction, in addition to the measurement of accumulation of PA and choline, has been widely used to detect PLD activity in the cells and to measure PLD activity in vitro to clarify the mechanisms regulating this enzyme.

Regulation of phospholipase D

The PLD activity in intact cells can be regulated by a number of factors, including PIP_2, PKCα, and the low molecular weight GTP-binding proteins Arf, Rho, Rac, and Cdc42.

Regulation by PIP_2

In addition to being a substrate for PLC and PI-3K, PIP_2 is also involved in the regulation of PLD. This lipid cannot be considered a real activator of PLD, but rather represents an essential cofactor for optimal expression of the PLD enzymatic activity. Such a role for PIP_2 emerged from the casual finding that PLD activity measured in vitro using phospholipid vesicles containing labeled PC as a substrate was markedly increased by the inclusion of PIP_2[148]. Activation of PLD partially purified from brain membrane was increase tenfold by PIP_2, but not by other acid phospholipids, including PIP and PI. Studies with permeabilized cells confirm the physiological relevance of the regulatory role of PIP_2 on PLD activation in vivo[149]. In this experimental system, inhibition of PI 4-kinase reduced by 80% the amount of membrane PIP_2 and fully suppressed activation of PLD in response to GTPγS and PMA. Subsequent studies showed that, in addition to PIP_2, PIP_3, which is the lipid product of PI–3K, also can support stimulation of PLD[150]. The role of PIP_2 and PIP_3 as cofactors for PLD establishes a functional link among the lipid-metabolizing enzymes PLD, PLC, and PI-3K, providing the basis for a possible coordinated regulation of this signalling molecule.

Stimulation of phospholipase D by low molecular weight G-proteins

The involvement of G-proteins in regulating PLD was suggested based on the evidence that PLD was activated by GTP and by its non-hydrolysable analogue GTPγS[151,152]. Stimulation of PLD by GTP was found to be mediated by a cytosolic factor that, upon purification, was recognized as a member of the Arf family of proteins[148,153]. Arf proteins are low-molecular-weight GTPases initially identified as cofactors required for efficient ADP-ribosylation of the α-subunit of Gs by cholera toxin[154]. It has been subsequently demonstrated, and it is now very well accepted, that Arf proteins play an essential role in vesicular membrane trafficking in eukaryotic cells by promoting the formation of coated vesicles and facilitating the transport between the endoplasmic reticulum and the Golgi complex[155]. Interestingly, different studies have suggested a role for PLD in agonist-dependent cellular secretion, and abundant levels of Arf-sensitive PLD activity has been detected in the Golgi membranes[156,157]. Activation of PLD by Arf requires the N-terminal myristoylation of the small G-protein, a posttranslational modification leading to membrane anchorage[148], and is mediated by a domain located at the N-terminal region of the protein, distinct from the

Cambridge Books Online © Cambridge University Press, 2009

domain necessary for activation of cholera toxin[158]. Moreover, a direct interaction between Arf and PLD has been suggested[159].

In addition to Arf, other activators of PLD include members of the Rho family of small G-proteins (RhoA, RhoB, RhoC, Rac1, Rac2, and Cdc42). This was initially suggested by evidence that GTPγS activation of PLD could be potentiated by smgGDS, a protein that facilitates the GDP/GTP exchange (and thus the activation) of Rho, and could by inhibited by RhoGDI, which prevents activation of Rho[160,161]. Significantly, the inhibitory effect of rhoGDI on PLD activity could be overcome by addition of recombinant Rho proteins[161]. Moreover, stimulation of PLD activity was also inhibited by treatment of the cell with the botulinum toxin C3, which promotes ADP-ribosylation and inactivation of Rho[162]. Finally, partially purified PLD activity could be activated in vitro by recombinant Rho proteins[163]. Interestingly Rho proteins activate PLD in a PIP_2-dependent mechanism. The ability of Rho proteins to stimulate PLD requires the membrane localization of the Rho proteins, which, as in the case of Arf, is dependent upon the isoprenylation of the C-terminal region of the protein[163].

Activation of phospholipase D by PKC

In cell-free preparations, PLD activity can be stimulated in a dose-dependent manner by purified PKC[164]. The mechanism of PLD activation by PKC is not completely known. Although it is well accepted that the classical PKCs (α, β, and γ) but not the newer or the atypical isoforms, are effective stimulators of PLD in the presence of PMA or Ca^{2+}[165], the role of the catalytic function of these enzymes is controversial. In some experimental systems, ATP is required for PKC-dependent PLD activation, suggesting a mechanism involving protein phosphorylation[166]. However, in HL60 cells, stimulation of PLD by PKC requires ATP, but is not affected by inhibitors of the PKC activity[167]. Moreover, some studies have shown that PKCα with depleted kinase activity maintains the ability to stimulate PLD[168]. By limited proteolysis, the PLD-activating fragment of PKCα has been identified as the regulatory, but not the kinase domain. Although the exact mechanism for PLD activation by PKC is not clear, this regulatory mechanism establishes an additional link between PLD and PLC.

Structure of phospholipase D isozymes

Although much less is known about the identity of PLD compared with PLC, it is now clear that, like PLC, PLD does not exist as a single protein, but represents a family of different isozymes. The first evidence that multiple PLD isozymes existed in mammalian cells came from fractionation studies on HL60 cells and porcine brain membranes that identified at least two separate PLD molecules with different regulatory properties[148,169]. The first enzyme displayed a molecular mass of about 200 kDa and was activated by sodium oleate but was insensitive to Arf. The second enzyme had a molecular mass of about 95 kDa, and was sensitive to Arf but not to sodium oleate.

The cloning of a PLD molecule was reported in 1995[170]. This enzyme, named PLD1, is a 120 kDa protein present in cells as two variant forms derived from alternative splicing[159]. Because PLD1 requires PIP_2 as a cofactor for enzymatic activity and is insensitive to sodium oleate, it therefore probably corresponds to the previously described 95 kDa form from porcine brain. The PLD1 molecule does not possess domains such as C2, SH2, or SH3 that frequently are found in other signalling proteins. A PH-like domain is present in the N-terminal portion of the protein, and it has been initially supposed to be involved in PIP_2 enzyme regulation. However, a recent piece of work demonstrates that although PLD1 directly binds to PIP_2, this interaction does not involve the PH domain[171]. PLD1 has a low basal activity, that is at least partially caused by the inhibitory effect of a sequence that is exclusive of this isoform and indicated as the 'loop region', located in the center of the protein[172]. Enzymatic activity of PLD1 can be strongly stimulated by PKCα and by members of the Arf and Rho family of small G-proteins. Interestingly, these modulators act synergistically in activating PLD1, suggesting that they bind to different regions of the protein[172]. Deletion of the N-terminal third of PLD1 attenuates regulation by PKC but not by other activators, and deletion of the C-terminal third reduces activation by RhoA. The site of interaction of PLD1 with Arf has not been identified.

A second PLD isozyme, called PLD2, was cloned in 1997[173]. PLD2 is approximately 50% identical to PLD1, but has a molecular mass slightly smaller. As PLD1, PLD2 requires PIP_2 as a cofactor for enzymatic activity. PLD2 has a different subcellular localization than PLD1 being predominantly localized at the plasma membrane in cells, whereas PLD1 is found exclusively in the perinuclear region in association with the Golgi complex and the endoplasmatic reticulum[174]. Cloned PLD2 exhibits a very high basal activity, about 1500-fold greater than that of PLD1[173]. Studies with deletion mutants demonstrated that the N-terminal portion of PLD2 is necessary to confer this high basal activity to the enzyme[174]. Moreover, in contrast to PLD1, the basal activity of PLD2 cannot be further stimulated in vitro by PKCα, Arf, or Rho proteins[173]. Because such

Cambridge Books Online © Cambridge University Press, 2009

a high PLD activity is not detected in lysate of cells naturally expressing PLD2, it has been proposed that this isoform is constitutively inhibited in vivo, and that its activation is achieved by removal of such inhibition. An 18 kDa protein that is not a small GTPase, has been identified as a possible PLD2 inhibitor. This protein is still to be further characterized[173]. More recently, it has been shown that, upon deletion of the N-terminal portion, PLD2 not only loses most of its typical high basal activity, but also becomes responsive to Arf, but not to Rho or PKC[174]. These results suggest that PLD2 may be regulated in vivo by proteolysis into an Arf-responsive isoform.

Activation and regulation of phospholipase D in platelets

Compared with PLC, very little is known about PLD activation in platelets. No more than 20 papers have documented PLD activation in agonist-stimulated platelets by means of measuring formation of PA, choline, or products of the transphosphatidylation reaction. Moreover, no reports describe the expression of the cloned PLD isozymes in human platelets. Despite this, it is now clear that one or more PLD molecules exist in these cells and can be activated upon stimulation with different agonists. The first evidence for the presence of an agonist-activated PLD in platelets was reported in 1988. Using ^{3}H-arachidonic acid-labelled human platelets, it was shown that, in the presence of ethanol, thrombin induced the accumulation of ^{3}H phosphatidylethanol in a time- and dose-dependent manner[175]. Activation of PLD was also deduced from the observed accumulation of ^{3}H-choline and ^{3}H-phosphocholine in labelled platelets stimulated with thrombin or collagen[146]. By contrast, no release of these labelled metabolites was observed in response to ADP, PAF or epinephrine. However, because a PC-PLC is present in platelets, the real contribution of PLD in the generation of labelled choline and phosphocholine is difficult to assess. Stimulation of PLD in human platelets has also been described in response to the TxA_2 analogue U46619[176]. Finally, measurement of the transphosphatidylation reaction in platelet membrane or permeabilized cells demonstrates that PLD can be activated in these cells upon treatment with GTP, GTPγS, calcium ionophore A23187, and phorbol myristate acetate (PMA)[176–178].

The biochemical mechanism for PLD activation in platelets clearly involves multiple signalling pathways. In thrombin and collagen-stimulated platelets, PLD activation is not affected by aspirin, indicating that it is a primary event that does not require the action of endogenous TxA_2[146,179]. However, recent work showed that the ADP scavenger apyrase and the purinergic receptor antagonist ARL 66096 totally block PLD activation induced by low concentrations of thrombin and strongly reduce that promoted by high concentrations of this agonist[180]. In addition, ADP scavengers or antagonists strongly inhibit PLD activation stimulated by TxA_2. Although ADP alone is not able to stimulate PLD activity, this agent can reinforce the effects of low doses of stimulatory agonists like thrombin[180]. This indicates that secreted ADP may provide an amplification mechanism for agonist-induced PLD activation. Several studies indicate that activation of PLD can be mediated by an increase in the intracellular concentration of Ca^{2+}. This is based on studies using permeabilized platelets or intact cells treated with the Ca^{2+} ionophore A23187[176,178,181]. Moreover, chelation of intracellular Ca^{2+} by BAPTA prevents PLD activation[181,182]. In addition, production of phosphatidylethanol can be stimulated by PMA and can be blocked by inhibitors of PKC[176,177], suggesting a role for PKC in the stimulation of platelet PLD.

Finally, studies on platelet membrane and on permeabilized platelets clearly show a stimulatory effect of GTP and GTPγS on PLD activity[177,181,183], indicating the involvement of GTP-binding proteins. Therefore, G-proteins, PKC, and Ca^{2+} may act as activators of PLD in platelets. However, their actions may not be direct, but indicate that PLD stimulation in platelets is secondary to activation of PLC.

Still controversial is the regulation of PLD by integrin $\alpha_{IIb}\beta_3$ and platelet aggregation. Some authors report that, in thrombin- and collagen-stimulated platelets, PLD activation occurs in parallel with aggregation and can be blocked by chelation of extracellular calcium or by the omission of stirring[146,179]. Moreover, high-density lipoproteins (HDL_3), which are proposed to bind to the integrin receptor, have been shown to induce activation of PLD[184]. In the presence of butanol, accumulation of phosphatidylbutanol induced by HDL_3 was not observed in platelets from Glanzmann's thrombasthenia patients lacking integrin $\alpha_{IIb}\beta_3$[184]. By contrast, a different work reported that thrombin and PMA were still able to stimulate PLD in thrombasthenic platelets as well as in normal platelets in which fibrinogen binding to integrin $\alpha_{IIb}\beta_3$ was prevented by the antagonistic peptide RGDS[176]. Therefore, it appears that two mechanisms for PLD activation, one dependent, and one independent of integrin $\alpha_{IIb}\beta_3$, exist in platelets.

Finally, a role for protein tyrosine-kinases in activation of platelet PLD has been proposed[185]. Pervanadate, an inhibitor of protein-tyrosine phosphatases, stimulates PLD activity, and some inhibitors of tyrosine kinases, such as genistein and tyrphostins, markedly reduce PLD activation

Cambridge Books Online © Cambridge University Press, 2009

induced by thrombin in intact platelets and by GTPγS in permeabilized platelets[185].

Although no doubt exists that PLD is activated in agonist-stimulated platelets, the role of this event in cell activation is still controversial. Several studies suggest that PLD may actually contribute to PA formation induced by platelet stimulation, but this contribution may not be significant. It has been calculated that upon stimulation with thrombin, only 13% of incremental PA arises from PLD activation, and most can be ascribed to the combined action of PLC on PIP_2 and DAG kinase[178,182]. These results seem to limit the physiological importance of PLD in platelets. PA generated by the action of PLD can be converted to DAG by a PA-phosphohydrolase. It was reported that accumulation of DAG in thrombin-stimulated platelets is actually biphasic[186]. The first phase of DAG production is rapid and transient, peaks at 10 seconds, and is concomitant with IP_3 production. Therefore, it is most likely that it derives exclusively from the action of PLC on PIP_2. The second phase of DAG production is more sustained, but delayed, peaking at 2–3 minutes when the concentration of IP_3 has returned to the basal levels. Moreover, in thrombin-stimulated platelets a decrease of membrane PC was measured. However, it was found that the decrease of PC was mainly caused by the action of PLA_2 rather than PLD, and that the delayed accumulation of DAG probably derived from hydrolysis of PI by PLC rather than by hydrolysis of PC by PLD[186]. Again, this study limits the possible physiological significance of PLD in platelets. By contrast, other authors report evidence suggesting that PLD may be involved in the regulation of platelet secretion. This is based on studies with permeabilized platelets showing that secretion correlated with PLD, but not with PLC activation, and suggesting that PLD may mediate this platelet response by PKC-dependent and PKC-independent mechanisms[182]. A role for PLD in regulating platelet secretion and aggregation was also suggested based on the finding that addition of PA resulted in shape change and reversible aggregation[179]. Moreover, PA was shown to shorten the latency period of platelet aggregation induced by collagen[179]. Despite these observations, the real effect of PLD activation in platelet response to extracellular agonists remains largely unknown.

Conclusions

This chapter describes the considerable progress made over the last three decades in the understanding of the roles of PLC and PLD in the biology of platelet responses. These phospholipases are critical for the formation of numerous second messengers, including inositol trisphosphate, diacylglycerol, phosphatidic acid, lysophosphatidic acid, calcium release and activation of protein kinases. Our increased knowledge of these signalling molecules has introduced the potential for therapeutic intervention in conditions of altered platelet activity.

Platelet signalling: calcium

Juan A. Rosado and Stewart O. Sage

Department of Physiology, University of Cambridge, UK

Introduction

An increase in the cytosolic calcium concentration $[Ca^{2+}]_i$ is a major signal underlying platelet activation[1–4]. Physiological agonists increase the $[Ca^{2+}]_i$ by stimulating both the release of Ca^{2+} from intracellular stores in the endoplasmic reticulum (ER) and the entry of Ca^{2+} across the plasma membrane (PM). After stimulation, the $[Ca^{2+}]_i$ can be reduced by sequestration of Ca^{2+} into the ER and extrusion across the PM. The Ca^{2+}-ATPases responsible also maintain the $[Ca^{2+}]_i$ around 30–50 nM in resting platelets by working against the leakage of Ca^{2+} into the cytosol from the ER and across the PM.

The release of stored Ca^{2+}

Most platelet agonists are able to release stored Ca^{2+} from the ER (the dense tubular system of platelets). The occupation of surface receptors results in the activation of phospholipase C (PLC) and so the formation of the Ca^{2+} releasing messenger, inositol 1,4,5-trisphosphate (IP_3), which acts on receptors on the ER. Many platelet agonists, including ADP, platelet activating factor (PAF), thrombin and thromboxane A_2, have been shown to activate PLC-β_1 via a heterotrimeric GTP-binding protein[3]. PAF and thrombin also appear to activate PLC-γ_1[3], and thrombin and collagen activate PLC-γ_2[5–7].

Platelets are reported to express three isoforms of the IP_3 receptor (IP_3R): IP_3R types I, II and III[8,9]. IP_3RI has been located in the intracellular membranes[8,9], in contrast to IP_3RIII which has been found exclusively at the PM[9]. The IP_3RII has been found associated with both internal membranes and the PM[8,9].

IP_3R function is influenced by a number of variables other than the $[IP_3]$. These include the $[Ca^{2+}]$ at both the cytosolic and lumenal faces of the receptor[10], and cAMP and cGMP via phosphorylation of the IP_3R by protein kinases A and G[11]. Increasing $[Ca^{2+}]$ at the lumenal face of the receptor increases sensitivity to IP_3[12], while at the cytosolic face increased, and then decreased, sensitivity are observed as $[Ca^{2+}]$ increases[13]. Modulation of the sensitivity of the IP_3R to IP_3 may underlie the complex spiking Ca^{2+} signals evoked in platelets by some agonists such as ADP[14]. The inhibitory effects of raising cAMP and cGMP levels on Ca^{2+} signalling contribute the actions of the endothelial products prostacyclin and nitric oxide in limiting platelet activity in vivo[4].

Calcium entry

The release of the finite intracellular Ca^{2+} store is insufficient for full platelet activation, which, in addition, requires Ca^{2+} entry from the external medium[2]. The participation of voltage-operated Ca^{2+} channels in Ca^{2+} influx in platelets is controversial. It is generally accepted that agonists evoke only small depolarizations (5–10 mV) of the platelet membrane potential[15] and eliminating depolarization by replacing external Na^+ with impermeant ions does not affect agonist-evoked Ca^{2+} signalling[16]. However, it has been shown that treatment with L-type Ca^{2+} channel blockers, such as nisoldipine, inhibits agonist-evoked Ca^{2+} influx in platelets[17]. Furthermore, the effect of canatoxin, a toxin protein isolated from *Canavalia ensiformis* seeds that induces Ca^{2+} influx without mobilizing Ca^{2+} from the stores, can be prevented by treatment with voltage-operated Ca^{2+} channel blockers[18]. On the other hand, induction of large membrane depolarizations using high K^+ concentrations does not affect resting $[Ca^{2+}]_i$[16]. Hence Ca^{2+} entry in platelets is mainly activated by receptor occupation by means other than membrane potential change. Receptor-

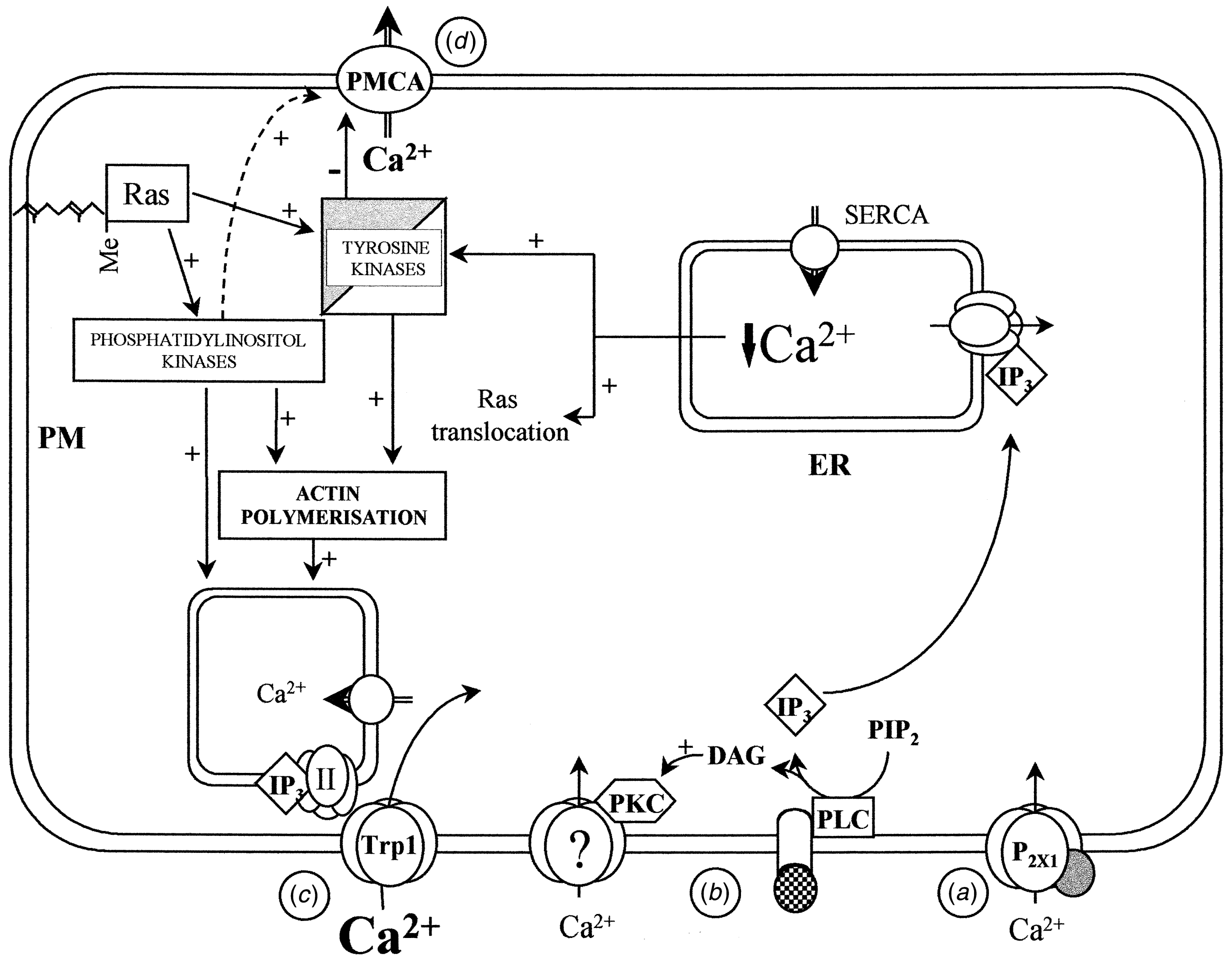

Fig. 17.1. Proposed mechanisms for calcium entry and extrusion in human platelets. (*a*) Adenine nucleotides evoke Ca^{2+} entry via the P_{2X1} purinoceptor. (*b*) Agonist-activated PKC-induced store-independent Ca^{2+} entry via an unidentified channel. (*c*) Store-mediated Ca^{2+} entry. Depletion of the intracellular Ca^{2+} stores induces activation of both unidentified tyrosine kinases and Ras proteins, which, in turn, induce the activation of phosphatidylinositol 3′ and 4′ kinases. Ras, phosphatidylinositol kinases and tyrosine kinases promote actin cytoskeleton rearrangement leading the trafficking of the endoplasmic reticulum (ER) towards the plasma membrane (PM). Reorganized actin filaments support the coupling between elements in the endoplasmic reticulum (IP_3 receptors type II) and Trp1 channels in the plasma membrane through a protein-protein interaction. (*d*) Calcium extrusion via the plasma membrane Ca^{2+} ATPase (PMCA). Activation of Ras proteins stimulates tyrosine phosphorylation of PMCA, which, in turn, inhibits PMCA activity resulting in sustained elevations in $[Ca^{2+}]_i$ required for the activation of Ca^{2+}-dependent events and refilling of the intracellular Ca^{2+} stores. In contrast, activation of phosphatidylinositol kinases increases PMCA activity.

mediated Ca^{2+} entry may take a number of forms[4], several of which appear to be present in platelets. Adenine nucleotides are able to initiate true receptor-operated Ca^{2+} entry, where the Ca^{2+} channel forms part of the P_{2X1} receptor protein[19] (Fig. 17.1(*a*)). Thrombin has been reported to activate a form of second messenger-operated Ca^{2+} entry, which involves diacylglycerol (DAG)[20] (Fig. 17.1(*b*)). However, present evidence indicates that the dominant mechanism employed by platelet agonists is store-mediated Ca^{2+} entry (SMCE), which is activated following depletion of the intracellular Ca^{2+} stores (Fig. 17.1(*c*)).

Ca^{2+} entry via the P_{2X1} purinoceptor

Studies of the early kinetics of agonist-evoked rises in $[Ca^{2+}]_i$, using stopped-flow fluorimetry with platelets loaded with the fluorescent indicator fura-2, revealed that ADP was the only platelet agonist that might act on a true

Cambridge Books Online © Cambridge University Press, 2009

receptor-operated channel[21,22]. In the presence of external Ca^{2+}, ADP was found to evoke a rise in $[Ca^{2+}]_i$ without measurable delay (<20 ms at 37 °C), while release from intracellular stores took some 200 ms at optimal agonist concentrations[22]. Maximally effective concentrations of other agonists, such as thrombin, only evoked Ca^{2+} entry after a latency of around 200 ms[22].

The rapid onset of ADP-evoked Ca^{2+} entry suggested that the ADP receptor might be directly coupled to a Ca^{2+} permeable channel. This was confirmed by the first patch clamp study of stimulated platelets. Cell attached patch clamp recordings revealed little or no activity in resting platelets. ADP was able to evoke single channel currents when added to the pipette filling solution but not when added to the bath[23]. These observations indicated the receptor-operated nature of the Ca^{2+} permeable channel and excluded any role for a diffusible messenger. Ionic substitution experiments indicated that ADP activated a non-selective cation channel, which was demonstrated to be permeable to the Ca^{2+} surrogate Ba^{2+}, and therefore presumably to Ca^{2+} itself[23]. Whole-cell patch clamp recordings of the ADP-evoked current indicated a latency as short as 7 ms[24], in good agreement with estimates of the latency of the ADP-evoked rise in $[Ca^{2+}]_i$[22].

It is now clear that Ca^{2+} entry can be rapidly activated in platelets by several adenine nucleotides including ATP[19] and diadenosine tetraphosphate[25], both of these being agents secreted by activated platelets themselves[26]. Pharmacological studies indicate that the receptor concerned is the ionotropic P_{2X1} receptor, which can be selectively stimulated by $\alpha\beta$-methylene ATP[19]. The presence of mRNA for the P_{2X1} receptor (identical to that first cloned from human bladder[27]) has been demonstrated in platelets using the polymerase chain reaction[28,29] and the expression of the receptor itself has been confirmed by Western blotting[29].

Selective stimulation of the P_{2X1} receptor evokes a relatively small rise in $[Ca^{2+}]_i$, which is also transient because of rapid desensitization[19]. This has led to the physiological significance of the P_{2X1} receptor being questioned. However, it seems the early Ca^{2+} entry via the P_{2X1} receptor has modulatory effects on the subsequent Ca^{2+} signalling evoked via the metabotropic (PLC-activating) P_{2Y1} receptor, which is responsible for ADP-evoked release of Ca^{2+} from intracellular stores[30]. The latency of this IP_3-mediated Ca^{2+} release from intracellular stores is increased when Ca^{2+} entry via the P_{2X1} receptor is prevented[31]. This can be explained by a rise in $[Ca^{2+}]_i$ sensitizing the IP_3 receptor such that release is activated at a lower $[IP_3]$ (see p. 00). Furthermore, the magnitude of ADP-evoked Ca^{2+} signals is reduced if the contribution of the P_{2X1} receptor is eliminated by prior desensitization with $\alpha\beta$-methylene ATP[32]. This effect is particularly pronounced if the levels of the inhibitory cyclic nucleotides, cAMP or cGMP, are elevated, as would be expected in vivo under the influence of the endothelial products, prostacyclin and nitric oxide. This role of the P_{2X1} receptor in enhancing ADP-evoked Ca^{2+} signalling is, like the effect on the kinetics of the response, likely to be due to sensitization of the IP_3 receptor to its ligand and a reduction in the inhibitory effects of IP_3 receptor phosphorylation by protein kinases A and G[11].

Recently, it has been reported that ADP is not an agonist at the platelet P_{2X1} receptor, and that earlier observations can be ascribed to contaminating ATP[33]. This work conflicts, however, with reports that platelets express a splice variant of the P_{2X1} receptor at which ADP is a more potent agonist than other adenine nucleotides[34]. This issue requires further investigation. Even if ADP is not active at the P_{2X1} receptor, this does not diminish its likely physiological significance, since platelets would be expected to encounter several adenine nucleotides together in vivo, notably ADP, ATP and diadenosine tetraphosphate in secretions from activated platelets themselves[26].

Second messenger-evoked Ca^{2+} entry

As in many cells, evidence for second messenger-operated channels (SMOCs) playing a role in platelet Ca^{2+} signalling is rather scarce. The suggestion that inositol phosphates may activate Ca^{2+} permeable channels in the platelet plasma membrane[35] has not gained wide support. However, these reports deserve re-examination in the light of evidence that IP_3 and the IP_3R are involved in the activation of SMCE (p. 265).

Recently, thrombin has been reported to activate Ca^{2+} entry in platelets under conditions which block SMCE[20]. This store-independent (non-capacitative) Ca^{2+} entry was not affected by prior desensitization of the P_{2X1} receptor, indicating that it was not mediated by thrombin-evoked secretion of adenine nucleotides, but it was abolished by inhibitors of protein kinase C (PKC). Since activators of protein kinase C could also evoke Ca^{2+} entry under conditions when SMCE was prevented, it appears that thrombin activates store-independent Ca^{2+} entry via the stimulation of PLC, the formation of DAG and so the activation of PKC. It is possible that other platelet agonists that activate PLC also activate store-independent Ca^{2+} entry in the same manner as thrombin. However, the magnitude of the Ca^{2+} entry activated by thrombin or direct activation of PKC is not large, and since thrombin is the most potent activator of PKC in platelets[36], the contribution of this pathway to the Ca^{2+} signals evoked by other agonists is likely to be small.

Cambridge Books Online © Cambridge University Press, 2009

The presence of a Ca^{2+} entry pathway, independent of Ca^{2+} store depletion, does not necessarily imply the presence of an entirely independent mechanism. Products of human homologues of the *Drosophila* transient receptor potential gene (hTrp) are reported to form Ca^{2+}-permeable channels. One of these, hTrp1, appears to be involved in SMCE in platelets (p. 265). Other Trps have been reported to form channels activated in the presence of DAG lipase inhibitors and by DAG analogues[37]. It may be that hTrp1 represents a point of convergence in store-dependent, and store-independent, PKC-mediated Ca^{2+} entry pathways in platelets.

Store-mediated Ca^{2+} entry

Communication between ER and PM

Although adenine nucleotides have been shown to generate Ca^{2+} entry via ionotropic P_{2X1} purinoceptors, which form non-selective cation channels (pp. 00), and thrombin has been shown to activate Ca^{2+} entry via the formation of diacylglycerol and the activation of protein kinase C (p. 261), the major mechanism generating Ca^{2+} entry in platelets as in other non-excitable cells appears to be that activated following depletion of the intracellular Ca^{2+} stores. The mechanism underlying the activation of this store-mediated Ca^{2+} entry (SMCE) is poorly understood.

A number of hypotheses have been put forward to explain how depletion of the intracellular Ca^{2+} stores might be communicated to the PM to activate Ca^{2+} entry. These can be divided into those that propose a role for a diffusible messenger and those that propose a direct interaction between proteins in the ER and PM (conformational coupling)[3,4,38,39]. Suggestions for diffusible messengers that might be involved in the activation of SMCE have included cyclic GMP[40], a product of cytochrome P450[41], a non-protein Ca^{2+} influx factor (CIF)[42], a tyrosine phosphorylation-dependent step[43–45], small GTP-binding proteins[46–49], the insertion of channels by intracellular trafficking and vesicle fusion[50], and a Ca^{2+}-calmodulin dependent step[51,52]. Conformational coupling models suggest an interaction between the IP_3 receptor (IP_3R) in the membrane of the ER and a Ca^{2+}-permeable channel in the PM[38,53].

Evidence for conformational coupling activating SMCE in platelets

Recently, work in several non-excitable cell types has started to favour conformational coupling as the mechanism responsible for the activation of SMCE[54–56]. These studies have led to the proposal of a secretion-like coupling model, with Ca^{2+} store depletion leading to trafficking of portions of the ER towards the PM to enable the coupling of proteins in the two membranes. Work in platelets indicates an important role for remodelling of the actin cytoskeleton in these events[56], and has provided perhaps the clearest evidence yet for Ca^{2+} store depletion leading to the coupling of an IP_3R in the ER to a Ca^{2+} channel in the PM[57].

Platelet activation involves a morphological transformation of the cells from smooth discs to irregular shapes which have multiple projections. This shape change is mediated by reorganization of the actin cytoskeleton, which is composed of a cytoplasmic actin network and a membrane associated cytoskeleton[58]. If activation of SMCE in platelets occurs following trafficking of the ER towards the PM, to enable coupling between proteins in the two membranes, one might expect this to require reorganization of the actin cytoskeleton. Recent work supports this notion.

SMCE can be activated in platelets by treatment with thapsigargin, an inhibitor of the sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA)[59]. With the Ca^{2+}-ATPase blocked, the resting leak of Ca^{2+} from the ER goes unopposed and results in depletion of the Ca^{2+} store[60]. Depletion of the Ca^{2+} store results in an increase in platelet F-actin content, an effect which is largely independent of any rise in the $[Ca^{2+}]_i$ since it is seen when the Ca^{2+} stores are depleted in platelets heavily loaded with the Ca^{2+} chelator dimethyl BAPTA such that any detectable change in $[Ca^{2+}]_i$ is prevented[61]. Inhibition of actin filament polymerization using the cell-permeant toxins cytochalasin D (which binds to the barbed ends of actin filaments) or latrunculin A (which binds to G actin monomers) has a biphasic effect with time on thapsigargin-evoked SMCE[49,56]. A brief (1 min) preincubation with these agents increased SMCE with only slight inhibition of thapsigargin-evoked actin polymerisation. Longer treatments with the inhibitors (40 min) resulted in complete abolition of thapsigargin-evoked actin polymerization and reduced SMCE by about 50%.

The initial increase in SMCE evoked by cytochalasin D and latrunculin A may be explained by the presence of a dense cortical actin layer in platelets, which is involved in the maintenance of the discoid shape. As the toxins diffuse into the cell, it is likely that they initially affect actin filaments near the plasma membrane. Disruption of cortical actin filaments might be expected to facilitate coupling between the ER and PM, in a manner similar to that whereby actin filament disassembly potentiates secretory exocytosis by enhancing secretory granule docking with the PM[62]. Confocal microscopy of platelets in which F-actin

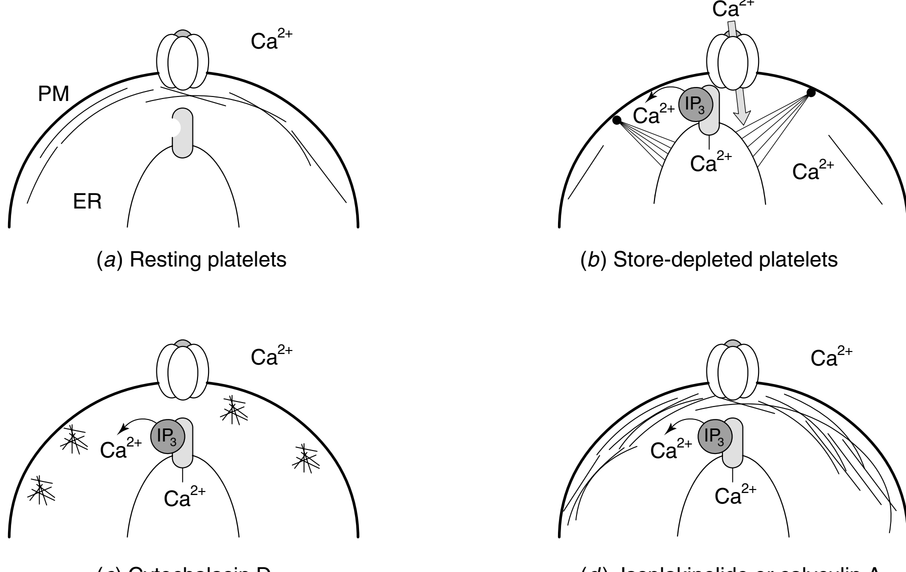

Fig. 17.2. Schematic representation of cytoskeletal organization and its effect on store-mediated Ca^{2+} entry. (*a*) Resting platelets where cortical actin filaments are the main component of the membrane skeleton. (*b*) Store-mediated Ca^{2+} entry in normal platelets mediated via physical coupling between IP_3R type II in the endoplasmic reticulum (ER) and Trp1 channels in the plasma membrane (PM). The coupling is supported by the actin cytoskeleton. (*c*) Cytochalasin D inhibits actin polymerisation and induces reorganisation of the actin filaments into dense foci, preventing the transport of portions of the ER towards the PM and the subsequent coupling. (*d*) Jasplakinolide induces actin polymerization and stabilization of actin filaments into a dense cortical layer displacing cortical ER and blocking store-mediated Ca^{2+} entry. Cytochalasin D and jasplakinolide do not modify IP_3-induced Ca^{2+} release.

has been stained with fluorescein isothiocyanate (FITC)-labelled phalloidin reveals that cytochalasin D results in reorganization of the cortical actin layer into dense foci[63]. This may well enhance ER-PM contact and hence the coupling of proteins therein[63]. These observations in platelets contrast with those reported in NIH 3T3 fibroblasts and in smooth muscle cell lines, where actin filament disruption was without effect on Ca^{2+} entry[54,64]. These differences may reflect the more even distribution of the actin cytoskeleton in fibroblasts and smooth muscle cells. In vascular endothelial cells and astrocytes, cortical actin is involved in maintaining a flat cell morphology[65,66] as it is in platelets[67]. In these cells, too, agents that affect the actin cytoskeleton influence SMCE[68,69].

Other observations also indicate a role for actin filament reorganization in the activation of SMCE in platelets. Agents which stabilize the cortical actin layer inhibit SMCE. Treatment of platelets with the cell-permeant peptide, jasplakinolide, which induces actin polymerization and stabilizes F-actin, increased platelet actin filament content by 100%[56] and resulted in the formation of a dense cortical actin layer[63]. Jasplakinolide treatment resulted in substantial inhibition of SMCE. Similar results were obtained with calyculin A[56], an inhibitor of protein phosphatases 1 and 2, which results in actin polymerization by facilitating the phosphorylation and so activation of the actin-binding proteins, ezrin, radixin and moesin. Fig. 17.2 provides a summary of the cytoskeletal modifications and their effects in the activation of SMCE in human platelets. These results, and those of similar studies in smooth muscle cell lines[54], provide clear evidence against the participation of a diffusible messenger in the activation of SMCE. Such a messenger would be expected to penetrate the actin filament network to activate Ca^{2+} entry, in the same way as IP_3 formed after stimulation by physiological agonists was still able to reach the ER to release stored Ca^{2+} in jasplakinolide-treated cells[54,56].

The actin cytoskeleton appears to play a role in the maintenance as well as in the activation of SMCE in platelets. If platelets are treated with cytochalasin D or latrunculin A after the intracellular Ca^{2+} stores have been depleted using thapsigargin, SMCE is completely inhibited. This inhibition is prevented by jasplakinolide[56]. These results suggest that the actin cytoskeleton may stabilize the coupling between the ER and PM.

Other agents that affect actin filament reorganization also affect SMCE in platelets. Members of the Ras superfamily of small GTP-binding proteins regulate the organ-

Cambridge Books Online © Cambridge University Press, 2009

ization of the actin cytoskeleton in a number of cell types. For example, Rho mediates the assembly of actin filaments and focal adhesion plaques[70,71] and Rac modulates actin filament accumulation by the plasma membrane[72–74]. Farnesylcysteine analogues, which inhibit the prenylation and so membrane association and activation of Ras proteins, reduce both actin polymerization and SMCE in platelets[49]. However, since farnesylcysteine analogues are more effective than agents like cytochalasin at inhibiting SMCE when evoking a similar degree of inhibition of actin polymerization, it appears that small GTP-binding proteins have effects on SMCE which are both dependent on, and independent of, the actin cytoskeleton[49].

Phosphoinositides also play a role in the reorganization of the actin filament network in a number of cell types including platelets[58]. For example, the phosphatidylinositol phosphates PtdIns-3–*P*, PtdIns-3,4–P_2 and PtdIns-3,4,5–P_3 can induce actin filament uncapping and so facilitate actin polymerization[75], and PtdIns-4–*P* and PtdIns-4,5–P_2 regulate cytoskeletal rearrangement by associating with actin binding proteins[76]. Inhibiting phosphoinositide 3-kinase (PI3-kinase) and phosphoinositide 4-kinase (PI4-kinase) using LY294002 or wortmannin, so reducing phosphatidylinositol phosphate levels, results in the inhibition of both actin polymerization and SMCE in platelets[77]. PI3- and PI4-kinases have been shown to be regulated upstream by small GTP-binding proteins such as Rac and Rho[71,78]. Hence Ras proteins and phosphoinositide kinases may be sequentially involved in the activation of SMCE[63].

Reports that inhibitors of tyrosine kinases can inhibit SMCE in platelets[43,44,79] may be explained by the roles of tyrosine kinases in the reorganization of the actin cytoskeleton[61]. The tyrosine kinase inhibitor methyl 2,5-dihydroxycinnamate can completely inhibit agonist or Ca^{2+} store depletion-evoked actin polymerization in platelets and results in a substantial reduction in SMCE[61]. The effect of the tyrosine kinase inhibitor was not additive with the inhibitory effect of the cytoskeletal disrupter cytochalasin D, indicating that the action of the tyrosine kinase inhibitor might be mediated entirely via effects on the reorganization of the actin cytoskeleton.

Thus there is a body of evidence supporting a role for reorganization of the actin cytoskeleton in the activation of SMCE in platelets. These data are compatible with a secretion-like coupling model in which Ca^{2+} store depletion results in the trafficking of a portion of the ER towards the PM. As yet, however, there is no ultrastructural evidence for the trafficking event itself.

The proteins responsible for conformational coupling in platelets

Recent work has confirmed the requirement for IP_3 and functional IP_3Rs in both the activation and maintenance of SMCE in platelets[57]. Blocking IP_3 recycling by treating platelets with Li^+ for 2 h completely eliminated thrombin-evoked release of Ca^{2+} from intracellular stores, indicating that IP_3 production had ceased. The application of thapsigargin together with the Ca^{2+} ionophore, ionomycin, was still able to elevate $[Ca^{2+}]_i$ in the absence of extracellular Ca^{2+}, confirming that the Ca^{2+} stores were intact. Li^+ treatment completely blocked SMCE in thapsigargin-treated (Ca^{2+} store depleted) platelets. If the Ca^{2+} stores were depleted using thapsigargin prior to treatment with Li^+, the subsequent addition of extracellular Ca^{2+} did not result in SMCE, indicating that IP_3 is required for both the activation and maintenance of SMCE. The effects of Li^+ could be reversed by co-incubation with *myo*-inositol, indicating that Li^+ was acting by interfering with IP_3 production.

The role of IP_3Rs in SMCE was assessed using xestospongin C, a cell permeant inhibitor of IP_3R function isolated from a marine sponge. Xestospongin C completely blocked thrombin-evoked release of Ca^{2+} from intracellular stores[57]. The same treatment did not affect the ability of thapsigargin to deplete the Ca^{2+} stores, but abolished SMCE. If xestospongin C was added after the Ca^{2+} stores had been depleted using thapsigargin, subsequent Ca^{2+} entry on the addition of external Ca^{2+} was also abolished. Thus functional IP_3Rs are required for both the activation and maintenance of SMCE in platelets.

The conformational coupling hypothesis for the activation of SMCE has proposed from the outset that the coupling involves IP_3Rs in the ER[53]. The nature of the protein or proteins involved in the plasma membrane has always been less certain. A major problem has been the clear identification of the channels which mediate SMCE. For a number of years now attention has focused on mammalian homologues of the *Drosophila* transient receptor potential (Trp) channel proteins. The presence of messenger RNA for human Trp1 (hTrp1) and its splice variant, hTrp1A, has been demonstrated in human platelets (D. Molin, E. den Dekker, G. Breikers, R. van Oerle, J.W. Akkerman & J.W.M. Heemskerk, personal communication), as has the expression of hTrp1 in these cells[57]. These observations led us to investigate the possible coupling of hTrp1 to IP_3Rs in platelets in a series of co-immunoprecipitation experiments.

Platelets are reported to express three isoforms of the IP_3R: IP_3R types I, II and III[8,9]. Coupling between each of these IP_3Rs and hTrp1 was tested for by looking for co-immunoprecipitation from lysates obtained from control

Cambridge Books Online © Cambridge University Press, 2009

(resting) platelets and platelets in which the intracellular Ca^{2+} stores had been depleted by treatment with thapsigargin[57]. After immunoprecipitation with anti-hTrp1, SDS–PAGE and Western blotting revealed the presence of IP_3RII in immunoprecipitates from store-depleted but not control platelets. IP_3RI and IP_3RII were undetectable in samples from both control and depleted cells. Converse experiments were also conducted in which platelet lysates were immunoprecipitated with anti-IP_3RI, anti-IP_3RII or anti-IP_3RIII antibodies and then Western blots were probed for the presence of hTrp1. Following immunoprecipitation with anti-IP_3RI or anti-IP_3RIII, hTrp1 was undetectable in samples from control and Ca^{2+} store-depleted platelets; however, hTrp1 was detected in immunoprecipitates obtained with anti-hTrp1 from store-depleted but not control cells[57]. These results indicate that only homotetramers of IP_3RII couple with hTrp1 upon Ca^{2+} store depletion in platelets, and that IP_3RI and IP_3RIII are not involved in the conformational coupling mechanism. Although it might be argued that the failure to detect coupling of hTrp1 with two of the IP_3R isoforms is due to low levels of expression and/or lower antibody sensitivity, the results are in good agreement with reports that only IP_3RII is located in both the plasma membrane and the intracellular membranes in platelets[8,9], with IP_3RI being restricted to the intracellular membranes[8,9] and IP_3RIII being located only in the plasma membrane[9].

Co-immunoprecipitation experiments not only provide strong support for conformational coupling underlying the activation of SMCE in platelets, but also indicate that hTrp1 is involved in forming the channels which mediate Ca^{2+} entry. Human Trp1 has been reported to form non-selective cation channels in other cells[80]. Whether hTrp1 alone conducts SMCE in platelets, or whether it forms heteromeric structures with hTrp1A or other proteins, remains to be determined. Coupling between various hTrp and IP_3R isoforms has been reported in other cell types[81–83]. In these studies in various transfected cell lines, the coupling appeared to be constitutive and independent of intracellular Ca^{2+} store depletion. Thus in these transfected cells, there appeared to be relatively stable interactions between IP_3Rs and hTrps, with channel activity presumably depending on changes in the concentration of IP_3 and/or the Ca^{2+} content of the store. These results contrast with the observations in platelets, where there is clear evidence for coupling between endogenously expressed IP_3RII and hTrp1, and for this coupling occurring *de novo* when the intracellular Ca^{2+} stores are depleted[57].

Recent work thus provides strong evidence for conformational coupling underlying the activation of SMCE in human platelets. Ca^{2+} store depletion leads to reorganization of the actin cytoskeleton, an event which appears to involve small GTP-binding proteins and phosphoinositides. These cytoskeletal changes appear necessary to permit, and may mediate, the events required to allow the coupling of elements in the ER and PM to occur. In accordance with the secretion-like coupling model for SMCE, these events are envisaged as a trafficking of portions of the ER towards the PM. Coupling itself appears to involve just one isoform of IP_3R, IP_3RII, and hTrp1. The tentative scheme we propose is illustrated in Fig. 17.1(*c*). Whether other proteins are also involved in the coupling process, and the precise relationship between the initial Ca^{2+} store depletion and the events outlined, remain to be determined.

Regulatory effect of integrin $\alpha_{IIb}\beta_3$ and adrenaline on Ca^{2+} influx

Integrin $\alpha_{IIb}\beta_3$ (glycoprotein IIb/IIIa) is a member of the integrin family of receptors that mediate cellular adhesion of different cell types to several ligands, such as fibrinogen, fibronectin and von Willebrand factor[84,85]. Occupancy of specific sites of the integrin $\alpha_{IIb}\beta_3$ by a ligand affects its structure, function and distribution[85]. It has been shown that peptides containing the Arg–Gly–Asp sequence, known as the RGD sequence, present in the A-α chains of human fibrinogen, bind to potential recognition sites on the integrin $\alpha_{IIb}\beta_3$ for the binding of soluble fibrinogen on activated human platelets, thus inhibiting binding of fibrinogen with the receptor[86,87]. Platelet agonists activate integrin $\alpha_{IIb}\beta_3$ (inside-out signalling) to allow the binding of soluble fibrinogen followed by outside-in signals involving phosphorylation events, cytoskeletal rearrangements and molecular translocation[88]. It has been reported that integrin $\alpha_{IIb}\beta_3$ contains high affinity Ca^{2+} binding sites[89] and might be involved in the regulation of $[Ca^{2+}]_i$ in platelets[84,90–92]; however, the mechanisms responsible have not been clearly addressed in these early reports, nor has whether occupation of the integrin influences Ca^{2+} store depletion or Ca^{2+} influx. Recent studies addressing this issue indicate that the binding of fibrinogen to integrin $\alpha_{IIb}\beta_3$ inhibits the activation of SMCE in platelets by a mechanism which may involve modulation of the reorganization of the actin cytoskeleton: an action that may be important in intrinsic negative feedback to prevent the further activation of platelets subjected to low level stimuli in vivo[93]. In the absence of agonist stimulation, PMA4-induced fibrinogen binding to the integrin $\alpha_{IIb}\beta_3$ does not induce Ca^{2+} influx or mobilization, suggesting that, in the absence of agonist-induced signalling, $\alpha_{IIb}\beta_3$ occupied by fibrinogen generates only a limited outside-in signal[94].

Cambridge Books Online © Cambridge University Press, 2009

It has been suggested that the integrin $\alpha_{IIb}\beta_3$ mediates the synergistic $[Ca^{2+}]_i$ rise that follows addition of both thrombin and adrenaline in human platelets[95]. The role of adrenaline as a $[Ca^{2+}]_i$ elevating agonist in platelets is controversial. Adrenaline has been shown by some authors to elevate $[Ca^{2+}]_i$ in platelets through a mechanism dependent on the presence of extracellular Ca^{2+}[95,96]. Ca^{2+} entry stimulated by adrenaline has been shown to be associated with fibrinogen binding to the integrin $\alpha_{IIb}\beta_3$[97]; however, treatment of platelets with antibodies that prevent fibrinogen binding does not inhibit adrenaline-induced Ca^{2+} influx[95]. Others have reported adenaline alone to be without effect on $[Ca^{2+}]_i$ in platelets[98]. In addition, it has been reported that adrenaline potentiates Ca^{2+} elevation stimulated by platelet agonists, such as ADP[99], thrombin[95,98] or collagen[100], an event that might be mediated by the activation of the $\alpha_{IIb}\beta_3$ integrin and fibrinogen binding[95,96] or by decreases in cAMP[98].

Removal of Ca^{2+} from the cytosol

Ca^{2+} may be removed from the cytosol by uptake into the ER, uptake into mitochondria and by extrusion across the plasma membrane. However, the application of mitochondrial inhibitors to platelets has little or no effect on resting $[Ca^{2+}]_i$[101] or on the return of $[Ca^{2+}]_i$ towards resting levels after an elevation[102]. These observations indicate that the mitochondria do not play a significant role in Ca^{2+} homeostasis in platelets.

The uptake of Ca^{2+} into the ER is required after store discharge in order to allow further signalling if platelets are not irreversibly activated and to allow the periodic discharge of Ca^{2+} which underlies agonist-evoked Ca^{2+} spiking[14,103]. Platelets express several isoforms of the sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA), with SERCA 2b[104], SERCA 3a[105,106], SERCA 3b[107] and SERCA 3c[108] all being reported. SERCA 3b appears to be associated with the IP_3-releasible Ca^{2+} store in platelets[109].

As well as being responsive to changes in $[Ca^{2+}]_i$, SERCA activity may be modulated by other factors which participate in the overall regulation of platelet Ca^{2+} signalling. For example, the inhibitory effects of elevated cAMP may, in part, be mediated by stimulated uptake of Ca^{2+} into intracellular stores[110,111]. The mechanism may involve the small GTP-binding protein, Rap 1b[112]. It is suggested that Rap 1b associates with SERCA 3b when Rap 1b is activated by a rise in $[Ca^{2+}]_i$, so inhibiting SERCA 3b activity and potentiating agonist-evoked Ca^{2+} signals. When Rap 1b is phosphorylated following a rise in cAMP, it dissociates from SERCA 3b, increasing its activity and so Ca^{2+} uptake into the intracellular stores[112]. Nitric oxide may also exert its inhibitory effect on platelet function in part by promoting Ca^{2+} uptake into the intracellular stores. This action has been reported as independent of[113], or only partially dependent on[114], increases in cGMP.

Removal of Ca^{2+} from the cell across the plasma membrane can be effected by Na^+/Ca^{2+} exchange or a plasma membrane Ca^{2+}-ATPase (PMCA). Na^+/Ca^{2+} exchange appears to be present in human platelets and the exchanger appears to be of the Na^+–Ca^{2+}–K^+ exchange type[115,116] found in retinal rods. However, the removal of extracellular Na^+ has little if any effect on resting $[Ca^{2+}]_i$[117] or the restoration of $[Ca^{2+}]_i$ after it has been elevated[102,118]. These observations indicate that Na^+/Ca^{2+} exchange plays no major role in normal platelet Ca^{2+} homeostasis and that the PMCA is the major extrusion mechanism across the plasma membrane[102].

Platelets are reported to express two isoforms of PMCA: PMCA 1b and PMCA 4b[108]. As with SERCAs, PMCAs appear to be subject to regulation by a number of signalling systems other than $[Ca^{2+}]_i$. An increase in platelet cAMP levels promotes Ca^{2+} extrusion across the plasma membrane[111] by increasing PMCA activity through phosphorylation of the enzyme[119]. This action is likely to contribute to the inhibitory effect of elevated cAMP on platelet activity. Conversely, inhibition of adenylyl cyclase by platelet agonists such as ADP would be expected to reduce PMCA activity, an action which may explain the reduction in the ADP-evoked Ca^{2+} signal when this mechanism is selectively blocked[32].

PMCA activity in platelets is inhibited by the phosphorylation of the enzyme on tyrosine residues[119]. The increase in protein tyrosine phosphorylation seen upon platelet activation may thus potentiate agonist-evoked Ca^{2+} signals and the activation process. Loss of this action may contribute to the reduction in agonist-evoked elevations in $[Ca^{2+}]_i$ observed in platelets treated with tyrosine kinase inhibitors[43,44]. Tyrosine phosphorylation and so inhibition of platelet PMCA activity appear to lie downstream of the activation of small GTP-binding proteins of the Ras family. Inhibition of Ras activation using farnesylcysteine analogues (p. 264) inhibited the increase in tyrosine phosphorylation of the PMCA seen when the intracellular Ca^{2+} stores in platelets were depleted and accelerated the decline in $[Ca^{2+}]_i$ towards basal levels[102] (Fig. 17.1(*d*)).

Platelet PMCA activity is also modulated by products of PI3-kinase and PI4-kinase. Inhibition of these kinases results in a reduction in the rate of decline in $[Ca^{2+}]_i$ in platelets which have been treated with thapsigargin and ionomycin[102] (Fig. 17.1(*d*)). These observations are consistent with reports that acidic phospholipids, such as

Cambridge Books Online © Cambridge University Press, 2009

PtdIns-4,5-P_2, activate the PMCA and are responsible for PMCA activity in resting cells[120,121].

Platelet signalling: protein kinase C

Charles S. Abrams and Marcelo G. Kazanietz

University of Pennsylvania, Philadelphia, USA

Protein kinase C, a family of serine-threonine kinases

Protein kinase C (PKC) isozymes are a family of kinases that play an essential role in the signal transduction mechanisms after activation of receptors. Although with a different pattern of isozyme expression, these phospholipid-dependent kinases are present in every single cell type, including platelets. PKC isozymes phosphorylate multiple cellular proteins in serine and threonine residues leading to a plethora of effects on cell proliferation and death, differentiation, morphology and adhesion[1,2]. In platelets, PKC isozymes control a variety of functions, including aggregation, release of granular contents, mobilization of intracellular calcium and regulation of cell shape. In addition, PKC isozymes play an important role in megakaryocyte differentiation.

PKC has been identified as the cellular receptor for the lipid second messenger diacylglycerol (DAG), and it is therefore a key enzyme in the signalling mechanisms after activation of receptors coupled to phospholipase C (PLC), a family of enzymes that leads to a transient elevation in membrane DAG levels. In addition, PKC isozymes are high affinity receptors for the phorbol ester tumour promoters, natural compounds which are the most common pharmacological activators of PKC both in vitro and in cellular systems. The higher potency of phorbol esters and their greater stability compared to the second messenger DAG make these compounds the preferred activators of PKC in experimental models. Because of the limitations of platelets as a system for genetic studies, pharmacological tools have been widely used in these cells. Both activation with phorbol esters (preferably with PMA or phorbol 12-myristate 13-acetate) and inhibition with specific PKC inhibitors have been the preferred approaches used to understand the involvement of PKC isozymes in platelet biology.

Table 18.1. PKC isoforms

Category	Isoform	Ca^{2+}-dependent?	DAG (or PMA)-responsive?	Present in platelets?
Classical	α	Yes	Yes	Yes
	β (βI & βII)	Yes	Yes	Yes
	γ	Yes	Yes	No
Novel	δ	No	Yes	Yes
	ε	No	Yes	Yes
	η	No	Yes	Yes
	θ	No	Yes	Yes
Atypical	λ	No	No	Yes, but low amounts
	ζ	No	No	Yes, but low amounts
Other	μ (aka PKD)	No	Yes	?
	ν	?	?	?

The PKC family comprises at least ten related kinases with differential expression in each cell type. PKC isozymes have been classified into three subclasses according to their structure and regulation: ‘classical’ (cPKCs), ‘novel’ (nPKCs) and ‘atypical’ (aPKCs). cPKCs comprise PKCα, βI, βII, and γ (Table 18.1) These PKC isozymes are calcium dependent. They can be activated not only by calcium but also by phorbol esters and DAG. The nPKCs (PKCδ, ε, η, and θ) are calcium insensitive but can be activated by phorbol esters and DAG. The third group (aPKCs) comprises PKCζ and λ. A unique characteristic of the aPKCs is that they do not bind phorbol esters or DAG even with low affinity, and therefore cannot be activated upon generation of DAG in the plasma membrane. A related enzyme, PKCμ or PKD, displays multiple unique features that makes it a distant relative of the PKC isozymes. Although some consider

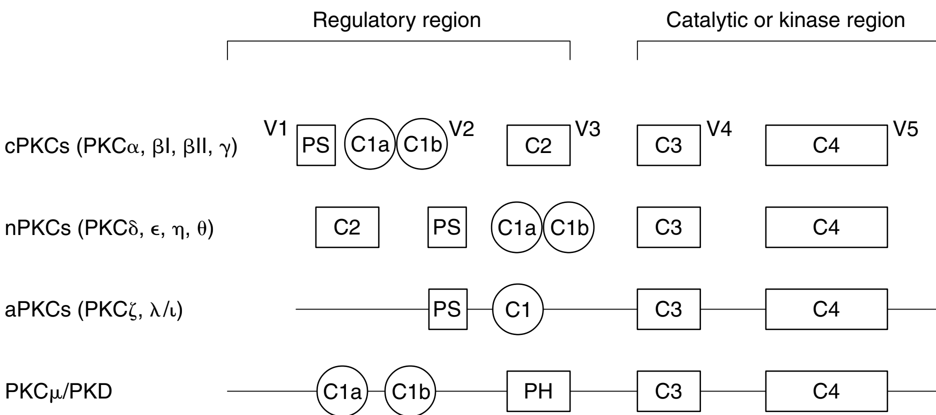

Fig. 18.1. Model showing the structure of PKC isoforms. Shown are the classical, novel, and atypical isoforms. Also shown is PKCμ/PKD.

PKCμ/PKD a member of the PKC family, this serine–threonine kinase has a unique pattern of substrate specificity that resembles that of calcium–calmodulin-dependent kinases. PKCμ/PKD is activated in cells by PKC phosphorylation and can therefore function downstream of PKCs. PKCν, a kinase related to PKCμ/PKD, has been recently cloned. No information exists on how this kinase is regulated in cells. Each PKC isozyme is the product of a separate gene, with the exception of PKCβI and βII, which are alternative spliced variants of the PKCβ gene[1–3].

All PKC isozymes are structurally related and have two well-defined domains: the N-terminal regulatory region and the C-terminal catalytic region (Fig. 18.1). The regulatory region possesses the motifs involved in the binding of the phospholipid cofactors, phorbol esters/DAG and calcium, and participates in protein–protein interactions that regulate PKC activity and localization. The C-terminal region is the kinase domain and includes motifs involved in ATP and substrate binding. A hinge region connects the regulatory and the catalytic domains. This flexible region is highly sensitive to proteolytic cleavage by cellular proteases. PKC isozymes possess domains that are highly conserved (C1 to C4) and variable domains (V1 to V5). The C1 domain in cPKCs and nPKCs is responsible for phorbol ester/DAG binding in membranes. Upon DAG binding, a conformational change relieves the autoinhibition conferred by the pseudosubstrate region located at the N-terminal region of PKCs. This autoinhibitory domain binds to the substrate binding site in the catalytic domain and keeps the enzyme in an inactive state in the absence of cofactors and activators. The C2 domain in cPKCs is involved in calcium and phospholipid binding, but only participates in phospholipid interactions in the calcium insensitive nPKCs. The C3 domain (or ATP binding site) and the C4 domain (or substrate binding site) present in the catalytic or kinase domain are essential for phosphotransferase activity[1,2].

Agonist-induced activation of PKC isozymes in platelets

One of the earliest responses of platelets to most agonists is the activation of PLC. Platelets contain β- and γ-forms of this enzyme. The β-forms are activated by G proteins, while the γ-forms (predominantly PLCγ_2) are regulated by tyrosine phosphorylation[4,5]. PLCβ is thought to be primarily responsible for the rapid burst of phosphoinositide hydrolysis that occurs during platelet activation by agonists such as thrombin and TxA_2 analogues. In general, PLCβ_1 and PLCβ_3 respond best to Gα, particularly members of the $G_q\alpha$ family, while PLCβ_2 responds best to Gβ_γ. Based upon studies with pertussis toxin and genetically modified mice, PAR-1 in platelets is thought to be coupled to PLCβ by Gα derived from G_q or G_{11}, as well as G$\beta\gamma$ derived from G_i[6–9]. TxA_2 receptors are coupled to PLC$\beta_{1/3}$ by Gα derived from G_q or G_{11}. Once activated, phospholipase C hydrolyses PI-4,5–P_2 to DAG plus IP_3[10–12]. DAG activates PKC and contributes to protein phosphorylation as will be discussed below[13,14]. IP_3 binds to receptors in the dense tubular system and releases sequestered Ca^{2+} [15–18]. Alternatively, atypical PKC isoforms have been shown to be activated by a PI3K-dependent pathway[19,20].

Platelets express multiple cPKCs, nPKCs and aPKCs. Although some discrepancies between different studies on PKC isozyme expression exist, it is clear that platelets express PKCα, β, δ, ε, η, and θ. PKCγ is not expressed in platelets. Although the presence of atypical PKCs has been

Cambridge Books Online © Cambridge University Press, 2009

detected in platelets, other studies reported very low levels for PKCζ and λ transcripts[21–24]. No information is available on the presence of PKCμ and PKCν in platelets.

cPKCs and nPKCs respond to phorbol esters by translocating from cytosol to membranes. Translocation of PKC isozymes is the hallmark for PKC activation and necessary for substrate phosphorylation. In platelets, PKC isozymes regulate multiple agonist-stimulated responses after activation of seven transmembrane receptors. Indeed, translocation of PKC isozymes in platelets occurs upon stimulation of numerous membrane receptors. For example, thrombin induces translocation of PKCα and PKCβ in human platelets. Translocation of PKC isozymes correlates with the increase in DAG levels in the plasma membrane observed upon stimulation with thrombin[25,26]. A stimulatory antibody (Mab.F11), which binds to the Fc gamma RII receptor and induces granular secretion and platelet aggregation, very potently translocates PKCα, β, δ, η, and θ. Interestingly, translocation of the DAG-unresponsive PKCζ also occurs, suggesting that other mechanisms in addition to DAG generation contribute to the subcellular redistribution of this aPKC[23].

As also reported in other cell types, PKC isozymes can get tyrosine phosphorylated in platelets. Studies in several cell types, including fibroblasts and keratinocytes, show that PKCδ is the main PKC isozyme that can be phosphorylated in tyrosine. Remarkably, platelet activation by thrombin induces tyrosine phosphorylation of PKCδ within 30 seconds. This leads to a 2–3 fold increase in kinase activity of this nPKC. The tyrosine phosphorylated form of PKCδ associates with a platelet particulate fraction (100,000 × g insoluble). This effect is not seen when platelets are activated by fibrinogen. Furthermore, $\alpha_{IIb}\beta_3$ receptor blockade did not affect the induction of PKCδ phosphorylation by thrombin, suggesting that the effect is independent of the $\alpha_{IIb}\beta_3$ pathway. The tyrosine kinase responsible for such phosphorylation upon thrombin receptor activation is not known. These results suggest that, in addition to the conventional PLC/DAG pathway, other regulatory mechanisms also take place in the control of PKC activity in platelets[27].

The role of PKC in platelet aggregation and secretion

The majority of the evidence that suggests a role for PKC in platelet activation is derived from studies that utilize pharmacologic activators, or inhibitors of this kinase. Although studies of this nature are subject to circumspection, certain themes do emerge from a large body of literature which use a diverse array of reagents. Collectively, these studies imply that PKC does contribute to both platelet aggregation and secretion. Genetic manipulation has created murine lines with null mutations in three different PKC isoforms (PKCβ, PKCγ and PKCε). As of yet there is no information whether these mutations induce a platelet phenotype[28–30].

Although seemingly contradictory, PKC may be involved in a variety of inhibitory responses in platelets. This hypothesis emerges from studies utilizing platelets which were preincubated with phorbol esters prior to the addition of an agonist. Examples of enzymes directly, or indirectly, inhibited by PKC include: PLC, adenylyl cyclase, phospholipase A2, phosphatidylinositol 3-kinase, and myosin light chain kinase[31–35]. This can lead to alterations in calcium release, cAMP production, and release of arachidonic acid. Several of the proteins that are directly phosphorylated by PKC during platelet activation have been identified, including the α subunits of the G proteins, G_z[36–38], G_{12} and G_{13}[39], myosin light chain (P20), pleckstrin (p47), actin binding protein[40], myosin light chain kinase and GP180, a transmembrane glycoprotein whose function is unknown[41]. Phosphorylation of Gzα appears to uncouple it from G$\beta\gamma$[42]. Phosphorylation of myosin light chain occurs at a site distinct from myosin light chain kinase[43] and is believed to affect the interaction of myosin with actin. Fig. 18.2 shows a model of these events.

Several reports have also indicated that PKC isozymes directly regulate receptor function in platelets. It is well known that, upon activation of seven-transmembrane receptors, PKC can phosphorylate these receptors leading to desensitization. An important example in platelets is the thromboxane receptor. Although a single thromboxane receptor gene has been identified, two splice variants have been cloned (TPα and TPβ). In human platelets, despite the presence of mRNA for both TP isoforms, isoform-specific antibodies against TP receptors detected only TPα. Upon activation of the TPα receptor with a TP agonist or arachidonic acid as a source of endogenous TxA_2, a rapid and transient phosphorylation of the receptor occurs. Pretreatment of platelets with the PKC inhibitor GF 109203X drastically reduced the phosphorylation of the receptor upon activation. Similarly, GF 109203X inhibits phorbol ester-induced phosphorylation of the receptor. PKC seems to phosphorylate the TPα receptor not only after activation with a TP agonist (homologous desensitization) but also after thrombin treatment (heterologous desensitization). The relative contribution of individual PKC isozymes to receptor desensitization mechanisms have yet to be determined[44,45].

Cambridge Books Online © Cambridge University Press, 2009

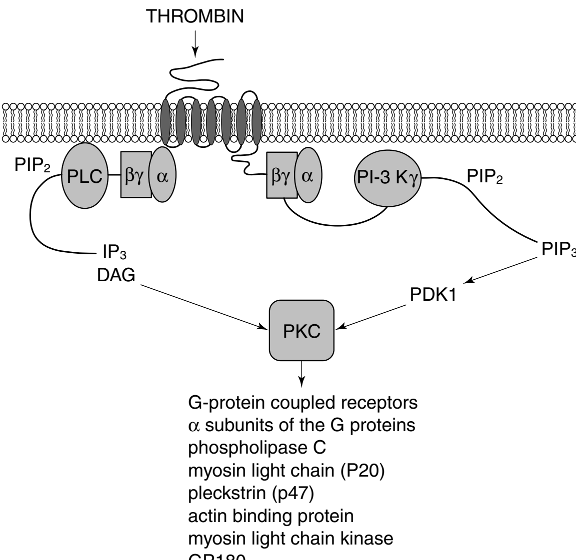

Fig. 18.2. Model showing the activation of different PKC isoforms. Stimulation of a pertussis toxin-insensitive G protein-coupled receptor, such as the thrombin receptor PAR1, stimulates $G\alpha$ subunit of heterotrimeric G-proteins. This can lead to the stimulation of PLCβ, and subsequently cPKCs and nPKCs. In contrast, stimulation of a pertussis toxin-sensitive G protein-coupled receptor releases free $G\beta\gamma$ heterodimers. This can also lead to the stimulation of PI3Kγ, and subsequently aPKC. This then enables PKC to phosphorylate platelet and megakaryocyte PKC substrates.

Platelet aggregation

The majority of agonists that lead to platelet aggregation also produce an increase in the activity of cPKCs and aPKCs. This association, along with the observation that phorbol esters induce platelet aggregation, suggests a potential role for PKC in platelet aggregation. Consistent with this hypothesis, inhibition of PKC by multiple different pharmacologic inhibitors prevents platelet aggregation in response to most platelet agonists. In addition, time-course experiments demonstrate that activation of PKC closely parallels the ability of αIIbβ3 to bind fibrinogen and support aggregation[46]. It is also notable that A.K. Rao and colleagues have described a patient with a bleeding disorder, who also has a defect in phosphorylation of platelet pleckstrin by PKC[47]. In addition, there is evidence that certain agents can potentiate subthreshold dosages of agonists through a PKC-dependent pathway ('PKC-priming')[48,49].

Which PKC isoform is required for platelet aggregation, and which signalling pathway is involved, is a subject of debate. Shattil and Brass have shown that a 'pseudo-substrate' like peptide which selectively inhibits cPKCs blocked activation of αIIbβ3[50]. This implies that cPKC isoforms contribute to 'inside-out' integrin signalling pathways in platelets. PKC may also contribute to 'outside-in' signalling pathways leading to actin assembly that are initiated after fibrinogen binds to αIIbβ3[51]. This will be discussed in the section on cytoskeletal changes.

Platelet secretion

Studies with PMA, a chemical stimulator of PKC, also suggest a role for this kinase in platelet secretion of both dense and alpha granules[52,53]. This appears to be independent of irreversible platelet aggregation. Further studies using stimulators of PKC such as PMA, mezerein, oleoylacetylglycerol, and (-)-indolactam V demonstrate that PKC can cause a calcium-dependent release of arachidonate[54]. In addition, multiple PKC isoform selective and non-selective inhibitors have been shown to block platelet secretion induced by several platelet agonists including thrombin[55,56].

The molecular mechanism by which PKC contributes to platelet secretion is just beginning to be elucidated. Agonist-mediated platelet secretion involves secretory pathways with homology to those found in other cells, including exocytosis in neurons[57]. These pathways involve the formation of SNARE complexes – a process facilitated by a platelet Sec1 protein called PSP. The ability of PSP to enhance SNARE complex formation is, in part, regulated by its phosphorylation by PKC. Although Rab proteins have been shown to play a role in vesicle trafficking in other cells, and several Rabs (isoforms 3b, 6, and 8) are phosphorylated by PKC, a direct connection between Rabs and platelet secretion has yet to be uncovered. There is some evidence that phosphorylation of MARCKS, an actin-associated protein, may also contribute to PKC-induced platelet secretion[58].

PKC, actin assembly, and pleckstrin

In platelets, PMA induces irreversible shape change and centripetal contractions[52,53,59]. Hartwig and coworkers have demonstrated that either thrombin-, or PMA-, induced stimulation of platelets leads to the assembly of F-actin, through a pathway that is independent of secretion[51]. This effect of PMA results in filopod extensions from the platelet surface. It appears to depend on PI3K since it coincides with the production of phospholipid products of this enzyme, and the actin effects are blocked by a chemical inhibitor of PI3K.

Cambridge Books Online © Cambridge University Press, 2009

The most visible substrate for PKC in platelets is p47 or pleckstrin, the 'Platelet and leukocyte C-kinase substrate'[60,61]. Pleckstrin is a 40–47 kDa hematopoietic protein which contains the two prototypic PH domains at its amino- and carboxyl-termini. Its phosphorylation has long been used as a marker for platelet activation. Though its function in vivo remains unclear, expressed pleckstrin can affect PIP_2-based signalling mediated by PLC, PI3K, and inositol phosphatases[35,62,63]. This may be mediated by the ability of pleckstrin to bind and sequester the substrate PIP_2. Ser^{113}, Thr^{114}, and Ser^{117}, the three residues phosphorylated by PKC, lie adjacent to, but not within, the amino-terminal PH domain, and phosphorylation at these sites has been shown to regulate the function of this PH domain[64]. A third functional motif has been described within pleckstrin[65]. This motif is termed the DEP domain, because of the first three proteins (Dishevelled, Egl-10 and pleckstrin) known to possess this sequence. The role of the DEP domain in pleckstrin, or other signalling proteins, is largely unknown.

Pleckstrin induces the formation of membrane ruffles

Based on the concept that PH domains recruit molecules to membranes, experiments were done to determine whether pleckstrin could bind to membranes and if so, whether this membrane attachment was mediated by the PH domains[66]. By cell fractionation it was determined that pleckstrin was associated with platelet membranes, and indirect immunofluorescence of transfected cells was used to answer the second part of this question. Overexpression of wild-type pleckstrin was able to induce the formation of membrane ruffles. Pleckstrin was associated with the plasma membranes and concentrated in the ruffles. By contrast, deletion of pleckstrin's amino terminal, but not its carboxyl terminal, PH domain created a pleckstrin variant unable to bind to membranes and alter its surface architecture. This argued that pleckstrin's effects on membranes was mediated by its amino- but not its carboxyl-terminal PH domain.

In order to evaluate the effect of phosphorylation on the ability of pleckstrin to induce membrane ruffle formation, two pleckstrin variants in which the sites of phosphorylation were mutated to either glycines or to glutamates were studied. The first variant is unable to be phosphorylated (non-phosphorylatable), while the second variant's charged residues mimic the state of phosphorylation (pseudo-phosphorylated)[64]. The pseudo-phosphorylated variant was fully able to associate with membranes and to induce ruffle formation. By contrast, the non-phosphorylatable variant was diffusely distributed and failed to lead to membrane ruffle formation, indicating that pleckstrin must be phosphorylated in order to attach to membranes and induce ruffle formation. Together, this implies that pleckstrin's ability to induce shape change is dependent on both its amino-terminal PH domains and is regulated by its phosphorylation sites.

Pleckstrin and actin organization

Based on the observations that pleckstrin could induce the formation of membrane ruffles, pleckstrin was analysed for its ability to cause reorganization of the actin cytoskeleton[67]. Experiments using fluorescently tagged phalloidin (a fungal toxin which binds and stains F-actin) demonstrated that pleckstrin-expressing Cos-1 cells had undergone cytoskeletal reorganization. Non-transfected cells had thick, central actin cables and an absence of actin around the periphery. Pleckstrin-expressing cells, by contrast, had no central actin cables and prominent cortical actin. Actin was found in small bundles underlying each of the membrane projections. Additional studies demonstrated that this effect on actin assembly was regulated by PKC phosphorylation of pleckstrin[67].

Small GTPases of the Rho family have been shown to play a critical role in cytoskeletal regulation[68]. The cortical actin polymerization initiated by G protein-coupled or growth factor receptors has been shown to require the action of Rac, a Rho family GTP-binding protein[69,70]. In order to determine if the actin reorganization induced by pleckstrin was similarly dependent on Rac, we coexpressed a myc-tagged, dominant negative variant of Rac (myc-V12N17 Rac), along with pleckstrin in Cos-1 cells and examined the pattern of phalloidin staining. We determined that coexpression of myc-V12N17 Rac was able to block many of the cytoskeletal effects of pleckstrin. Cells expressing the dominant negative Rac variant lacked cortical actin staining and dorsal projections. This argues that some of pleckstrin's effects on the actin cytoskeleton required the activity of Rac. By contrast, coexpression of a myc-tagged, dominant negative Cdc42 variant (myc-N17 Cdc42) had no effect on the pleckstrin-induced actin rearrangements. Cells expressing both pleckstrin and myc N17 Cdc42 remained with their cortical actin and small actin bundles intact and had no central actin cables. The data thus indicate that pleckstrin's effects on the actin cytoskeleton are at least partially dependent on the activation of Rac, but are independent of Cdc42.

Taken together, these studies have demonstrated a role for pleckstrin and its amino-terminal PH domain in reorganizing the actin cytoskeleton. Phosphorylation by PKC

Cambridge Books Online © Cambridge University Press, 2009

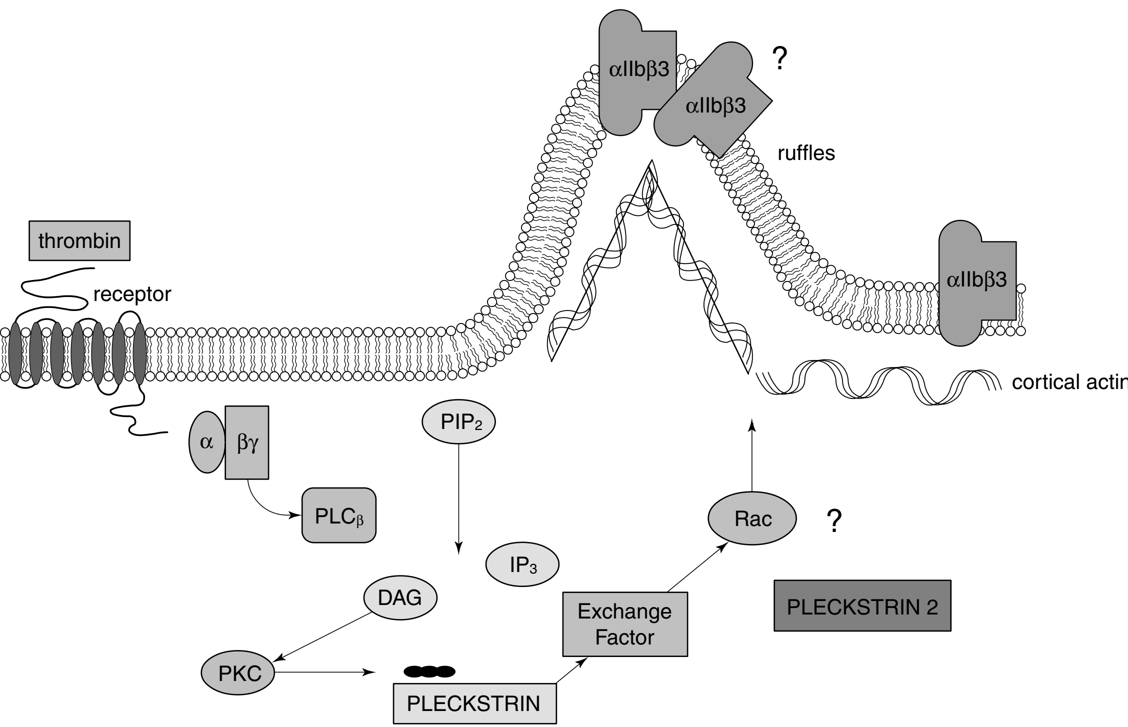

Fig. 18.3. Model showing the potential effect of pleckstrin on actin reorganization. Activation of PAR1, the predominant platelet thrombin receptor, leads to the stimulation of PLC*β*, and subsequently PKC, which phosphorylates pleckstrin. Presumably by a pathway dependent on stimulation of an exchange factor, this leads to activation of the small GTP-binding protein Rac. Stimulation of Rac then leads to some of the pleckstrin-induced cytoskeletal changes, including cortical actin and ruffle formation, through an integrin-dependent pathway.

at Ser^{113}, Thr^{114}, and Ser^{117} appears to be a regulatory mechanism for this function, perhaps by controlling the availability of sites for PIP_2-binding to the amino-terminal PH domain. Pleckstrin's effects on the cytoskeleton depend at least partially on Rac, but appear to be independent of Cdc42.

Pleckstrin and integrin-dependent cell spreading

Given the role of integrins in cytoskeletal organization and cell spreading, we investigated whether signalling from pleckstrin cooperated with signalling pathways involving the platelet integrin, αIIbβ3. Pleckstrin induced cell spreading in both transformed (Cos-1 and CHO) and non-transformed (REF52) cell lines, and this spreading was regulated by pleckstrin phosphorylation[71]. In REF52 cells, pleckstrin-induced spreading was matrix dependent, as evidenced by spreading of these cells on fibrinogen but not on fibronectin. Coexpression with αIIbβ3 did not enhance pleckstrin-mediated cell spreading in either REF52 or CHO cells. However, co-expression of the inactive variant αIIbβ3 Ser753Pro, or β3 Ser753Pro alone, completely blocked pleckstrin-induced spreading. This implies that αIIbβ3 Ser753Pro functions as a competitive inhibitor by blocking the effects of an endogenous receptor which is utilized in the signalling pathway involved in pleckstrin-induced cell spreading. Thus, expressed phosphorylated pleckstrin promotes cell spreading that is both matrix and integrin dependent. A model of the role of pleckstrin in these events is shown in Fig. 18.3.

Protein kinase C and megakaryocyte differentiation

Work from several laboratories has demonstrated a role for PKC isozymes in hematopoietic lineage commitment decisions. It is well established that the phorbol ester PMA promotes megakaryocyte differentiation. Experiments using HEL cells show that PMA causes a complete inhibition of proliferation and a marked increase in the surface expression of GP IIIa, a marker of megakaryocytic differentiation. These effects can be blocked by the selective PKC inhibitor GF 109203X[72]. Thrombopoietin (TPO), a major regulator of

Cambridge Books Online © Cambridge University Press, 2009

megakaryocytic lineage development transduces signals through activation of PKC. TPO induces the translocation of PKC from cytosol to membrane fractions. Western blot analysis revealed that PKCα and PKCβ translocate to the membranes upon TPO treatment. Although PKCα and PKCβ are involved in the mitogenic effect of TPO, PKC activation is not required for TPO-induced expression of megakaryocytic surface markers[73]. However guinea pig megakaryocyte spreading in culture is stimulated by PKC, and is blocked by the PKC inhibitors calphostin C and K5720[74].

Stimulation of PKC leads to the activation of the ERK (MAPK) signalling pathway, a cascade that plays an important role in proliferation and differentiation in many cell types. In K562 cells, sustained activation of the ERK (MAPK) cascade is required for megakaryocytic differentiation. PD09059, an inhibitor of MEK (the kinase that activates ERKs) completely abrogates megakaryocytic differentiation induced by PMA[75]. With the use of specific inhibitors for individual PKC isozymes, it was recently demonstrated that nPKCs but not cPKCs or aPKCs may be involved in the process of megakaryocytic differentiation. Using several different approaches, Racke et al.[76] showed that nPKCε may be a key transducer of signalling in differentiation. Moreover, constitutively active mutants of PKCε but not of other PKC isozymes strongly influence the function of GATA-1, a transcription factor known to be important in megakaryopoiesis and in the activation of the αIIb promoter[76].

Platelet signalling: tyrosine kinases

Sylviane Levy-Toledano

INSERM U.348, IFR Circulation Lariboisière, Hôpital Lariboisière, Paris, France

Introduction

Protein phosphorylation plays a cardinal role in regulating many cellular processes in eukaryotes. In particular, protein phosphorylation is a major currency of signal transduction pathways. Processes that are reversibly controlled by protein phosphorylation require not only a protein kinase but also a protein phosphatase. Target proteins are phosphorylated at specific sites by one or more protein kinases and these phosphates are removed by specific protein phosphatases. In principle the extent of phosphorylation at a particular site can be regulated by changing the activity of the cognate protein kinase or protein phosphatase or both.

Protein tyrosine kinases (PTKs) catalyse the transfer of γ-phosphate of ATP to tyrosine residues of protein substrates and are critical components of signalling pathways that control a variety of biological responses including cell proliferation, migration, differentiation and survival. PTKs can be subvided in two large families: receptor tyrosine kinases (RTKs) and non-receptor tyrosine kinases (NRTKs). Although platelets contain a small number of receptor tyrosine kinases on their surface, including the PDGF receptor[1,2], the majority of tyrosine kinases identified in platelets thus far are non-receptor forms, including members of the Src-kinase family, Syk kinase family, focal adhesion kinase (FAK) family, the Janus kinase (JAK) family and the Tec kinase family. Because of the key roles PTKs play in cellular signalling processes, their catalytic activity is tightly controlled in normal cells by protein tyrosine phosphatases, by other protein tyrosine or serine/threonine kinases and by autoregulatory mechanisms. The recent crystallographic structures of several members of both the RTK and NRTK families, together with extensive biochemical studies, afford an understanding at the molecular level of the autoregulation mechanisms to which PTKs are subject.

Src-family tyrosine kinases: members, structural features, and activation

The prototype member of the Src family protein tyrosine kinases was first identified as the transforming protein v-Src of the oncogenic retrovirus, Rous sarcoma virus[3]. c-Src is the cellular proto-oncogene of the v-Src oncogene. c-Src is expressed in a wide variety of tissues with a highest protein level detected in platelets, constituting 0.2–0.4 % of total platelet protein. Src kinase family includes at least eight members: Fyn, Lyn, Yes, Hck, Lck, Fgr, Blk and Yrk. Six of these have been identified in resting platelets: Fyn, Hck, Lyn, Yes and more recently Fgr and Lck[4,5]. Src, Fyn, Lck and Lyn are significantly tyrosine phosphorylated and all except Src are concentrated in detergent-insoluble fractions, suggesting a different subcellular localization of the Src-related kinases vs. Src.

Src protein kinases are 52–62 kDa proteins composed of distinct functional regions (Fig. 19.1). The N-terminal region, which includes a myristic acid moiety, is involved in targeting Src PTKs to cellular membranes. The highly conserved regulatory apparatus of the Src family members consists of two peptide binding modules, the Src-homology domains SH2 and SH3. The SH2 domain is approximately 100 amino acids long and binds to phosphorylated tyrosine residues in a sequence specific context. The specificity of individual SH2 domains lies in the 3–5 residues following the phosphotyrosine. Amino acids preceding phosphotyrosine may also be important for regulating binding affinity. The SH3 domain contains approximately 75 amino acids and binds to proline containing sequences. However, amino acids surrounding the prolines confer additional affinity and specificity for individual SH3 domains[6]. These modules, therefore mediate the formation of protein–protein interactions during signalling. Another critical structural feature of all Src-like kinases is the conserved C-terminal tyrosine residue which plays a

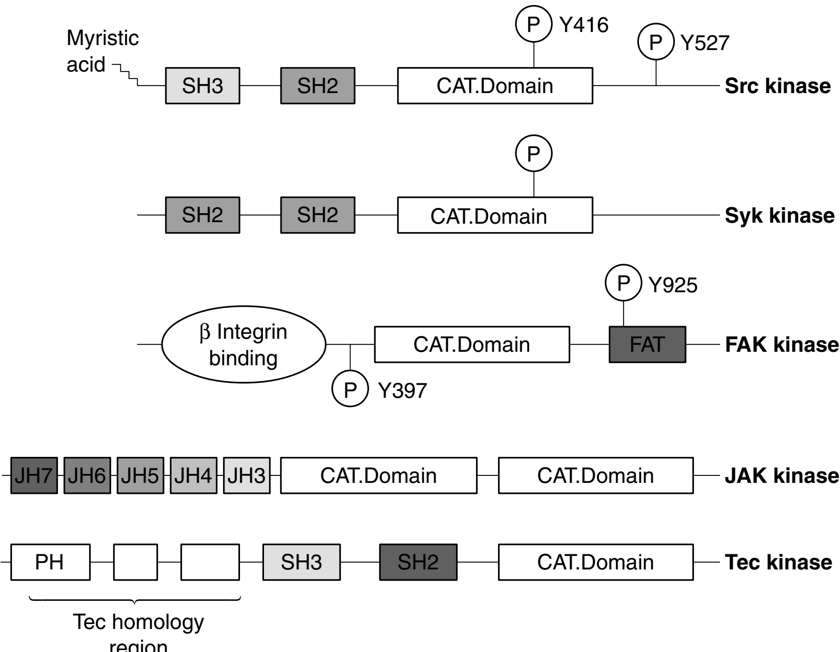

Fig. 19.1. Structural features of platelet non receptor tyrosine kinases. Linear diagrams of the different kinases illustrating their structural motifs as described in the text. CAT: catalytic domain, FAT: focal adhesion targeting domain, PH: pleckstrin domain.

critical role in regulating their catalytic activity. Phosphorylation of this C-terminal tyrosine (Tyr 527) is mediated by a distinct tyrosine kinase, Csk (c-Src kinase). The recent crystal structure of nearly full length Src has elucidated the role of the SH2 and SH3 domains in the autoregulation of Src family kinases[7]. Interactions between the SH2 domain and a C-terminal phosphotyrosine residue result in repression of catalytic activity, with additional inhibitory interactions provided by the SH3 domain. Dephosphorylation of the Tyr 527, or the binding of antibodies to the C-terminus, results in the catalytic activation of the Src-related kinases. The mechanisms by which the inhibitory phosphotyrosine residue is dephosphorylated and Src activation achieved have been investigated and suggest that the tyrosine phosphatase SHP1 would interact with Src and may serve by dephosphorylation of the COOH-terminal regulatory tyrosine[8,9]. The SH2-tail interaction is important for repression of Src activity because regulation is lost upon dephosphorylation of the phosphotyrosine. This dephosphorylation event is thought to be critical for Src activation by dissociating the C-terminal tail from the N-terminal SH2 domain, thereby allowing the autophosphorylation at another tyrosine residue (Tyr 416) located within the catalytic domain and required for catalytic activity (Fig. 19.2). The catalytic domain alone is functional as a tyrosine kinase but the SH2 and SH3 domains are required for full biological activity. Alternatively, Src can be activated by proteins containing proline-rich sequences that effectively compete with the SH2-kinase linker for binding to the SH3 domain, which again results in disruption of the inhibitory intra molecular constraints. Once released from the autoinhibited state, Src undergoes *trans*-autophosphorylation on a conserved tyrosine residue (Tyr 416) which stabilizes the active conformation[10] (Fig. 19.2).

Protein phosphorylation is regulated in large part by the subcellular localization of these kinases and their respective substrates. Stenberg et al.[11] reported that, unlike Src which is associated to plasma membranes, the other kinases colocalize with the coated vesicle protein, clathrin, confirming their association with this class of endocytotic vesicle.

Thrombin treatment of platelets causes an early integrin-independent activation of Src and Y527 dephosphorylation. However, the mechanisms by which Src is activated remain unclear. Very recently it has been described that Src tyrosine kinase is a novel direct effector of G proteins[12]. The authors demonstrate that Gαs and Gαi but neither Gαq, Gα12 nor G$\beta\gamma$, directly stimulate the kinase activity of down regulated c-Src by binding to the catalytic domain, changing the conformation of Src and leading to increased accessibility of the active site to sub-

strates. If Src activation is uncoupled from integrin activation upon thrombin stimulation, it becomes associated with integrin complexes after platelet aggregation mediated by αIIb3. Therefore, there is a redistribution of activated c-Src to integrin dependent cytoskeletal complexes that allows accessibility of its SH2 and SH3 domains to other cellular proteins. One such protein is FAK, a protein tyrosine kinase that is phosphorylated and activated following engagement of αIIbβ3. FAK coprecipitates with Src and this coprecipitation is dependent on an intact FAK autophosphorylation site Y397 that binds to Src SH2 domains with a high affinity. It has been postulated that Src association with FAK may facilitate Src-mediated phosphorylation of other residues on FAK, some of which serve as binding sites for additional SH2 containing proteins. For example, phosphorylation of Y397 is required for phosphorylation of FAK on Y925, a Grb2-binding site and on Y576 and Y577 required for maximal kinase activity of FAK and for FAK: p130^{cas} complex formation. Indeed p130^{cas} and paxillin are phosphorylated by the FAK-Src complex enabling the recruitment of even more proteins[6]. c-Src also associates with the SH2-containing inositol 5-phosphatase, SHIP1, and is involved in its tyrosine phosphorylation downstream of αIIb3 integrin in human platelets[13]. SHIP1 may contribute to the phosphatidylinositol 3,4 bisphosphate (PI3,4 P2) accumulation, by dephosphorylation of phosphatidylinositol 3,4,5 trisphophate (PI 3,4,5 P3), playing a role in the strengthening of irreversible aggregation[14]. Once recruited and tyrosine phosphorylated, SHIP1 may also play a role as a docking protein allowing the formation of adequate signalling complexes at the proximity of integrin clusters.

The generation of mice bearing homologous disruption of Src genes develop severe osteopetrosis[15]. However, targeted disruption of the Src, Fyn, Yes and Lyn genes has revealed that the loss of a single Src family member does not perturb the hemostatic function of platelets. This would indicate that the presence of multiple Src kinases within the cell can compensate for the loss of an individual family member.

Syk tyrosine kinase

Syk, a 72 kDa tyrosine kinase, is expressed by all hematopoietic cells. It contains two N-proximal SH2 domains, two interdomain spacer regions, a catalytic domain and a C-terminal tail (Fig. 19.1). It is homologous to Zap 70 whose expression is limited to T-lymphocytes and NK cells. Syk is essential for lymphocyte development and for signal transduction via immune receptors in non-lymphoid cells.

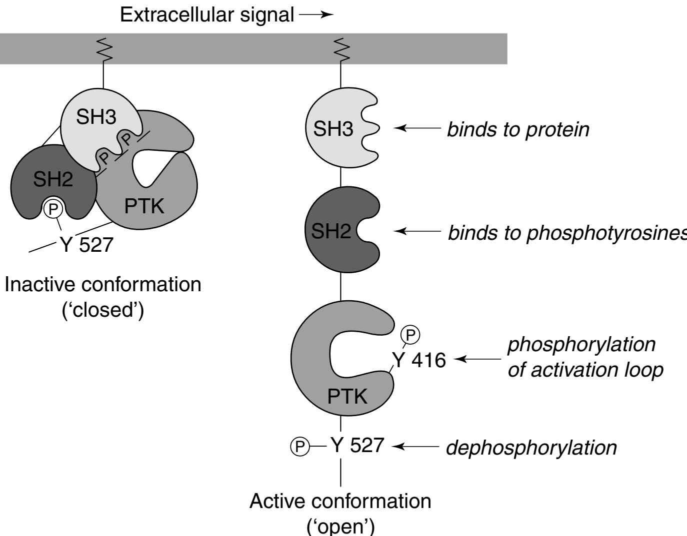

Fig. 19.2. Activation model of Src. Src kinases are found in either an active or inactive state depending on intramolecular associations. Interactions occur between the SH3 domain and polyproline helix II motif, and between the SH2 domain and the C-terminal phosphotyrosine residue. These associations which prevent activation of a Src kinase, are broken principally with the dephosphorylation of the C-terminal phosphotyrosine by a protein tyrosine phosphatase. This leads to an alteration of the three-dimensional structure of the molecule allowing the enzyme to assume an active conformation.

Although the extracellular domains of immune receptors are quite different, they share the ability to associate with invariant subunits which contain an immunoreceptor tyrosine-based activation motif (ITAM) in their cytoplasmic domains[16]. This motif is characterized by a consensus sequence that includes two tyrosines, typically 10–12 amino acids apart, which are rapidly phosphorylated following engagement of the immune receptor. A model for Syk activation has been proposed in lymphoid cells whereby the ligand-induced receptor clustering stimulates tyrosine phosphorylation of ITAMS by one or more Src family kinases resulting in Syk engagement through the tandem SH2 domains leading to Syk activation.

Syk has been identified in platelets and like Src family kinases it is rapidly activated following thrombin, ADP or collagen regardless of the activation and/or ligand binding status of the αIIbβ3 integrin. Syk activation correlates with its tyrosine phosphorylation; however, full activation of Syk requires integrin engagement[17]. The modes of Syk activation through immune response receptors and thrombin and integrin receptors are distinctly different. Syk has recently been implicated in collagen-induced platelet

Cambridge Books Online © Cambridge University Press, 2009

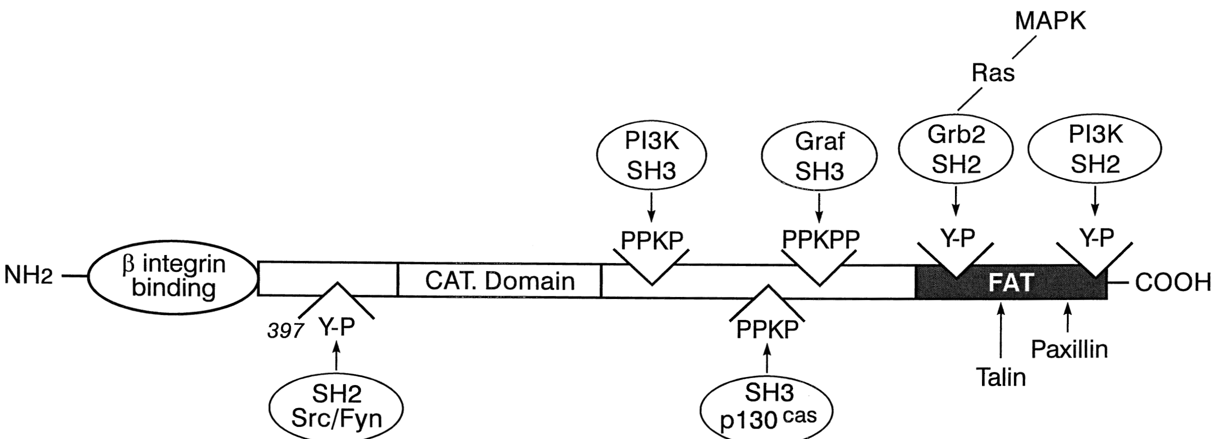

Fig. 19.3. Potential molecular interactions of FAK with cytoskeletal and signalling proteins. The phosphotyrosine residues serve as docking sites for SH2 containing signal transduction molecules such as Src/Fyn, PI3K, Grb2. The proline-rich sequences serve as docking sites for SH3 containing molecules such as p130cas, Graf and PI3K. Binding sites in the N and C terminal tails are required for FAK binding cytoskeletal proteins such as the unit of integrin, talin and paxillin.

signalling. Syk becomes tyrosine phosphorylated upon collagen-induced platelet activation and associates with GPVI through the ITAM containing Fcγ signalling subunit and Syk deficient murine platelets fail to respond to collagen[18].

Since the thrombin receptor and integrins do not possess an immuno receptor tyrosine-based activation motif, the mechanism of thrombin-induced activation of Syk remains unclear. Concerning the integrins, Gao et al.[19] demonstrated that Syk activation could be triggered by the binding of soluble fibrinogen to αIIb3 and that the cytoplasmic tails of both αIIb and β3 were needed for this activation since it was abolished by the truncation of αIIb or β3 tails. Moreover, Src or a related kinase appeared to be required for Syk activation by αIIbβ3 since a kinase inactive variant blocked αIIbβ3-induced Syk phosphorylation. Finally Sada et al.[20] present evidence that thrombin induces association of Syk with FAK in human platelets and this association is dependent upon the state of actin polymerization.

The identity of substrates and effectors of Syk is not well defined. Syk is reported to interact with and phosphorylate or activate several proteins including PLCγ[18], Vav (a guanine nucleotide exchange factor for small ras-like GTPases)[21], PI3 kinase[22] and an actin-binding protein cortactin[23,24]. Experiments conducted in Syk knockout mice indicate a critical role for this kinase in hemostasis as Syk $-/-$ mice suffer from severe hemorragic complications in utero and die within the perinatal period[25]. Experiments conducted in Syk deficient murine platelets, generated using targeting methodology, fail to respond to collagen.This would be due to the absence of phosphorylation of PLCγ leading to inhibition of PI4,5 P2 hydrolysis, absence of inositol 1,4,5 trisphosphate (IP3) synthesis, Ca^{2+} release and pleckstrin phosphorylation[18]. However, these same authors demonstrated the ability of Syk deficient platelets to aggregate in response to thrombin stimulation. It is conceivable that some other kinase can compensate for the lack of Syk in these platelets. Finally, no increase in tail bleeding time was observed when Syk $-/-$ animals were compared with Syk $+/-$ or Syk $+/+$ controls[18]. However, Syk deficiency was associated with rebleeding after primary hemostasis in two of five animals, indicating an unstable hemostatic plug formation, which can contribute to death due to hemorrhage that happens to most Syk knockout mice shortly after birth[25].

Focal adhesion kinase

Focal adhesion kinase has emerged as a primary mediator of integrin signalling. FAK is a non receptor tyrosine kinase of 125 kDa that colocalizes with integrins at sites at which a cell makes close adhesive contact with the extracellular matrix substratum[26,27]. Integrin-mediated cell adhesion promotes rapid FAK tyrosine phosphorylation, which results in the activation of signalling functions. Unlike the Src family tyrosine kinases, p125 FAK does not contain SH2 or SH3 domains. It has a catalytic domain flanked by large N and C terminal domains (Fig. 19.1). FAK has been shown to bind a variety of adapter and signalling molecules (Fig. 19.3). Six FAK tyrosines (397, 407, 576, 577, 861 and 925) have been identified as sites of adhesion dependent phos-

phorylation. Tyr 397 is the only apparent site of autophosphorylation. Phosphorylation of Tyr 397 creates a high affinity binding site for the SH2 domains of Src-family tyrosine kinases including c-Src and Fyn, which could promote the activation by C-terminal tail displacement[28]. Phosphotyrosine 397 appears also to mediate interactions with SH2 domains of the p85 subunit of phosphatidylinositol 3-kinase (PI3K), which could subsequently stimulate its activity[29]. FAK can also bind to PI3K upon ligand engagement of integrin in thrombin-stimulated platelets. Guinebault et al.[30] have demonstrated that a GST fusion protein containing the p85 SH3 domain can bind to FAK as well as to a synthetic peptide derived from a proline-rich region of FAK, indicating a role of the SH3 domain of p85 in FAK association with PI3K. Phosphorylation of Tyr 576 and Tyr 577, which lie in the FAK kinase domain activation loop, appears to elevate FAK catalytic activity. Tyr 925 of FAK which is phosphorylated by Src in vitro has been identified as the binding site for the SH2 domain of Grb2[31]. Grb2 binding to phosphorylated FAK would be followed by recruitment of Sos and the activation of Ras/MAP kinase pathways. Recently, it has been reported that FAK can directly interact with PLCγ1. This interaction is mediated by the C-terminal SH2 domain of PLCγ1 binding to FAK phosphorylated Tyr 397[32]. FAK-null mice die in fetal life and, ex vivo, their fibroblasts form focal adhesions but migrate poorly[33].

Several groups have reported the identification of a second related FAK PTK referred to as RAFTK (related adhesion focal tyrosine kinase) also known as Pyk2 or CAK-β. RAFTK is related to FAK (48% identity, 65% similarity), which is known to play an important role in cell adhesion. RAFTK phosphorylation, unlike FAK phosphorylation occurs in the early phase of platelet activation, is not dependent on platelet aggregation and does not require integrin engagement[34]. Moreover, the activation of Pyk2 coincides with increased association with PI3K as determined by both anti-PI3K and anti Pyk2 immunoprecipitates. In addition, both increased PI3K activity and increased Pyk2 activity could be detected in immunoprecipitate following thrombin stimulation[35]. Finally, in immunoprecipitation studies, Pyk2 as well as FAK seems to associate with Shc through Grb2[36].

JAK family kinases

The JAK (JAnus Kinase or Just Another Kinase) family of kinases are a recently described group of signalling enzymes involved in cytokine and growth factor mediated signal transduction[37]. Four members of this family have been identified including JAK1, JAK2, JAK3 and TYK2 which share a high degree of structural similarity. The structure contains two C-terminal kinase related domains and five N-terminal other homology domains (JH3–JH7) (Fig. 19.1). Recently, it has been demonstrated that both JAK2 and TYK2 are present in human platelets. Signal transduction pathways activated by TPO, the ligand for c-Mpl, or thrombin, comprised the tyrosine phosphorylation of JAK2 and TYK2[38–41]. However, the time course of JAK2 phosphorylation in thrombin-stimulated platelets is slow, suggesting a potential role for this enzyme in the regulation of postaggregation responses.

Tec family kinases

Bruton's tyrosine kinase (77 kDa) (Btk) and Tec kinase (65 kDa) regulate the phosphorylation of PLCγ2 in B and T lymphocytes, respectively[42]. Btk is essential for normal B cell receptor signalling since the lack of expression of functional Btk in humans leads to the B-cell deficiency X-linked agammaglobulinemia (XLA). The structure of these enzymes shows that, in addition to containing an SH2 and an SH3 domain, the Tec family of kinases has two unique features: a pleckstrin (PH) domain and a Tec homology domain, which mediates association of Tec with Lyn[43] (Fig. 19.1). Btk and Tec kinase are also expressed in platelets and undergo phosphorylation in response to collagen-related peptide (CRP) and collagen. A role for Btk in platelets was recently demonstrated by the observation of decreased in vitro collagen-induced aggregation of platelets from XLA patients. It has been described that CRP and collagen, which bind to GPVI, induce Btk phosphorylation which plays a crucial role by regulating tyrosine phosphorylation and activation of PLCγ2[44].

However, since PLCγ2 tyrosine phosphorylation is only partially reduced in Btk-deficient platelets, there must be alternative pathways that regulate tyrosine phosphorylation of this enzyme. Other tyrosine kinases including Tec, a homologue of Btk, that is expressed in platelets[45] might partially substitute for Btk in regulating the tyrosine phosphorylation of PLCγ2 in XLA platelets[44,46]. Aggregation of Btk deficient platelets in response to low and high concentrations of thrombin was not significantly different from controls indicating that Btk is not essential for thrombin-mediated activation and that thrombin may selectively signal through Tec, the phosphorylation of which is highly dependent on platelet aggregation[46].

Protein tyrosine phosphorylation events in human platelets

Platelet aggregation in response to a number of agonists is precipitated by an extremely rapid and complex set of signalling pathways. Initial signalling events activated by the G-protein coupled receptors, leads to stimulation of polyphosphoinositide turnover, arachidonic acid metabolism, calcium mobilization and influx and changes in protein phosphorylation on both serine/threonine and tyrosine residues. These events lead to activation of αIIbβ3, the major integrin receptor on platelets, by increasing its affinity/avidity for fibrinogen through a process known as inside-out signalling. In turn, ligand occupancy and clustering of αIIb3 trigger outside- in signalling that involves a rapid and dramatic increase in tyrosine phosphorylation of multiple proteins, influences cytoskeletal reorganization and culminates in platelet aggregation[47]. Towards the later stages of aggregation, tyrosine dephosphorylation occurs coincident with activation and/or redistribution of protein tyrosine phosphatases[19].

Inside–out signalling events

In the case of thrombin, which binds to heptahelical receptors coupled to heterotrimeric G proteins, one consequence important to inside-out signalling is activation of the PLCβ by the α subunit of Gq resulting in hydrolysis of PI4,5 P2 and production of second messengers, diacylglycerol and IP3. Mouse platelets that have been rendered null for Gq undergo shape change but fail to aggregate in response to thrombin, ADP or a thromboxane A2 receptor agonist[48]. Occupancy of many G protein-coupled receptors also leads to rapid activation of non-receptor protein tyrosine kinases including Src, Syk and Pyk2. This leads to tyrosine-phosphorylated proteins such as Vav (a guanine nucleotide exchange factor for the Rac GTPase)[49], PLCγ[50] and cortactin (a cortical actin-binding protein)[51]. Syk tyrosine phosphorylation takes place during the period when platelets are changing shape upon low concentrations of a thromboxane analogue, IBOP, and cortactin is associated with Syk[24]. This emphasizes the role of cortactin in cell morphological changes which involve cytoskeletal rearrangements. Phosphorylation of cortactin is also described in thrombin-stimulated thrombasthenic platelets, which do not aggregate, confirming the role of the actin-binding protein in the early steps of platelet activation independently of platelet aggregation[51] (Fig. 19.4).

Agonists binding to G protein coupled receptors also lead to activation of non-receptor tyrosine phosphatases including SHP1. Thrombin stimulation has been shown to induce very rapid increases in SHP1 tyrosine phosphorylation and association of SHP1 with Src[9], suggesting that SHP1 may serve to activate Src by dephosphorylating the COOH-terminal regulatory tyrosine.

Outside–in signalling

A dramatic increase in tyrosine phosphorylation is observed in platelets when fibrinogen binds to αIIbβ3 and promotes integrin clustering. Signalling is propagated by interactions between integrin cytoplasmic tails, signalling molecules and structural cytoskeletal proteins including vinculin, talin and α actinin. When platelets begin to form microscopic aggregates, there is detectable activation of c-Src. Furthermore studies in CHO cell transfectants indicate that fibrinogen binding can trigger activation of Syk due to combination of autophosphorylation and phosphorylation of Src[19]. Full aggregation is then associated with activation of the tyrosine kinase FAK which binds to the cytoplasmic tail of β3 integrin and results in an increased number of tyrosine phosphorylated substrates. These substrates include the 60 kDa band, Src, the 64 kDa band, the 77/80 kDa cortactin, the 100/105 kDa and 125/130 kDa doublets (Fig. 19.4). The first experimental evidence correlating platelet aggregation with platelet tyrosine phosphorylation came from the study of platelets from patients with Glanzmann thrombasthenia. This inherited platelet disorder, characterized by defective platelet aggregation consecutive to the failure of patient's platelets to bind fibrinogen after agonist stimulation, is due to a quantitative or qualitative defect in αIIbβ3 integrin. The tyrosine phosphorylation patterns of platelets from three thrombasthenic types differed significantly from the controls and showed identical alterations[51].

The most affected bands were the 100–105 kDa doublet

Cambridge Books Online © Cambridge University Press, 2009

and the 125 kDa (FAK), which were completely absent, confirming the key role of αIIbβ3 in protein phosphorylation of these substrates (Fig. 19.4). According to Izaguirre et al.[52], αIIbβ3 mediates tyrosine phosphorylation of a 105 kDa protein in activated platelets which would correspond to α actinin. The protease calpain[53], the phosphatases SHIP (an SH2 domain-containing inositol 5 phosphatase) and SHP1 (Src homology protein tyrosine phosphatase) and the non receptor protein tyrosine kinases Tec and FAK are among the proteins that become phosphorylated at this stage.

FAK provides a great number of potential molecular interactions with cytoskeletal and signalling proteins (Fig. 19.3). Autophosphorylation of FAK at Tyr 397 creates a binding site for Src through its SH2 domain. Ligand binding to integrin promotes the association of the Ras-activating complex Grb2–Sos with phosphotyrosine 925 on FAK and activation of MAP kinase. There is evidence that the association of FAK and PI3K is also regulated by tyrosine phosphorylation of FAK[29,54] leading to an increase in PI 3,4 P2 necessary to stabilize fibrinogen binding. The SH2 domain-containing SHIP is tyrosine phosphorylated and relocated to the cytoskeleton in an aggregation and integrin-dependent manner. This inositol phosphatase is known to dephosphorylate PI3,4,5 P3 and contributes to the accumulation of PI3,4 P2 shown to participate in the stabilization of platelet aggregates[55]. The localization of FAK to focal adhesions is, in turn, stabilized by its ability to associate with paxillin and talin[56].

It has been shown, recently, that outside-in signalling mediated by the αIIbβ3 involves the phosphorylation of tyrosine residues on the cytoplasmic tail of β3. Shc was the primary protein binding to phosphorylated β3, and transient Shc phosphorylation was observed when thrombin-stimulated platelets were allowed to aggregate[57]. It is possible that events downstream of Shc binding to phosphorylated β3 involve activation of the MAP kinase ERK 1/2 pathways.

Upon thrombin stimulation, the protein tyrosine phosphatase SHP1 was found to be tyrosine phosphorylated and translocated to the cytoskeleton after αIIbβ3 engagement[58]. SHP1 can therefore develop its tyrosine phosphatase activity, thereby modulating the signal propagation as described in erythropoietin (EPO)-mediated cell signalling. The association of SHP1 to the EPO receptor causes termination of proliferative signals, probably through receptor dephosphorylation or the dephosphorylation of downstream signalling molecules[59]. We do not know the precise role of SHP1 in platelet signalling. However, the importance of the protein tyrosine phosphatases in general is suggested by the powerful effects that result from the use of the inhibitor pervanadate. Previous data obtained in our laboratory[60] show that pervanadate induces platelet aggregation accompanied by generation of a huge amount of tyrosine-phosphorylated substrates. This would suggest that tyrosine phosphatase activity is absolutely necessary for platelets to avoid being activated.

Conclusions

Platelet tyrosine kinases play a critical role in coordinating, integrating and amplifying signals from multiple cell surface receptors. Many of them have been demonstrated to translocate to the cytoskeleton fraction of aggregated platelets.

The translocation and activation of FAK which binds to the integrin could represent one of the earliest signalling events induced by integrin occupancy on the cell surface due to FAK's numerous molecular interactions with signalling and cytoskeletal proteins. The formation of this protein network at focal adhesion sites is responsible for the irreversible platelet aggregation.

Despite considerable progress having been made in this area, many questions remain unsolved including the absence of knowledge of the effectors of the tyrosine kinases. A complete understanding of the substrates of these protein tyrosine kinases may allow us to better understand the role of tyrosine phosphorylation in regulating platelet function. Knockout mouse models as well as new pharmacological agents will help to define the molecular interactions and hierarchies between these enzymes.

History

The first report that cyclic AMP had an effect on platelets came from Marcus and Zucker[1], who showed that dibutiryl cyclic AMP, a cell permeant cyclic AMP analogue, inhibited platelet aggregation. Ardlie et al.[2] showed that methyl xanthines, which inhibit cyclic AMP phosphodiesterase and hence elevate cyclic AMP levels, also inhibit platelet aggregation and proposed that cyclic AMP is an important mediator of platelet function. In 1969, several groups of investigators reported that the level of platelet cyclic AMP regulated platelet function and showed that both platelet agonists and antagonists could affect the intraplatelet concentration of cyclic AMP[3–6]. Salzman suggested that cyclic AMP might be the ultimate mediator of platelet activation in that agents that inhibited aggregation increased cyclic AMP, while agents that activated platelets did so by lowering the basal level of cyclic AMP[7]. However, the idea that agonists activate platelets by lowering basal cyclic AMP was convincingly refuted by Haslam et al.[8].

Elevated levels of cyclic GMP also inhibit platelet activation[9,10] and platelet activators elevate cyclic GMP[11]. However, the latter effect has been shown to be a consequence of aggregation and does not occur during other forms of platelet activation[12]. A schematic summary of the information in this review is shown in Fig. 20.1.

Platelet receptors coupled to adenylyl cyclase activation

Prostaglandins that elevate cyclic AMP levels are potent inhibitors of platelet activation. Adenosine acts through the A2A receptor to activate adenylyl cyclase. The rank order of potency of prostaglandins as inhibitors of human platelet activation is PGI2 > 6 keto-PGE1 > PGE1 > PGD2 > 6-ketoPGF2α > PGE2 > PGF2α. The order reflects the importance of the prostacyclin (IP) receptor in mediating prostaglandin effects on platelet adenylyl cyclase. There are three distinct receptors for PGE2, and separate receptors for PGD2 and PGF2α. Table 20.1 shows a summary of the platelet receptors coupled to adenylyl cyclase.

IP receptor

The IP receptor mediates the action of PGI2. PGE1 also binds to the IP receptor with relatively high affinity. The IP receptor is linked to stimulation of adenylyl cyclase through the G protein Gs. Cloning and expression of the receptor confirmed that the receptor also couples to Ca^{2+} mobilization. The IP receptor is desensitized by protein kinase C but not by protein kinase A[13]. Studies on isolated platelets show that the IP receptor is also susceptible to down-regulation[14].

EP2 receptor

The EP2 receptor was defined when relaxant and contractile effects of PGE2 on guinea pig trachea smooth muscle were separated using the selective EP1 antagonists, SC 19220 and AH 8609[15]. The selective EP2 agonist butaprost has also proved useful in functional characterization of the receptor. The EP2 receptor couples to an increase in cyclic AMP. However, recent identification of the EP4 receptor, which also couples to an increase of cyclic AMP formation, suggests that some of the functions of PGE2 may not be mediated by EP2. The recombinant EP2 receptor is resist-

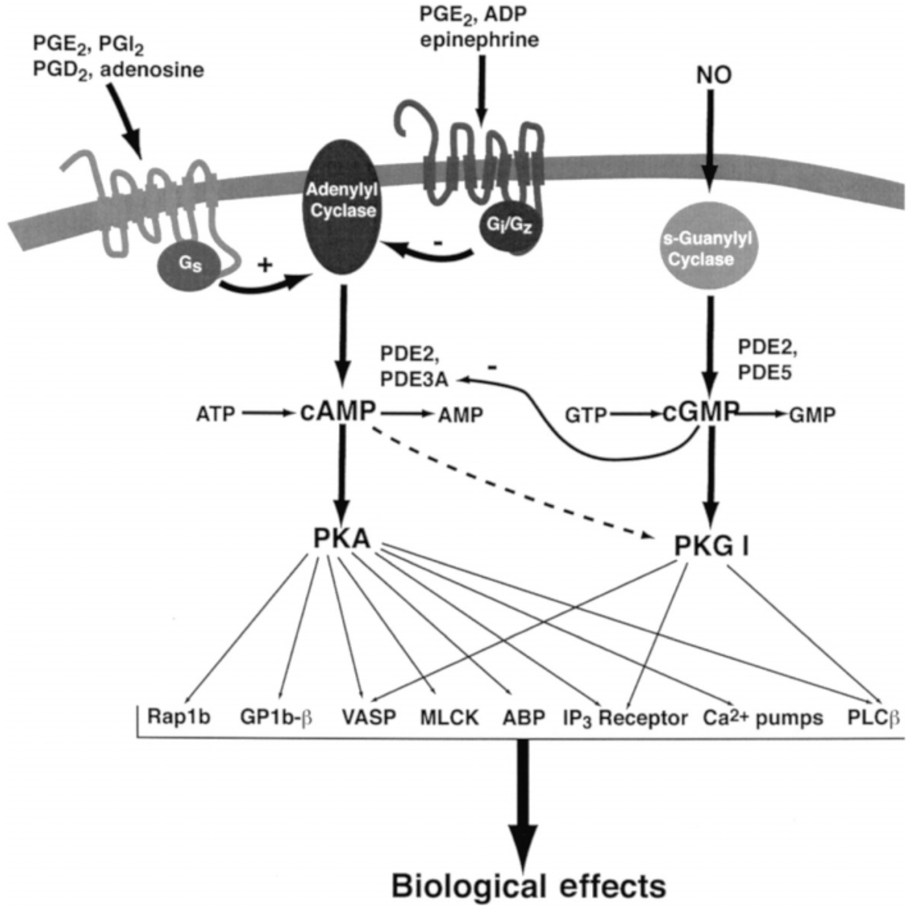

Fig. 20.1. A schematic summary of the receptors coupled to cAMP and cGMP and downstream effectors of cyclic nucleotides in platelets.

Table 20.1. Platelet receptors coupled to adenylyl cyclase regulation

Receptor name	Principal agonists	Selective agonists	Antagonists	adenylyl cyclase regulation
IP	PGI2	Iloprost		Positively
EP2	PGE1, PGE2	Butaprost	SC 19220, AH 8609	Positively
EP4	PGE1, PGE2		AH 23848B	Positively
DP	PGD2	9-deoxy-D^9-PGD2	BWA868C	Positively
A2A	Adenosine	CGS 21680	ZM241385	Positively
EP3	PGE2	Sulprostone, enprostil		Negatively
P2Y12	ADP		AR-C66096, thienopyridine	Negatively
α2a-adrenergic	Epinephrine, norepinephrine	Clonidine	Yohimbine	Negatively

ant to agonist-induced short-term desensitization but undergoes down-regulation in response to long-term desensitization. Because PGE2 can cause an increase in cyclic AMP and inhibit platelet function, platelets almost certainly possess either the EP2 or the EP4 receptor.

EP4 receptor

The EP4 receptor couples to an increase in cyclic AMP, similar to the EP2 receptor. There are no selective agonists for the EP4 receptor; the EP2 selective agonist butaprost is not active at the EP4 receptor. Actions of PGE2 at the EP4 receptor can be assigned by comparison of butaprost and other EP receptor agonists. The receptor has a long carboxy terminal domain containing numerous serine and threonine residues. The EP4 receptor is susceptible to agonist-induced short-term desensitization, which distinguishes it from the EP2 subtype. Truncation of the carboxy terminal domain abolishes short-term desensitization[16] and internalization[17]. The EP4 receptor also undergoes down-regulation following long-term exposure to agonist (>12 h), however, down-regulation is also seen with the EP2 receptor.

DP receptor

The DP receptor is the only class of receptor identified to date that mediates the actions of PGD2[15]. Selective DP agonists include 9-deoxy-D^9-PGD2. Several DP receptor antagonists are available including BWA868C. PGD2 exerts its effect by causing an increase in intracellular cyclic AMP. The DP receptor cDNA codes for a protein of 359 amino acids and the recombinant receptor couples to stimulation of adenylyl cyclase. The evidence for DP receptors on platelets is based on the fact that PGD2 inhibits platelet aggregation.

Adenosine receptors

There are four distinct adenosine receptors named A1, A2A, A2B and A3. Platelets contain A2A receptors[18]. Adenosine acts via an A2A receptor to stimulate adenylyl cyclase in platelets and inhibits platelet activation. Mice lacking A2A receptors exhibit slight increases in platelet aggregation[19]. ADP released from platelets can be catabolized to adenosine by ectonucleotidases. This may provide an important mechanism for limiting inappropriate platelet aggregation in an intact blood vessel.

Receptors coupled to inhibition of adenylyl cyclase

In all cases, receptors coupled to inhibition of adenylyl cyclase have no measurable effect on basal adenylyl cyclase activity. In order to demonstrate a Gi or Gz-dependent decrease in adenylyl cyclase, it must be activated with one of the agonists discussed above or by direct stimulation with forskolin.

EP3 receptor

PGE2 acts through the EP3 receptor to inhibit adenylyl cyclase[15]. Selective EP3 agonists include sulprostone, and enprostil. The human EP3 receptor occurs as at least eight isoforms that are the product of alternative splicing of a single gene[20,21]. The isoforms are identical over the first 369 amino acids but differ in carboxyl-terminal region, which varies in length from 6–65 amino acids following the seventh transmembrane helix. While all of the EP3 isoforms couple to inhibition of adenylyl cyclase, they differ in properties including susceptibility to desensitization and degree of constitutive activity. Some of the isoforms also couple to Ca^{2+} mobilization. The EP3 receptor has been functionally demonstrated on platelets by the action of the selective agonist, sulprostone in inhibiting adenylyl cyclase[22]. Co-localization of the EP3 receptor on platelets with the IP, EP2 or EP4, and DP receptors, all of which couple to stimulation of adenylyl cyclase, has led to the description of a novel mechanism of desensitization involving distinct stimulatory and inhibitory receptors[23]. Since prostaglandins are local mediators their concentration might be expected to vary as the autocoid is released and diffuses away from its site of action so that the role of the inhibitory receptor may be to provide homeostatic control of cyclic AMP level, buffering against rapid variations in agonist concentration. Recent studies on EP3 knockout mice indicate that loss of the EP3 receptor in a model of venous inflammation protects against formation of intravascular clots[24].

ADP receptor

The recently cloned P2Y12 receptor has been shown to be coupled to inhibition of adenylyl cyclase[25,26]. While it has been known for a relatively long time that ADP can inhibit activated adenylyl cyclase, the separation of the action of ADP effects on platelets into a Gi-mediated response via a $P2T_{AC}$ receptor (P2Y12) and a Gq-coupled P2Y1 was made only recently[27].

Cambridge Books Online © Cambridge University Press, 2009

Epinephrine receptor

Platelets contain α2a adrenergic receptors that had long been thought to be coupled to the inhibition of adenylyl cyclase via Gi[28]. Recently, it was shown in mice lacking Gz, that epinephrine induced-inhibition of cyclic AMP formation was lacking and aggregation was impaired[29]. The Gz deficient mice were also more resistant to fatal thromboembolism than normal mice.

Thromboxane and thrombin receptors

The question of whether thromboxane A2 receptors in platelets are coupled to adenylyl cyclase inhibition has been controversial. Ushhibucki et al.[30] reconstituted platelet thromboxane A2 into lipid vesicles along with either Gq or Gi2. They found that a thromboxane analogue stimulated GTPγS binding by Gq and Gi2. Hirata et al.[31] showed by RT–PCR that platelets contain cDNA for both thromboxane A2 receptor isozymes. TPα has been shown to couple to activation of adenylyl cyclase and TPβ has been shown to couple to inhibition of cyclase. However, Paul et al.[32] have indicated that the thromboxane mimetic, U46619, does not inhibit adenylyl cyclase directly. Effects of U46619 on cyclic AMP levels can be attributed to secreted autocoids such as ADP or epinephrine. Faruqi et al.[33] have reported that PAR1 but not PAR4 can inhibit platelet adenylyl cyclase in cultured cells. Giesberts et al.[34] showed that the PAR1 specific agonist TRAP can inhibit prostacyclin elevated cyclic AMP. This result has been disputed by Kim et al.[35], who failed to find TRAP-induced adenylyl cyclase inhibition when agents that prevented ADP dependent feedback were included. Thrombin as opposed to the peptides, however, may be able to inhibit adenylyl cyclase

Adenylyl cyclase

There are nine isoforms of adenylyl cyclase that have been cloned and characterized from mammalian sources. The exact isoform of adenylyl cyclase in platelets has not been proven directly. However, several indirect lines of evidence indicate that AC 7 is the major isoform of platelets[36,37]. AC 7 was first found in megakaryocytic HEL cells, which are considered to be a model for platelets. In addition, the level of platelet adenylyl cyclase activity has been proposed to be an indicator of alcoholism[38] and HEK293 cells transfected with AC 7 show greater sensitivity to ethanol than cells expressing other adenylyl cyclase isoforms[39]. AC 7, like most other isoforms, is activated by Gαs and inhibited by Gαi. A brief exposure of cells to ethanol causes an increase in both basal and receptor mediated cyclic AMP production. This effect is probably not direct since ethanol does not activate adenylyl cyclase in membranes. Both ethanol and phorbol dibutyrate (PDBu) treatment enhanced PGE1-stimulated AC activity in HEL cells, platelets and HEK 293 cells transfected with AC 7[40]. Inhibitors of protein kinase C (PKC) blocked the stimulatory effects of both ethanol and PDBu. In cells transfected with AC 7, treatment with either ethanol or PDBu increased the phosphorylation of AC 7. AC 7 was found to be an in vitro substrate of protein kinase C and the use of an isoform specific inhibitor implicated PKC delta in the regulation of AC 7. This study is in contrast to earlier studies of Williams et al.[41], who showed that activation of protein C inhibits the ability of PGE1 to activate platelet adenylyl cyclase. Bushfield et al.[42] also found that phorbol ester treatment of platelets inhibited PGD2 stimulated cyclase, but failed to detect an effect of protein kinase C activation on PGE1-activated adenylyl cyclase.

Guanylyl cyclase

Guanylyl cyclase is found as two major forms, a membrane bound form, which is mainly activated by atrial natriuretic factor (ANF) or intestinal peptide, and soluble guanylyl cyclase that is activated by nitric oxide[43]. The primary form of guanylyl cyclase found in platelets is the soluble form[44]. Soluble guanylyl cyclase is a heterodimer that requires both subunits for activity[43]. Soluble guanylyl cyclase contains a prosthetic heme that is the site for interaction with nitric oxide. Several pharmacologic agents (nitrovasodilators) such as sodium nitroprusside activate guanylyl cyclase by released nitric oxide.

Protein kinases as downstream effectors of cyclic nucleotides

Cyclic AMP dependent kinase

The major, if not only, effect of elevated cyclic AMP levels in platelets is to activate cyclic AMP-dependent protein kinase, also known as protein kinase A (PKA). PKA is a tetramer formed of two catalytic subunits and two regulatory subunits. The regulatory subunits suppress the activity of the catalytic subunits. When the regulatory subunits bind cyclic AMP, they release the catalytic subunits allowing the expression of catalytic activity. Thus, the R-subunits of protein kinase may be detected by its ability to bind

Cambridge Books Online © Cambridge University Press, 2009

cyclic AMP. Using a photoaffinity label, the presence of the regulatory subunits in the particulate fraction in the soluble fraction of platelets has been demonstrated[45]. Using a combination of several techniques, Salama and Haslam[45] have provided convincing evidence for the existence of membrane-bound PKA and soluble PKA in platelets.

Cyclic GMP dependent kinase

Cyclic GMP can alter several effectors but it is probable that the major target in platelets is cyclic GMP-dependent kinase or PKG. PKG is a homodimer. Each subunit contains a catalytic domain and a regulatory domain. When the regulatory domain binds cyclic GMP a conformational change occurs that unmasks the catalytic site. There are two major isozymes of PKG, type I and type II. Platelets contain PKG I[46]. Platelet PKG I but not endothelial or smooth muscle PKG I is essential to prevent intravascular adhesion and aggregation of platelets after ischemia. The defect in platelet PKG I is not compensated by the cyclic AMP/cyclic AMP kinase pathway supporting the essential role of PKG I in prevention of ischemia-induced platelet adhesion and aggregation[47].

Cyclic nucleotide phosphodiesterases

The presence of several different PDE isozymes was initially shown by classical enzyme purification techniques[48]. The members of these PDE families were later cloned yielding six distinct PDE isozymes labeled PDE1-PDE6. More recently, five additional nucleotide sequences encoding additional PDE families (PDE7-PDE11) have been identified[49,50]. Current nomenclature uses arabic numbers to designate 1 of the 11 families with a letter indicating individual genes within a family, and further numerals indicating splice variants[51,52]. A summary of PDE families and their distribution in tissues is reported in Table 20.2. Table 20.3 shows the inhibitors of each PDE isoform.

Table 20.2. Phosphodiesterase (PDE) families and tissue expression

Isoforms	Tissue expression
PDE1	Cardiac muscle, vascular smooth muscle, brain
PDE2	Platelets, cardiac muscle, endothelial cells
PDE3	Platelets, vascular smooth muscle
PDE4	Cardiac muscle, vascular smooth muscle, brain, inflammatory and immune cells
PDE5	Platelets, vascular smooth muscle
PDE6	Retinal rods and cones
PDE7	T-lymphocytes, B-lymphocytes, skeletal muscle, cardiac muscle
PDE8	Testis, eye, liver, kidney, skeletal muscle, embryo, ovary, brain.
PDE9	Small intestinal smooth muscle, liver, kidney, lung, brain, testis, skeletal muscle, hearth, thymus.
PDE10	Testis and brain
PDE11	Skeletal muscle, prostate, kidney, liver, pituitary salivary glands and testis

Table 20.3. Drugs inhibiting PDE isoforms

Isoforms	Drugs
PDE1	Vinpocetine
PDE2	EHNA
PDE3A	Cilostazol, Milrinone, Vesnarinone, and Lixazinone
PDE4	Rolipram, Etazolate, Zardaverine
PDE5	Sidenafil, E4021, DMPPO, Zaprinast, Dypiridamole
PDE6	Sidenafil, Zaprinast, Dypiridamole
PDE8	Dypiridamole
PDE9	Zaprinast
Non-selective	Methylxanthine, theophylline

The major PDE's found in platelets

Hidaka and Asano[48] were the first to resolve the PDE activity of platelets into three distinct peaks. The first enzyme eluted prefers cyclic GMP as substrate with a Km of about 1 mM and is selectively inhibited by PDE5 inhibitors. The second peak of activity hydrolyses both cyclic AMP and cyclic GMP almost equally well[53]. The cyclic AMP activity of enzyme is stimulated by cyclic GMP and selectively inhibited by a PDE2 inhibitor. A third peak of phosphodiesterase activity hydrolyses cyclic AMP much more rapidly than cyclic GMP, has a high-affinity for both cyclic AMP and cyclic GMP and is selectively inhibited by PDE3 inhibitors. The effects of isozyme-selective inhibitors on total PDE in lysed platelets also indicate that these PDE isozymes account for at least 90% of platelet PDE activity. Thus, the best evidence indicates that, in platelets, cyclic AMP is hydrolysed by PDE3 and PDE2 and cyclic GMP is hydrolysed by PDE5 and PDE2.

Phosphodiesterase 2 (PDE2) family

PDE2 isozymes were initially named cyclic GMP-stimulated PDE2 because cyclic GMP enhances PDE2 catalyzed cyclic AMP hydrolysis. These enzymes hydrolyse both cyclic AMP and cyclic GMP with similar $Vmax_s$ and cooperative kinetics. They are homodimers of 105 kDa containing two allosteric cyclic GMP binding sites per subunit. One PDE2 gene with three amino-terminal splice variants (PDE2A, PDE2A2 and PDE2A3) has been identified. The only known inhibitor is erythro-9-(2-hydroxy-3-nonyl)adenine (EHNA) which can also inhibit adenosine deaminase.

The human platelet PDE2 was purified by affinity chromatography on cyclic GMP-Sepharose. The resulting enzyme had 105 kDa subunits and hydrolysed cyclic AMP and cyclic GMP at similar rates and half-maximal activities were obtained with approximately 50 μM cyclic AMP and 35 μM cGMP[54]. Hydrolysis of both cyclic AMP and cyclic GMP was positively cooperative. In addition, 5–10 μM cyclic GMP stimulated the activity of the purified enzyme up to tenfold. The particular PDE2 isozyme present in platelets has not been identified.

Phosphodiesterase 3 (PDE3)

Members of the PDE3 family have been referred to as cyclic GMP-inhibited cyclic AMP phosphodiesterases, reflecting relatively high affinity for both cyclic AMP and cyclic GMP but a much lower efficacy of hydrolysis for cyclic GMP, which would mean that cyclic GMP may competitively inhibit cyclic AMP hydrolysis by PDE3[55]. There is evidence that this mechanism could occur in platelets in which agents that activate guanylyl cyclase potentiate the effects of activators of adenylyl cyclase[56]. Two genes that encode PDE3 isozymes have been identified. Both cDNAs encode 124 kDa proteins with N-terminal hydrophobic amino acid sequences. PDE3B is membrane-bound and PDE3A is usually a soluble enzyme that is found in platelets[57].

Because of its presence in cardiovascular tissue (platelets, as well as cardiac and vascular smooth muscle) there has been much interest in developing specific inhibitors of PDE3A. Specific PDE3A inhibitors include cilostazol, milrinone, vesnarinone, and lixazinone.

It has been shown that PDE3A can be phosphorylated in intact platelets when cyclic AMP levels are raised. The cyclic AMP phosphodiesterase activity of phosphorylated PDE3A isolated from the platelets shows enhanced activity[58]. The regulation of PDE3A by in vitro phosphorylation through the catalytic subunit of PKA has also been shown to cause an increase in activity[58].

Phosphodiesterase 5 (PDE5)

PDE5s are homodimers with 100 kDa subunits. They are cyclic GMP-specific phosphodiesterases ($K_m \approx 5$ μM) displaying very little cyclic AMP hydrolysis activity. In addition to the catalytic domains, there are two high-affinity non-catalytic cyclic GMP-binding sites homologous to those found in the PDE2 family. One PDE5 gene has been found and two splice variants have been cloned. Three PDE5 selective drugs are available: E4021, DMPPO, and sildenafil. The bovine platelet enzyme has been purified by a combination of chromatography, affinity chromatography and density-gradient centrifugation[59]. The platelet PDE5 has a molecular weight 190 000 and is composed of two subunits (MW 95 000). This enzyme can be phosphorylated by both cyclic AMP- and cyclic GMP-dependent protein kinases, suggesting a possible mechanism of regulation. Platelet PDE5 shows the same relative sensitivity to selective inhibitors as PDE5 from other cells. PDE5 inhibitors alone have little effect on platelet responses to aggregating agents. However, they do potentiate the effects of agents that activate guanylyl cyclase.

Regulation of cyclic AMP levels by phosphodiesterases

With the discovery of type 3 phosphodiesterase and the fact that cyclic GMP is a competitive inhibitor of PDE3, it became important to know whether cyclic GMP-dependent processes had a direct effect on platelet function or whether all cyclic GMP's effects could be explained by elevation of cyclic AMP. Early studies indicated a synergistic interaction between sodium nitroprusside and prostacyclin in inhibiting platelet aggregation[9]. Experiments in which the effect of guanylyl cyclase activators on cyclic AMP levels was measured directly were first done using rabbit platelets. Incubation of the platelets with sodium nitroprusside caused dose-dependent inhibition of platelet function associated with large increases in cyclic GMP and up to 3.0-fold increases in cyclic AMP. However, addition of sodium nitroprusside with a concentration of PGE1 that had little effect alone caused much larger increases in cyclic AMP and greatly enhanced the inhibition of platelet aggregation. Inhibition of adenylyl cyclase with 2′,5′-dideoxyadenosine (DDA) diminished the increases in cyclic AMP caused by nitroprusside in both the presence and absence of PGE1 but reduced the inhibition of platelet function caused by the nitrovasodilators only in the presence of PGE1. These results suggest that, although cyclic GMP may mediate the inhibition of rabbit platelet function

Cambridge Books Online © Cambridge University Press, 2009

by high concentrations of nitrovasodilators added alone, the synergistic interaction of lower concentrations with PGE1 depends on an enhanced accumulation of cyclic AMP. Later, it was shown that in human platelets as well, nitrovasodilators synergize with activators of adenylyl cyclase to inhibit platelet function[60]. However, enhancement of cyclic levels by nitroprusside added alone is limited to 50% in human platelets as opposed to 200% in rabbit platelets.

While it was immediately recognized that PDE3 is an important regulator of cyclic AMP levels, the importance of PDE2 could be questioned since ENHA has no direct effect on cyclic AMP levels[53]. This may be due to the relatively high Km of PDE2 for cyclic AMP. EHNA can cause small increases in the presence of high concentrations of prostacyclin. EHNA potentiated nitroprusside-induced cyclic AMP formation and inhibition of platelet aggregation. Based on these data Haslam et al.[53] proposed 'a PDE inhibitor that acts on both PDE3 and PDE2 could be a particularly potent antithrombotic'.

The effect of the adenylyl cyclase and guanylyl cyclase systems on platelet function

Cyclic AMP

Level of cyclic AMP and inhibition of platelet activation

Inhibition of platelet activation begins when cyclic AMP starts to increase and is proportional to the level of cyclic AMP at the time of response stimulation; the degree of inhibition does not appear to depend on the mechanism by which cyclic AMP is increased[61,62]. This strongly indicates that it is cyclic AMP itself that mediates the inhibition of platelet activation. Small changes in cyclic AMP can have profound effects on platelet activation. For example, about a two- to three-fold rise in cyclic AMP above basal can inhibit ADP-induced aggregation and a 20% increase can inhibit by about 50%[62]. However, one should be cautioned that all the measured basal cyclic AMP may not be available to activate protein kinase A.

Protein phosphorylation induced by elevated cyclic AMP

Incubation of $^{32}PO_4$-labelled platelets with agonists that elevate cyclic AMP causes prominent labelling of two proteins with molecular weights of 24 kDa (P24) and 50 kDa (P50) within the time period required for development of inhibition of platelet responses[63]. P24 was found to be enriched in particulate fractions containing storage granules, mitochondria, and microsomes while P50 was confined to the soluble fraction[64]. P24 was proposed to have a function in regulation of cytosolic Ca^{2+} concentration but has been shown to be the β-subunit of glycoprotein 1b[65]. Platelet responses to agonists are still inhibited by elevating cyclic AMP in Bernard–Soulier platelets, which lack GP1b.

In the early studies of Haslam's group[63], other proteins with molecular weights of 22, 36, 49, and 82 kDa are also phosphorylated. However, these phosphorylations occur too slowly to be of importance for inhibition of platelet response. The 22 kDa protein has been identified as rap1b, a member of the ras super family of small GTP-binding proteins[66]. However, rap1b evidently plays no role in inhibition of platelet function[66] because when it was completely converted into its phosphorylated form in iloprost (a stable form of prostacyclin) pretreated platelets and the iloprost was removed, the platelets that contained phosphorylated rap1b were found to respond when challenged with a wide variety of agonists.

The 49 kDa protein is likely to be the 46/50 kDa vasodilator-stimulated phosphoprotein (VASP). VASP is associated with microfilaments and concentrated at sites of focal adhesion plaques. VASP is phosphorylated by both PKG and PKA at three sites[67]. Both kinases phosphorylate the 'serine 1 site' rapidly and the threonine 1 site 'slowly' in vitro. However, PKG phosphorylates the 'serine 2 site' more rapidly than PKA. In intact platelets both serine sites are phosphorylated in response to either cyclic GMP or cyclic AMP elevation. In mice in which the VASP gene was deleted, cyclic AMP- and cGMP-mediated inhibition of platelet aggregation required significantly higher concentrations of either cyclic nucleotide[68]. Cyclic-nucleotide-mediated inhibition of increases in cytosolic Ca^{2+} and granule secretion were not altered by the absence of VASP. These authors suggest that cyclic nucleotide-dependent phosphorylation of VASP may involve regulation of integrin function.

Myosin light chain kinase (MLCK) has been shown to be a substrate for cyclic AMP-dependent protein kinase[69]. Phosphorylation of MLCK interferes with the ability of calmodulin to bind to MLCK and thus causes an overall inhibition of MLCK.

Actin-binding protein (ABP; 250 kDa), thought to stabilize actin filaments, is also phosphorylated in platelets. ABP phosphorylation was induced by prostaglandin E1 (PGE1) in intact platelets and a platelet kinase preparation phosphorylates ABP in the presence of cAMP[70]. In the PGE1– treated platelets, ABP was proteolysed at a slower rate than in control platelets indicating the cAMP-

Cambridge Books Online © Cambridge University Press, 2009

dependent phosphorylation of ABP may protect ABP from proteolysis by calpain.

The effect of elevated cyclic AMP on platelet signal transduction pathways

When platelets are activated, there is an increased phosphorylation of a 20 kDa protein (myosin light chain) and 47 kDa protein (pleckstrin). Inhibition of platelet responses by substances that elevate cyclic AMP is accompanied by a substantial decrease in the phosphorylation state of both the P20 and P47 proteins. For myosin light chain, the decrease may be explained by inactivation of Ca^{2+}-calmodulin-dependent myosin light chain kinase by phosphorylation by the catalytic subunit of cyclic AMP-dependent protein kinase. However, the physiological significance has been questioned for smooth muscle relaxation[71]. Increase in cyclic AMP also causes decrease in the agonist-stimulated cytosolic concentration of Ca^{2+} which also may contribute to the inactivation of the myosin light chain kinase. For P47, the decrease is also most likely due to inhibition of its kinase, protein kinase C, through lowering of the concentration of its activators Ca^{2+} and diacylglycerol. Elevated cyclic AMP levels in activated platelets reverses the formation of the cytoskeleton[72].

The level of cytosolic Ca^{2+} increases rapidly when platelets are stimulated. This increase is inhibited by prior elevation of the cyclic AMP level of the platelets[73]. Elevating cyclic AMP after platelet activation reverses the activation process which is accompanied by a decrease in the cytosolic Ca^{2+} level[73]. These observations suggest that the cytosolic Ca^{2+} level in platelets can be controlled by cyclic AMP.

Platelet activation by agonists causes hydrolysis of phosphatidylinositol and polyphosphoinositols with a corresponding formation of inositol phosphates and diacylglycerol, the latter being rapidly phosphorylated to phosphatidic acid. Elevation of cyclic AMP has been shown to inhibit agonist-induced accumulation of phosphatidic acid and diacylglycerol[74]. Rink et al.[75] showed that the slow activation of platelets by direct activation of protein kinase C by phorbol ester or exogenous DG is not inhibited by elevation of cyclic AMP.

Stimulation of cyclic AMP formation has no effect on the conversion of added arachidonic acid to prostaglandins and other metabolites, while the agonist-induced liberation of the fatty acid from endogenous phospholipids is inhibited[76]. These results suggest that, while neither cyclooxgenase nor thromboxane synthetase is inhibited by elevated cyclic AMP, phospholipase A2 is inhibited.

Cyclic AMP-stimulated uptake of Ca^{2+} by platelet microsomal particles

Microsomal preparations from platelets have been shown to accumulate Ca^{2+} in an ATP-dependent manner. It has been shown that this uptake is stimulated by addition of cyclic AMP and PKA. During cyclic AMP-stimulated uptake, a protein with a molecular weight of about 22 KDa is phosphorylated and when the membrane vesicles were prepared from platelets with elevated cyclic AMP, the microsomal vesicles contained phosphorylated P24 and had greater Ca^{2+} uptake than membranes from control platelets[77]. This group has suggested that the calcium pump in the membrane vesicles may be regulated by cyclic AMP-dependent phosphorylation of a P22–24 protein and that this pump may be important in regulating Ca^{2+} levels in the platelet cytoplasm and controlled by external agonists via cyclic AMP. While two proteins in the range have been identified, neither can regulate the Ca^{2+} pump since one is rap1b and the other is part of glycoprotein 1b. Adunyah and Dean[78] showed that antibodies raised against phospholamban (the regulator of the sacroplasmic reticular Ca^{2+} pump in the heart) did not crossreact with the platelet 22 kDa protein. In addition, when the platelet protein was boiled in sodium dodecylsulfate, it did not dissociate into lower molecular weight subunits characteristic of cardiac phospholamban. Recently, Dean et al.[79] showed that elevated cyclic AMP resulted in phosphorylation of the platelet membrane Ca^{2+} pump on a tyrosine residue. This phosphorylation was found to inhibit the activity of this pump.

Cyclic AMP-dependent regulation of the IP3 receptor

The IP3 receptor is a receptor operated Ca^{2+} channel that is opened by an increase in cytosolic inositol 1,4,5-trisphosphate (IP_3). Contrary to earlier reports, O'Rourke et al.[80] found that PKA-dependent phosphorylation of the IP3 receptor had no effect on its ability to release stored Ca^{2+}. Quinton et al.[81] found that IP_3 receptor was initially dephosphorylated, its rate of Ca^{2+} release was not inhibited by cyclic AMP-dependent phosphorylation. However, the rate of Ca^{2+} release from IP_3 receptor that had been phosphorylated by endogenous kinase showed a twofold greater rate of Ca^{2+} release and phosphorylation by PKA inhibited this rate by 50% back to the dephosphorylated rate. In studies on living megakaryocytes, Tertyshnikova and Fein[82] concluded that the 'principal mechanism of cyclic AMP-dependent inhibition of Ca^{2+} mobilization in

Cambridge Books Online © Cambridge University Press, 2009

megakaryocytes appears to be by inhibition of IP3-induced Ca^{2+} release'. Wojcikiewicz and Luo[83] found that all three types of IP_3 receptors could be phosphorylated by PKA. However, they found that in a variety of permeabilized cells types there was a slight increase in sensitivity to IP_3 if the IP_3 receptor was phosphorylated irrespective of the isoforms of IP_3 receptor present.

The effect of cyclic AMP on collagen-stimulated platelet activation

Most of the conclusions about the effect of increases in cyclic AMP and cyclic GMP on collagen-stimulated platelet activation were drawn from experiments using agonists whose receptors couple through guanine nucleotide binding proteins (G proteins) to their effector enzyme, usually phospholipase C. The exact mechanism by which collagen activates platelets was unclear at this time and experiments were done with low concentrations of collagen which relied on the products of secretion such as ADP and products of arachidonic acid metabolism such as thromboxane A2 to activate the majority of the platelets. Researchers studying adhesion of platelets to collagen routinely used an agent that elevated cyclic AMP in the incubation buffer. In many cases, elevation of cyclic AMP cause enhanced adhesion of platelets to collagen[84]. Surprisingly, Smith et al. found that several agents that elevated cyclic AMP failed to inhibit collagen-induced Ca^{2+} mobilization but enhanced the level of Ca^{2+} mobilization commensurate with the increase in adhesion. In addition, and in contrast to activation by thrombin, neither collagen-induced secretion nor phosphatidic acid formation was decreased by elevation of cyclic AMP. In addition, the collagen-induced tyrosine phosphorylation of platelet proteins was not inhibited by elevation of platelet cyclic AMP levels[85]. The significance of these results became clearer when it was proposed that collagen signal transduction occurs through a tyrosine kinase-dependent activation of phospholipase $C\gamma2$[86,87]. This mechanism for collagen-induced signalling is now well established and significantly different from the mechanism for G protein-coupled receptors. Figure 20.2 shows the effect of elevation of either cyclic AMP or cyclic GMP on collagen-induced Ca^{2+} mobilization. While ADP-induced Ca^{2+} mobilization is substantially inhibited by elevated cyclic nucleotides, collagen mediated Ca^{2+} signalling is almost unaffected either in the absence or presence of the excellular calcium chelator EGTA. In the case of carbacyclin-treated platelets, some enhancement of Ca^{2+} mobilization is seen due to enhanced adhesion[84].

Consistent with the effect of collagen, Riondino et al.[88] found that it is possible to bypass cyclic AMP's inhibitory effect on fibrinogen binding site exposure induced by the thromboxane A2 synthetic analogue U46619, the snake venom toxin convulxin, or by the direct PKC activator OAG, by concomitantly activating a Gi-coupled receptor by means of epinephrine or by inducing cytosolic calcium influx by means of ionomycin.

Level of cyclic GMP and inhibition of platelet activation

The effects of elevated cyclic GMP are difficult to distinguish from those of cyclic AMP. Again, a small increase in cyclic GMP appears to be sufficient for inhibition of platelet activation by agonists. A major problem is the fact that increases in cyclic GMP result in increases in cyclic AMP via inhibition of PDE3. In addition, there is evidence for cross-talk between the two cyclic nucleotide systems at the level of protein kinases[53]. For example, cyclic AMP can activate PKG I.

Protein phosphorylation induced by elevated cyclic GMP

There are no major differences in the proteins phosphorylated in platelets when cyclic GMP is elevated from those seen with the elevation of cyclic AMP[62]. As mentioned above, it has been shown that VASP is a substrate for both PKA and PKG[67]. In addition, the IP3 receptor appears to be phosphorylated by cyclic GMP-dependent mechanisms[82].

Protein kinase G I deficient mice

One of the best pieces of evidence implicating the cyclic GMP pathway is from a mouse model in which the mice are PKG I-deficient[47]. The authors studied platelet–endothelial cell and platelet–platelet interactions in an ischemia/reperfusion model. Platelet PKG I but not endothelial or smooth muscle PKG I was found to be essential to prevent intravascular adhesion and aggregation of platelets after ischemia. The authors conclude: 'the defect in platelet PKG I is not compensated by the cAMP/cAMP kinase pathway supporting the essential role of PKG I in prevention of ischemia-induced platelet adhesion and aggregation.'

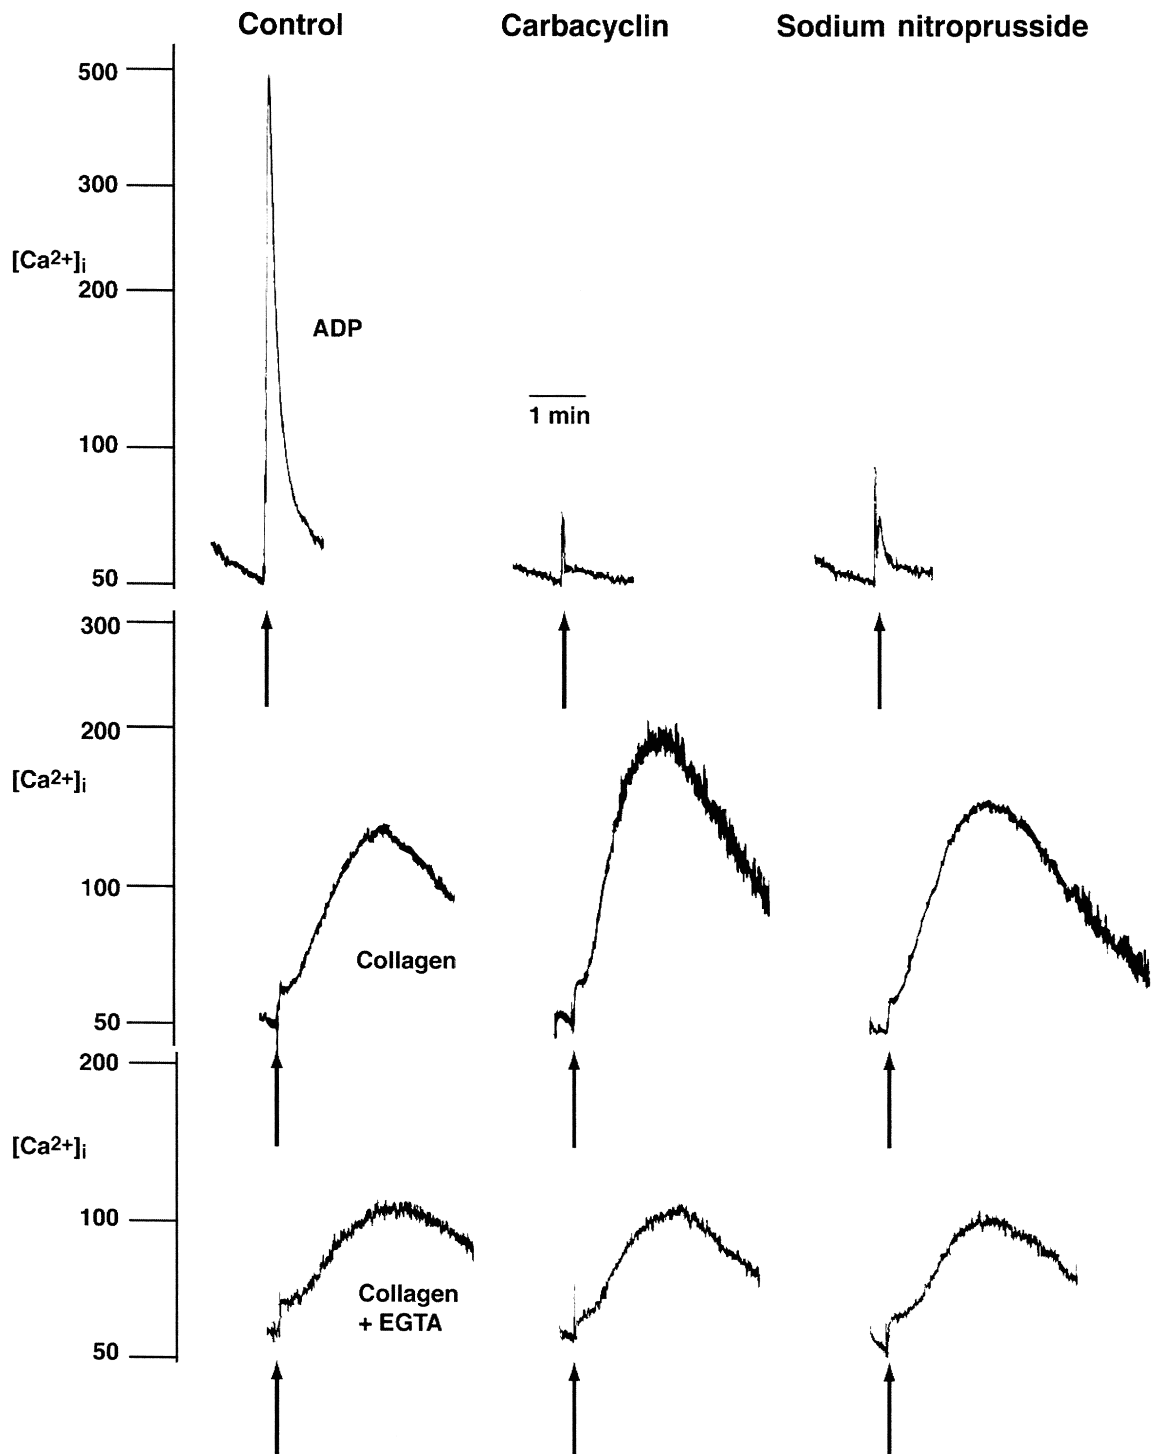

Fig. 20.2. The effect of elevated cyclic nucleotides on collagen-induced Ca^{2+} mobilization. Platelets were aspirinated and loaded with Fura-2. Collagen samples were treated with creatine phosphate (20 mM), creatine phosphokinase (50 U/ml), and 1 mM SC57101 (an aggregation inhibitor). ADP samples contained 1 μM SC57101. Collagen samples were stimulated with 50 μg/ml of Horm collagen. ADP samples were stimulated with 10 μM ADP. The EGTA samples contained 0.5 mM EGTA. Cyclic AMP was elevated with 100 nM Carbacyclin an analogue of prostacyclin. Cyclic GMP levels were elevated with 100 μM sodium nitroprusside.

Conclusions

After one third of a century the exact mechanism by which cyclic nucleotides inhibit platelet function remains unknown. Of the several possible mechanisms, none can fully explain the difference between the effects of elevated cyclic nucleotides on G protein-coupled events and collagen-induced platelet activation. It seems likely that this difference points to either G proteins themselves or one of the various isoforms of phospholipase C as targets of cyclic nucleotide regulation. There has been one report that PKG II can regulate Gαq through both phosphorylation of Gαq and by binding to Gαq[89]. Since G protein-coupled agonists activate phospholipase C of the β isoform, the effects of cyclic nucleotides could be explained if β but not γ2 isoforms of phospholipase C were inhibited by cyclic nucleotide-dependent phosphorylation. It has been shown that PKA directly phosphorylates serine residues of the PLC-beta 2 in vivo and in vitro[90]. Cyclic AMP-dependent protein kinase specifically inhibits G$\beta\gamma$-activated PLC-beta 2 activity. Recently, it has been shown that both phospholipase C-β2 and phospholipase C-β3 can be phosphorylated by both PKA and PKG[91,92] by expressing phospholipase C-β3 in COS cells this group showed that phosphorylation of a specific serine inhibited Gαq-stimulated PLCβ3 activity. Whether this mechanism accounts for cyclic nucleotide-dependent inhibition of platelet activation remains to be seen. However, inhibition of PLCβ would account for the difference seen between platelet activation by collagen and by other agonists.

Platelet adhesion

Philip G. de Groot and Jan J. Sixma

Department of Haematology, University Medical Center, Utrecht, The Netherlands

Platelets contribute to the maintenance of the normal circulation of blood through the vasculature by taking care of the integrity of the vessel wall[1]. They continuously 'examine' the inner lining of the vessel wall for leakage without adhering to the intact endothelial cell lining. They respond immediately, however, when the endothelium is injured and they rapidly adhere to the exposed subendothelial structures[2]. After the adherence of a first layer of platelets a series of complicated reactions are initiated that finally result in the formation of a platelet plug stabilized by an insoluble fibrin network. This so-formed hemostatic plug prevents further loss of blood. Platelets, however, cannot distinguish between a dissected vessel wall, which results in bleeding wounds, and superficial lesions of the endothelium occurring in atherosclerosis. Adhesion of platelets to these superficial lesions may be the onset of the formation of a plug in an intact vessel, a mural thrombus that occludes a blood vessel and prevents the supply of blood to a vital organ, resulting in a serious pathological condition, such as heart attack and stroke.

Platelet adhesion is the first step in the hemostatic response and knowledge of the mechanisms of platelet adhesion is an important lead to the development of selective antithrombotic drugs. The adhesive proteins responsible for optimal platelet adhesion are different from adhesive proteins involved in the adhesion of other cells. Platelet adhesion has several unique features. Platelet adhesion occurs in flowing blood, which means that the adhesive process must occur rapidly and the interaction must be firm enough to resist the shear forces of the flowing blood. This has led to the evolution of adhesive receptors and ligands that are unique for platelet adhesion.

General mechanism of adhesion

Before the first interaction of a platelet with the injured vessel wall, von Willebrand factor present in plasma will bind to exposed collagens present in the vessel wall[3]. The initial contact of platelets can then take place via the interaction of the platelet receptor complex GPIb/V/IX with the immobilized von Willebrand factor (vWF)[4]. This interaction initiates the tethering of circulating platelets to the vessel wall[5]. Platelets roll over von Willebrand factor in the direction of flow driven by the shear forces (Fig 21.1). A continuous loss of GPIb–vWF interactions at one side of the platelet and the formation of new interactions at the other side of the platelet support the rolling process[6]. The rolling of the platelet will finally end in firm attachment through the participation of other platelet membrane receptors, some of which become available via activation of the rolling platelets. The adhesion of platelets to subendothelium involves, besides the GPIb/V/IX complex, the functioning of at least four other receptors: the collagen receptors $\alpha_2\beta_1$[7] and GPVI[8,9], the fibronectin receptor $\alpha_5\beta_1$[10] and the fibrinogen receptor $\alpha_{IIb}\beta_3$ (GPIIbIIIa)[11]. Spreading of the platelet will follow the firm adhesion and is essential to withstand the shear forces exerted by the flowing blood. GPIIbIIIa mediates the spreading of the platelets[12]. Before the firm adhesion and spreading is established, part of the platelets will detach and return to the circulation[13]. The spread platelet is a new surface for a next platelet to adhere to and is the basis of a platelet aggregate. Historically, platelet adhesion and platelet aggregate formation were considered as two separate stages of the formation of a thrombus. Nowadays, the similarities between adhesion and aggregation are more prominent[14,15]. For both adhesion and aggregation, circulating platelets must attach to an adhesive protein, while shear forces are generated on the platelet by the flowing blood. An adhered and subse-

quently spread platelet binds fibrinogen and von Willebrand factor from the circulation to GPIIbIIIa and GPIb, respectively, creating an ideal surface for the next platelet to adhere. Although platelet adhesion is dependent on additional receptors such as $\alpha_2\beta_1$ and aggregation is strongly supported by responses to thrombin and ADP, the fundamental mechanism for both processes, an interaction between a platelet receptor (GPIIbIIIa and GPIb/V/IX) with its substrate (fibrinogen and vWF) in flowing blood is similar[16,17,18]. This is highlighted by the important observation that, both for adhesion and aggregation, the importance of von Willebrand factor increases with increasing shear rate.

Influence of shear stress

Knowledge of the rheological factors that influence the adhesion of platelets was greatly enhanced by the development of perfusion chambers[19]. These chambers enable the study of platelet adhesion under conditions of flow. The relevant fluid dynamic factors to describe the influence of flow on platelet adhesion are shear rate (γ) and shear stress (τ)[20]. The fluid shear stress is defined as the tangential force per unit area exerted in the direction of flow. In case of a liquid obeying Newton's Second Law, the shear stress is proportionally related to the shear rate: $\tau = \eta.\gamma$ in which η is the viscosity of the blood. Shear rates and shear stresses can be calculated for various parts of the vasculature from the known vascular diameter and volume flow rates (Table 21.1). The shear rates are low in large vessels but increase up to 5000 s^{-1} in capillaries. The shear rates in stenosed arteries are even much higher. One should keep in mind that the calculations of shear rate and shear stress are based on a simplified model. All the calculations are based on a steady flow and not on pulsatile flow. The calculations are also related to laminar flow, while branching and abnormal vascular curvature will strongly influence rheology. Also blood is not a Newtonian fluid, the viscosity of blood is not constant but decreases with increasing shear rates. The non-Newtonian flow properties of whole blood are due to the presence of red blood cells as they are the major part of the cellular volume of the blood. Nevertheless the use of shear rates and shear stress enables us to describe the role of blood flow in platelet adhesion.

One of the main factors determining platelet adhesion is the transport of platelets to the vessel wall surface. This process is driven by the shear rate of the blood in combination with the presence of red cells. Platelet adhesion increases with increasing shear rate up to about 2000 s^{-1}. At higher shear rates, platelet adhesion remains more or less unchanged till shear rates of 5000 s^{-1}. The distribution of red cells in flowing blood is not homogeneous. Red cells are concentrated in the middle of the stream, while the smaller platelets are pushed aside towards the vessel surface due to collisions with the red cells. The consequence is that the local concentration of platelets near the vessel wall increases with increasing shear rate. The increased local platelet concentration is one of the main reasons for the increased adhesion found with increasing shear rate. Two rate-limiting mechanisms can be distinguished for platelet adhesion[21]. When the wall shear rate is low (<300 s^{-1}), the adhesion is diffusion controlled. When the wall shear rate is high (>1300s^{-1}), the adhesion is reaction controlled. In the area in-between both shear rates both processes contribute.

Table 21.1. Fluid dynamic parameters

Vessel	Diameter (cm)	Wall shear rate (s^{-1})	Wall shear stress (dyne/cm^2)
Aorta ascendens	2.3–4.5	50–300	2–10
Arteria femoralis	0.5	350	11
Small arteries	0.03	1500	55
Capillaries	0.0006	2000–5000	[a]
Large veins	0.5–10	200	7
Vena cava inferior	2.0	50	2
Stenosed arteries	0.025	40 000	3000

Notes:
The results presented are from references [20, 133, 134, 135, 136] and [137].
[a] Calculations are not meaningful since flow regime is totally different and bulk viscosity is not applicable.

The transport of platelets by the red cells is dependent on the hematocrit, red cell rigidity and red cell size. The rotation of the red cells enhances the diffusion of the platelet to the vessel wall[22]. This effect is dependent on the rigidity of the red cells. Together with the plasma viscosity the red cell rigidity determines the viscosity of the blood[23]. An increase in plasma viscosity will result in an increase in platelet deposition[24]. The increased blood viscosity found in patients with, e.g. diabetes mellitus might explain in part the increased thrombotic tendency that has been found in these patients.

The influence of shear forces on platelet adhesion is depicted in Fig. 21.2. The influence of shear can be described by the factors influencing the concentration of platelets in the boundary layer near the vessel surface (diffusion controlled) and by the affinity of the receptors for their adhesive proteins in combination with the forces exerted on the platelet (reaction controlled). Platelet con-

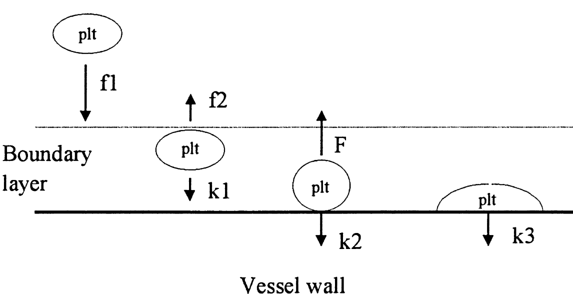

Fig. 21.2. Schematic representation of the hemodynamic and biochemical processes involved in platelet adhesion under flow. Platelet concentration in the boundary layer is increased due to convective diffusion of platelets from the bulk concentration (f1) and Brownian diffusion from the boundary layer (f2), resulting in an equilibrium concentration. Platelets will attach with a certain rate (k1) and will adhere with certain affinity (k2). After spreading of the cells the affinity increases (k3). Shear forces (F) will detach (a fraction of the) platelets resulting in transport back into the bulk concentration.[137].

centration in the boundary layer is determined by convective diffusion from the bulk concentration and Brownian diffusion, resulting in an equilibrium concentration. Platelets will attach to proteins present in the vessel wall with a certain velocity (k_1), adhere with a certain affinity (k_2) and firmly attach with another affinity (k_3). Shear forces will try to detach platelets (F) resulting in a platelet transport from the wall.

Platelet–vessel wall interaction at the molecular level, the adhesive proteins

Various components of the subendothelium, including von Willebrand factor, various types of collagen, fibronectin and fibrinogen, can act as substrate for platelet adhesion[25]. Most studies on platelet adhesion have been performed with isolated proteins and we can now describe and understand the interaction of platelets with single proteins. The individual contributions of these proteins to the interaction of platelets with a much more complex subendothelium remain to be investigated. On the one hand, there may be synergy of multiple substrate receptor interactions whereas on the other hand, mutual interactions between proteins in the subendothelium might specifically shield off certain adhesive domains. It is apparent, however, that vWF is essential and unique in tethering rapidly flowing platelets to an exposed thrombogenic surface.

Von Willebrand factor

vWF is an adhesive protein that circulates in plasma but that is also present in the subendothelium and in α-granules of platelets. It is synthesized by endothelial cells and megakaryocytes[26,27]. The average plasma concentration is 10 µg/ml, the average concentration in the platelet is 280 ng/10^9 platelets[28]. The normal range of plasma vWF, however, is broad and is strongly influenced by the blood group with 25% lower levels in blood group O and high levels in persons with the AB loci[29]. Platelet vWF is independent of ABO blood type. vWF is a multimeric protein that interacts with ligands in the subendothelium and on platelets. It bridges the platelet and the surface that otherwise poorly interact under conditions of shear. The multimeric structure is essential for its biological activity. Low molecular weight forms as found in patients with type 2A von Willebrand disease lack adhesive activity[30]. The multimeric structure results from connection of two C-termini by disulfide bonds followed by disulfide bonds between N-termini, resulting in a long thread with a molecular weight of over 20 million[31]. vWF in the circulation does not bind spontaneously to platelets. When damage of the vascular surface occurs, vWF will bind immediately to the exposed collagens[3]. The interaction with collagen results in 'activation' of vWF, which enables the recognition of vWF by platelet GPIb/V/IX complex. The activation of vWF must be a conformational change, but the mechanism of activation has not been elucidated yet. Recently, the conformational change due to a gain of function mutation in vWF has been elucidated by crystallization of the A1 domain of a I546V mutant[32]. The I546V substitution alters the charge distribution within the proposed GPIb binding site at a significant distance from the mutation. The interaction between vWF and platelet glycoprotein GPIb can also be promoted in vitro by an obsolete antibiotic ristocetin and the snake venom protein botrocetin[33,34] or by mutations in vWF or GPIb[35]. These mutations in vWF and GPIb are also effective in vivo.

Mature vWF-monomer is built up of a number of domains[36] (Fig. 21.3). These domains are thought to be independent structural and functional units of the protein. The domains are arranged in the order D–D3–A1–A2–A3–D4–B1–B2–B3–C1–C2–CK. The A1- and the A3-domains in vWF have been identified as the main binding sites for GPIb and collagen, respectively. Within the C1-domain an RGD sequence is present that is responsible for the interaction of vWF with platelet GPIIb–IIIa[37]. Studying loss- or gain-of-function mutations has identified lysine 599 within the vWF A1-domain as essential for the interaction with GPIb[38]. The interaction of ristocetin and botrocetin with vWF could be dissociated within the A1-domain[38].

Cambridge Books Online © Cambridge University Press, 2009

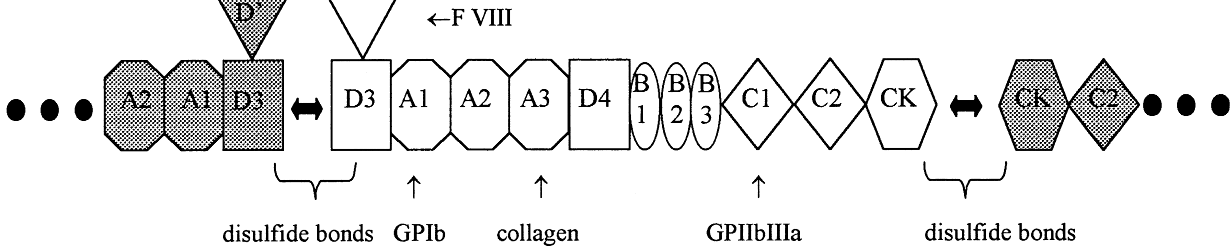

Fig. 21.3. The schematic structure of vWF is shown. The location of binding sites for several ligands are indicated. In the endoplasmic reticulum, von Willebrand monomer is dimerized through disulfide linkage through the cysteine knot (CK domains) at their carboxy termini. In the Golgi large multimers are formed through additional disulfide bonds in the D3-domains.

Ristocetin-induced binding to GPIb was reduced selectively by substitutions in the A1-domain at positions Lys-534, Arg-571, Lys-572, Glu-596, Glu-613, Arg-616, Glu-626, and Lys-642, whereas botrocetin-induced binding to GPIb was decreased selectively by mutations at Arg-636 and Lys-667.

Recently, the crystal structures of both the A1- and the A3-domain have been elucidated[39,40,41]. Both domains are similar in organization and related to A- or I-domains found in integrins. Both domains have a typical α/β fold, consisting of a central hydrophobic parallel β-sheet flanked by amphipathic α-helices on each side. The difference with the homologous A-domains of integrins is that the typical metal ion-dependent adhesion site (MIDAS) motif is incomplete and a metal ion is not present. Consequently, the binding site for GPIb and collagen is not localized in the MIDAS site, where the binding sites are located in integrins.

To localize the collagen-binding site, the crystal structure of a complex of A3 with a Fab fragment of an antibody that inhibits collagen binding was determined. The antibody recognized a non-linear epitope located distant from the top face of the domain, where collagen-binding domains were found in homologous integrin I-domains. The domain consists of sequences 962–966, 981–997 and 1022–1026. With this information as a lead, site-directed mutagenesis was performed that identified His 1023 within the A3-domain as essential for the interaction with collagen type I. Also, mutation of Arg-963 and Arg-1016 reduced collagen binding by 25%[42]. The residues are part of a domain consisting of two β-sheets and one α-helix. His-1023 displays multiple conformations in available A3-crystal structures suggesting that binding of A3 to collagen involves changes in the conformation[40,41].

Collagens

Collagens are distinguishable from other extracellular matrix proteins by their triple helical conformation[43]. All fibrillar collagens have a very similar tertiary protein structure. These collagens are composed of three peptide chains (α-chains). The amino acid sequences of the α-chains show two unique features. There is a glycine at every third residue, generating a repeating $(\text{Gly–X–Y})_n$ pattern and a high proportion of the X and Y residues are proline or hydroxyproline. These features of collagen are essential for the generation and stability of the triple helix. The triple helix conformation consists always of three parallel polypeptide chains that are staggered by one amino acid. The glycine residues are buried in the backbone of the helix while the X and Y are exposed to the solvent[44]. The amino acids at the X and Y position determine the specificity of collagen for certain interactions. The triple helix conformation of collagen is essential for its interaction with cells; a single chain collagen polypeptide has lost its biological activity[45,46]. Apparently, the 3D-conformation of the amino acid sequence is critical. Also platelet adhesion and activation under conditions of flow only occur when the tertiary structure is intact.

At present, 19 different types of collagens have been identified of which collagen types I, III, IV, V, VI, VIII and sometimes XI occur in the vessel wall. These collagens can be broadly divided into reactive and less reactive types for platelets of which collagen types I, III and IV belong to the reactive ones[47]. These three major types of collagen support platelet adhesion also at relatively high shear rates and also cause platelet aggregate formation. These collagens have separate sites for adhesion and aggregation[48]. Platelet adhesion to collagen is strongly affected by the presence of Mg^{2+} and Ca^{2+}[49]. Platelet adhesion to collagen is stimulated by the presence of Mg^{2+} whereas Ca^{2+} has an inhibitory effect. Mg^{2+} mediates its effect via the collagen receptor $\alpha_2\beta_1$. Collagen type VI has been shown to be a binding site for vWF in the subendothelium and, as such, it is involved in platelet adhesion to superficial injuries in vessels[50].

Platelet reactive adhesive domains in collagen are deter-

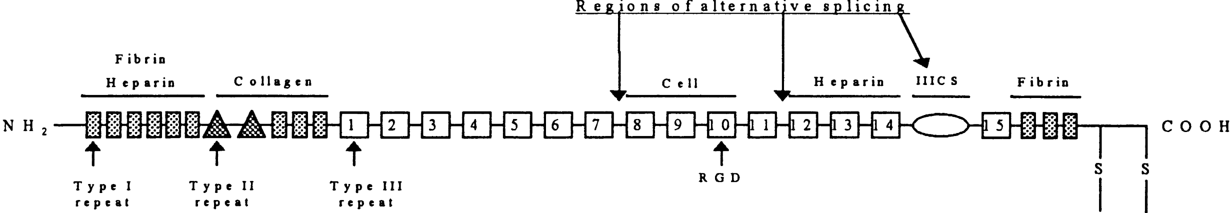

Fig. 21.4. Diagram of the fibronectin subunit.

mined by linear sequences present in one chain. The first sequence described as a recognition site for $\alpha_2\beta_1$, DGEA present within the α1-chain of collagen type I, was suggested to be independent of conformation[51]. However, others were unable to confirm the data and the role of DGEA as an $\alpha_2\beta_1$ recognition site is questionable. Examination of synthetic peptides with the basic structure of collagens, glycine–proline–hydroxyproline $(GPO)_n$, showed that they are very potent activators of platelet aggregation[52]. Polypeptides consisting of GPO-triplets spontaneously form a triple helical conformation and it has been shown that this sequence interacts with the collagen receptor GPVI on platelets. Although the GPO sequence contributes to the overall mechanism of platelet adhesion to collagen, GPVI is the primary collagen receptor on platelets for activation and not for adhesion[53,54]. The primary adhesive receptor on platelets is $\alpha_2\beta_1$[55]. Elegant experiments using overlapping peptides derived from cyanogen bromide fragments of collagen type I, have elucidated an $\alpha_2\beta_1$ recognition site in collagen type I, GFOGER[56]. Triple helical peptides containing this sequence inhibit platelet adhesion not only to collagen type I but also to collagen type III. Recently, the crystal structure has been elucidated of a complex between the I-domain fragment of the α_2-chain of the platelet receptor $\alpha_2\beta_1$ and the synthetic collagen peptide containing the critical GFOGER-sequence that mimics the collagen-binding site[57]. Integrin I-domains contain a divalent cation binding site. In the I-domain of the α_2-chain this metal ion is Mg^{2+}. Three loops on the upper surface of the I-domain provide five amino acid side chains that coordinate the Mg^{2+}. The sixth coordination site of the bound magnesium was provided by the glutamate present in the peptide, completing the coordination sphere of the metal. The interaction between collagen and the I-domain is supported almost exclusively by one of the three α-chains of the triple helix.

An octapeptide sequence KOGEOGPK has been described within the α1-chain of collagen type III (residues 497–504) that was able to support platelet adhesion under conditions of flow[58]. Recently, a new collagen-binding protein, TIIICBP, with a molecular weight of 68 kD, that recognizes this sequence has been isolated[59]. The peptide inhibited platelet adhesion to collagen type III but not to collagen type I. The status of this sequence, however, remains controversial as others never found adhesion to triple helical peptides containing this sequence[60].

Fibronectin

Fibronectin is a ubiquitous glycoprotein composed of two structurally similar but non-identical subunits of approximately 220 kD. The two chains are different due to alternative splicing in the so-called III connecting segment (IIICS)[61]. Two forms of fibronectin exists, a soluble plasma form that is produced by hepatocytes and that consists of a disulfide-bonded dimer[62] and a tissue form of fibronectin that is insoluble and occurs in high molecular weight forms. The tissue fibronectin differs also from plasma fibronectin in an extra type III domain, again due to alternative splicing. Each subunit of fibronectin is composed of three types of homologous repeats, type I, type II and type III. The tenth type III repeat contains the RGD sequence that can interact with GPIIbIIIa or $\alpha_5\beta_1$ on the platelet membrane (Fig. 21.4).

Purified fibronectin supports platelet adhesion and spreading up to shear rates of 1300 s^{-1} [10]. The adhesion is mediated by both $\alpha_5\beta_1$ and GPIIb–IIIa while the spreading is dependent on GPIIb–IIIa. Under conditions of flow, interaction between GPIb and von Willebrand factor is necessary for optimal adhesion[63]. The presence of von Willebrand factor in platelets is sufficient. In a more complex substrate, such as a subendothelium, fibronectin has an additive role. Under these conditions it is not the RGD-site in domain III-10 that is involved, but an, as yet not very well characterized, site in domain III-9[64]. A candidate is the PHSRN sequence in the 9th repeat recognized by the integrin $\alpha_5\beta_1$[65].

Fibrinogen/fibrin

Fibrinogen is not a structural component of the vessel wall, because vessel wall cells do not synthesize it. Nevertheless it is present in vessel wall segments as the result of adsorption from plasma. It is one of the major substrates for

Cambridge Books Online © Cambridge University Press, 2009

platelets. Platelet adhesion to fibrinogen has received much attention, because fibrinogen is the dominant plasma protein to adsorb to biomaterials. As a consequence, the adsorbed fibrinogen provides an ideal surface for platelets to adhere[66]. Also, the adhesion of platelets to a fibrin network is a key event in the maintenance of a hemostatic response. Studies with monoclonal antibodies show that GPIIbIIIa is the major receptor involved in the adhesion to fibrin and fibrinogen at all shear rates[67]. Fibrinogen has three potential reactive domains that are able to interact with GPIIbIIIa. There is a RGDS sequence between residues 572 and 575 and a RGDF sequence between residues 95 and 98 on the α-chain, and AGDV sequence at position 407–411 of the γ-chain. Studies with recombinant fibrinogens have shown that the RGD sequences are not important for platelet adhesion whereas the sequence in the γ-chain is essential[68,69].

Platelet adhesion to fibrin and fibrinogen at high shear rates ($>500\ s^{-1}$) depends not only on the interaction via GPIIbIIIa but also on a secondary interaction between vWF and GPIb[70]. This second interaction is necessary to enable the anchored platelets to withstand the shear forces. The participation of vWF in platelet-fibrin interaction is indirect. vWF must first bind to platelets before it can interact with fibrin. Without platelets no interaction of vWF with fibrin is seen. The underlying molecular mechanism is not clear but may be explained by two effects. First, the local concentration of vWF will be increased as more vWF filaments are held near the surface. This will enhance binding through a mass action effect. Secondly, there is an entropy term that must be considered in any binding reaction. A strong decrease in entropy loss after binding of vWF to platelets may facilitate the interaction of vWF with fibrin.

While non-stimulated platelets express GPIIb–IIIa on the platelet membrane, binding of soluble fibrinogen only takes place after stimulation of platelets with agonists, resulting in a transformation of GPIIb–IIIa into a functional state. However, fibrinogen adsorbed on a surface supports adhesion of non-stimulated platelets via GPIIb–IIIa[71].

Laminin

Laminin is a ubiquitous basement membrane protein[72]. The molecule, as visualized by rotary shadowing, is a cross-shaped molecule with a molecular weight of 850 kDa. It consists of three distinct chains of 400 kD, 215 kD and 205 kD, and it interacts with collagen type IV and heparan sulphate proteoglycans to form the structural part of the basement membrane. Platelet adhesion to laminin is mediated by the integrin $\alpha_6\beta_1$[73]. Adhesion to laminin is strongly dependent on the presence of the divalent cations Mg^{2+} and Ca^{2+}. Antibodies directed against the E8 domain, the terminal half of the long arm, completely inhibit adhesion. The participation of laminin to the platelet reactivity of the more complex subendothelium is unknown.

Platelet-vessel wall interaction at the molecular level: the platelet receptors

Proteins of the integrin family are central molecules in the adhesion process[74]. They mediate cell–cell communications and cell-extracellular matrix interactions. They are heterodimers composed of an α and a β-subunit, both transmembrane glycoproteins. Up to 17 different α-subunits and 8 β-subunits have been identified, leading to a large number of dimers with different biological functions. Platelets contain four integrins involved in platelet–substrate interaction: $\alpha_2\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$ and $\alpha_{IIb}\beta_3$ (= GPIIb–IIIa), the receptors for collagen, fibronectin, laminin and fibrinogen, respectively. Besides integrins also the GPIb–IX–V complex, a platelet specific complex consisting of members belonging to the leucine-rich protein family[4] and GPVI, a member of the immunoglobulin superfamily[75], are essential for optimal platelet adhesion.

Glycoprotein Ib/V/IX

The GPIb–V–IX complex is made up of four distinct gene products[76,77]. The disulfide bonded GPIbα and GPIbβ are non-covalently linked to GPIX and GPV. The four polypeptides GPIbα, GPIBβ, GPIX and GPV are present in a 2:2:2:1 stoichiometry. GPIb–V–IX is constitutively expressed on the platelet surface with about 25 000 copies/platelet. It does not bind spontaneously to vWF, it requires either association of vWF with a surface or, alternatively, exposure of the platelets and vWF to high shear rate in vivo ($>10\,000\ s^{-1}$)[78]. GPIb has also been identified as a thrombin-binding site on platelets[79]. Activation of platelets with thrombin results in a 50% down-regulation of GPIb. The down regulation does not influence platelet adhesion; 10 000 copies of the complex per platelet are enough for optimal adhesion[80]. A number of studies have localized the vWF-binding site to the N-terminal domain of GPIα[81]. The most potent inhibitor is a 45kD N-terminal fragment (His1–Arg293). This suggests that the interaction of the complex with vWF requires conformational dependent epitopes that could not be mimicked by linear peptides. The binding site for vWF within this domain consists of more than one site. One binding site is the sulfated tyrosine sequence Tyr276–Glu282 containing sulfated tyrosines at Tyr-276, Tyr-278 and Tyr-279[82]; the other binding site is located in the leucine-rich repeats 2, 3, and 4 of GPIbα[83].

Congenital abnormalities present in three chains of the complex, GPIbα, GPIbβ and GPIX are associated with the

Cambridge Books Online © Cambridge University Press, 2009

Bernard–Soulier syndrome. Most of the mutations found lead to truncated or defective polypeptides and are not informative for the localization of the binding site. Two mutations have been described leading to in-frame substitutions in the first and sixth leucine-rich repeat resulting in a dysfunctional GPIb complex[84,85]. Whether these mutations disrupt an adhesive site or the conformation of the whole domain is unknown.

GPIIb–IIIa

Glycoprotein IIb–IIIa ($\alpha_{IIb}\beta_3$) is the most abundant platelet receptor[86]. It is a receptor for fibrinogen, fibronectin, vitronectin, von Willebrand factor and thrombospondin. It is not only involved in platelet aggregation but also in platelet adhesion. Both the α-subunit and the β-subunit on GPIIb–IIIa contribute to binding of ligands[87]. It is not known whether the α- and β-subunit ligand binding regions form one extended binding area or are separate binding sites recognizing different epitopes in the ligand. The amino-terminal 334 amino acids of α_{IIb} have been implicated in the ligand binding[88]. Mutations in the sequence 184–193 (GAPGGYYFLG) significantly decrease binding of $\alpha_{IIb}\beta_3$ to soluble fibrinogen without affecting the expression of $\alpha_{IIb}\beta_3$[89]. The sequence between the disulfide bond Cys-146–Cys-167 is also involved in ligand binding. An (Asp-163–Ala) mutation abolishes ligand-binding properties, indicating that this residue might be critical for ligand binding[90]. The Ca^{2+} binding sites in GPIIb are essential for the maintenance of the proper conformation of GPIIb–IIIa but seem not to be involved in ligand binding.

Thrombopoietin (TPO) is a major regulator of platelet formation in vivo[91]. In vitro studies suggest that TPO sensitizes platelets for activation by several agonists[92]. Experiments in our laboratory have shown that the changed affinity and/or avidity of the integrin GPIIb–IIIa results in an inhibition of platelet rolling and a rapid firm adhesion immediately after the first adhesion. The decreased time period for de-adhesion of platelets results in an increased platelet adhesion to fibrinogen and von Willebrand factor[93]. These observations show that the activation stage of platelet receptors determines the final amount of platelet adhesion.

Collagen receptor α2β1

In 1985, a patient with a hemorrhagic disorder and an excessively long bleeding time was described. The patient's platelets were only non-responsive to collagen, they responded normally to other platelet stimuli. Analysis of the platelet membrane glycoproteins showed that the platelets were deficient in glycoprotein Ia which is the α2-chain of the integrin $\alpha_2\beta_1$[7]. Platelet adhesion to collagen and subendothelium was almost absent[94]. Additional experiments with antibodies and purified receptor confirmed that $\alpha_2\beta_1$ is the major adhesion receptor on the platelet for collagen[95]. Platelet $\alpha_2\beta_1$ levels among randomly selected individuals can vary up to tenfold; this correlates with differences in adhesiveness to type-I or type-III collagens[96]. The N-terminal region of the α2-chain contains seven tandem repeats with internal homology[97]. In addition, it contains an inserted segment of about 200 amino acids in between the second and third repeats. This so-called insertion domain or I-domain has homology with A-domains present in vWF and it contains the collagen-binding site[98].

The I-domain of the α2-chain has been crystallized in the absence and presence of GPO-peptides[58]. Comparison of the liganded domain with the non-liganded I domain reveals a change in metal coordination linked to a reorganization of the upper surface that together create a complementary surface for binding collagen. Conformational changes propagate from the upper surface to the opposite pole of the domain, suggesting both a basis for affinity regulation and a pathway for signal transduction.

According to the crystal structure, the aspartic acid-219 of the I domain forms a salt bridge with Arg in the GFOGER sequence and the side chains of the phenylalanine of this sequence interact with glutamine-215, asparagine-154, tyrosine-157 and leucine-286.

Collagen receptor GPVI

Recently, the platelet collagen receptor glycoprotein (GP) VI was cloned[75]. It codes for a protein of 339 amino acids including a putative 23-amino acid signal sequence and a 19-amino acid transmembrane domain between residues 247 and 265. GPVI belongs to the immunoglobulin superfamily, and its sequence is closely related to $F_c\alpha R$ and to the natural killer receptors. Purified GPVI, as well as Fab fragments of polyclonal antibodies made against the receptor, inhibited collagen-induced platelet aggregation. An arginine residue is found in position 3 of the transmembrane portion, which should permit association with $F_c\gamma$ and its immunoreceptor tyrosine-based activation motif via a salt bridge. With 51 amino acids, the cytoplasmic tail is relatively long and shows little homology to the C-terminal part of the other family members. No information is available yet about domains involved in binding to the GPO motif in collagen and no mutations have been described influencing platelet adhesion.

Fibronectin receptor

The fibronectin receptor $\alpha_5\beta_1$ binds simultaneously to a PHSRN sequence in the 9th type III repeat of fibronectin

Cambridge Books Online © Cambridge University Press, 2009

and the RGD-sequence in the 10th type III repeat[65]. The X-ray crystal structure of a fibronectin fragment reveals that both binding sites are located 35 Å apart on the same side of the molecule[99]. The recombinant fragment 229–448 of the α5-subunit contains the minimal domain for fibronectin recognition[100].

Genetics of platelet adhesion

Platelet thrombus formation is a multistep process determined by the platelet receptors GPIb, GPIIb–IIIa, $\alpha_2\beta_1$ and GPVI and their ligands von Willebrand factor, fibrinogen and collagen. The recent developments in genetic technology have resulted in the discovery of polymorphisms coding for qualitative or quantitative variation of these determinants in platelet thrombus formation. The genetic markers proved to be important determinants to study an etiological relationship between these markers and the risk of cardiovascular diseases in large prospective evaluations. A major functional polymorphism in platelet receptors is a 807T polymorphism of $\alpha_2\beta_1$ coding for an increased density of $\alpha2\beta1$ on the platelet membrane[96]. The presence of this 807 T polymorphism correlates with cardiovascular mortality. In separate studies it was shown that the presence of this 807T polymorphism resulted in an increased adhesion to collagen in vitro[101,102]. Other polymorphisms are a 5T polymorphism of GPIb coding for increased expression of GPIb[103] and a PI^{A2} polymorphism of GPIIbIIIa coding for a change in structure of GPIIb–IIIa[104], both possibly related to increased cardiovascular accidents.

There are also polymorphisms found in matrix proteins. An interesting genetic variation is the blood group difference. Blood groups AA, AB and BB are predictive for cardiovascular disease probably due to the increased levels of vWF in blood group AB[105,106]. A G/T polymorphism in a transcription factor Sp1 binding site of collagen type I[107] and a G/A polymorphism in the promoter region of the fibrinogen β-chain, which is associated with elevated fibrinogen levels[108,109] are other interesting genetic markers for an increased risk of platelet thrombus formation.

Platelet adhesion in disease

Thrombocytopenia

Optimal platelet adhesion depends on the platelet number. The normal range of circulating platelet counts $\times 10^9$ is $150–400 \times 10^9$/l. A good inverse correlation was found between a bleeding time and a platelet count of between 10×10^9/l and 100×10^9/l. At platelet numbers above 100×10^9/l no abnormalities were found[110]. Platelet adhesion studies in vitro showed a similar relation between adhesion and platelet number; 100×10^9 platelets/l are sufficient for optimal adhesion. At higher shear rates fewer platelets were necessary for optimal adhesion. Whether the bleeding tendency at lower platelet count is primarily due to impaired adhesion or impaired aggregate formation is not known. Bleeding tendency as seen in May–Hegglin syndrome and Wiskott–Aldrich syndrome are primarily explained by the low platelet count.

von Willebrand's disease (vWD)

This is characterized by absence or abnormality of vWF and it is one of the most common inherited bleeding diseases[111,112]. The prevalence of vWD has been estimated at about 100 cases per million persons. vWD is classified in three major categories[35]. Type 1 refers to a partial, quantitative deficiency of vWF. vWD type 2 characterizes all qualitative abnormalities in vWF function, whereas type 3 refers to an essentially complete deficiency of vWF. Type 2 is further subdivided into four variants based on differences in structure-function relation. The bleeding symptoms are mild to moderate for most patients, although life-threatening bleeding may occur, especially in vWD type 3. In vitro experiments showed an adhesion defect at shear rates over 500 s^{-1} [113]. Although platelets of vWD patients did not show defects in platelet aggregation in the aggregometer, there is a defect in thrombus formation when the experiments were performed in flowing blood[114]. The lack of thrombus formation in flowing vWD blood becomes more prominent at higher shear rates. When platelets adhere to more reactive surfaces, vWF present in the α-granules of platelets also participates in adhesion[115,116]. As mentioned above, type 1 refers to a quantitative disorder with a normal multimeric distribution. vWF in plasma has apparently a normal function and the bleeding tendency should correlate with the residual amount of vWF in plasma. However, variations in the bleeding tendency have been seen, partly explained by the amount of vWF present in the platelets. Type 2A is characterized by the absence of large multimers of vWF. The large multimers are the effective form of vWF and the functional activity of vWF is much lower than could be explained by the amount of the antigen. The lower multimers lack the ability to bind to collagen while the interaction with GPIb is still present[117]. The lack of ability of type 2A vWF to bind to collagen could contribute to the bleeding disorder. As vWF is also involved in platelet aggregate formation, the ristocetin agglutination is impaired; an impaired aggregate formation could also be the cause of bleeding. Type 2B is defined by an increased affinity of the mutant vWF for platelet GPIb. This results in spontaneous binding of large multimers to platelets in vivo, followed by a rapid clearance of

Cambridge Books Online © Cambridge University Press, 2009

the complex. The remaining multimers are of low molecular weight and less active. The combination of a thrombocytopenia, lower vWF levels and the prevalence of inactive low multimers explains the bleeding disorder[118]. The loss of platelet adhesion is reinforced because once vWF is bound to a platelet it is unable to bind to collagen any longer. The circulating vWF–platelet complexes are hemostatically inactive. The mutations found in type 2B are all found in and around the A1-domain[119]. Type 2M is characterized by vWF with a normal multimeric structure associated with a defective platelet function. This variant is caused by mutations that inactivate the binding site of vWF for GPIb. All the mutations that have been characterized so far are located within the A1-domain[120]. Mutations that result in an inactive binding site for collagen should also be included in this variant, however, until now such mutations have never been found. Type 2N is characterized by mutations in the binding site for factor VIII. The bleeding tendency mimics hemophilia A and no abnormalities in platelet adhesion are found. Type 3 includes patients with vWF levels less than 1% of normal in plasma. There is a secondary deficiency of factor VIII and the patients have a combined defect in primary hemostasis and fibrin formation. The pathology of platelet adhesion is not different from type 1 because both variants are due to a quantitative defect.

Pseudo-vWD has a clinical picture comparable to type 2B. The mutation, however, is not present in vWF but in GPIb[121,122]. The final result is the same, an increased binding of vWF to platelets, resulting in thrombocytopenia, low vWF levels and a prevalence of inactive low multimeric forms of vWF in the circulation.

Acquired vWD is a rare bleeding disorder, which mimics most of the clinical and laboratory features of vWD[123]. The occurrence of acquired vWD is in most cases explained by the presence of circulating autoantibodies to vWF. The presence of these antibodies can result in clearance of antibody-vWF complexes resulting in a deficiency of vWF or the antibodies can inhibit specific functions of vWF such as the interaction of vWF with collagen[124].

Other bleeding disorders

Absence or abnormal function of the GPIIbIIIa complex characterizes Glanzmann's thrombasthenia[125,126]. This defect results in complete absence of platelet aggregation, but in only a limited decrease in platelet adhesion at higher shear rates[11,127]. The loss of platelet adhesion is probably caused by lack of platelet spreading, which is observed at all shear rates. The lack of spreading results in less firmly attached platelets that are more easily detached at shear rates over $1600 s^{-1}$.

Bernard–Soulier syndrome is a form of macrothrombocytopenia characterized by absence or abnormality of GPIb–V–IX complex[128]. In general the combination of a large platelet size and low platelet number results in a total platelet mass that is not reduced in comparison with the normal situation. Comparison of platelet adhesion in macrothrombocytopenia with that of normal platelets at similar platelet counts has shown no adhesion defect. The severe bleeding tendency seen in Bernard–Soulier syndrome is due to a combination of low platelet number and an absence in GPIb–vWF interaction.

Storage pool deficiency is characterized by reduction of the dense granules in platelets, leading to a reduced secretion of ADP after activation. Platelet adhesion is not affected, a reduced aggregate formation explains the bleeding tendency in these patients[11].

No information is available as to whether increased adhesion will lead to thrombotic complications. Increased levels of vWF have been shown to be an increased risk for cardiovascular events but a correlation with increased adhesion has never been shown. Patients with Diabetes mellitus and Hypercholesterolemia, diseases associated with atherosclerotic vessel disease, showed no increased platelet adhesion[129] (P. de Graaf et al., unpublished observations).

Conclusion

Platelet adhesion is a complex process in which many adhesive ligands and their receptors participate. In spite of considerable progress during the last twenty years, initiated by the development of perfusion chambers that enabled the study of platelet adhesion under conditions of flow, the mechanisms that regulate platelet adhesion remain to be elucidated. Which pathways are responsible for the activation of, e.g. GPIIb–IIIa when a platelet is rolling over vWF? Is this process reversible? A mouse model, in which both von Willebrand factor and fibrinogen were deficient, still showed adhesion and platelet aggregation, pointing to other components in the vessel wall and/or plasma capable of supporting adhesion[130]. A mouse model lacking thrombospondin-2 showed an unexplained bleeding diathesis[131] suggesting a role for thrombospondin in the regulation of adhesion[132]. The observation that the severe bleeding tendency of patients with Glanzmann's disease can be treated efficiently with factor VIIa points to a more intensive interaction between platelet function and coagulation than was originally assumed. Also induction of fibrinolysis may quickly reduce the affinity of surfaces such as fibrin for platelets[62]. Another

not well explored area is the increased reactivity of atherosclerotic lesions[133] that may be the result of inflammatory modulation of the composition of the plaque. Further experiments with genetically modified animals in combination with appropriate experimental flow models will enhance our ability to understand, diagnose and treat bleeding disorders and arterial thrombosis.

The platelet shape change

Adrian R.L. Gear and Renata K. Polanowska-Grabowska

Department of Biochemistry and Molecular Genetics
University of Virginia School of Medicine
Charlottesville, USA

Introduction

Blood platelets respond to many stimuli by changing shape from their resting, normal discoid form into more rounded structures possessing blebs and pseudopodia[1–5]. These morphological transitions are generally referred to as the platelet '**shape change' (SC)**. As described earlier in Chapters 2 and 3, platelets are subcellular fragments derived from megakaryocytes and circulate in the blood as small anucleated ovoid discs, with average dimensions of about 3.0×0.5 μm and volumes of 6–8 fl[6,7]. The surfaces of resting platelets are almost featureless except for indentations or pits that represent entrances into the open-canalicular system (OCS) illustrated in a freeze–fracture micrograph (Fig. 22.1). Platelets exhibit significant heterogeneity in both size, density and biochemical composition[8–12], with a corresponding heterogeneity in aggregation and adhesion characteristics[8,13–15]. Shape-change behaviour is also heterogeneous, such that some platelets will remain discoid while neighbouring cells will have undergone significant morphological changes[16].

The transformations in platelet morphology associated with the SC represent highly sensitive indices of platelet activation. They are generally considered to be the first measurable physiological responses after activation by specific platelet agonists such as ADP or thrombin, and to begin before significant aggregation occurs. Platelet SC is usually characterized morphologically by spheration and contraction of the cell, cytoskeletal rearrangements, folding or ruffling of the surface membrane, and formation of pseudopodia[17,18]. An example of the major changes from the resting discoid shape to more rounded forms possessing multiple pseudopodia is illustrated in Fig. 22.2. Changes in morphology also occur following platelet contact with the foreign particles or surfaces, centrifugation, by exposure to heat, cold, calcium chelation such as with EDTA or EGTA, and by depressed energy metabolism[19–22].

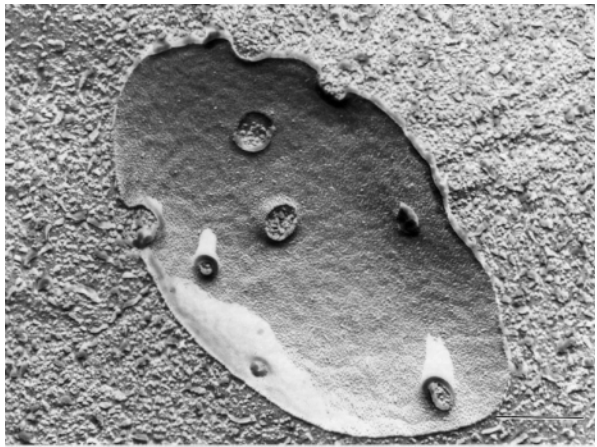

Fig. 22.1. A resting blood platelet. The nearly smooth surface of a blood platelet visualized by freeze- fracture electron microscopy[187] and rapid spray freezing to avoid chemical fixation[38]. The surface 'pits' represent entrances to the open canalicular system or OCS[7]. The bar represents 0.5 μm.

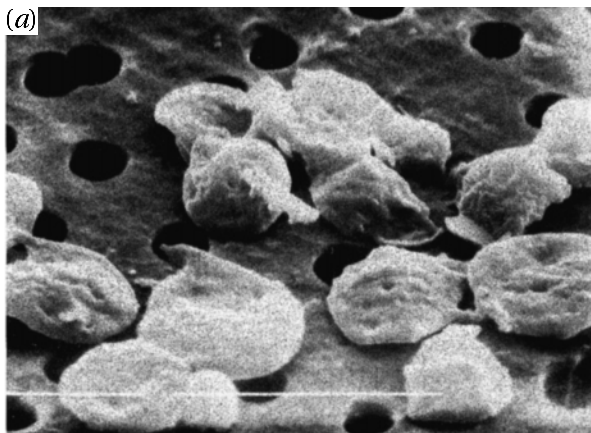
As mentioned above, the initial phases of the SC precede aggregation and can even occur in the absence of any aggregation as seen in thrombasthenic platelets which lack the $\alpha_{IIB}\beta_3$ integrin[23]. Transformation from a discoid shape to one possessing many pseudopodia dramatically increases the external platelet surface area, facilitating aggregation. The details and interrelationships of the intracellular signalling pathways involved in the platelet SC and reorganization of the cytoskeleton are not yet fully understood. An overview of



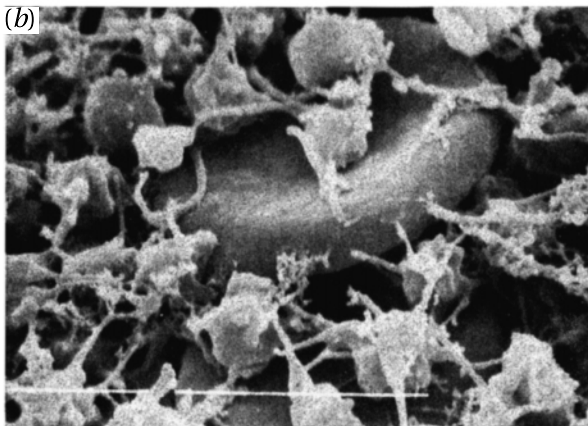


Fig. 22.2. The platelet shape change (SC). Scanning electron micrographs (SEM) reveal the dramatic transformation of the surface morphology following stimulation by the important agonist ADP. Upper figure, resting (control) platelets; Lower figure, after 10 s exposure to ADP (10 μM) at 37 °C. The formation of long, actin-rich pseudopodia is characteristic of the SC and can proceed very rapidly as demonstrated in Fig. 22.4. Platelets were activated in dilute suspensions to minimize aggregation[19]. The middle bar on the bottom represents 5 μm.

current research into signal-transduction events occurring during the SC, including calcium-dependent and independent mechanisms, will be presented on pp. 324–329. Overall, the rapid and dramatic changes in surface morphology characteristic of the SC have fascinated investigators interested in the fundamental mechanisms of platelet activation and for understanding links to normal and abnormal haemostasis.

Definitions of the platelet 'shape change'

An issue in SC studies, whether for basic research or clinical purposes, concerns the meaning of the term 'shape change'. Therefore, it is important to be aware of the varied definitions and procedures that have been used. These are summarized below and will be discussed in more detail on pp. 324–326.

(a) Alterations in the light-scattering properties of platelet suspensions, reflecting transitions from the discoid shape of resting platelets to more spherical forms possessing blebs and pseudopodia.
(b) Alterations in platelet morphology visualized by a variety of microscopic procedures, including light microscopy, as well as by scanning, transmission and freeze–fracture electron microscopy.
(c) Alterations in platelet volume or size, normally detected by resistive-particle counters, but also by flow cytometry.
(d) Alterations in the surface exposure of platelet antigens usually detected by immunological means and flow cytometry.

Events associated with the normal platelet shape change

The 'optical shape change'

The original definition of the platelet SC stems from observations that, when platelet agonists are added to stirred, platelet-rich plasma (PRP), there is very often a brief, initial **decrease** in light transmission (increase in optical density) before the major **increase** associated with platelet aggregation[1]. The early decrease in transmission usually lasts about 10 to 20 s and amounts to about 10% of the total change caused by aggregation. The diagrammatic tracing in Fig. 22.3 represents a 'classical' form when an intermediate dose of ADP elicits the initial SC, followed by two waves of aggregation. The first wave has been termed 'primary aggregation' and the subsequent one 'secondary aggregation'. Higher doses of ADP or thrombin will elicit only a single phase of aggregation after the initial SC. Low doses of agonist may induce the SC and only a brief reversible phase of aggregation.

Events sensed by light scattering or optical devices, whether as the SC reflected by the initial decrease in light transmission (p. 321) or the subsequent decreases indicating platelet aggregation, need to be correlated with other observational techniques. Thus, alterations in platelet morphology (p. 322), volume (p. 324), or new epitope expo-

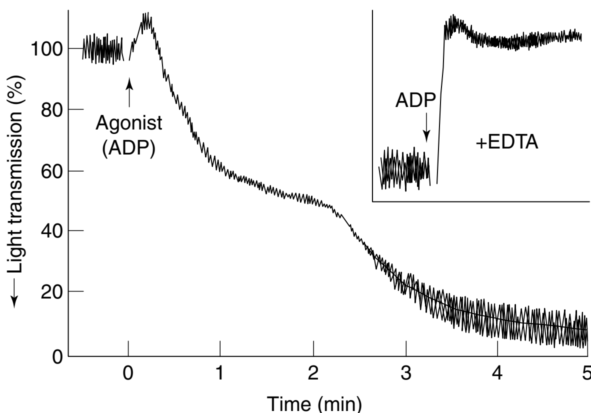

Fig. 22.3. The platelet SC assessed optically. The trace is a representation of a typical progression of changes in light transmission through platelet rich plasma following the addition of threshold levels of ADP (usually 2 to 5 μM). Three phases may occur; an initial 'shape change' (SC) lasting about 20 s, followed by two phases of aggregation. High doses of ADP or thrombin induce the SC and only one aggregation phase. Standard procedures usually involve setting the transmission through platelet poor plasma (PPP) at 0%, and for platelet rich plasma (PRP) at 100%. Samples are stirred at about 1000 rpm to provide optimal sensitivity for detecting the 'SC' and to ensure platelet aggregation by efficient particle collision[28]. The inset shows SC occurring in the absence of aggregation. PRP is treated with EDTA (typically 2–4 mM) to chelate calcium and diluted 1 to 4 to minimize any tendency to aggregation[1,19,38] and the decrease in transmission is typical of stimulation by ADP.

sure (p. 323), provide important complementary information on SC kinetics and characteristics. An indication of this need for multiparameter assessment of the SC comes from the fact that single-particle disappearance, representing platelet micro-aggregation, is essentially complete before the peak (Fig. 22.3) in the optical SC at about 10–20 s[24], and does not correlate with the aggregation kinetics sensed by the optical traces[25]. Thus, the optical SC is compromised by concurrent aggregation. In a similar vein, the later aggregation phases (30 s – 5 min) need to be distinguished from the very rapid (<5 s) formation of micro-aggregates detected as the loss of single platelets. The capture angle of the photometers used to detect transmitted or scattered light can also impact on whether or not an initial decrease in transmission is seen[26].

Light-scattering devices provide additional information about platelet shape. Thus, the width of the oscillations or 'noise' of the transmitted light prior to adding agonist is normally large when the platelets are discoid, and becomes much narrower when sphering occurs[24,27]. The schematic tracing in Fig. 22.3 provides an example of this 'noise' seen in platelet suspensions subjected to shear forces caused by stirring in the small tubes used in standard aggregometers. In addition, when stirring is stopped, light transmission decreases in proportion to the particle axial ratio which reflects platelet discoid shape[26]. These effects contribute to the characteristic 'swirling' of fresh platelet preparations. A review by Frojmovic[28] presents the varied optical parameters employed to describe both the SC and aggregation phases of platelet function. In addition, the use of polarized light and assessing light scattering changes at 90° to the incident light can yield valuable information about the SC[5]. An in-depth study by Hantgan involved 90° light scattering to define the kinetics of the optical SC induced by ADP, and showed that only about 3 s was needed to reach one-half maximal change[29].

Use of calcium chelating agents to study the SC

The inset to Fig. 22.3 shows the optical SC detected in the presence of EDTA at concentrations sufficient to block platelet aggregation[19,30]. Measurements can also be made in very dilute platelet suspensions to minimize any further chance of aggregation, with the result that an agonist still causes the decrease in light transmission without any major subsequent increases. Kinetics derived from such traces are similar to those obtained by Hantgan[29], with $t^{1/2}$ values of <5 s. Such strategies to 'isolate' the optical SC have been effective in many studies and most recently for dissection of specific, signal-transduction events linked to induction of the SC[31,32]. EDTA may, however, be deleterious since it can also elicit significant platelet swelling[19] and sphering[22,33–35].

Morphological shape changes

The ability of agonists such as ADP and thrombin to alter platelet shape as visualized by light and electron microscopy was reported in the 1960s at the same time that light scattering was used as an easy way to sense the SC. Platelet rounding was noted as well as the appearance of multiple pseudopodia[3–5,27,36]. The study by White[33,36] using transmission electron microscopy provided the first important observations on details of external morphology and internal events during the ADP-induced SC. Multiple long pseudopodia appeared by 10 s after adding ADP and central grouping of internal organelles was noted.

An analysis of even earlier morphological changes by scanning electron microcopy (SEM) revealed that 50% of platelets lost their discoid shape by 0.5 s after platelet exposure to ADP or thrombin and that about 60% of cells had formed multiple pseudopodia by 1.7 s[16]. Platelets were

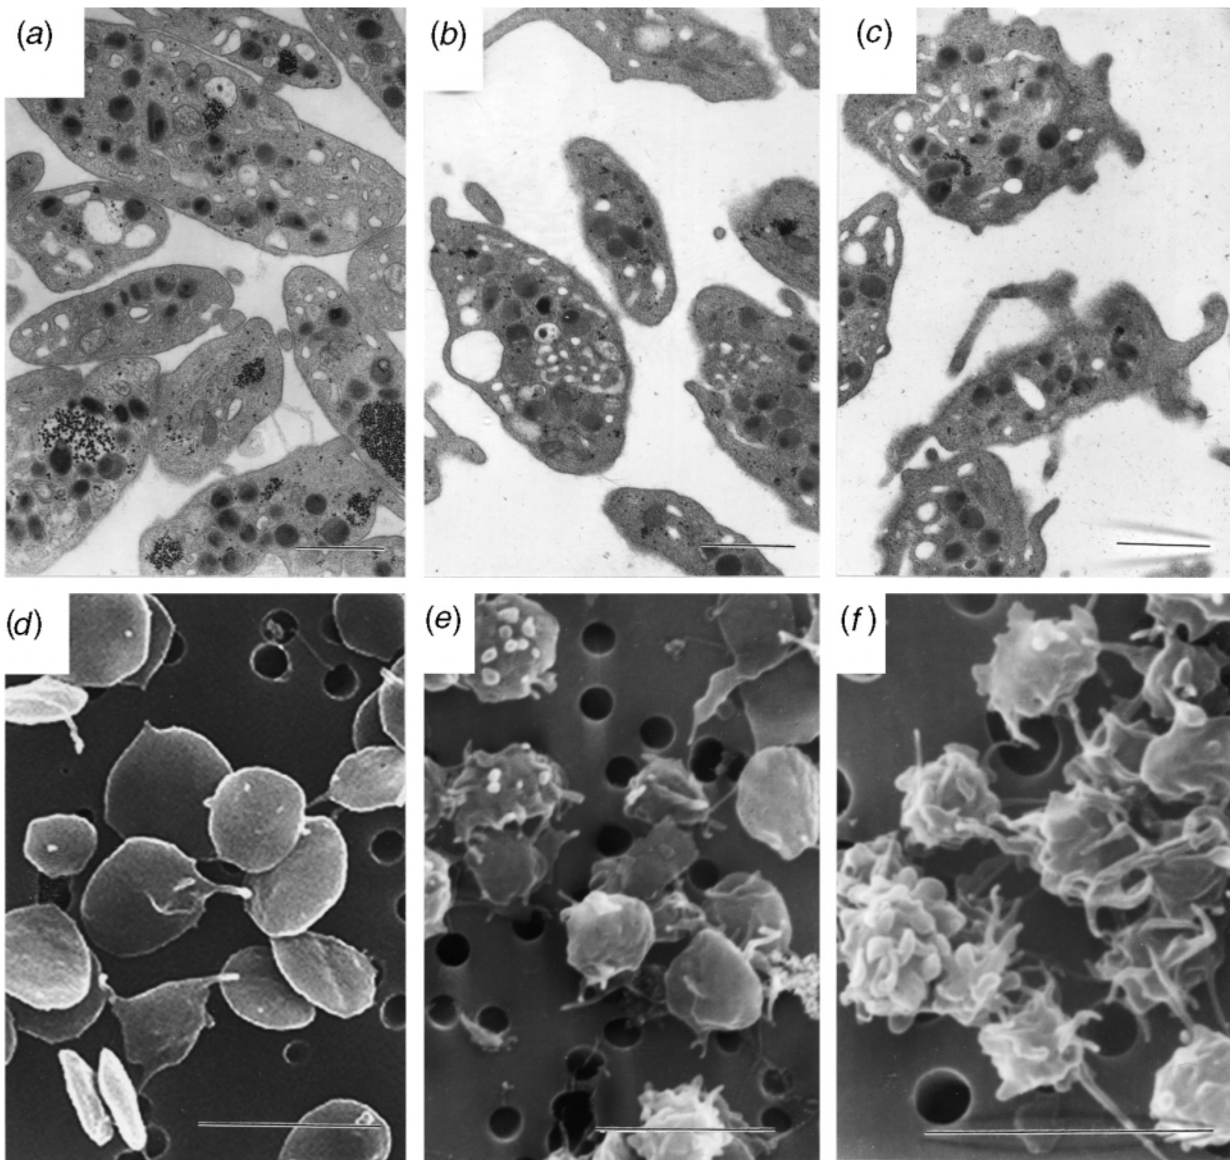

Fig. 22.4. The speed of the platelet SC. Platelets previously warmed for 15 min at 37 °C were exposed to ADP (10 μM for panels (*a*)–(*c*)) or to thrombin (1 U/ml for panels (*d*)–(*f*)) in a quenched-flow system under arterial shear forces before quenching with glutaraldehyde and processing for transmission electron microscopy (TEM) or SEM (Gear, 1984). The TEM images shown are: control resting platelets (*a*), cells reacted with ADP for 0.5 s (*b*), and for 1.25 s (*c*): SEM images; control platelets (*d*), cells reacted with thrombin for 0.5 s (*e*) and for 1.7 s (*f*) (Magnifications are provided on the figures as bars; 1 μm for (*a*)–(*c*), 5 μm for (*d*)–(*f*).

exposed to arterial shear forces and use of rapid quenched-flow methods enables study of second and to subsecond kinetics[19,37]. Results from platelets stimulated for 0.5 and 1.25 s by ADP under flow conditions and examined by transmission electron microscopy (TEM) are illustrated in Fig. 22.4(*a*)–(*c*) and by SEM for thrombin-activated platelets in Fig. 22.4(*d*)–(*f*). Similar kinetics are seen for either agonist. Freeze–fracture electron microscopy of spray–frozen platelets activated for about 1 s by ADP provides an alternative fixation-free approach for studying the platelet SC under arterial shear forces[38]. The image presented in Fig. 22.5 can be compared to the control platelet seen in Fig. 22.1 subjected to the same arterial shear forces in the continuous-flow pumping system.

Cambridge Books Online © Cambridge University Press, 2009

Fig. 22.5. ADP-activated platelets visualized by freeze–fracture electron microscopy. Cells were reacted to ADP for about 1 s and quenched by spray freezing . The image reveals the presence of 'blebs' compared to the smooth surface seen with control, spray–frozen cells (Fig. 22.1) (Magnification bar is 1 μm.

Volume increases

Shape change can also be sensed by changes in platelet volume. The ability of platelet aggregating agents such as ADP to increase cell volume by about 20% was reported in the 1960s[3,39,40]. Born then questioned the validity of measurements based on resistive-particle counting[1]. He used centrifugation procedures in the presence of EDTA and a version of the hematocrit to suggest that the optical SC was not associated with an increase in platelet volume. However, EDTA itself can induce platelet swelling and sphering[33,34,39,41]. These effects, plus the stress of centrifugal forces in causing platelet swelling, serve to mask the ability of ADP to cause an increase in cell volume[19]. Other observations consistent with agonist- induced swelling are decrease in cell density[19] and an increase in Na^+ content[42–44]. Direct morphometric estimation of ADP- activated platelets also supports the volume increases sensed by resistive-particle counters[45].

This brief background serves to underpin present confidence in volume measurements as a useful alternative approach to sensing the platelet SC. A useful description of some general aspects by Jackson and Carter[46] and Jagroop et al.[47] provide valuable correlations between agonist-induced volume increases and platelet shape directly observed by SEM. However, to study the kinetics of agonist-induced increases rather than long-term or static situations, continuous-flow systems are required[37,48]. ADP and thrombin can induce major increases by 0.5 to 1.0 s, and by 10 s, net increases may be 10 to 20% above resting platelet volumes of 6 to about 7.7 fl. The initial speeds of reaction (<0.5 s) approach those needed for efficient platelet function under arterial-flow conditions[49]. In conclusion, platelet-volume measurements now offer an important extra dimension for assessing the platelet SC. A schematic summary of the initial kinetics of the volume increase occurring during the SC, as well as major morphological events, is presented in Fig. 22.6.

The SC defined by exposure of 'new' platelet surface structures and antigens

Activation of platelets by some agonists or by shear stresses can alter platelet morphology and expose new features or molecules on the platelet surface without triggering detection of the SC defined by the criteria presented above

Cambridge Books Online © Cambridge University Press, 2009

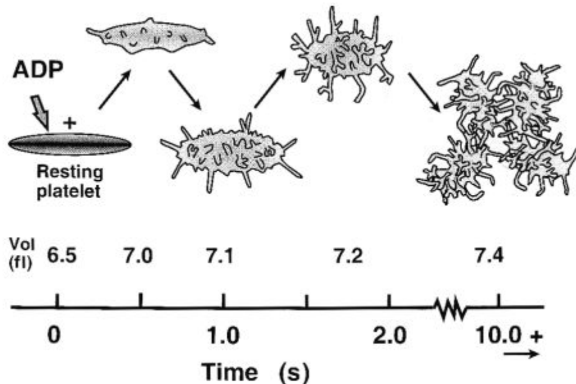

Fig. 22.6. Summary of initial SC events. The scheme illustrates the kinetics of SC visualized by SEM and TEM (Fig. 22.4), as well as reflected in the volume increases caused by agonists such as ADP. The absolute volumes and kinetics of the changes in volume are as published[16,19,47].

(pp. 320–323). Such changes may represent a significant step in the initiation of platelet function, with important overall consequences for hemostasis. For example, the 'weak' agonist epinephrine characteristically fails to elicit an optical SC or increase in platelet volume[19,37]. Aggregation occurs only in the presence of very low levels of a primary agonist such as ADP[50], with little evidence of a SC detected optically[51]. Recent studies have now shown that other weak agonists such as chemokines stimulate platelet function and cause the formation of 'blebs' on the platelet surface, with epinephrine behaving similarly[52]. Of particular interest was the finding that the platelet α-granule protein CD62P (P-selectin) is exposed as detected by flow cytometry even though there was no evidence for dense granule secretion.

Flow cytometry has been used for many years to detect markers of platelet activation such as the activated conformations of the fibrinogen receptor, the $\alpha_{IIB}\beta_3$ integrin[53]. A review article by the European group on clinical cell analysis[54] provides a valuable perspective on the expanding capabilities of flow cytometry with regard to platelet function. The SC represents an important initial phase of function and availability of well-defined antibodies will provide useful ways to assess platelet activation not just for ex vivo investigations, but also for in vivo monitoring of circulating platelet status in different clinical situations[55]. P-selectin is just one of a number of activation-dependent markers; others include procoagulant anionic phospholipids and the $\alpha_{IIB}\beta_3$ integrin.

Mechanisms and regulation of shape change – intracellular signalling

Less is known about the biochemical events associated with the SC compared to subsequent phases of platelet function[56,57]. An early study highlighted the rapid phosphorylation of myosin light chains in ADP-stimulated platelets, and how this parallelled the kinetics of the SC assessed optically as well as by scanning electron microscopy[58]. Although initial interest was mostly on calcium and myosin light chain phosphorylation in relation to the SC, more recent studies have revealed other participants such as small GTP-binding proteins including Rho, Rac, and Cdc42 and the p160 Rho-associated kinase (Rho-kinase). In addition, new information is helping elucidate the roles of many proteins and factors involved in regulating platelet shape and structure, the dynamics of the actin cytoskeleton, membrane skeleton and microtubules. The aim of this section is to provide a sense of what is now known about signalling events involved in the SC as well as questions for the future.

Intracellular calcium

Major increases in cytosolic calcium levels $[Ca^{2+}]_i$ usually occur during activation of platelet function[59]. When platelets are stimulated by many agonists such as ADP or thrombin, cytosolic calcium levels rapidly increase (<5 s), associated with both a large influx through the plasma membrane and increased mobilization of calcium from intracellular stores[59–61]. However, SC-induced by certain platelet agonists can be mediated through pathways that does not require elevation of $[Ca^{2+}]_i$[62,63]. Agonists that have been shown to induce this calcium-independent pathway of SC include the heptapeptide ligand of the thrombin receptor, YFLLRNP, low concentrations of thrombin[57,64], the endoperoxide analogues U46619 and U44069[31], and mildly oxidized, low-density lipoprotein (mox-LDL)[65]. Consistent with this is the observation that stimulation of G_q-deficient mouse platelets by various stimuli fails to activate phospholipase C and alter $[Ca^{2+}]_i$ levels, but the platelets still undergo SC in the absence of aggregation and degranulation[66]. In addition, the initial rate and the onset of the SC are markedly delayed in platelets exposed to the intracellular calcium chelator BAPTA-AM[67].

Myosin light chain phosphorylation

A strong correlation exists between phosphorylation of the myosin light chain (MLC) and the initiation of SC[58,68], and the time course of MLC phosphorylation parallels that of

Cambridge Books Online © Cambridge University Press, 2009

association of myosin with the actin cytoskeleton[67,69]. Phosphorylated myosin interacts mainly with central actin filaments in platelets, and the myosin-actin complex has been suggested to be involved in the granule centralization process[17,69]. The 20 kDa MLC is phosphorylated during SC induced by ADP, serotonin, vasopressin, PAF, collagen, A23187, endoperoxide analogues and by chilling[58,68,70–72]. Epinephrine by itself does not stimulate MLC phosphorylation or the typical SC from discoid to spheroid platelets[73], but in combination with ADP contributes strongly to SC and volume increases[16,50].

MLC phosphorylation is very rapid ($t^{1/2}$ about 1.5 s) and precedes the induction of the optical SC ($t^{1/2}$ about 2.5 s). Dephosphorylation occurs soon after platelet activation by ADP or thrombin and does not parallel reversal of platelet shape back to a discoid form[58,72,74,75]. Therefore, myosin phosphorylation may not be required for the maintenance of the SC response. Net phosphorylation represents a balance between the activity of the Ca^{2+}/calmodulin dependent MLC kinase (MLCK) and MLC-phosphatase (MLCP) and there is now strong evidence that MLC phosphorylation can be induced independently of changes in cytosolic Ca^{2+} concentration[76]. This theme will be developed below.

Rho kinases and the SC

Recent studies have revealed that Rho-kinases, which can be activated by the small guanosine triphosphate (GTP)-binding protein RhoA, directly phosphorylates the 130-kDa myosin-binding, regulatory subunit (MBS) of protein phosphatase 1 (PP1), inhibiting phosphatase activity. The overall effect is to increase MLC-phosphorylation[77,78]. This mechanism for stimulating the SC is independent of any increase in cytosolic $[Ca^{2+}]_i$[31]. Several platelet agonists induced the SC through both Ca^{2+}-sensitive and -insensitive pathways which independently contributed to the SC and MLC phosphorylation[67]. The Ca^{2+}-dependent myosin phosphorylation is very rapid, peaking near 2 s after stimulation with ADP, thrombin or the thromboxane A_2 (TXA_2) analogue, U46619[67]. These kinetics are very similar to earlier evidence for ADP and thrombin stimulation of MLC phosphorylation[8,79]. Experiments with the relatively selective inhibitors Y-27623 and HA 1077 of the $p160^{ROCK}$ or Rho-kinase and with BAPTA-AM, support the conclusion that Rho kinase is involved in stabilizing the phosphorylation of the MLC[80].

In summary, these recent reports highlight the fact that an increase in intracellular calcium is not the only signal involved in stimulating the SC via MLCK. While an important parallel role for Rho-kinases is clearly involved, the relative significance of the two kinase pathways, and possibly others, has yet to be clarified for different platelet stimuli.

Heterotrimeric G-proteins and the SC

Platelets from G_q-deficient mice appear to undergo SC when exposed to TXA_2- receptor agonists, thrombin or collagen, even though they lack phospholipase C activation and formation of inositol phosphates, and are unable to aggregate fully or secrete their granule contents[81]. SC can therefore be mediated by $G_{12/}G_{13}$ activation and as discussed above may involve the Rho/Rho- kinase pathway leading to MLC phosphorylation. In contrast, ADP does not induce SC in G_q-deficient mouse platelets[66,82,83]; and ADP-induced SC of human platelets is insensitive to the Rho-kinase inhibition[32]. Thus, ADP- induced platelet SC can be mediated by the G_q-coupled $P2Y_1$ receptor[31,67,81]. Similarly, activation of G_q-coupled $5HT_{2A}$ receptors by serotonin is sufficient to induce SC[84–86]. Increased levels of cAMP and cGMP may inhibit platelet function via activation of cAMP and cGMP-dependent kinases. However, Klages et al.[81] reported that cAMP but not cGMP analogues inhibit SC and MLC phosphorylation in G_q-deficient mouse platelets activated by the G_{12}/G_{13}-coupled TXA_2 receptor. They propose that SC mediated by Rho/Rho-kinase is specifically inhibited by a cAMP-dependent pathway.

In conclusion, the SC can be activated via several G-protein coupled receptors responding to a variety of different platelet stimuli. G_q- and G_{12}/G_{13}-deficient mouse platelets provide valuable models for studying signalling mechanisms not just for the SC alone, but also for linkages to aggregation and secretion. Soon, other genetically modified animal models may be available to understand even better the complex pathways involved in the SC. Shown in Fig. 22.7 is a basic scheme by which activation of G-protein coupled receptors is believed to elicit the platelet SC. Figure 22.8 illustrates a series of signalling events resulting from G-protein stimulation, including both activating and inhibitory steps as well as some of the important enzymes and regulatory compounds involved in regulating actin and myosin function, leading to the SC.

Protein tyrosine phosphorylation and the SC

Relatively little evidence exists for the SC being directly linked to tyrosine phosphorylation of specific proteins[56]. **Cortactin**, a 77–80 kDa protein which binds to actin filaments, is phosphorylated relatively early (30 s) in thrombasthenic platelets activated with low levels (0.05 U/ml) of thrombin, which induces the SC but no aggregation[81]. A

Cambridge Books Online © Cambridge University Press, 2009

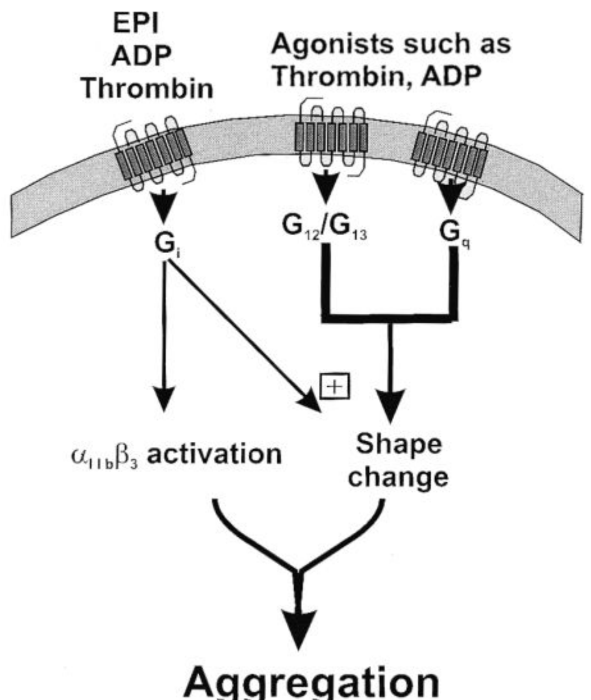

Fig. 22.7. The platelet SC and its linkage to overall platelet function. The main classes of G-protein coupled receptors are indicated[86].

p130 band was also tyrosine phosphorylated early, and a 64 kDa band later (>60 s). The tyrosine kinase Syk is found associated with cortactin by immunoprecipitation experiments[56]. Tyrosine phosphorylation of $p72^{Syk}$ and $p60^{src}$ has also been observed in mouse platelets deficient in G_q, which undergo SC in response to TXA_2, but do not aggregate[81]. Exposure of human platelets to the peptide YFLLRNP, an antagonist of aggregation stimulated by the SFLLNRP thrombin-receptor activating peptide, induces SC without secretion from platelet granule contents, internal Ca^{2+} mobilization, or pleckstrin phosphorylation[64]. The induction of the SC by the YFLLRNP peptide causes protein tyrosine phosphorylation of novel substrate bands at p62, p68, and p130, even in the presence of BAPTA-AM, suggesting an essential role of protein tyrosine kinases for activation of the platelet SC[88]. Mox-LDL induced SC is also accompanied by tyrosine phosphorylation of p62, p68 and p130 and by activation of tyrosine kinase $p72^{Syk}$[65]. In addition, inhibition of ADP-induced SC in aspirin-treated gel-filtered platelets by agents that elevate cAMP and cGMP parallels inhibition of protein tyrosine phosphorylation, suggesting that some of the proteins being tyrosine phosphorylated are important in regulating the ADP-induced SC[11]. A recent study, however, indicates that the ADP- or thrombin-induced SC measured by routine light-transmission methods is not prevented by PP2, an inhibitor of src-family tyrosine kinases[32,89]. On the other hand, broad-spectrum tyrosine kinase inhibitors such as genistein and tyrphostin A23 appear to block SC induced by thrombin or mox-LDL[88,90]. These results support the possibility that unidentified protein tyrosine kinases, unrelated to src-family kinases, may be functionally involved.

Protein kinase C

During SC induced by thrombin, PAF, ADP, vasopressin, concanavalin A, serotonin, thromboxane A_2 analogues, a rapid increase (<2 s) in the phosphorylation of a p47 kDa protein (pleckstrin), a major protein kinase C (PKC) substrate is observed[78,91,92]. Although the non-specific protein kinase inhibitor, staurosporin, strongly blocks pleckstrin phosphorylation and SC induced by ADP, thrombin or U46619, the relatively specific PKC inhibitors Ro 31–8220, GF 109203X and Ro 31–7549 have no effect on agonist-induced SC[67,93,94]. This observation and the demonstration that phorbol esters or diacylglycerol induce maximal phosphorylation of p47 without evoking the rapid spheration of platelets[95], argue against a direct role for PKC in the initial SC.

Role of actin-modulating proteins in the SC

The discoid form of unstimulated platelets is maintained by circumferential bundles of microtubules beneath the plasma membrane, a network of short actin filaments forming a membrane skeleton and an actin gel filament that links the submembrane skeleton and transmembrane proteins[17,18,96]. After activation, actin filaments undergo rapid disassembly and reorganization into new actin structures, including filopodia and lamellipodia, with dynamics closely related to the SC[17,18,97,98]. Thus, actin-modulating proteins must play a critical role in mediating the transmembrane signals that regulate the actin dynamics responsible for the SC. These proteins include myosin, gelsolin, VASP, moesin, adducin and cofilin, with a more complete accounting provided in a recent review of platelet morphology[99]. Early evidence suggested that the circumferential or marginal band of microtubules, which helps maintain resting discoid platelet shape, disappears during the SC[36]. However, the kinetics of this process are not known with regard to the very rapid (<2 s) major changes in platelet shape that have already occurred as assessed optically, or by quenched-flow approaches[1,16,29].

The formation of filopodia and lamellipodia is thought

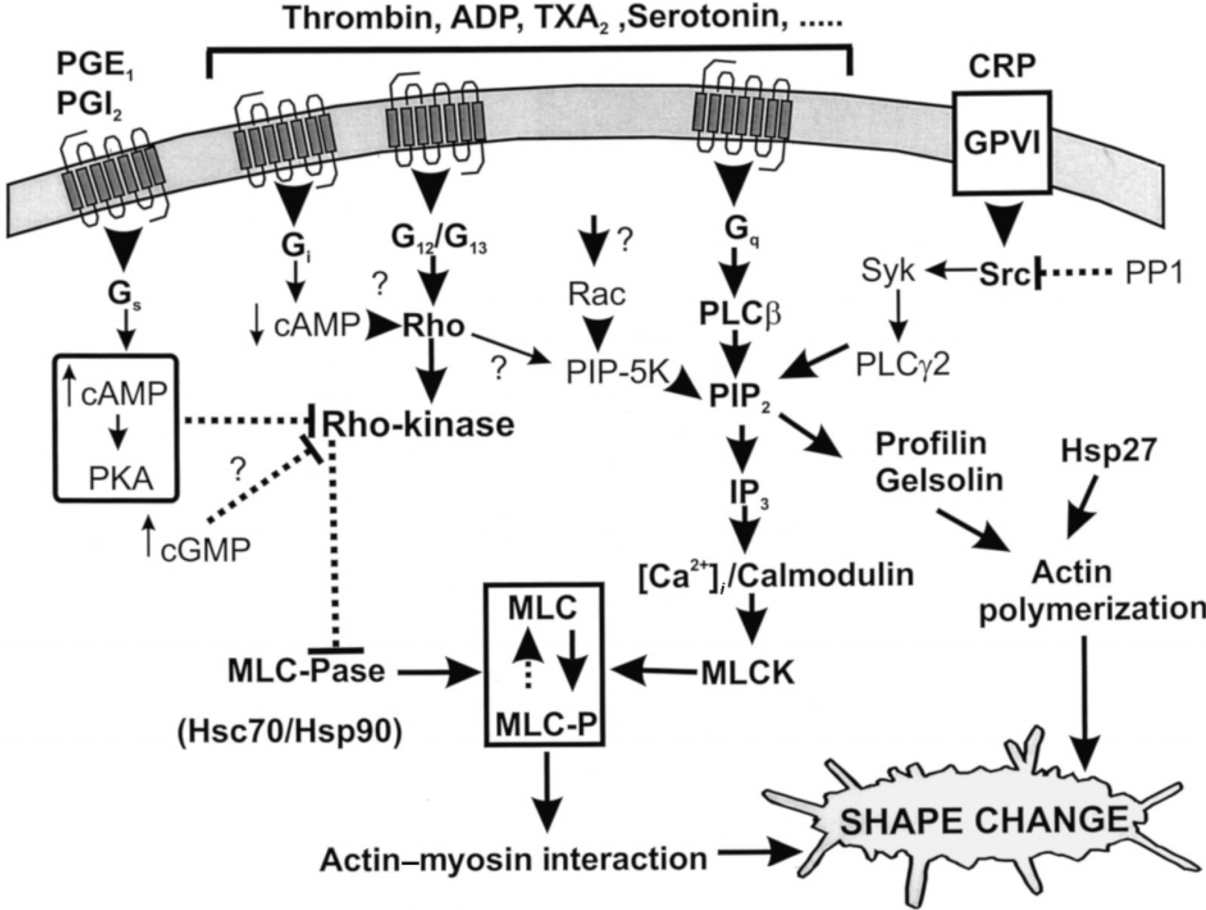

Fig. 22.8. Signalling events during the platelet SC. The main players involved in causing actin polymerization and myosin phosphorylation are shown, together with activation by plasma-membrane receptors, calcium, protein kinases and phosphatases, and heat-shock proteins. The heat-shock proteins, Hsp27 and Hsc70/Hsp90 are also indicated, since there is evidence that they may regulate actin polymerization and the activity of the myosin phosphatase[109,110,116].

to be mediated primarily by **gelsolin**, an abundant actin-filament severing protein. Platelet SC is decreased in gelsolin-deficient mouse platelets and is abnormal in hereditary gelsolin Asp187Asn-related amyloidosis[100,101]. In contrast, the 48–50 kDa vasodilator-stimulated phosphoprotein (**VASP**) is phosphorylated in response to vasodilators and platelet inhibitors that increase cAMP and cGMP levels (prostaglandin E1 (PGE1), forskolin, NO, sodium nitroprusside (SNP)[102–104]) and VASP is believed to inhibit SC by stabilizing actin filaments and preventing their disassembly by gelsolin[105,106]. In VASP-deficient mouse platelets stimulated with collagen, the SC occurs more rapidly than in normal platelets[107]. Earlier studies were consistent with a slow (minutes) phosphorylation of VASP in intact platelets[102]. Recently, it has been shown that platelets from control or VASP-deficient mice exposed to PGE1 are inhibited similarly with regard to platelet function. This result suggests that the inhibitory effects of cAMP are mediated in part via a VASP-dependent mechanism[108], and a clear understanding of the function of VASP and its phosphorylation status in the SC remains to be reached.

Small heat-shock proteins (sHsps) are also involved in regulation of the actin-cytoskeleton[109,110]. In particular, phosphorylation of Hsp27 may play a role in regulating actin polymerization[111–113] and stabilizing the actin cytoskeleton[114]. Recently, Hsp27 has been reported to be phosphorylated by a cGMP-dependent protein kinase (cGK) and thus may be involved in inhibition of platelet responses[115]. In addition, the **large heat-shock proteins**, hsc70 and hsp90, exist in a large signalling complex in resting platelets, which is highly phosphorylated and contains the PP1–M regulatory and catalytic subunits[116]. The roles of this complex in the SC remain to be established.

Cambridge Books Online © Cambridge University Press, 2009

Moesin is a member of the ezrin/radixin/moesin (ERM) family of proteins that acts as a linker between the plasma membrane and actin cytoskeleton and is involved in the formation and stabilization of filopodia[117]. Thrombin stimulation induces a transient increase in moesin phosphorylation at Thr558[118] that correlates with its F-actin binding activity[119]. Phosphorylated moesin binds F-actin only in the presence of phosphoinositides such as $PI(4,5)P_2$. Following thrombin activation, the cytosolic moesin redistributes to the membrane skeleton and co-localizes with actin filaments in newly-formed filopodia and lamellipodia[120]. Moesin is also required for actin assembly mediated by Rho family GTPases[121]. Recently, it has been shown that lysophosphatidic acid (LPA) induces MLC and moesin phosphorylation in a Ca^{2+}- independent manner via Rho/Rho-kinase[122]. However, observations that the moesin-gene-knockout does not affect platelet aggregation[123] might question significance of a critical role for moesin in platelet function.

Adducin, a membrane-skeleton protein, stimulates the binding of spectrin to actin filaments[124]. There is also strong evidence that Rho-kinase and myosin phosphatase (PP1–M) can regulate the F-actin binding activity of adducin through its phosphorylation, promoting the assembly of the spectrin-F-actin network[125,126]. Adducin is also phosphorylated by PKA and PKC[127,128].

Cofilin is an 18 kDa actin-binding protein that can bind to F-actin and depolymerize it[129]. In resting platelets cofilin is phosphorylated and localized to the cytoplasm, but after activation becomes dephosphorylated and translocates to the plasma membrane, complexed with F-actin[130]. The actin-binding and depolymerizing activity of cofilin can be regulated by phosphatidylinositol 4-phosphate (PIP) and 4,5-bisphosphate (PIP_2)[131]. Dephosphorylation kinetics and correlation with the onset of SC have not yet been fully studied. An inhibitor of serine/threonine protein phosphatases, okadaic acid (OA), that causes a dramatic change in platelet morphology[132,133], also blocks dephosphorylation of cofilin in T lymphocytes[134,135]. Since dephosphorylation of cofilin activates its actin-depolymerizing function, activation of serine/threonine protein phosphatases such as PP1 may be involved in the dynamic rearrangement of the actin cytoskeleton.

Kinetics of platelet shape change with regard to signalling

As presented above, the major morphological changes are nearly complete within 2 s after platelet activation by ADP or thrombin[16]. The rapid increases in cytosolic free Ca^{2+} maximal within 2 to 3 s accompany the morphological changes in platelets[60,61]. ADP induces significant increases in MLC phosphorylation by 0.3 s, that reaches a maximum at 3 s and increases are approximately twice as much as with thrombin. The ADP-induced MLC phosphorylation is transient and reverses within 1 min[136,137]. However, during the first 5 s after stimulation MLC phosphorylation by ADP[138] or by thrombin[92] is not well correlated with Ca^{2+}-dynamics. This suggests that other mechanisms are also involved, possibly Rho-kinase. The early kinetics (<5 s) of other serine/threonine protein phosphorylations potentially associated with the SC are not known, nor for phosphotyrosine-containing proteins.

Effect of platelet inhibitors

A number of compounds regulate platelet protein kinases/and phosphatases and cause platelets to lose their disc shape and develop pseudopodia. Nevertheless, treatment with these agents appears to desensitize platelets to further stimulation with physiological agonists and block their physiological responses. Increases in cyclic AMP which inhibit platelet activation can actually induce pseudopod-like structures, indicating PKA activation of PKA may cause cytoskeletal reorganization leading to a platelet SC[139,140]. Inhibitors of serine/threonine protein phosphatases types 1 (PP1) and 2A (PP2A), okadaic acid (OA) and calyculin A (CLA), also induce changes in platelet morphology[132,141] that are correlated with inhibition of platelet aggregation and secretion. The phosphotyrosine phosphatase inhibitor vanadyl hydroperoxide induces morphological alterations in platelets that correlate with increased tyrosine phosphorylation and potentiation of cell adhesion. In ADP-stimulated platelets, the cGMP-elevating agent, sodium nitroprusside, inhibits SC by 50%[142].

Phosphoinositides and the SC

Polyphosphoinositides (PPI) play a key role in the reorganization of the actin filament network in different cells, including platelets by interacting with proteins that modulate actin assembly such as gelsolin and capping protein[18,99,143,144], profilin[144–147], cofilin[128,130,148–150] and the ERM protein, moesin[119]. Bursts of actin polymerization in vivo involve the transient appearance of free barbed-ends. It is thought that the two most abundant barbed-end capping proteins gelsolin and capping protein can be released from capped actin filament ends by interacting with the PIP_2 and PIP. In platelets, uncapping of gelsolin-capped filaments seems to generate free barbed ends and contributes to actin polymerization. Uncapping would occur at the membrane so that additional actin polymer-

Cambridge Books Online © Cambridge University Press, 2009

ization would result in formation of filopodia and lamellipodia. A recent review[151] summarizes the role of polyphosphoinositides in forming signalling protein complexes and regulating actin assembly in human platelets, focusing on pleckstrin homology (PH) domains. Platelet stimulation induces rapid phosphoinositide hydrolysis that is associated with actin polymerization and PIP_2 binding to actin-capping proteins, leading to the generation of actin-free ends and initiation of actin polymerization. Important interactions occur between the phosphoinositide kinases and small GTP-binding proteins such as Rac, Cdc42, and Rho, that are implicated in controlling the organization of actin cytoskeleton[152]. Thus, activation of Cdc42 may lead to rapid filopodial protrusions[152,153]. Activation of Rac causes fibroblasts to extend lamellipodia[154] while Rho is thought to be involved in the formation of stress fibres and focal contacts[155]. In platelets, Rac stimulates the uncapping of actin filaments through a PPI-dependent mechanism[156]. Rho and Rac regulate phosphatidylinositol 4-phosphate 5 kinase (PIP-5K) that is necessary for PIP_2 production[156–159]. Platelet stimulation with thrombin leads to activation of PI3–K and production of $PI(3,4)P_2$ and $PI(3,4,5)P_3$, that correlates with the kinetics of actin assembly and shape change[95]. The production of $PI(3,4)P_2$ correlates with the translocation of PI3–K to the platelet actin cytoskeleton and an increase in PI3–K enzyme activity[160]. Both activated-Rac and -Cdc42 associate with PI3–K. Interestingly, the inhibition of PI3–K activity by specific inhibitors such wortmannin does not alter the kinetics of actin assembly and shape change induced by TRAP or ADP suggesting that PI3–K is not required for actin assembly[93,161].

Shape change and disease: clinical relevance

There are relatively few examples of platelet-specific SC abnormalities associated with pathological situations, suggesting that an inability to undergo efficient SC may prove fatal in embryonic development. However, there are some conditions in humans and in animals such as dogs, where abnormal SC can occur. More common are clinical situations where an abnormal plasma environment influences platelet function. This section will consider known examples and also the usefulness of SC measurement in the important area of platelet storage in blood banks.

There is evidence that hypertension is associated with an enhanced SC measured optically[162–164]. Surface expression of CD62P (P-selectin) measured by flow cytometry is enhanced in acute and recent cerebrovascular ischemia, while the proportion of resting discoid platelets assessed by phase-contrast microscopy is unchanged compared to control subjects[55]. Thus, the information obtained and conclusions reached can be influenced by the techniques used. SC in unstable angina is enhanced three–fourfold compared to controls when assessed by the amplitude of the optical tracing[165], while exercise of postmyocardial infarction patients caused a significant activation of platelet morphology judged by light microscopy detection of the appearance of pseudopodia and loss of discoid shape[166].

Several other conditions or diseases are linked to SC abnormalities. Platelets in the rare **May-Hegglin anomaly** are large (mean volume of about 12 fl) and spherical and the disease is characterized by thrombocytopenia and mild bleeding[167]. Platelet aggregation induced by ADP or collagen is apparently normal, while SC in 15 subjects was completely absent as reflected in the optical tracings. Electron microscope studies indicate limited pseudopodia formation[168]. Abnormal SC has been reported in several other giant-platelet syndromes[169], including the Bernard–Soulier syndrome. Wilson's disease represents another situation where SC is usually absent[170], associated with a mild thrombocytopenia and a bruising tendency.

Platelet SC may be modulated abnormally by plasma factors in certain diseases. Thus, in both **thrombotic thrombocytopenic purpura** (TTP) and **hemolytic uremic syndrome** (HUS), inflammation and disturbances in endothelial cell function may contribute to the SC problem by releasing proteins and platelet-active substances into the blood[171]. An early indication of plasma factors which could induce the platelet SC was reported in1975[172]. Plasma from subjects with **acute** or **chronic heart disease** caused normal platelets to exhibit spread forms as visualized by electron microscopy. A number of factors might be responsible for these SC plasma effects, including oxidized-LDL[121,173], platelet-active amines such as epinephrine, or serotonin (5–OH tryptamine)[50,174], and most recently, chemokines which may link inflammatory conditions with cardiovascular disease and platelet activation[52,175–178].

An interesting linkage exists between the disease **hereditary gelsolin-related amyloidosis** (A Gal amyloidosis) and defective platelet SC induced by ADP or collagen[100]. This disorder is caused by a G654A or G654T mutation in the gene coding for gelsolin, an actin filament severing protein, as described earlier. Only light scattering was used to study SC and more direct information by SEM would have been valuable since gelsolin is believed to play a major role in the formation of filopodia and lamellipodia.

Measurement of platelet volume provides a useful index of the SC as outlined earlier. The existence of large platelets has been described for a variety of diseases or conditions[46]. Thus, large platelets may be associated with the development of atherosclerosis[179,180], although interpretations of

Cambridge Books Online © Cambridge University Press, 2009

such relationships are compounded by the fact that platelet populations are heterogeneous in size, density and other parameters[8,181–183]. For example, large platelets may be more sensitive to an aggregating agent than smaller cells, but their maximal rates of aggregation are lower[8,13,181]. Large, dense platelets adhere to collagen much more rapidly than lighter, small cells[184], causing the non-adherent platelet population to appear smaller. An interesting example of volume changes reflecting the platelet SC and relevant to clinical situations was recently reported. The drug Naftidrofuryl (NAF), which improves claudication distance associated with peripheral vascular disease (PVD), prevents the ability of the vasoconstrictor endothelin-1 and 5–OH tryptamine (serotonin) to cause the platelet SC sensed as an increase in mean platelet volume[174].

Several areas of research suggest the utility of SC measurements in **non-disease situations**. Thus, optical analysis of the ability of ADP to induce a SC in EDTA-treated platelets to minimize aggregation, and by a hypotonic-shock test indicate good correlation with in vivo platelet survival[185]. This information has proved important for developing optimal in vitro storage conditions of platelet concentrates. The effects of diet and environmental factors on platelet function, usually studied as light-scattering aggregation, have been studied for many years, often without clear resolution. The antioxidant Vitamin E does not block platelet aggregation, even at high dietary supplementation. However, much lower doses of Vitamin E it strongly inhibit adhesion under flow to surfaces coated with fibrinogen or collagen[186]. Examination of adherent platelets by SEM revealed that the SC of platelets from Vitamin E-supplemented individuals was much reduced, with few blunt pseudopodia compared to the longer narrower pseudopodia of platelets from control individuals. The reasons for dietary Vitamin E blocking the SC caused by platelet adhesion are not clear[186].

Conclusions and questions for the future

Conclusions

1. The shape change (SC) represents one of the earliest functional events (<5 s) after platelet stimulation. It is characterized by the loss of resting discoid shape with the formation of more rounded cells which initially exhibit short blebs and later, longer pseudopodia.
2. Detection and definition of the SC depend on the methods used for its study. Four main ones are most appropriate and combinations are recommended: (*a*) changes in the light-scattering properties of platelet suspensions; (*b*) changes in morphology assessed by light microscopy and by transmission, scanning and freeze-fracture electron microscope; (*c*) changes in platelet volume detected by resistive-particle counters; and, (*d*) by exposure of 'new' surface epitopes, by techniques such as flow cytometry.
3. Two major cell-signalling pathways mediate the SC, Ca^{2+}-dependent and independent ones, and simultaneous inhibition of both blocks SC. The former involves G_q-linked activation of the myosin light-chain kinase (MLCK), and the latter $G_{12/13}$ activation of Rho, leading to stimulation of Rho- kinase and inhibition of myosin phosphatase, also promoting phosphorylation of myosin light chains.
4. The important role of serine/threonine phosphorylation in regulating the SC is supported by the fact that okadaic acid, which inhibits protein phosphatase-1 and -2A (PP1 and PP2A) activities induces strong changes in platelet shape.
5. Evidence for roles of protein tyrosine phosphorylation is more limited. Src-kinase inhibitors do not prevent the ADP or thrombin-induced SC, while the collagen-related peptide (CRP) induced SC can be completely prevented. Tyrosine phosphorylation of cortactin, $p72^{Syk}$ and $p60^{src}$, and protein bands at 62, 68 and 130 kDa has been noted for various agonists, but direct relevance to the SC has yet to be established.
6. A number of additional proteins and factors are involved in the SC. Moesin, a linker protein between the plasma membrane and the actin cytoskeleton, is transiently phosphorylated and redistributed to the membrane skeleton and into pseudopodia. Other proteins include cofilin which is dephosphorylated during the SC, moving from the cytoplasm to the actin cytoskeleton, and adducin a membrane-skeleton protein associated with F-actin, and which can be phosphorylated.
7. Phosphoinositides play important roles in the SC and organization of the actin cytoskeleton, by interaction with proteins such as gelsolin and profilin, and by tethering proteins containing pleckstrin homology or 'PH' domains, to form signalling complexes.
8. Platelet-specific disorders of the SC are rare, while abnormal SC is associated with a number of clinical situations. Thus, cardiovascular disease such as hypertension, angina, ischemia or congestive heart failure, may be linked to an enhanced SC. In addition, inflammatory conditions such as TTP and HUS are associated with platelet activation, including the SC.

Cambridge Books Online © Cambridge University Press, 2009

Future avenues for research

A number of issues about the platelet SC need to be addressed to help our understanding of the fundamental mechanisms involved in initiating and regulating the SC and linkage to overall aspects of platelet function with correlations with clinical situations. The topics outlined below provide a window on where profitable research is likely.

1. The important question of whether the SC is essential for subsequent platelet function, particularly aggregation, should be resolved; or, is the SC more related to the role of platelets in the clotting cascades?
2. There is a critical need to discover signal-transduction events that are specific to the SC. Only limited information is available about protein tyrosine phosphorylation and little is known about the earliest kinetics of signalling changes before aggregation begins at about 1 s after agonist activation. Such studies should be related to later events such as full, stable aggregation.
3. Information is also needed about initial SC and concurrent signalling events occurring during platelet adhesion to surfaces such as collagen or fibrinogen under static and flowing conditions. This should be contrasted with knowledge about changes seen during solution activation as has been the situation for almost all studies to date.
4. The role of signalling complexes in maintaining resting platelet shape requires study, as well as how scaffold proteins and their partners, including associations with the plasma membrane, membrane skeleton and cytoskeleton may be involved.

Introduction

Platelet aggregation is involved in the formation of hemostatic plugs and arterial thrombi. Under normal circumstances, platelets are non-adhesive and circulate singly, but following vessel wall injury they adhere to the injury site and to each other. During the hemostatic process, platelet aggregates, stabilized by fibrin, arrest bleeding from injured or severed vessels. In contrast to this useful function, platelet aggregates that form on injured vessels, on ruptured atherosclerotic plaques, or in regions of high shear contribute to the narrowing of blood vessels. If thrombi are unstable, they may embolize and block smaller vessels downstream from an injury site. Since platelet aggregation has a major role in the clinical complications of atherosclerosis (myocardial infarction, ischemic stroke, and peripheral vascular disease), there is intensive study of the processes involved in platelet aggregation and of inhibitors of platelet activation.

In vivo, activators of platelets include the agonists that are listed in Table 23.1. Receptors for some of the most important agonists are discussed in Chapters 8–11. Aggregating agents can act singly, and are frequently studied singly in vitro, but in vivo they undoubtedly act in concert with each other in a process described as synergism. Synergistic responses result in a combined effect that is greater than the additive effects of the single stimuli[1,2]. In vivo, the most important aggregating agents are collagen in the vessel wall, ADP from red blood cells or released from the platelets themselves, thromboxane A_2 formed by stimulated platelets, and thrombin, although other agonists such as serotonin may contribute to the aggregation process. Epinephrine alone does not cause platelet aggregation, but it can strongly enhance aggregation by other agonists[3–5].

Table 23.1. In vivo aggregating agents and conditions

ADP
Collagen
Arachidonic acid and prostaglandin endoperoxides PGG_2 and PGH_2, and thromboxane A_2
Thrombin and the cleaved peptide of the protease-activated receptor, PAR1
Epinephrine and norepinephrine[a]
Platelet activating factor (PAF)
Serotonin
Arginine vasopressin (AVP)
Thrombospondin
Cathepsin G
Plasmin
Bacteria and endotoxin, viruses, and parasites
Tumour cells
Immune complexes and antiplatelet antibodies
High levels of fluid shear stress

Note:
[a] Epinephrine is not a true aggregating agent, but exerts strong synergistic effects with other agonists (see text).

When an aggregating agent interacts with its receptor(s) on the platelet surface, intracellular signalling reactions occur that result in a change in the conformation of glycoprotein (GP)IIb/IIIa (αIIbβ3) (inside-out signalling) so that it becomes a receptor for fibrinogen or von Willebrand factor. Each of these proteins can form bridges between the stimulated platelets, leading to the formation of a mass of aggregated platelets[6]. Binding of fibrinogen or von Willebrand factor causes further changes in the conformation of GPIIb/IIIa, and also additional internal changes (outside-in signalling)[7,8].

The number of inhibitors of platelet function is enormous and constantly increasing. In 1991, George and Shattil[9] provided a large list of drugs, foods, spices and vitamins that may cause abnormalities of platelet function. The inhibitory effect of most of these substances has been found by in vitro testing, and there are few reports of bleeding problems, except with aspirin. Some of the drugs that are routinely recommended for inhibition of thrombosis in subjects at risk, or to inhibit platelet aggregation after bypass surgery, percutaneous transluminal coronary angioplasty (PTCA), endarterectomy, transplantation, etc. (for example, aspirin, ticlopidine or clopidogrel) are discussed in Part IV. The most recently developed inhibitors of arterial thrombosis are those that inhibit the interaction of fibrinogen with its receptor, GPIIb/IIIa, on activated platelets[10,11] (Chapter 63). However, any of these antithrombotic agents that interfere with platelet aggregation carry with them the risk of bleeding since platelet aggregation is involved in hemostasis as well as in the formation of arterial thrombi.

A number of naturally occurring, but rare, abnormalities of platelet aggregation have contributed significantly to our understanding of the processes by which platelets adhere to each other. Some of these are considered in Chapters 42–44 and in the chapters concerning platelet receptors (Chapters 8–13). They include Glanzmann's thrombasthenia in which abnormalities of GPIIb/IIIa have been identified[12,13]; von Willebrand disease[14]; the Bernard–Soulier syndrome in which glycoprotein Ib/IX/V is defective[15]; platelet storage pool defects[16,17]; abnormalities of the thromboxane A_2 receptor[18]; disorders of signal transduction and secretion[19]; and defects of the ADP receptor[20–22].

Platelet aggregation in vitro

A number of devices have been used to measure platelet aggregation in vitro (Chapters 30 and 31). Initially, aggregation was observed visually in anticoagulated platelet-rich plasma, or microscopically. The development of aggregometers in which changes in light transmission could be measured at 37 °C in rapidly stirred platelet-rich plasma or in suspensions of washed platelets provided a far greater opportunity for measuring platelet responsiveness to a variety of stimuli and the effect of inhibitors of platelet aggregation[23,24]. More recently, platelet aggregation in diluted whole blood has been studied by impedance aggregometry[25,26]. Other techniques involving quenched-flow single-particle counting devices[27]; platelet function analysers (PFA-100, Dade)[28,29]; and RPFA (rapid platelet function assay, Accumetrics)[30], cone-and-plate devices[31,32], and flow cytometry[33] have been used to assess the extent of platelet aggregation. Some of these methods have been compared by Bennett[34] and by Nicholson and colleagues[35]. Currently, there is intense interest in bedside devices such as the RPFA to monitor platelet reactivity during the administration of inhibitors of GPIIb/IIIa[36,37].

Turbidometric platelet aggregation

After interaction with an aggregating agent, platelets rapidly change shape from discs to spiny spheres with pseudopodia (see Chapter 22). In an aggregometer, this change results in a decrease in light transmission, and a decrease in the amplitude of the oscillations of light transmission that are characteristic of disc-shaped platelets. Shape change can occur without platelet aggregation, for example, if platelets are exposed to an aggregating agent without stirring, or if no fibrinogen or von Willebrand factor is available for binding. In a stirred system, there usually appears to be a lag phase before an increase in light transmission occurs, but small aggregates (2–6 platelets) have been found to be present during this time[38–41]. The formation of larger aggregates is indicated by an increase in light transmission and eventually by large oscillations as the aggregates interrupt the light beam (Fig. 23.1). If the platelets deaggregate, light transmission decreases. Upon stimulation with most aggregating agents (ADP is a major exception, see below), platelets form thromboxane A_2 and release the contents of their storage granules, P-selectin (CD62P, an alpha granule membrane protein) appears on the platelet surface, and the surface develops procoagulant activity (see Chapters 24–26). Strong stimulation, for example with a combination of collagen and thrombin, results in the formation of microparticles[42]. The presence of circulating, procoagulant microparticles has been demonstrated in several clinical conditions[43]. These events are the result of the intracellular signalling reactions that are set in motion when an agonist interacts with its receptor(s) on the platelet surface. Among the internal changes that occur are an increase in cytosolic calcium, activation of phospholipase A_2 leading to mobilization of arachidonic acid which is converted to thromboxane A_2, and activation of phospholipase C, causing breakdown of inositol phospholipids to form 1,2-diacyl glycerol (DAG) and 1,4,5-inositol trisphosphate (IP_3). DAG activates protein kinase C and IP_3 causes mobilization of calcium from internal stores. More detailed descriptions of internal signalling and cytoskeletal changes are given in other chapters in this section.

The extent to which platelets aggregate in vitro is influ-

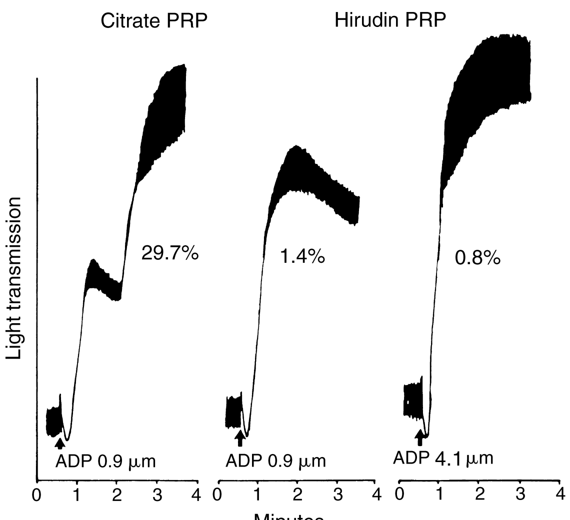

Fig. 23.1. Effect of the anticoagulant on aggregation and release of ^{14}C-serotonin from prelabelled platelets stimulated with ADP. Platelets in citrated plasma (low calcium concentration) undergo two phases of aggregation and release ^{14}C-serotonin from their amine storage granules in response to 0.9 μM ADP (left tracing). Platelets in plasma from blood anticoagulated with hirudin undergo only a single phase of aggregation and do not release amine storage granule contents (centre tracing), even when the concentration of ADP is higher (4.1 μM) (right tracing). The percentages of ^{14}C-serotonin released in three minutes after the addition of ADP are shown beside the aggregation tracings. Reprinted with permission[44].

enced by the conditions under which the blood is collected. Care should be taken to avoid stressing the donor who should not have had antiplatelet drugs during the preceding week; the time between venipuncture and testing should be monitored since the responsiveness of platelets may increase as the time after venipuncture lengthens if CO_2 is lost and the pH rises; hemolysis must be avoided because red blood cells contain ADP; siliconized or plastic tubes should be used to prevent platelets sticking to the sides of the containers; storage temperature, plasma pH, platelet count, length of stir bar and speed of stirring should be standardized. These requirements have been discussed in detail elsewhere[44–47]. When aggregation is to be tested in suspensions of isolated platelets in artificial media, a physiological concentration of ionized calcium (1–2 mM), a source of metabolic energy such as glucose, a protective protein such as albumin, and apyrase to degrade any ADP that is lost from the platelets should all be present to retain platelet sensitivity to low concentrations of weak agonists. Added fibrinogen is also necessary in studies of aggregation by ADP or other weak agonists that do not cause the release of appreciable amounts of the contents of the platelet storage granules.

Impedance platelet aggregometry

In this method, anticoagulated whole blood is diluted 1:1 with saline and warmed to 37 °C in a cuvette in which a two-electrode assembly is inserted[34]. While the sample is stirred, an aggregating agent is added and the increase in impedance (measured in ohms) is recorded as platelets aggregate and adhere to the electrodes. The recording is similar to that resulting from turbidometric aggregation in platelet-rich plasma, except that the lag phase is prolonged to 10 to 30 s and shape change and second phase aggregation are not evident[26]. Inhibitors of platelet aggregation appear to be less effective in this whole blood impedance method[26] and it is affected by the hematocrit[48,49] and the platelet count[50]. The advantages over turbidometric aggregometry are that less blood is required, the preparation of platelet-rich plasma is avoided, and aggregation of lipemic blood samples can be measured[49]. Impedance aggregometry, like turbidometric aggregometry, is insensitive to the formation of small platelet aggregates[34].

Effects of the anticoagulant

The choice of anticoagulant affects the aggregation response. When EDTA is used, the concentration of ionized calcium is too low to support platelet aggregation, although shape change occurs. However, in some individuals, platelets are agglutinated in EDTA-anticoagulated blood by autoantibodies, leading to falsely low platelet counts; this phenomenon was at one time described as spontaneous aggregation, but it is now referred to as pseudothrombocytopenia[51–53]. In contrast, normal platelets that are stored at 37 °C for 5–7 minutes or longer in citrated plasma to which EDTA has been added, lose their ability to aggregate in response to ADP and other weak agonists when adequate concentrations of calcium are restored[54]. This loss of aggregability caused by strong calcium chelation is attributed to an irreversible change in the fibrinogen receptor, GPIIb/IIIa.

Anticoagulants that preserve the physiological concentration of ionized calcium are hirudin (now available as recombinant hirudin) and PPACK (D-phenylalanyl-L-prolyl-L-arginine chloromethyl ketone), both of which act by inhibiting the thrombin that forms after blood collection. However, although PPACK is a satisfactory anticoagulant for human blood, it agglutinates rabbit platelets[55]. Heparin has had a long history of use as an anticoagulant,

Cambridge Books Online © Cambridge University Press, 2009

but as Zucker[56] pointed out in 1975 'platelet aggregates are commonly found in blood collected directly into heparin. Their presence can be inferred from the low platelet count that may be noted in platelet-rich plasma'. The platelet aggregates sediment with the red blood cells or stick to the walls of the tube[46].

By far the most commonly used anticoagulant is sodium citrate, which acts by lowering the concentration of ionized calcium into the micromolar range (40 μM when 10.9 mM citrate is used[57] and <5 μM when 12.9 mM citrate is used[58]), thus inhibiting thrombin formation so that aggregation can be tested in platelet-rich plasma. However, this low concentration of ionized calcium has two effects that are seldom understood. The first effect is that, in this low calcium medium, platelets brought into close contact with each other by rapid stirring are induced to form thromboxane A_2, release their granule contents, including ADP from the amine storage (dense) granules, and undergo a second phase of aggregation that is not readily reversible (Fig. 23.1)[59]. This phenomenon occurs not only in citrated platelet-rich plasma, but in suspensions of washed platelets in media to which no calcium salt has been added. In such a medium the concentration of ionized calcium is ≈20 μM and ADP will induce a primary phase of aggregation, followed by the secondary phase (Fig. 23.2), as it does in citrated platelet-rich plasma. However, if calcium (0.5 mM or higher) is added to the medium, only the primary phase of ADP-induced aggregation occurs, thromboxane A_2 does not form and little release of granule contents occurs (Fig. 23.2). Other agents that bring platelets into close contact with each other in a low calcium medium can be shown to have the same effect, such as polylysine[60,61] or the agglutinating agent ristocetin[62]. The secondary phase is abolished by aspirin or other non-steroidal anti-inflammatory drugs which prevent the formation of thromboxane A_2. Because of this inhibition by aspirin, some investigators have chosen to study aggregation in the presence of aspirin to prevent the secondary aggregation effect. However, the primary response of platelets to aggregating agents is diminished in a low calcium medium (compare the extent of primary aggregation in citrated platelet-rich plasma with that in hirudin platelet-rich plasma in Fig. 23.1)[59]. This weaker response is the second, largely unrecognized effect of testing platelet aggregation in a low calcium medium. An important consequence of this effect is the finding that citrate anticoagulation 'enhances the apparent inhibitory activity' of inhibitors that interfere with the interaction of fibrinogen with GPIIb/IIIa, as shown by Phillips and colleagues[63] with Integrilin (eptifibatide). These investigators reported that lower concentrations of Integrilin inhibited platelet aggregation in plasma anticoagulated with citrate

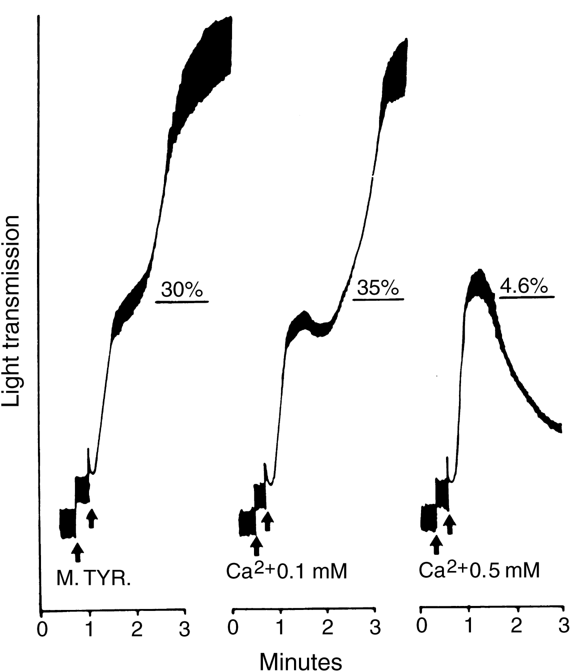

Fig. 23.2. Effect of calcium concentration in the suspending medium of washed human platelets prelabelled with ^{14}C-serotonin and aggregated by ADP (0.8 μM). Platelets were suspended in a modified Tyrode-albumin solution (from which calcium was omitted) containing apyrase and fibrinogen. Without added calcium or with 0.1 mM calcium (left tracings), the platelets undergo two phases of aggregation and release ^{14}C-serotonin (percentage released in two minutes is indicated beside the aggregation curves). In the presence of 0.5 mM calcium, only the primary phase of aggregation occurs and release of ^{14}C-serotonin is greatly inhibited (right tracing).
Reprinted with permission[44].

than with PPACK, and suggested that since the inhibitory activity was overestimated in blood samples collected with citrate, 'it may be possible to achieve greater antithrombotic efficacy beyond that observed in clinical trials to date with Integrilin'. Similar observations have been reported by other investigators[64,65].

Clinically, routine tests of platelet responsiveness to aggregating agents usually involve the use of ADP, collagen, epinephrine, arachidonic acid and ristocetin with platelets in citrated platelet-rich plasma. With platelets from individuals with Glanzmann's thrombasthenia, none of these aggregating agents induces aggregation, but the agglutinating agent ristocetin causes platelets to adhere to each other. Lack of aggregation in response to arachidonic acid and epinephrine, abnormally low responsiveness to collagen, and only a primary phase of aggregation in response to ADP, usually indicates that the subject has taken aspirin

Cambridge Books Online © Cambridge University Press, 2009

or one of the large number of other substances that inhibit thromboxane A_2 formation. (In 1974, Leist and Banwell[66] provided a list of about 250 drugs that contain aspirin.) Rarely would an individual with a defect in the formation of thromboxane A_2[67] or of the thromboxane A_2 receptor(s)[18] be encountered. If ristocetin-induced agglutination is defective, either von Willebrand disease or Bernard–Soulier syndrome is indicated. A more definitive test for von Willebrand disease can be done with fixed or lyophilized platelets[68].

ADP-induced aggregation

In the early days (1964), ADP was administered intravenously to humans[69], but other experiments of this type have been done only with experimental animals[70,71]. ADP injected into the blood stream causes a rapid fall in the platelet count and many platelet aggregates are observable in arterioles, venules and capillaries. After a short time, however, the platelet count returns to the pre-infusion level and few platelet aggregates are visible upon histological examination. Thus, in vivo, ADP-induced aggregation is readily reversible, undoubtedly because only the primary phase of aggregation occurs, and because the ADP phosphohydrolase in plasma[72] and the ecto-ADPase on other blood cells and on the endothelium[73,74] rapidly dephosphorylate the ADP.

The role of ADP in platelet aggregation was first recognized by Gaarder and her colleagues[75] in 1961 when they showed that ADP from red blood cells could cause aggregation. 'Spontaneous' aggregation occurs under conditions of high shear and is much greater in whole blood than in platelet-rich plasma; ADP from red blood cells is at least partly responsible since enzymatic removal of ADP inhibits this effect[76–78]. ADP from red blood cells may be important in the formation of the platelet aggregates in arterial thrombi, particularly at sites of high shear and in conditions in which hemolysis occurs[73].

ADP is also released from stimulated platelets themselves and plays an important synergistic role in aggregation by all agonists that induce the release of platelet granule contents. It also has been shown to take part in stabilizing aggregates induced by other agonists such as thrombin[79,80].

There appear to be three ADP receptors on platelets, namely $P2X_1$, an ion channel linked to Ca^{2+} influx, the purinergic $P2Y_1$ receptor that is responsible for shape change through intracellular calcium mobilization, and a $P2_{cyc}$ ($P2T_{AC}$) receptor that causes adenylyl cyclase inhibition and is involved in enhancing aggregation[12,81]. (See Chapter 9.)

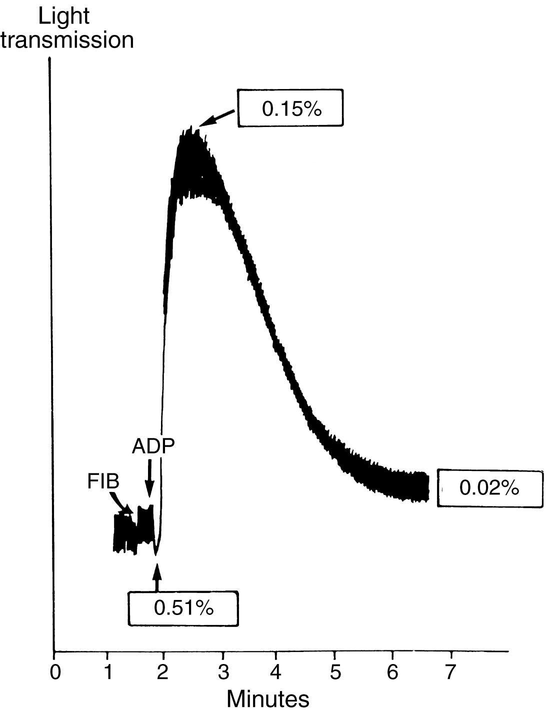

Fig. 23.3. Association of ^{125}I-fibrinogen with washed human platelets during shape change, aggregation and deaggregation induced by 10 μM ADP. Percentages of radioactive fibrinogen associated with the platelets are shown in the boxes beside the aggregation curve.

In vitro, in a medium with a physiological concentration of ionized calcium, ADP causes only a primary phase of platelet aggregation that is readily reversible since it is not accompanied by thromboxane A_2 formation or significant release of platelet granule contents. Little P-selectin appears on the platelet surface and procoagulant activity does not develop. The fibrinogen that binds to the platelets during aggregation dissociates during deaggregation (Fig. 23.3)[82]. Primary aggregation of this type is readily demonstrable in platelet-rich plasma from human blood anticoagulated with hirudin or PPACK, and in suspensions of washed platelets in media containing a physiological concentration of ionized calcium (Figs. 23.1, 23.2). Under these conditions, although high concentrations of ADP cause extensive aggregation, the changes associated with secondary aggregation do not occur (Fig. 23.1). However, as discussed above, when human platelets in a low calcium medium such as citrated platelet-rich plasma are aggregated by ADP at concentrations above 1–2 μM, primary aggregation does not reverse, but is followed by secondary aggregation. At intermediate concentrations of ADP, this secondary response is evident as a second wave of the

Cambridge Books Online © Cambridge University Press, 2009

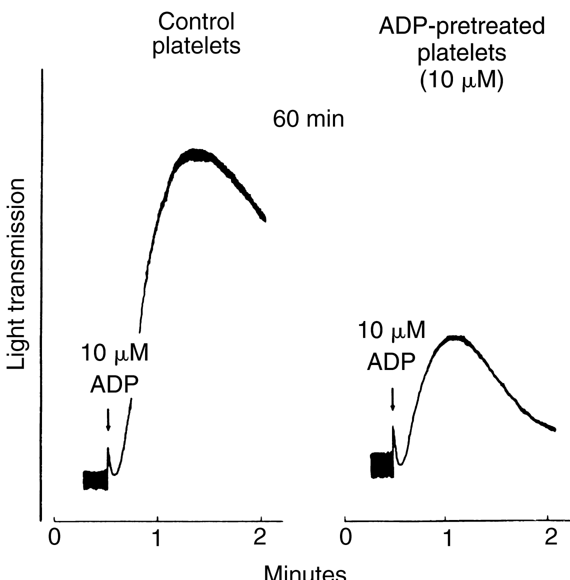

Fig. 23.4. Effect of pretreating platelets with 10 μM ADP on their subsequent response to a second stimulation with ADP. Washed platelets in Tyrode-albumin solution were exposed for 60 minutes to the diluent solution (control, left tracing) or ADP (right tracing) before the addition of fibrinogen and 10 μM ADP.

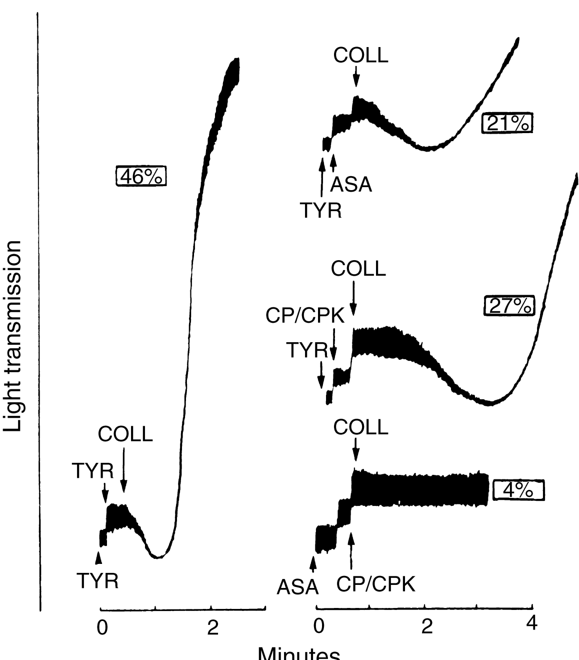

Fig. 23.5. Effect of creatine phosphate/creatine phosphokinase (CP/CPK, to convert released ADP to ATP) and aspirin (ASA, to prevent formation of thromboxane A_2) on platelet aggregation and release of ^{14}C-serotonin from prelabelled platelets. In combination, these inhibitors block the responses of platelets to collagen (COLL). Tyrode solution (TYR) was added to maintain constant volume. The percentages of released ^{14}C-serotonin 3 minutes after the addition of collagen are shown in the boxes beside the aggregation tracings.

increase in light transmission in an aggregometer (Fig. 23.1), but with high ADP concentrations (10 μM or higher) the first and second waves fuse. There is a species difference in the effect of a low concentration of ionized calcium on ADP-induced aggregation. Platelets from humans and most other primates, cats, piebald and rosette guinea pigs (but not white guinea pigs), and about one third of mongrel dogs undergo secondary ADP-induced aggregation, but platelets from rabbits, rats, mice, pigs, mink, cows, goat, sheep, horses and most dogs do not[83–85].

In vitro, platelets that have undergone the primary phase of ADP-induced aggregation and have deaggregated are temporarily refractory to subsequent additions of ADP (Fig. 23.4)[23,86–89]. Platelets that have been isolated and resuspended in an artificial medium also become refractory to ADP. Because the development of this refractoriness can be prevented by the inclusion of apyrase (ATPDase EC 3.6.1.5) in the suspending medium, it is evident that ADP lost from the platelets themselves is responsible for this diminished responsiveness[90,91]. Recently, the refractory state has been attributed to desensitization of the $P2Y_1$ receptor caused by its internalization[89].

One to two days following their oral or intravenous administration, the thienopyridines ticlopidine and clopidogrel (actually their metabolites) specifically inhibit ADP-induced aggregation[92,93]. This inhibition has been attributed to their blocking the inhibitory effect of ADP on adenylyl cyclase[94,95]. (See Chapter 62.)

Aggregation by collagen

Several components of the platelet surface have been implicated as receptors for collagen[96,97]. (See Part 1, Chapter 11.) Although at least 19 types of collagen have been characterized, types I and III are most effective as platelet aggregating agents. The native triple–helical structure of collagen is required[98] and usually fibrils from equine tendon are used. GPIa/IIa (integrin $\alpha2\beta1$) and GPVI are the receptors on platelets through which they adhere to collagen and are activated[12].

When collagen is tested as a platelet aggregating agent in vitro, there may be a lag phase of up to a minute before there is an appreciable increase in light transmission in an aggregometer (Fig. 23.5). During this time some of the platelets adhere to the collagen fibrils and are induced to

Cambridge Books Online © Cambridge University Press, 2009

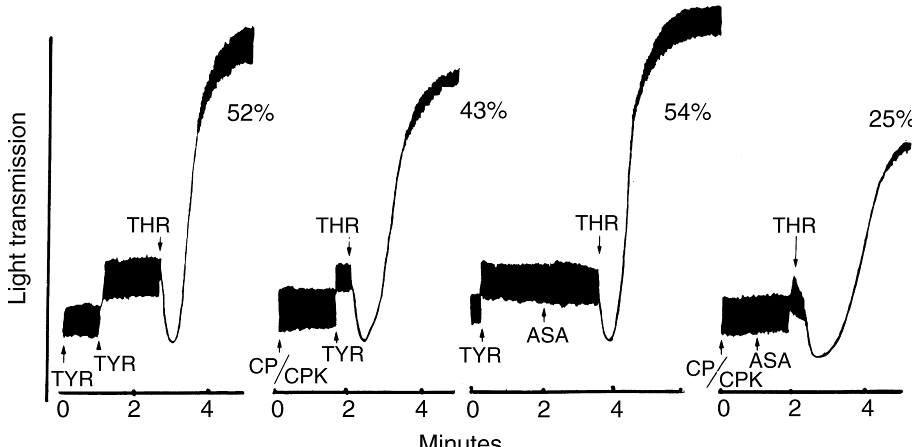

Fig. 23.6. Effect of creatine phosphate/creatine phosphokinase (CP/CPK, to convert released ADP to ATP) and aspirin (ASA, to prevent formation of thromboxane A_2) on platelet aggregation and release of ^{14}C-serotonin from prelabelled platelets. This combination of inhibitors reduces, but does not abolish, platelet responses to 0.05 U/ml thrombin (THR). Tyrode solution (TYR) was added to maintain constant volume. The percentages of released ^{14}C-serotonin three minutes after the addition of thrombin are shown in the boxes beside the aggregation tracings.

form thromboxane A_2 and to release ADP. These two aggregating agents act synergistically on the non-adherent platelets, causing aggregation. Aggregation can be lessened by inhibiting either agonist, for example, by the use of aspirin to prevent formation of thromboxane A_2, or by rapid removal of ADP with apyrase or creatine phosphate/creatine phosphokinase (CP/CPK); the combination of these two types of inhibitors may be completely inhibitory (Fig. 23.5)[99,100].

Aggregation induced by arachidonic acid and thromboxane A2

When platelets interact with most aggregating agents, phospholipase A_2 is activated and liberates arachidonic acid from membrane phospholipids. The cyclo-oxygenase and thromboxane synthase enzymes in the platelets convert arachidonic acid to thromboxane A_2[101] which causes aggregation and the release of platelet granule contents (Chapter 10). Non-steroidal anti-inflammatory drugs inhibit cyclo-oxygenase, but aspirin is unique in that it irreversibly acetylates the enzyme so that it is inhibited for the remainder of the life of the platelet. Thus the effect of the ingestion of aspirin lasts for several days and is indicated by absent or diminished responsiveness of the platelets to arachidonic acid. Since thromboxane A_2 is very short-lived, tests of it as an aggregating agent are generally done with stable mimetics, such as U46619 (9,11 dideoxy-11α-epoxymethano-prostaglandin $F_{2\alpha}$)[102].

Some drugs with both thromboxane synthase inhibitory activity and thromboxane receptor-blocking effects have been developed to prevent the activation of platelets by thromboxane A_2[103].

Thrombin-induced aggregation

Thrombin is the strongest aggregating agent that platelets encounter in vivo. As described in Chapter 8, the protease-activated receptors, PAR1 and PAR4, are responsible for the induction of aggregation by thrombin[104]. Although thrombin causes the formation of thromboxane A_2 and releases ADP from the platelet dense granules, and these aggregating agents increase the extent of thrombin-induced aggregation, it is not prevented when thromboxane A_2 formation is blocked and ADP is rapidly removed (Fig. 23.6)[99,100]. However, ADP has been shown to stabilize thrombin-induced aggregates[79,80].

Although thrombin-induced aggregation cannot be studied satisfactorily in platelet-rich plasma because of the formation of fibrin, the effects of thrombin are readily studied in suspensions of washed platelets in artificial media. After the thrombin receptor, PAR1, and its mechanism of action were discovered by Coughlin's group[105], peptides of the tethered ligand such as SFLLRN (also called TRAP, i.e. thrombin receptor-activating peptide) have been used to study aggregation in platelet-rich plasma as well as in suspensions of washed platelets. In using such peptides as surrogates for thrombin, one must be aware that they do

Cambridge Books Online © Cambridge University Press, 2009

not interact with other thrombin receptors such as PAR4 or the high affinity thrombin receptor on glycoprotein Ib. In addition, SFLLRN does not aggregate platelets from rabbits, rats, dogs, pigs and hamsters[106,107].

Unexpectedly, Furman and colleagues[108] have shown an aggregating effect on human platelets of the peptide that is cleaved from the thrombin receptor when the tethered ligand is exposed.

When platelets have been aggregated by thrombin, they are not readily deaggregated, because fibrin formed from fibrinogen released from the alpha-granules binds them together; it is necessary to use a proteolytic enzyme such as chymotrypsin or plasmin to achieve deaggregation[109,110]. (In vivo, fibrinolytic agents are effective in disrupting arterial thrombi.) It is, however, possible to activate platelets with thrombin to induce them to release their granule contents without aggregation and recover them as discrete, degranulated platelets[111]. Degranulation with SFLLRN has been developed as an even gentler method[112]. Degranulated platelets have P-selectin and procoagulant phospholipid on their surface. Despite the reactions that they have undergone, in experiments with rabbits and baboons, degranulated platelets have been shown to survive normally upon reinjection[109,113]. P-selectin is lost from the surface of thrombin-activated baboon platelets in the circulation[113], but the length of time that they retain their procoagulant activity in vivo is not established (in vitro it is present for up to 4 hours[114]). If the procoagulant surface persists for an appreciable time in vivo, platelets that recirculate following disruption of a thrombus by fibrinolysis and the forces of flowing blood may contribute to thrombin generation and further aggregation at other sites in the circulation.

Epinephrine

Although epinephrine is not a true aggregating agent[3–5], it does aggregate platelets in citrated platelet-rich plasma[115]. However, an initial change in platelet shape does not occur[3,47,86,116]. Epinephrine rarely aggregates platelets in plasma from blood anticoagulated with hirudin or PPACK (Fig. 23.7)[3,57]. Epinephrine-induced aggregation in citrated platelet-rich plasma is invariably inhibited if subjects have recently ingested aspirin or other drugs that prevent thromboxane A_2 formation, providing an excellent test for the presence of such inhibitors.

Epinephrine interacts with α_2-adrenergic receptors on human platelets, synergistically and strongly enhancing the effects of other aggregating agents, even when they are tested at concentrations too low to have measurable aggregating effects by themselves[1,3]. The epinephrine-induced aggregation in citrated platelet-rich plasma is probably the result of traces of ADP and/or thrombin[4,117]. It seems likely that the wide variations in the responsiveness of human platelets to epinephrine is related to the concentration of other agonists in the plasma, and/or the presence of inhibitors from ingested substances.

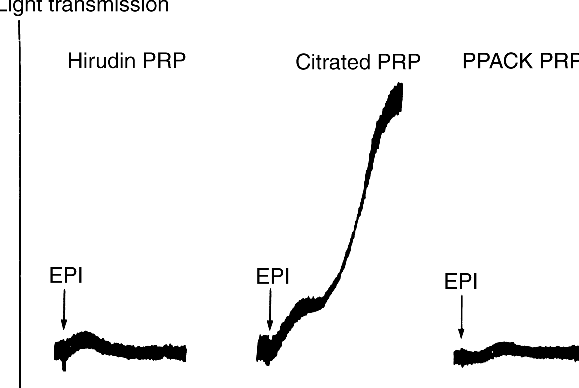

Fig. 23.7. Effect of 10 μM epinephrine (EPI) in platelet-rich plasma (PRP) from blood anticoagulated with hirudin (50 U/ml), sodium citrate (1 part 3.8% to 9 parts of blood), or PPACK ($FPRCH_2Cl$, 40 μM). Platelets maintain their disc shape, indicated by the oscillations of light transmission, and extensive aggregation occurs only in citrated PRP. (Reprinted with permission[3].)

It has been suggested that stress, leading to elevated levels of circulating epinephrine, may be linked to coronary heart disease[118,119].

Aggregation induced by platelet activating factor (PAF)

The wave of interest in PAF (1–O-alkyl-2-acetyl-sn-glyceryl-3-phosphorylcholine) as a platelet aggregating agent[120] has passed and its other functions have been recognized as of more importance[121]. PAF originates from IgE-sensitized basophils, stimulated macrophages and neutrophils, and platelets themselves[122], although human platelets, in contrast to rabbit platelets, form very little upon stimulation with thrombin[123]. Human platelets are much less sensitive to PAF than are guinea pig or rabbit platelets with which much of the early work was done; platelets from rats, mice and most primates are insensitive to PAF[120,124]. At one time PAF was considered as possibly responsible for a postulated third pathway of thrombin-induced aggregation, but with

Cambridge Books Online © Cambridge University Press, 2009

the identification and elucidation of the action of the thrombin receptor, PAR1, this suggestion regarding the role of PAF is no longer considered.

Nevertheless, PAF is a weak aggregating agent, similar to ADP in that in a medium with a physiological concentration of calcium it does not cause thromboxane A_2 formation or extensive release of granule contents. However, in citrated platelet-rich plasma or an artificial medium with no added calcium, PAF induces human platelets to form thromboxane A_2 and release ADP[120]. There may be circumstances in vivo in which PAF acts synergistically with other agonists to enhance aggregation.

Serotonin-induced aggregation

Serotonin (5-hydroxytryptamine, 5-HT) is a weak agonist for human platelets and the slight aggregation response is followed by deaggregation[115,125]. In contrast, cat platelets in citrated platelet-rich plasma undergo second phase aggregation in response to serotonin at concentrations greater than 3 μM[126]. Serotonin exerts mild synergism with other agonists[1,127]. Platelet activation by serotonin involves 5-HT_2 receptor binding sites which differ from the sites responsible for serotonin uptake[128] as shown by experiments with ketanserin, a selective 5-HT_2 receptor antagonist.[127,129]. Platelets carry all the serotonin in the blood in their amine storage granules and when it is released upon stimulation with agonists such as thrombin or collagen, it enhances their effects.

Aggregation induced by arginine vasopressin (AVP)

Arginine vasopressin is a nine amino acid peptide hormone with effects on many systems in addition to its effect on platelets. Wun[130] has reviewed the evidence that the receptor on human platelets is of the V_{1a} type.

In 1972, Haslam and Rosson[131] discovered that platelets are aggregated by vasopressin, although it is classified as a 'weak' agonist. A concentration of at least 2.5 nM is required for minimal aggregation, with a maximum response at 100 nM, and this concentration is several orders of magnitude greater than physiological levels. However, in heparinized platelet-rich plasma, 1 pM has been shown to cause the appearance of P-selectin on the platelet surface, indicating activation of the platelets[132]. In addition, vasopressin can act in synergy with other aggregating agents[118,133]. The aggregation response of human platelets to vasopressin has been shown to be heterogeneous[134]. Platelets from some normal individuals display only primary aggregation, followed by deaggregation, induced by concentrations of vasopressin as high as 100 nM, whereas platelets from other subjects undergo extensive secondary aggregation in response to as little as 10 nM[134].

The beneficial effect of vasopressin infusions in gastrointestinal bleeding may be related to a combination of vasoconstriction with the release of von Willebrand factor, and platelet activation[130].

The synthetic analogue of vasopressin, Desmopressin (1-desamino-8-D-arginine vasopressin, DDAVP) has not been shown to aggregate platelets, but it does increase platelet aggregation induced by collagen or ADP[135]. DDAVP primarily acts on V_2 receptors and has only minor V_1 agonist activity[130]. However, in concentrations reached after the usual therapeutic dose, DDAVP does induce the expression of P-selectin on the platelet surface[136].

Thrombospondin-induced aggregation

The interactions of thrombospondin with platelets have been reviewed by Mosher[137] and by Legrand and coworkers[138]. It is released from the alpha granules of stimulated platelets and binds to the platelet surface; it is also present in the subendothelial matrix. Thrombospondin is responsible for the endogenous lectin activity of stimulated platelets[139]. It has been suggested that thrombospondin binds to fibrinogen and to the platelet surface and thus strengthens fibrinogen binding[140]. In vitro, thrombospondin has been reported to slowly aggregate platelets in a reaction involving GPIV (CD36), but not GPIIb/IIIa[141]. It also promotes aggregation induced by other agonists. Mosher[137] has pointed out that aggregated thrombospondin could agglutinate platelets, and that there are many possible interactions of thrombospondin with molecules at the platelet surface. Recently, thrombospondin has been shown to activate platelets via integrin-associated protein (IAP/CD47), a five membrane-spanning receptor[142]. Chung and colleagues[143] have raised the possibility of a role for IAP and thrombospondin in the early activation of platelets upon adhesion to collagen.

Aggregation induced by cathepsin G

The proteolytic enzyme cathepsin G from activated leukocytes can induce platelet aggregation, release of granule contents, thromboxane A_2 formation, increase in cytosolic calcium and activation of protein kinase C[144–146]. In 1994, Selak[147] obtained evidence that the receptor for cathepsin

Cambridge Books Online © Cambridge University Press, 2009

G differed from the receptor for thrombin, and it has now been shown that the protease-activated receptor, PAR4, mediates the responses of platelets to cathepsin G[148]. Cathepsin G also has synergistic effects with other aggregating agents and these effects are partly due to released ADP[149]. Pretreatment of platelets with this enzyme cleaves the thrombin receptor PAR1 so that the tethered ligand is lost and the platelet responses to thrombin are greatly reduced. Their responsiveness to some other aggregating agents (collagen, SFLLRN, U46619) is diminished, but they remain normally responsive to ADP in the presence of fibrinogen[150]. Thus, although cathepsin G activates platelets, if they recirculate after interaction with it, their subsequent responses to aggregating agents will be lessened.

Effects of plasmin

The proteolytic enzyme plasmin cleaves GPIb and GPIIb/IIIa on the platelet surface, in addition to its fibrinolytic action[151–153]. In vivo, platelets are exposed to endogenous plasmin, but they are also exposed to high concentrations when plasminogen activators are infused to disrupt thrombi in arteries[154]. When platelets that have been exposed to plasmin during fibrinolysis return to the circulation, their subsequent responses to aggregating agents are changed. Coller[154] has reviewed the platelet-activating and platelet-inhibiting effects of fibrinolytic agents in vivo.

In vitro, plasmin at concentrations ≥1 caseinolytic unit causes platelet aggregation, release of granule contents, an increase in cytosolic calcium, inositol phospholipid breakdown and activation of protein kinase C[155,156]. Lower concentrations of plasmin have been reported to inhibit platelet responses to thrombin and other agonists[157–159]. Experimentally, the effects of plasmin on platelets are affected by its concentration and the time and temperature of incubation of the platelets with plasmin[160]. Plasmin has been reported to activate platelets in the same way as thrombin, cleaving PAR1 at Arg 41 and thus revealing the tethered ligand, SFLLRN[161]. However, pretreatment of platelets with plasmin reduces their responsiveness to thrombin[157,158,162]. It was suggested and later shown[163] that plasmin cleaves PAR1 at a point distal to Arg 41 so that SFLLRN is lost (PAR4 could also be a target for plasmin on human platelets.)

Plasmin causes limited cleavage of GPIIb/IIIa, leading to a conformational change that converts it to the receptor for fibrinogen and von Willebrand factor[153,164]. Consequently, when plasmin-pretreated platelets are stirred in the presence of fibrinogen, they are aggregated/agglutinated. Rabhi-Sabile and colleagues[164] have implicated von Willebrand factor rather than fibrinogen in this process. The observed potentiation of aggregation of plasmin-pretreated platelets by agonists other than thrombin[162] is probably due to increased binding of ligands that interact with partially cleaved GPIIb/IIIa.

Other in vivo aggregating agents

Although high concentrations (>1 μM) of PGE_2 inhibit human platelet aggregation, lower concentrations in the range produced by activated platelets potentiate aggregation by most agonists[165]. There is evidence that this potentiation involves the 'priming of protein kinase C to activation by other agonists'[166]. Interestingly, in heparinized platelet-rich plasma, PGE_2 directly aggregates pig platelets[165].

Beta-amyloid peptides aggregate platelets[167], and augment ADP-induced aggregation[168]. Stromal cell-derived factor 1 and macrophage-derived chemokine are weak agonists, but enhance platelet responses to other aggregating agents[169]. Thrombopoietin potentiates aggregation induced by other agonists[170,171].

It has been suggested that zinc ions may be a requirement for ADP-induced aggregation by activating protein kinase C and enhancing fibrinogen receptor exposure[172,173]. Short-term zinc deficiency impairs platelet aggregation induced by ADP or arachidonate[174].

Many bacteria induce platelet aggregation and the release of granule contents in vitro and in vivo, and the endotoxin formed by gram negative bacteria can cause disseminated intravascular coagulation (DIC) (see Chapter 51). The very weak effects of endotoxin on human platelets are in contrast to the strong effects of endotoxin on platelets from other species, particularly rabbits.

Several viruses have been shown to cause platelet aggregation and the release of granule contents (see Chapter 52).

Some parasites and tumour cells have also been found to aggregate platelets (see Chapters 53 and 54).

Immune complexes can cause platelet aggregation[175,176] and some platelet antibodies also have this effect. Heparin-induced thrombocytopenia (HIT) is caused by IgG antibodies that recognize complexes of heparin and platelet factor 4, resulting in platelet aggregation via platelet Fc gamma IIa receptors[177,178]. Procoagulant microparticles from the stimulated platelets generate thrombin in vivo, which may be largely responsible for thrombosis associated with HIT[179] (see Chapter 39).

Shear-induced aggregation

Shear-induced platelet aggregation is thought to be responsible for the formation of arterial thrombi at sites where vessel walls have been narrowed by atherosclerotic plaques[180,181]. High wall shear rates also occur during bleeding from severed arterioles[182].

In vitro, platelets aggregate without the addition of an agonist when they are subjected to high levels of fluid shear stress in devices such as a cone-and-plate viscometer[31]. This aggregation response requires the presence of von Willebrand factor multimers, extracellular calcium, ADP released from the platelets, and GPIb and GPIIb/IIIa on the platelet membrane[183]. Shear stress-induced aggregation does not depend on the formation of thromboxane A_2 and thus is not inhibited by aspirin.

Evidence has been obtained that during thrombus formation under high shear stress, von Willebrand factor binds to GPIb and to GPIIb/IIIa and the thrombi are stabilized by fibrinogen binding to GPIIb/IIIa on the activated platelets[184–186]. Shear-induced platelet aggregation is enhanced in platelet-rich plasma from patients with acute myocardial infarction, apparently as a result of an increase in the concentration of von Willebrand factor in the plasma[187,188] (see Part I, Chapter 13).

Spontaneous aggregation and platelet hypersensitivity

In some conditions, spontaneous aggregation occurs upon stirring anticoagulated blood or platelet-rich plasma. Peerschke and Zucker[189] observed spontaneous aggregation upon rewarming and shaking chilled platelets in the presence of fibrinogen. Spontaneous aggregation is a feature of the Montreal Platelet Syndrome[190]. Triplett and colleagues[45] listed a number of conditions in which spontaneous aggregation had been observed, including transient cerebral ischemia, angina pectoris, myocardial infarction, acute peripheral vascular occlusion, and diabetes. Platelet hypersensitivity to aggregating agents has also been reported in these conditions and in hyperbetalipoproteinemia, paroxysmal nocturnal hemoglobinuria, migraine, gout, acute renal failure and hypertension[191,192].

Trip and colleagues[193] have indicated that spontaneous platelet aggregation in vitro is a useful biologic marker for prediction of coronary events and mortality in survivors of myocardial infarction. However, sensitivity of platelets to ADP-induced aggregation does not appear to be predictive of the risk of first episodes of ischemic heart disease[194].

Agglutination induced by ristocetin or botrocetin

The antibiotic ristocetin induces agglutination rather than aggregation, involving von Willebrand factor forming bridges between the platelets. In tests of von Willebrand factor activity, ristocetin is used with paraformaldehyde-fixed platelets[68]. Botrocetin, derived from a snake venom, is used in a similar manner. Unlike aggregation, agglutination does not depend on the metabolic capability of the platelets. When ristocetin is added to unfixed platelets in stirred, citrated platelet-rich plasma, agglutination is followed by a second phase that is aggregation caused by thromboxane A_2 and released ADP.[62].

Bovine or porcine von Willebrand factor causes agglutination of human platelets without the addition of ristocetin[195,196].

Endogenous inhibitors of platelet aggregation

Foremost among inhibitors of aggregation that platelets encounter in the circulation are those that stimulate an increase in the concentration of cyclic AMP in platelets (see Part I, Chapter 20). Adenosine, arising from the dephosphorylation of ATP and ADP, is one of these[197]. With platelets from humans, sheep, dogs and rabbits, adenosine is a potent inhibitor, but it is less effective with platelets from horses, guinea pigs, cats, rats and mice.

Normally, adenosine formed in plasma is rapidly taken up by red blood cells, but this uptake is blocked by the vasodilator dipyridamole, and related pyrimido-pyrimidines. Although these drugs can also raise cyclic AMP levels by inhibition of phosphodiesterase, it is considered that they exert most of their inhibitory effects on platelets by increasing the concentration of adenosine in plasma[198].

Prostacyclin (PGI_2), produced from arachidonic acid by endothelial cells, also raises the concentration of cyclic AMP in platelets and is a potent inhibitor of platelet aggregation[199]. Prostaglandin D_2 is also an inhibitor formed in vivo in small amounts[200].

The vasodilator nitric oxide (NO, originally called endothelium-derived relaxing factor) is a short-lived inhibitor that acts by increasing the concentration of cyclic GMP in platelets[201]. It is formed by the endothelium, platelets and leukocytes[202,203].

ATP and AMP inhibit ADP-induced aggregation by interfering with the binding of ADP to its receptors[204]. ADP is broken down by phosphohydrolases in plasma[72] and by the ecto ADPase on other blood cells and on the endothelium[73,74].

Cambridge Books Online © Cambridge University Press, 2009

Antithrombin (antithrombin III) inhibits the action of thrombin, particularly in the presence of heparin[205]. Heparin cofactor II also inhibits thrombin, and tissue factor pathway inhibitor (TFPI) interferes with the generation of thrombin[206]. The protein C anticoagulant pathway also reduces thrombin formation; its action involves the combination of thrombin with thrombomodulin to activate protein C. Activated protein C forms a complex with plasma protein S that inactivates coagulation factors Va and VIIIa on membrane surfaces[207].

Non-physiological aggregating agents used only in vitro

A large number of reagents that aggregate platelets have been used in vitro in studies of the mechanisms involved in aggregation[204,208], but a comprehensive list of these is beyond the scope of this review. Only a few of the most commonly used agonists will be mentioned here.

The calcium ionophores A23187 and ionomycin induce shape change, aggregation, and the release of granule contents[209]. They have been used extensively to investigate the effects of raising the concentration of calcium in platelets. A23187 is a strong stimulus for microparticle formation[42].

The tumour-promoting agent, phorbol myristate acetate, is an aggregating agent[210] that exerts its effect by activating protein kinase C[211]. Diacylglycerols have a similar effect[212].

Sodium fluoride and fluoroaluminate (AlF_4) have been used to explore G-protein mediated platelet responses[213–215].

Since thromboxane A_2 is a very short-lived compound, several more stable mimetics, such as U46619 are used to stimulate the thromboxane A_2 receptor[102].

Thrombin receptor activating peptides (TRAP), such as SFLLRN or the 14 amino acid peptide that contains it, stimulate the thrombin receptor, PAR1, but do not bind to the other thrombin receptors on platelets[104].

Abnormalities of platelet aggregation

A number of reviews are available that describe hereditary and acquired conditions associated with decreased platelet aggregation and those associated with increased platelet aggregation[12,19,45,216]. Acquired abnormalities of platelet aggregation can be subdivided into those acquired because of disease, and those acquired because of drugs and other ingested substances[9]. The recent increased use of herbal medicines will undoubtedly add to the list of agents that influence platelet function in vivo.

Currently there is considerable interest in ethanol which is a weak inhibitor of aggregation induced by some agonists[217]. This interest has arisen because of the epidemiological evidence that moderate consumption of ethanol is associated with a reduction in the thromboembolic complications of coronary artery disease[218].

Part III has a number of chapters concerning platelet abnormalities, both inherited and acquired.

Conclusion

Platelet aggregation plays a significant role in hemostasis and thrombosis, particularly arterial thrombosis. A wide variety of agents cause platelet aggregation or contribute to its extent. A very large number of inhibitors have been identified and many new ones have been developed. The complexities of receptors and the signalling pathways in platelets are still unfolding. As a result of increased understanding of the mechanisms involved in aggregation, several therapeutic interventions are in use that have significantly reduced the morbidity and mortality from hemorrhagic and thrombotic disorders.

Amplification loops: release reaction[1]

Marc F. Hoylaerts

Center for Molecular and Vascular Biology, University of Leuven, Belgium

Introduction

As a consequence of vessel wall damage, circulating platelets adhere to subendothelial ligands, targeting them to the site of injury. Adhering platelets undergo a multitude of signalling events, which result in platelet activation and spreading. Whereas platelet spreading on collagen and binding of adhesive proteins facilitate subsequent recruitment of additional platelets from the circulation, the activation of platelets also leads to the controlled release of their contents. Thus, the local secretion of further agonists of platelet activation, via a signalling controlled exocytosis reaction, contributes to the rapid recruitment of circulating platelets to the injury site; secreted proteins also facilitate fibrin formation.

In a forming platelet aggregate, as a result of inside-out signalling, the platelet receptor for fibrinogen, i.e. GPIIb/IIIa, is assembled[1]. The binding of fibrinogen to this receptor not only enables platelet cross-linking, but further contributes to the ongoing platelet activation via outside–in signalling[2]. This highly localized enhancement of ongoing platelet activation leads to marked degranulation in a confined area. Thus, platelet aggregate formation occurs as the result of both platelet adhesion and localized secretion, leading to the formation of a platelet plug, in which large numbers of platelets are completely degranulated[3].

Platelet granules and exocytosis

Morphologically, three types of platelet granules can be released: dense core granules (δ-granules), α-granules and platelet lysosomes (λ-granules).

Platelet granule contents

Alpha-granules contain proteins relevant for platelet interactions (the GPIIb/IIIa fibrinogen receptor, fibrinogen, von Willebrand factor, thrombospondin-1, fibronectin, vitronectin, GAS6, see further), but also proteins relevant for coagulation and fibrinolysis (multimerin carrier protein for coagulation factor V, coagulation factor V, plasminogen, α_2-antiplasmin, plasminogen activator inhibitor-1, protein S), markers of platelet activation (P-selectin, β-thromboglobulin, platelet factor 4), activators of chemotaxis and cell function (transforming growth factor-β, platelet-derived growth factor) and plasma proteins (albumin, von Willebrand antigen II, immunoglobulins, plasma protease inhibitors, histidine-rich glycoprotein). Some proteins are synthesized by the megakaryocyte and platelet[4] (and references therein), others are taken up by a process of receptor mediated endocytosis. Dense granules on the contrary store serotonin, ATP, ADP, calcium and pyrophosphate; they can be distinguished morphologically from alpha-granules using electron microscopy, as detailed in Chapter 4. Finally, lysosomal granules contain enzymes such as cathepsin D, cathepsin E, carboxypeptidase A and B, proline carboxypeptidase, β-*N*-acetyl-D-hexaminidase, β-D-glucuronidase, β-D-galactosidase, α-D-mannosidase, α-L-arabinofuranosidase, α-D-galactosidase, α-L-fucosidase, β-D-fucosidase, β-D-glucosidase, α-D-glucosidase, acid phosphatase and arylsulphatase[5].

Lysosomes (λ-granules) differ from the other platelet granules by the type of stimulus required to induce secretion. Indeed, while the release of α- or δ-granules can be achieved by stimulation with almost all known agonists, including weak stimuli such as ADP, the secretion of λ-granules requires strong stimuli, such as thrombin or high doses of collagen[6,7]. Much less attention has been given to

[1] To the memory of my father

the molecular pathways regulating lysosomal exocytosis in platelets than to those controlling α- and δ-granule secretion. Nevertheless, it was recently shown that λ-granule release takes place in vivo, and that markers of lysosomal secretion can be detected in the blood oozing from a skin wound inflicted for the measurement of the bleeding time[8].

Characteristics of platelet dense granules

Although the lumen of platelet dense granules is less acidic than that of conventional lysosomes and appears to be devoid of lysosomal hydrolases, there is accumulating evidence that these organelles belong to the lysosomal lineage. The dense granule membrane appears to be enriched in the lysosomal proteins CD63/LAMP-3 and LAMP-2[9]. Moreover, genetic disorders that affect the biogenesis of melanosomes and lysosomes also result in platelet dense granule deficiency[10]. Further, a H^+ pumping ATPase, distinct from that at the plasma membrane, acts to maintain the low pH of the granule lumen[11]. Low molecular mass monomeric GTP binding proteins in platelets[12] are involved in the docking of granules to the plasma membrane, preceding exocytosis (see further: GTP-binding proteins in exocytosis). Dense granule membranes contain typical plasma membrane receptor complexes such as GPIb and GPIIb/IIIa, as revealed by immunohistochemical studies[13]. Dense granules also contain P-selectin, a leukocyte binding protein, initially localized in α-granules[14].

Dense granules, like α-granules, arise from both endogenous synthesis in the megakaryocyte as well as from heterotypic fusion with endocytic vesicles budding from the plasma membrane[13].

Physiology of dense granule exocytosis

Intragranular concentrations were calculated to be 65 mM for serotonin, 436 mM for ATP, 653 mM for ADP, 2.2 M for calcium and 326 mM for pyrophosphate[5]. The granular adenine nucleotide pool, which is likely in the form of insoluble calcium complexes, is distinct from the cytoplasmic nucleotides, and these two pools are not readily exchangeable. Serotonin is not synthesized in megakaryocytes/platelets but is actively taken up from the plasma and accumulated in dense granules, where it is likely complexed with ATP and potentially with calcium. The serotonin released by exocytosis is relatively stable and functions as a weak platelet agonist on $5HT_2$ receptors[15]. ADP released during exocytosis is capable of interacting with two different receptors on the platelet $P2Y_1$, that activates phospholipase C via $Gq\alpha$[16] and $P2Y_{12}$, that inhibits adenyl cyclase via $Gi\alpha$[17]. ADP has been shown to play a central role in secondary platelet aggregation following induction of platelet activation by various agonists such as thrombin, TXA_2 and collagen[18,19]. Released ADP can also interact with P2Y receptors present on endothelial cells to release nitric oxide and prostacyclin, which in turn cause vasodilation[20]. Dense granules also release ATP; platelets contain a membrane receptor for ATP, called $P2X_1$, which is a ligand gated ion-channel, causing extremely fast inwardly rectifying Ca^{2+}-currents upon stimulation with ATP. The role of this ion-channel in blood platelet activation however still is unclear[21]. We have recently described a mutation of the $P2X_1$ gene and a defective $P2X_1$ ion channel in a patient with a bleeding disorder, suggesting a role for platelet $P2X_1$ in haemostasis[22]. At physiological Ca^{2+}-concentrations, stimulation of the $P2X_1$ ion channel triggers fast and reversible platelet shape change and causes protein kinase C activation[23]. Fig. 24.1 summarizes how dense granule release amplifies platelet aggregation. Lages and Weiss[24] have also emphasized that secreted dense granule adenine nucleotides promote calcium influx and the maintenance of elevated cytosolic calcium levels in stimulated human platelets, thereby sustaining secondary platelet aggregation.

α-granule release

As outlined above, during exocytosis, platelet α-granules release several proteins into the surrounding medium or onto the surface of the platelet, which participate in platelet aggregate formation and stabilization. Thus, the large von Willebrand factor multimers secreted by platelets play a role in the initial platelet aggregate formation in flowing blood; they interact with both the GPIb complex and the GPIIb/IIIa receptor on platelets streaming by and activate platelets via these receptors[25]; these interactions are reinforced by the binding of fibrinogen to GPIIb/IIIa. Released thrombospondin-1 stabilizes aggregates by interacting with GPIIb/IIIa bound fibrinogen[26]. The α-granule membrane protein P-selectin appears on the surface of the activated platelet and mediates platelet–leukocyte interaction via binding to its ligand on leukocytes and endothelial cells, the P-selectin glycoprotein ligand-1 (PSGL-1); this is a mucin-like transmembrane protein constitutively expressed on leukocytes[27]. Decoration by activated platelets enhances monocyte deposition onto endothelial cells[28,29]. The platelet–monocyte interaction also decrypts monocyte tissue factor by providing the phospholipid environment required for effective coagulation[30]; secreted factor V facilitates local thrombin generation. The fibrin formed on the activated platelets is stabilized by the

Cambridge Books Online © Cambridge University Press, 2009

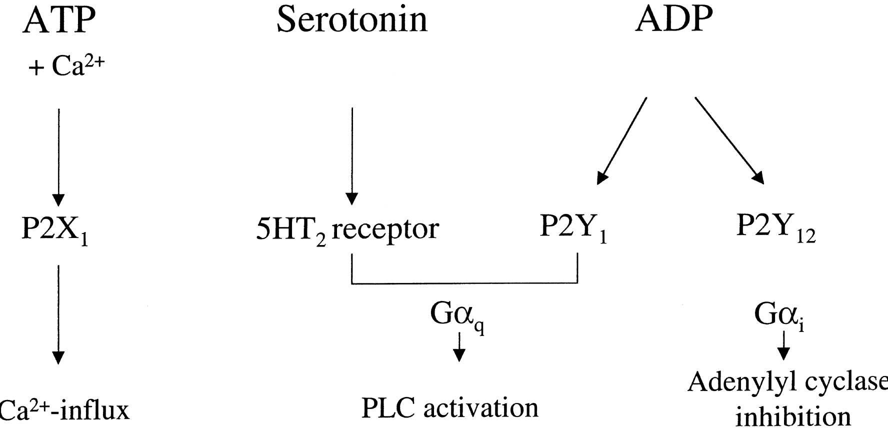

Fig. 24.1. Platelet receptor activation by dense granule release products. Dense granules release ADP, which stimulates two different G-protein coupled receptors, leading to Ca^{2+}-mobilization and to a reduction of intracellular cAMP levels. Serotonin is a weak agonist of Ca^{2+}-mobilization and released ATP will trigger fast influx of Ca^{2+}, thus modulating ongoing platelet activation.

release of inhibitors of fibrinolysis by the platelet α-granule, such as active plasminogen activator inhibitor-1 (PAI-1)[31]. Released growth factors play an important role in eliciting smooth muscle cell proliferation following vascular trauma; induction of thrombocytopenia in animal models induces a clear drop in medial smooth muscle cell migration and proliferation following vessel wall injury[32].

Membranes of the alpha-granules contain proteins found on the plasma membrane (e.g. GPIIb/IIIa, CD36, CD9, Rap1b). As much as 10% of the glycoprotein Ib complex can be found associated with the alpha granule membrane[33]. Thus, the α-granule seems to develop from the homotypic fusion of trans-Golgi vesicles in megakaryocytes as well as from heterotypic fusion of these vesicles with endocytic vesicles[34].

Although dense granule release is more directly coupled to immediate amplification of platelet activation, α-granule exocytosis also contributes to platelet stimulation. Besides activation through secreted vWF, we recently found that the protein S homologous protein GAS6 is rapidly released upon platelet stimulation and binds to GAS6 receptors on the platelet surface, resulting in further platelet activation and exocytosis[35]. Fig. 24.2 schematically shows how, following a primary platelet activation signal, α- and dense granule release products promote further platelet activation and aggregation. Thus, platelet activation and release reactions have to be viewed as fast but

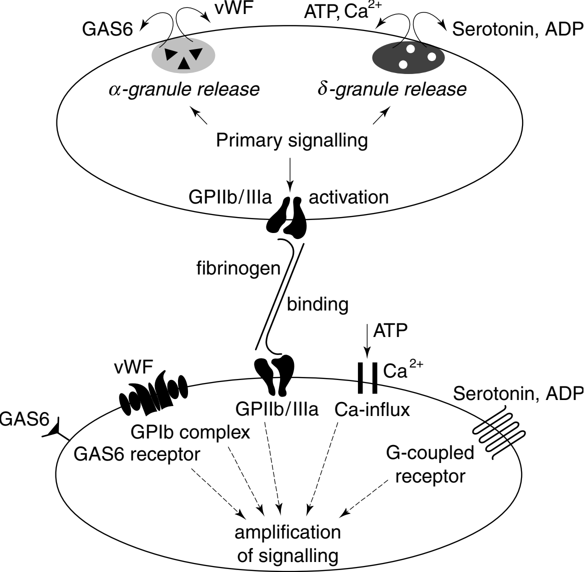

Fig. 24.2. Platelet secretion and activation are intertwined processes. Primary activation by various agonists induces intracellular signalling, leading to the release of α- and δ-granule contents (top). Released proteins from α-granules and released low molecular weight substances from δ-granules lead to further receptor mediated signalling, reinforcing ongoing activation, recruiting additional platelets and eventually leading to complete degranulation and platelet aggregation (bottom).

Cambridge Books Online © Cambridge University Press, 2009

intertwined processes, leading to the typical progressive morphological changes in platelets and to aggregation.

Formation of microvesicles

Strong platelet activation or potent shear stress not only induce granule secretion, but also the release of microvesicles[36]. Platelet-derived microvesicles have been observed in standardized bleeding time wounds[37] and have been associated with autoimmune thrombocytopenic purpura[38] and cardiopulmonary bypass[39]. Microvesicles can be analysed by flow cytometry and express at their membrane surface a number of platelet glycoproteins such as the GPIb complex, the fibrinogen receptor GPIIb/IIIa, but also P-selectin. Platelet microvesicles are fragments of the platelet membrane, released following disruption of the underlying cytoskeleton. The accumulation of phosphatidylserine on the outer membrane provides a negatively charged phospholipid surface for the binding of the γ-carboxyglutamic acid containing coagulation factors, and of factor V and factor VIII through their C_2 domain[40]. Thus, detached microvesicles have the potential to provide a procoagulant surface, also distant from the site of primary platelet activation.

In addition, vesicles can originate from exocytosis of endocytic multivesicular bodies as so-called exosomes[41]. This phenomenon also exists in platelets[42]. Therefore, during platelet activation, two different vesicle populations are released: microvesicles derived from the plasma membrane and a separate population of exosomes. The exosomes, too small to be detected via flow cytometry, are selectively enriched in the tetraspan protein CD63. Annexin V primarily binds to microvesicles and only to a small extent to exosomes. It therefore seems that released platelet exosomes have an extracellular function other than a procoagulant activity, mainly attributed to microvesicles[36].

Protein kinase C and platelet secretion

Protein kinase C activation

Several agonists of platelet activation, such as thrombin, ADP, platelet-activating factor (PAF), and thromboxane A_2 bind to a specific receptor on the platelet surface, which triggers activation of phospholipase C. This enzyme in turn catalyzes the hydrolysis of phosphatidylinositol 4,5 bisphosphate (PIP_2) into 1,4,5-inositol-triphosphate (IP_3) and diacylglycerol (DG). IP_3 then mobilizes Ca^{2+} from internal stores and DG activates protein kinase C (PKC), which translocates away from the membrane and phosphorylates its substrates, the 40–47 kD protein pleckstrin and the 20 kD myosin light chain[43]. Several PKC isoenzymes have been identified, ranging from the conventional calcium-dependent cPKC (α, βI-IV and γ), the calcium-independent isoenzymes nPKC (δ, ε, η and θ) and the atypical aPKC (ζ, λ, ι and μ;[44] and ref therein). In addition to the stimulation of PKC activity in platelets by thrombin, PAF or collagen, phorbol esters such as phorbol 12-myristate 13-acetate (PMA) are capable of directly activating PKC and of inducing protein phosphorylation and platelet secretion[44] (and ref therein). Thus, platelet activation both by thrombin and by PMA is accompanied by translocation of PKC isoenzymes α, β and ζ, whereas the δ isoenzyme is specifically translocated during thrombin activation[45].

Studies focusing on the relationship between platelet secretion and PKC-dependent and tyrosine kinase-dependent phosphorylations of proteins, have claimed that protein kinase C-dependent pleckstrin phosphorylation is a prerequisite for platelet secretion. This process appears to be regulated by other phosphoproteins; in particular the serine/threonine phosphorylation of 27 and 68 kD proteins and the tyrosine phosphorylation of the p60c-src were found to be associated with a decrease in the secretory activity[46].

PKC phosphorylates MARCKS

Activation of PKC in other secretory systems, such as the chromaffin system, potentiates secretion and this effect of PKC activation is due to disassembly or disruption of cortical actin networks[47,48]. This allows a large number of secretory vesicles to move to release sites on the plasma membrane[5] (see further: cytoskeletal fibres and secretion). Elzagallaai et al.[49] hypothesized that PKC activation in platelets also produces actin filament disassembly and thereby enhances the secretory response. These authors observed that myristoylated alanine-rich C kinase substrate (MARCKS), in addition to pleckstrin, is phosphorylated during platelet activation. MARCKS has the property of binding actin and of crosslinking actin filamants[50,51]. Phosphorylation of MARCKS by PKC inhibits its ability to crosslink actin filaments. Elzagallaai et al.[49] demonstrated MARCKS phosphorylation in platelets in response to PMA stimulation. They furthermore showed that a peptide (MPSD) with the amino acid sequence corresponding to the phosphorylation site of MARCKS blocks both MARCKS phosphorylation and serotonin release from permeabilized platelets in response to PMA stimulation. Because pleckstrin and myosin light chain phosphorylation were

Cambridge Books Online © Cambridge University Press, 2009

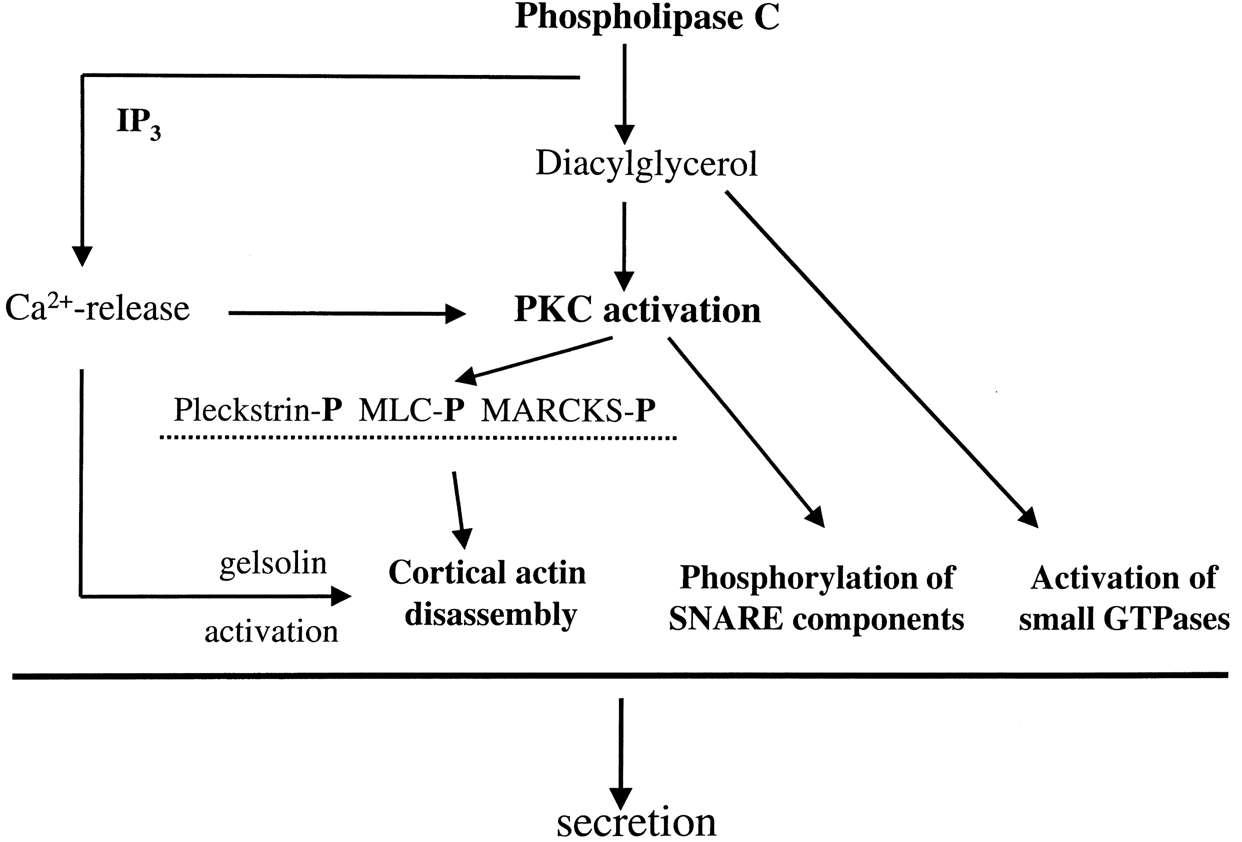

Fig. 24.3. Role of protein kinase C (PKC) in platelet exocytosis. Following receptor mediated activation of phospholipase C, diacylglycerol and Ca^{2+} activate PKC, that phosphorylates several proteins directly involved in actin disassembly. This process occurs in conjunction with PKC dependent phosphorylation of SNARE components and PKC-like activation of small GTPases, ultimately leading to secretion. MLC: myosin light chain; MARCKS: myristoylated alanine-rich C kinase substrate; PKC: protein kinase C; SNARE: SNAP receptor (see section on The SNARE family).

not affected by the peptide, the authors conclude that MARCKS may play a role in platelet secretion. Moreover, because pleckstrin phosphorylation has a different time course than that of MARCKS, they question the role of pleckstrin in secretion and suggest that it might only be involved upstream in the cascade of events leading to exocytosis. The role of MARCKS in platelet secretion is schematically represented in Fig. 24.3.

Additional roles of PKC in platelet secretion

As will be discussed on p. 362, PKC also is involved in the fusion of granules with the plasma membrane. Syntaxin 4 and a platelet sec I protein (PSP) are phosphorylated by PKC, thereby modifying the plasma membrane in a way to allow granule docking and fusion.

Furthermore, as presented on p. 364, protein kinase C-related activities may be implicated in the activation of small GTPases involved in secretion, by promoting the exchange of GDP for GTP.

PKC independent secretion

Hashimoto et al.[52] have proposed a protein kinase C-independent mechanism of dense granule exocytosis in human platelets. In agreement with this, Sloan and Haslam[53] found that secretion stimulated by Ca^{2+} or by guanosine 5–[γ-thio]-triphosphate (GTPγ[S]) and Ca^{2+} utilizes membrane-associated Ca^{2+}- and GTP-binding proteins and occurs independently of PKC activation. GTPγ[S] did not stimulate secretion from streptolysin O-permeabilized platelets in the absence of Ca^{2+}, but greatly potentiated secretion in the presence of low PMA or low Ca^{2+}. However, GTPγ[S] did stimulate myosin P-light chain phosphorylation in the absence of Ca^{2+}, an effect that was associated with morphological changes,

Cambridge Books Online © Cambridge University Press, 2009

including granule centralization. Inhibition of PKC and of pleckstrin phosphorylation by Ro 31–8220 blocked secretion induced by PMA or by GTPγ[S] and PMA in the absence of Ca^{2+}, but did not prevent the GTPγ[S]-induced phosphorylation of myosin P-light chains or secretion induced by Ca^{2+} at pCa 5. These experiments indicate that myosin light chain phosphorylation can occur independently of PKC activity and suggest that GTP-binding proteins and Ca^{2+} may induce exocytosis by activating processes downstream of PKC, as will be further discussed on p. 364 and is illustrated in Fig. 24.3.

Cytoskeletal fibres and secretion

Platelets contain at least three systems of cytoskeletal fibres: the membrane skeleton, microtubules, and microfilaments (long actin filaments). Filamentous actin rapidly increases during platelet activation[54,55]. The membrane skeleton is associated with the network of cytoplasmic actin filaments, various actin-binding proteins, and surface membrane glycoproteins[56,57]. This skeleton is a continuous layer and is preserved as such following platelet lysis with Triton X-100[58]. Circumferential bundles of microtubules play an important role in maintaining the discoid shape of resting platelets, which is lost during microtubule depolymerization[59].

Microtubules seem to be involved in platelet secretion because colchicine (a tubulin ligand[60]) and monoclonal antibodies to alpha and beta subunits of tubulin[61] inhibit secretion in permeabilized platelets. Microtubule-associated proteins may play a role in microtubule reorganization, because they regulate the stability and phosphorylation of the microtubules[62]. The contractile ring and stress fibers of platelets may also be involved in exocytosis and retraction[63]. Cytoskeletal reorganization is mediated through actin polymerization and depolymerization and is regulated by phosphatidylinositol-4,5-bisphospate (PIP_2), which binds to actin regulatory proteins such as scinderin and gelsolin[64]. Consistent with these observations, recombinant scinderin potentiates Ca^{2+}-induced serotonin release in permeabilized platelets, whereas PIP_2, or 2 peptides that interfere with scinderin-actin interactions, block exocytosis[65].

Granule and plasma membrane fusion

Recent insights into molecular mechanisms of secretion indicate that platelet granule secretion is homologous to exocytosis in neurons and other cells but involves a platelet-selective machinery that is uniquely coupled to cell activation. It is generally believed that neuronal exocytosis proceeds through a sequence of vesicle *docking*, *priming*, *triggering* and *fusion*, leading to release of neurotransmitters into the synaptic cleft[4]. The docking or close apposition of vesicles to the plasma membrane at the active site of neurons has been demonstrated by electron microscopy. However, only a subset of these vesicles will be released rapidly, indicating that additional priming or activation of the docked vesicle is necessary, a process apparently involving Mg^{2+} and ATP[66]. Increases in intracellular Ca^{2+}-concentration then trigger the release, which is mediated via SNARE complex interactions (see below).

While neurotransmitters are released from small synaptic vesicles within 200 μs, platelet granules release their contents over an interval of 2 to 5 s. Whereas in each case, exocytosis is triggered by an increase in intracellular Ca^{2+}, significant differences exist between these cells in the magnitude of the Ca^{2+}-signal and the pathway followed to generate it. In neurons, membrane depolarization down the axis elicits Ca^{2+}-influx via Ca^{2+}-channels. This leads to local Ca^{2+}-concentrations as high as 200 μmol/l, triggering the exocytosis of vesicles in close proximity. Platelet secretion on the contrary is triggered by extracellular agonists that bind to platelet receptors, coupled to G-proteins. Following activation, Ca^{2+} is liberated from internal stores and reaches intracellular concentrations ranging from 2–10 μmol/l, in conjunction with diacylglycerol formation leading to protein kinase C activation, as outlined above. The degree of exocytosis is determined by the magnitude of the activation signal and strong platelet agonists can induce full platelet degranulation. In contrast, vesicles in neurons are released in a quantal fashion[4].

The fusion process itself can be described by the general SNARE hypothesis. This hypothesis states that vesicle fusion requires the involvement of three different components: t-SNAREs, v-SNAREs and a soluble SNAP/NSF component. This hypothesis and the molecular entities involved are explained below.

The SNARE family

SNAREs (Soluble NSF Attachment protein Receptor) comprise distinct families of conserved membrane-associated proteins, which facilitate membrane fusion in eukaryotes[67]. They are found throughout the secretory pathway and participate in a number of membrane-trafficking events, including trafficking of cargo-containing carrier vesicles, compartmental organization and organelle fusion. The term SNARE refers to entities which participate in the binding of soluble factors, such as the ATPase NSF

Cambridge Books Online © Cambridge University Press, 2009

(N-ethylmaleimide-Sensitive Fusion protein) and its Soluble NSF-Attachment Proteins (SNAPs) to membranes derived from bovine brain homogenates[68,69]. The so-called SNAP Receptors (hence the name SNAREs) turned out to be proteins previously identified and characterized, at least in part, by groups studying neuronal transmission or protein trafficking in yeast.

Several reviews have outlined the molecular entities involved in SNARE mediated vesicle docking[70,71]. These molecular entities belong to the three major SNARE families: the *syntaxin*, *SNAP-25* and *synaptobrevin/VAMP* families. Two distinct categories of SNAREs have been described. SNAREs present on the vesicle compartment are known as v-SNAREs, while those on the target compartment are known as t-SNAREs. In the original study by Söllner et al.[72], the v-SNARE identified was a synaptic Vesicle-Associated Membrane Protein (abbreviated VAMP) or termed synaptobrevin. The v-SNARE family comprises the following components: *VAMP1, VAMP2, VAMP3, VAMP5, VAMP7/TI-VAMP, VAMP8/Endobrevin, Synaptotagmin I, II, III, V, X.* The t-SNARE family consists of *Syntaxin 1A* and *1B, Syntaxin 2, Syntaxin 3, Syntaxin 4, SNAP 25 A* and *B, SNAP23/Syndet.*

v- and t-SNARE regulation

The assembly of the key players in the SNARE hypothesis is schematically represented in Fig. 24.4. At the level of the presynaptic membrane in neurons, the physical association of the v-SNARE synaptobrevin (or VAMP) with both the t-SNAREs of the plasma membrane, SNAP-25 and syntaxin, leads to the formation of a stable ternary (or 'core') SNARE complex of 7S[72], that docks the vesicle to its target membrane. This core complex then binds SNAPs followed by NSF to form a particle of 20S. The central element in the SNARE hypothesis states that the specificity of membrane targeting thus relies on specific pairing of 3 SNAREs. Within the core complex, the v- and t-SNAREs are aligned in parallel[73–75]. The individual SNAREs were found to undergo a significant increase in helicity upon association with their SNARE partners[76–78], suggesting that formation of the complex is energetically favourable. This lends credence to the idea that SNARE assembly overcomes the electrostatic forces, which prevent membrane fusions from occurring. At the end of a fusion event, the highly conserved NSF, together with SNAPs, dissociates the stable v/t-SNARE complexes by using energy provided by the hydrolysis of ATP. Following this dissociation step, the vesicle and target membrane can fuse, since they have been brought into sufficiently close contact.

In addition to the key proteins in the SNARE hypothesis,

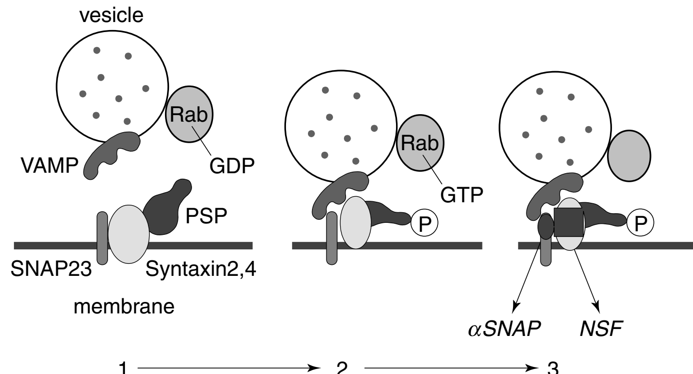

Fig. 24.4. The SNARE hypothesis. In resting platelets, membrane t-SNARES SNAP23 and syntaxin 2 and 4 are complexed. The association with the platelet secI protein PSP prevents syntaxins from interacting with the counterpart v-SNARE VAMP, present on the membrane of the vesicle (step 1). During platelet activation, phosphorylation reactions of syntaxin and of PSP weaken the interactions between SNAP23 and syntaxins and relieve the inhibition of the interaction with the v-SNARE; Rab exchanges GDP for GTP and facilitates SNARE complex formation (step 2). Thus a 3 SNARE protein complex is formed which subsequently binds the soluble proteins αSNAP and the ATPase NSF (step 3). Following ATP-hydrolysis by this enzyme, the SNARE complex disassembles, enabling the fusion of the vesicular and target membranes, which are now in physical proximity.

other factors exist that control exocytosis[67]. Thus, the Sec1/Munc 18 proteins bind to syntaxins and through this binding prevent formation of the core SNARE complex. Protein kinase C has been implicated in modulating synaptic transmission. This stems in part from studies which show that neurotransmitter release from presynaptic terminals and various other exocytic events are modulated by exposure to phorbol esters[79,80] which are known PKC agonists. Moreover, PKC has been shown to phosphorylate substrates involved in vesicle fusion (i.e. Sec1/Munc18, which thereby loses its inhibitory role on membrane fusion)[81].

SNAREs in platelets

Recent studies have revealed that the secretory machinery in platelets has important homologies to the machinery found in neurons and other cells. Platelets can form core SNARE complexes in vitro that support αSNAP-dependent NSF-ATPase activity[82] and the αSNAP-dependent NSF-ATPase activity has been shown to be critical for exocytosis of both α- and dense granules[83,84]. Platelet membranes contain the t-SNARES syntaxins 2 and 4, which play distinctive roles in granule exocytosis; syntaxin 2 is involved

Cambridge Books Online © Cambridge University Press, 2009

in dense granule release whereas syntaxin 4 is necessary for platelet α-granule secretion[82,85–87]. Platelets contain abundant amounts of the t-SNARE SNAP-23, and the v-SNARE VAMP, which interact and form SNARE complexes. SNAP-23 is required for dense granule exocytosis, but it is not yet clear which VAMP is functionally involved in secretion[84,88].

In resting secretory cells neighbouring membrane SNARE proteins are interacting with one another, thus preventing v- and t-SNAREs from fusing. Thus, Flaumenhaft et al.[86] demonstrated that the t-SNARES SNAP-23 and syntaxin 4 form a heterotrimeric complex in platelets. When human platelets were activated with a potent agonist such as thrombin, Chung et al.[89] found that syntaxin 4 was phosphorylated by PKC in human platelets. Cellular activation by thrombin or phorbol 12-myristate 13-acetate decreased the binding of syntaxin 4 to SNAP-23. A PKC inhibitor blocked syntaxin 4 phosphorylation and restored binding of syntaxin 4 to SNAP-23 to that seen in non-stimulated platelets. Thus, these experiments support a model in which phosphorylation of SNARE proteins weakens their interaction in the plasma membrane and prepares them for v-SNARE–t-SNARE interaction.

Chen et al.[90] have furthermore shown that also release from the platelet lysosome requires ATP and NSF. The SNAREs syntaxin 2 and 4, together with SNAP-23, appear to make up the heterodimeric t-SNAREs required for lysosome exocytosis.

A platelet secI protein (PSP) has been cloned, which is orthologous to Munc-18[87]. PSP forms a tight complex with syntaxin 2 and syntaxin 4 that can prevent the formation of the SNARE complex[87,91]. PSP is phosphorylated in platelets activated by thrombin through a protein kinase C-dependent mechanism; this phosphorylation weakens interaction with syntaxin 4 and relieves the inhibitory effect of PSP on SNARE complex formation. Thus, the PKC dependent phosphorylations of several proteins seem to control SNARE protein interactions.

In summary, it is clear that all three platelet exocytosis events, i.e. release from α-granules, from δ-granules and from lysosomes require the general membrane fusion protein N-ethylmaleimide Sensitive Factor (NSF)[83,84]. The role for the t-SNAREs syntaxin 2 and SNAP-23 has been established for dense granule and lysosome release[90] and syntaxin 4 appears to be required for lysosome and α-granule release[86,92].

GTP-binding proteins in exocytosis

Presence on secretory vesicles

As outlined above, exocytosis is a regulated process involving the docking of secretory granules at specific sites on the plasma membrane, with subsequent fusion and release of granule contents. In addition to the proteins involved in the SNARE hypothesis, our understanding of other proteins involved in vesicular trafficking has increased dramatically. In an extensive review paper, Watson[93] presents evidence from a genetic, biochemical, immunological and functional angle to support a role for ras-like monomeric GTP-binding proteins as well as heterotrimeric GTP-binding protein (G-protein) subunits in various steps of the vesicular trafficking pathway, including the transport of secretory vesicles to the plasma membrane.

Monomeric GTP-binding proteins may be divided into four subfamilies*: ras, rho/rac, rab* and *ARF* (ADP-ribosylation factor). Rab proteins have been found to regulate defined steps of intracellular membrane trafficking, including endocytosis and exocytosis[94].

The RabGTPase family

The RabGTPase family is composed of more than 30 members and belongs to the Ras-related small GTPase superfamily[95,96]. Like other GTPases, Rab proteins have both GTP-bound active and GDP-bound inactive forms regulated by the GDP/GTP cycles. GTP is exchanged for GDP by a specific guanine nucleotide exchange protein (GEF). The active GTP-bound forms exert their function by association with effector molecules[95–97]. RabGTPases are also controlled by a unique negative regulator named Rab GDP dissociation inhibitor (GDI)[98,99]. Rab-GDI is a cytosolic protein, which forms a complex with GDP-bound Rab proteins to inhibit the GDP/GTP exchange, and extracts Rab proteins from the membrane into the cytosol. Several RabGTPases including Rab3B, -4, -6, -8 and -27 have been demonstrated to be present in platelets[100,101]. Rab4 is present on lysosomes, Rab6, Rab 8 and Rab 27B on α-granules, Rab27A on dense granules. The small GTP-ase Rap 1B has also been found in the α-granules of platelets[102].

GEFs stimulate the dissociation of the tightly bound GDP nucleotide from the small GTP-binding protein in response to upstream signals[103]. Thus, the GEF exchanging GDP for GTP Vav is activated via tyrosine phosphorylation by Syk, which stimulates its GEF activity for Rac1[104]. Recently, it was shown that the GEF protein RasGRP possesses a single C1 domain homologous to that of PKC and appears to be a high-affinity target for diacylglycerol and

Cambridge Books Online © Cambridge University Press, 2009

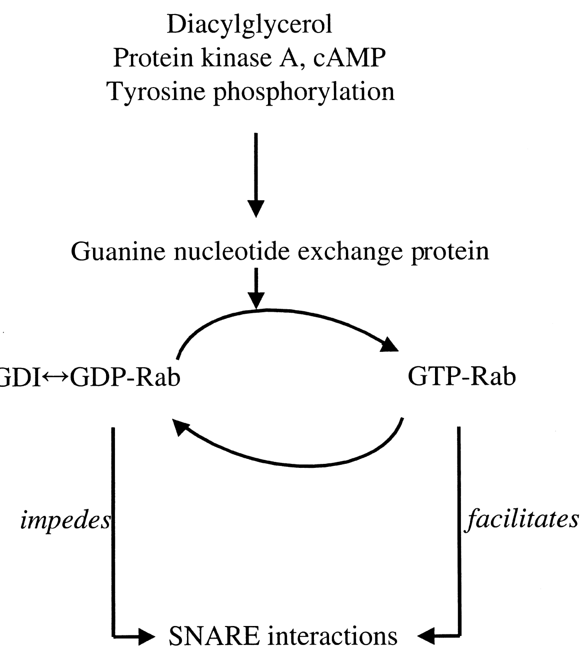

Fig. 24.5. Rab activation in SNARE interaction control. Diacylglycerol, cAMP, tyrosine phosphorylation and protein kinase A tentatively mediate activation of the guanine–nucleotide exchange protein, which causes Rab to exchange GDP for GTP. Whereas GDP-Rab impedes SNARE interactions, GTP-Rab interacts with its effector protein and promotes SNARE complex formation. Granule binding of GDP-Rab is controlled by the Rab GDP dissociation inhibitor (GDI).

phorbol esters[105], thus providing evidence of a PKC related activation process. Furthermore, the GEF for Ras CDC25Mm/GRF1 contains sites of phosphorylation for protein kinase A[106]. A guanine nucleotide exchange factor for Rap1 was described that is directly activated by cAMP[107]. One would tentatively assume that Rab-GDP, associated to the granule, impedes exocytosis, impediment that is removed by the exchange of GDP for GTP (Fig. 24.5). How this comes about requires further study.

Platelet granule dysfunctions

The importance of platelet granule secretion is illustrated by a number of clinical granule release dysfunctions that are associated with loss of platelet function and bleeding syndromes. These syndromes are discussed in more detail in Chapter 11.

Conclusion

Platelet granule exocytosis is an essential part of platelet function. Exocytosis involves the release of different granule types, all of them having their own role in platelet activation, shape change induction, adhesion and secondary amplification of ongoing platelet activation. This process is controlled via a multitude of biochemical events, ranging from receptor stimulation, intracellular signal transduction and vesicle docking and fusion. The similarity in the machinery used by the platelet and by other secretory cells makes the platelet a unique tool to study the molecular basis of vesicle-to-membrane fusion, a process that has just been initiated.

Amplification loops: thromboxane generation

Paola Patrignani and Maria G. Sciulli

Department of Medicine and Aging, Division of Pharmacology, 'G. D'Annunzio' University of Chieti, Italy

Inducible and constitutive pathways of prostanoid biosynthesis

Prostanoids [prostaglandin (PG) E_2, $PGF_{2\alpha}$, PGD_2, prostacyclin (PGI_2) and thromboxane (TX) A_2] are a family of biologically active compounds participating in cell–cell communication[1], as a consequence of the activation of membrane associated receptors that belong to the G-protein-coupled rhodopsin-type family[2]. Their biosynthesis is triggered by different types of stimuli that may be classified primarily according to the time employed to induce detectable levels of prostanoids in the surrounding milieu of the cell. Thus, a rapid and delayed prostanoid biosynthesis can occur[1] (Fig. 25.1). The coordinated activity of three consecutive enzymatic steps is involved in both rapid and delayed prostanoid biosynthesis: (i) the release of arachidonic acid (AA) from membrane phospholipids carried out by phospholipase(PL)s, primarily PLA_2s[1,3], (ii) the transformation of AA to the unstable endoperoxide PGH_2 by prostaglandin H synthases[4] and (iii) its metabolization to the different prostanoids by terminal synthases which have different structures and exhibit a cell- and tissue-specific distribution[5–7]. What differentiate these two pathways of prostanoid biosynthesis is the involvement of an enzymatic machinery constitutively expressed (for rapid biosynthesis) or induced in response to inflammatory and mitogenic stimuli (for delayed biosynthesis). Two isoforms of prostaglandin H synthase have been identified, COX-1 and COX-2, that catalyse the same reactions, i.e. the conversion of AA to PGG_2 by their cyclooxygenase activity.

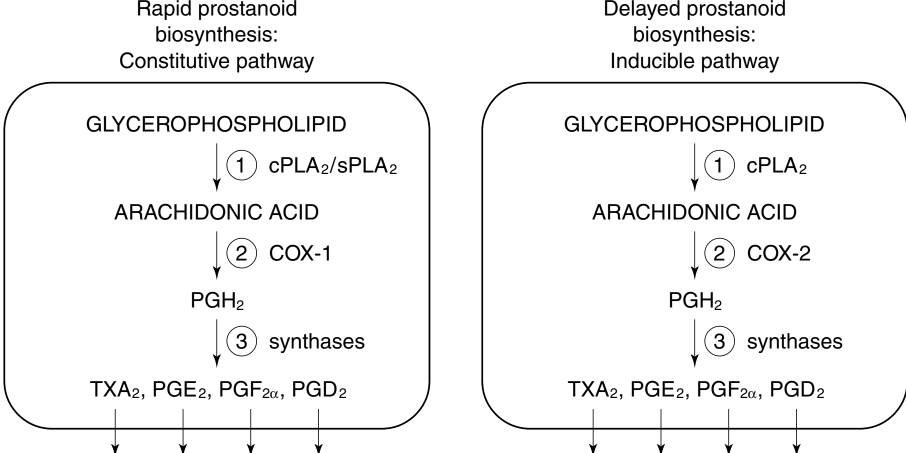

Fig. 25.1. Rapid and delayed pathways of prostanoid biosynthesis. The coordinated activity of three consecutive enzymatic steps are involved in both rapid and delayed prostanoid biosynthesis: (i) the release of arachidonic acid from membrane glycerophospholipids by the secretory and/or cytosolic phospholipaseA_2s ($sPLA_2$ and $cPLA_2$, respectively); (ii) the conversion of arachidonic acid to PGH_2 by the activity of the two isoforms of PGH synthase, COX-1 and COX-2; (iii) the transformation of PGH_2 to different prostanoids (PGE_2, $PGF_{2\alpha}$, PGD_2, PGI_2 and TXA_2) by specific synthases.

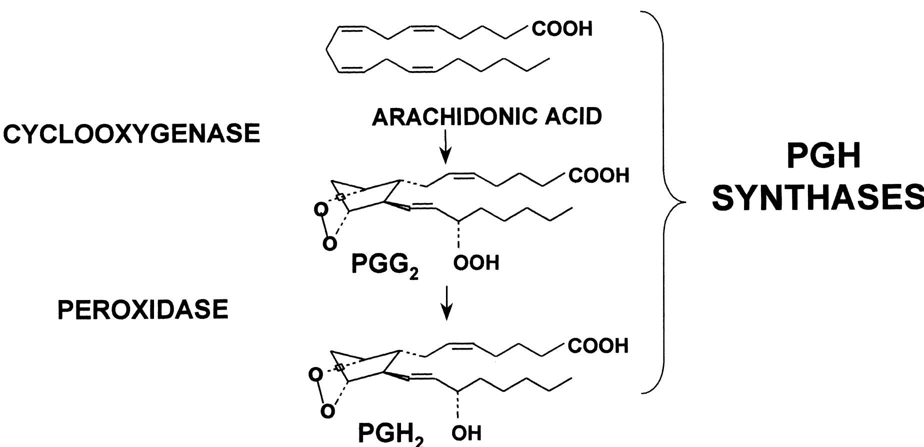

Fig. 25.2. The cyclooxygenase and peroxidase reactions catalyzed by the prostaglandin (PG) H synthases. Arachidonic acid is oxygenated to PGG_2 by the cyclooxygenase activity of PGH synthases (i.e. COX-1 and COX-2); PGG_2 is then reduced to PGH_2 by their peroxidase activity.

Table 25.1. Expression of COX-1 and COX-2

COX-1	COX-2
Chromosome 9	Chromosome 1
Constitutive, found in all tissues; highly expressed in stomach, kidney and platelets	Predominantly inducible in response to inflammatory and mitogenic stimuli in macrophages/ monocytes, synoviocytes, fibroblasts, vascular cells
Can increase from 2- to 4-fold	
	Constitutive in kidney, brain, uterus, vascular cells
	Can increase from 10- to 20-fold

and then the reduction of PGG_2 to PGH_2 by their peroxidase activity[4,8] (Fig. 25.2). Apart from platelets that only contain COX-1[9], most nucleated cells have the gene for COX-2 which can be expressed in response to inflammatory and mitogenic stimuli[4,10] (Table 25.1). COX-1 displays the characteristics of a 'housekeeping gene' and is constitutively expressed in virtually all tissues. It is mainly utilized in the immediate biosynthesis of prostanoids, which occurs within several minutes after stimulation with Ca^{2+} mobilizers. Differently, the inducible COX-2 is an absolute requirement for delayed prostanoid biosynthesis, which lasts for several hours following proinflammatory stimuli.

It has been suggested that the two COX isozymes are differently coupled with specific terminal synthases. For instance, rat peritoneal macrophages produce TXA_2 and PGD_2 through COX-1 in the Ca^{2+} ionophore A23187-induced immediate response and PGE_2 and PGI_2 through COX-2 in the lipopolysaccharide (LPS)-induced delayed response[11,12]. TXA_2 generation by activated platelets depends entirely on COX-1[9,13], whereas PGE_2 production by osteoblasts occurs predominantly through COX-2 irrespective of the co-presence of COX-1[14]. By co-expression of the various prostanoid–biosynthetic enzymes, it has been recently shown that prostanoid synthases are classified into three categories in terms of their localization and COX isozyme preference: (i) the perinuclear enzymes which prefer COX-2 [TXA_2 synthase (TXAS), PGI_2 synthase (PGIS) and membrane-bound PGE_2 synthase (mPGES)], (ii) the cytosolic enzyme which prefers COX-1 [cytosolic PGES (cPGES)] and (iii) the translocating enzyme which utilizes both COX isozymes depending on the stimulus [hematopoietic PGD_2 synthase (H-PGDS)][7]. Alteration in AA supply through endogenous and exogenous routes significantly affects the coupling between COX isozymes and terminal prostanoid synthases. TXAS which resides in the endoplasmic reticulum and perinuclear membranes, preferentially utilizes COX-2 over COX-1 when limited amounts of AA are supplied and can efficiently metabolize COX-1-derived PGH_2 when AA supply is increased[7]. Thus, the coupling of TXAS to COX isozymes is substrate-dependent. In platelets, a coupling between COX-1 and TXAS is promoted for the high availability of free AA upon receptor stimulation.

The inducible pathway of prostanoid biosynthesis causes an intense and localized increase in prostanoid formation that may be rapidly shut up for the instable nature of COX-2 mRNA and protein[15].

A condition where the constitutive pathway of prostanoid biosynthesis plays an important role in the local amplification of cell activation, is exemplified by the bio-

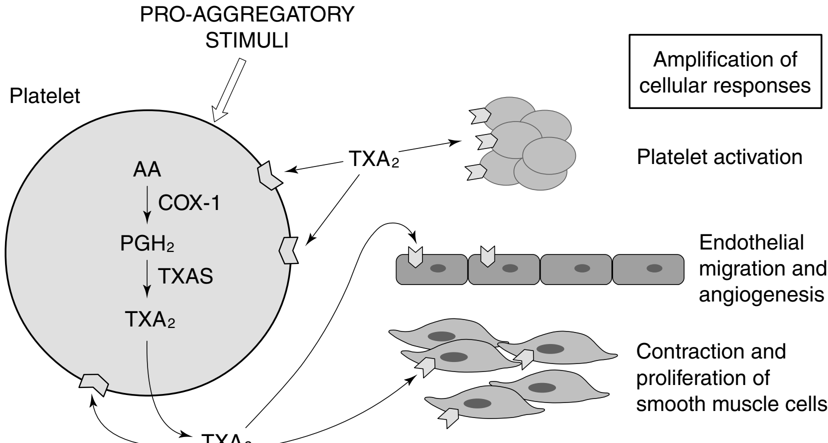

Fig. 25.3. Amplification of cellular responses by platelet-derived TXA_2. Platelet TXA_2, produced in response to pro-aggregatory stimuli, is responsible for the propagation of the initial activation signal to adjacent platelets, vascular smooth muscle cells and endothelial cells, through the interaction with TP receptors.

synthesis of TXA_2 in platelets[16,17] (Fig. 25.3). TXA_2, produced in response to other stronger, primary agonists, such as thrombin and ADP, causes the propagation of the initial activation signal to adjacent platelets, by inducing further platelet activation and TXA_2 formation. TXA_2 is also a potent trigger of vascular smooth muscle cell contraction and proliferation and it has been recently shown to be a mediator of endothelial migration and angiogenesis[18–20] (Fig. 25.3).

TXA_2 biosynthesis in platelets

TXA_2 is the major product of AA in platelets[16,21]. Its biosynthesis is a rather unique example of prostanoid release largely dependent on enhanced substrate availability[22]. Thus, the activation of PLs is a rate-limiting step in TXA_2 production. Once released, AA is offered to COX-1 for its transformation to PGH_2 that is, then, isomerized to TXA_2 by the activity of TXAS[4,8,23,24].

Similarly to all prostanoids, TXA_2 is rapidly metabolized in vivo into biologically inactive compounds. TXA_2 is chemically unstable and is rapidly transformed non-enzymatically to its hydrolysis product, TXB_2[21] (Fig. 25.4); this can then undergo enzymatic metabolism by β-oxidation, resulting in the formation of 2,3-dinor-TXB_2, and by dehydration of the hemiacetal alcohol group at C-11, resulting in the formation of 11-dehydro-TXB_2, the most abundant of a series of metabolites with a Δ-lactone ring structure[25] (Fig. 25.4). These enzymatic metabolites circulate in plasma at low concentrations and are excreted in urine[26–28]. The measurement of these metabolites in

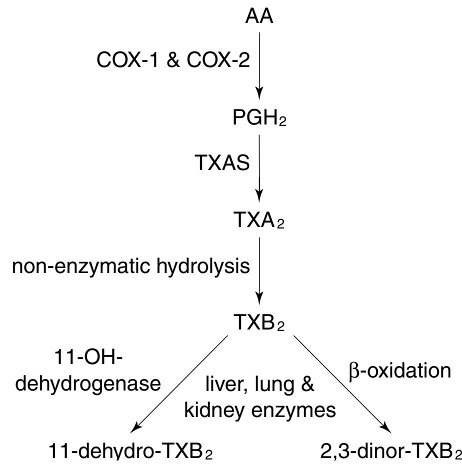

Fig. 25.4. Metabolism of TXA_2. TXA_2, formed by the activity of PGH synthases (COX-1 and COX-2) and TXA_2 synthase (TXAS), is rapidly transformed non-enzymatically to its hydrolysis product TXB_2 which can then undergo two major enzymatic pathways of metabolism: β-oxidation, resulting in the formation of 2,3-dinor-TXB_2, and dehydrogenation of the hemiacetal alcohol group at C-11, resulting in the formation of 11-dehydro-TXB_2.

plasma and urine provides a reliable indication of the systemic biosynthesis of TXA_2. Studies with low-dose aspirin have demonstrated that platelets are the major source of both metabolites in urine[29].

It is interesting to note that the maximal biosynthetic capacity of human platelets to produce TXA_2 when challenged in vitro by endogenous thrombin exceeds, by several thousandfold, the actual rate of TXA_2 biosynthesis

Cambridge Books Online © Cambridge University Press, 2009

in vivo, as reflected by the measurement of urinary excretion of 2,3-dinor-TXB_2 and 11-dehydro-TXB_2[26]. This may explain, at least in part, the unusual requirement of virtually complete suppression of platelet COX-1 activity in order to detect an antithrombotic efficacy[30]. In fact, the relationship between the pharmacological inhibition of platelet COX-1-dependent biosynthetic capacity ex vivo, as assessed by the measurement of TXB_2 production during whole blood clotting, and that of the actual rate of TXA_2 biosynthesis in vivo, as assessed by the measurement of its major enzymatic urinary metabolites, is not linear. Thus, inhibition of TXA_2 biosynthesis in vivo occurs when platelet COX-1 activity, assessed ex vivo, is reduced $>95\%$[31].

Enzymes involved in TXA_2 biosynthesis

Phospholipases (PLs)

The release of AA from platelet membrane glycerophospholipids can occur by two major pathways: PLA_2 and PLC/diacyl glycerol lipase. However, there is substantial evidence to indicate that the activation of PLA_2 is the most important pathway[32,33]. Platelets contain a low (14 kDa) and a high (85 kDa) molecular weight PLA_2, localized in α granules and cytosol, respectively. They are known as secretory PLA_2 ($sPLA_2$)[34] and cytosolic PLA_2 ($cPLA_2$)[35], respectively. PLA_2s hydrolyze the *sn*-2 fatty acyl ester bond of glycerophospholipids, producing non-esterified fatty acids, often represented by AA, and lysophospholipids. The increase in intracellular Ca^{2+} (i.e. μmolar range for $cPLA_2$ and mmolar range for $sPLA_2$) by receptor-operated events is an essential requirement for PLA_2 activation[3]. This event induces the translocation of $cPLA_2$ from the cytosol to cellular membranes[36,37]. Moreover, $cPLA_2$ phosphorylation at Ser^{505}, residing within a mitogen-activated protein kinase (MAPK) consensus sequence (Pro–Leu–Ser^{505}–Pro), causes a severalfold increase of its catalytic activity[37,38]. In thrombin- and collagen-stimulated platelets, p38 kinase, a member of MAPK family, is involved in the early phosphorylation of $cPLA_2$[39]. On the other hand, $cPLA_2$ phosphorylation via a protein kinase C (PKC)/p42/$p44^{MAPK}$-dependent pathway takes place in platelets treated with phorbol esters and Ca^{2+} ionophore[40].

$sPLA_2$ can be released from platelets in response to various stimuli and it has been reported to activate platelets through its binding to a glycophosphatidylinositol (GPI)-anchored platelet-membrane heparan sulfate proteoglycan. This may induce the stimulation of AA metabolism, protein tyrosine phosphorylation and Ca^{2+}-mobilization[41]. However, the involvement of $sPLA_2$ in platelet AA release is not unequivocally accepted[42].

COX-1

Similarly to COX-2, COX-1 is a homodimer of ~70 kDa subunits. Each subunit contains one molecule of heme and comprises three domains: an epidermal growth factor, a membrane-binding and a catalytic domain. The cyclooxygenase and the peroxidase active sites are located in the catalytic domain and are separated by the heme prosthetic group. Tyr-385 residue, at the top of the cyclooxygenase active site, is positioned perfectly to react with AA and to remove the 13-pro-*S*-hydrogen, i.e. the first step in the formation of PGG_2 from AA. Then, PGH_2 is produced via the peroxidase-dependent reduction of PGG_2 peroxyl radical[8] (Fig. 25.2).

Because circulating platelets lack a nucleus and consequently cannot synthesize mRNA, the involvement of constitutively expressed COX-1 in TXA_2 biosynthesis has been assumed. This is supported by cDNA cloning and immunoaffinity purification of only COX-1 from human platelets[43]. In contrast, it has been recently reported that circulating platelets from healthy subjects express COX-2 protein and mRNA, as assessed by Western blot and reverse transcription coupled polymerase chain reaction (RT-PCR), respectively[44]. However, in highly purified human platelet suspensions (containing <0.5 leukocytes per 1000 platelets), analysed immediately after isolation to avoid any ex vivo expression of COX-2 in contaminating monocytes, we failed to detect COX-2 while COX-1 was readily detectable (Fig. 25.5). The involvement of COX-1 in platelet TXB_2 biosynthesis is further supported by the finding that its production is spared by concentrations of NS-398 (a selective COX-2 inhibitor) that completely inhibit monocyte COX-2 activity[9]. The results of over 50 clinical trials showing saturation of the antithrombotic efficacy of aspirin at low-doses (50–100 mg daily)[30] sustain convincingly the COX-1 dependence on platelet TXA_2 biosynthesis.

Aspirin is the only non-steroidal antiinflammatory drug (NSAID) known to react covalently (and time-dependently) with the cyclooxygenase channel of COX-1 and COX-2 causing a selective acetylation of a specific serine residue (Ser^{529} for human COX-1 and Ser^{516} for human COX-2)[45,46]. Aspirin acetylation of platelet COX-1 results in a persistent blockade of AA oxidation to PGH_2 that is cumulative on repeated low-dose administration[13]. An almost complete suppression ($>95\%$) of platelet COX-1 activity is obtained after 5–7 days of treatment with low-dose aspirin. In contrast, in a nucleated cell, the irreversible inactivation of COX-1 and COX-2 by the drug can be rapidly reversed by *de novo* synthesis of the enzymes[47].

Cambridge Books Online © Cambridge University Press, 2009

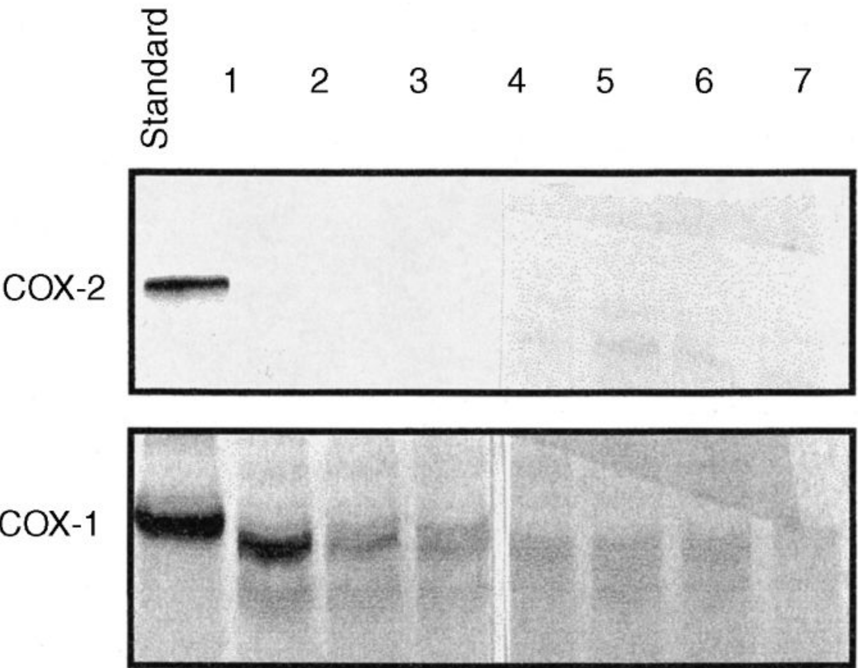

Fig. 25.5. Western blot analysis of COX-1 and COX-2 in human platelets. Platelets were isolated from citrated human whole blood drawn from seven healthy volunteers. COX-1 and COX-2 levels were analysed by SDS-polyacrylamide gel electrophoresis and immunoblotting techniques, using rabbit polyclonal antibodies directed against COX-1 or a carboxyl-terminal sequence present only in human COX-2. In the first lane, COX-1 and COX-2 standard proteins are shown; the numbers (1–7) indicate the 7 healthy volunteers.

TXAS

TXAS catalyses the isomerization of PGH_2 to TXA_2 that is accompanied with the formation of 12-L-hydroxy-5,8,10-heptadecatrienoic acid (HHT) and malondialdehyde (MDA) at a ratio of 1:1:1. However, the biological functions of HHT and MDA are unclear. TXAS, a protein with a molecular weight of 58.8 kDa, is a member of the cytochrome P450 superfamily and is associated with endoplasmic reticulum and perinuclear membranes[48]. Human TXAS was assigned as CYP 5A1. TXAS is synthesized by numerous tissues, including kidney and brain. In blood derived cells, TXAS has been detected in macrophages and platelets[49]. Its mRNA and protein are present in normal megakaryocytes[50]. Cloning of TXAS has revealed that the promoter region has a TATA box and several potential binding sites for transcription factors and a glucocorticoid response element[51]. TXAS is expressed during differentiation of megakaryocytes through the regulation of $p45^{NF-E2}$, a transcription factor that plays a crucial role in the regulation of erythroid gene expression. However, megakaryocyte TXAS expression and TXA_2 biosynthesis do not play a role in the platelet production process[50]. This is supported by the finding that patients with TXAS deficiency present bleeding disorders in the absence of thrombocytopenia[52]. A variation in the promoter region of TXAS, i.e. a T to G substitution at nucleotide-386, has been reported[53]. In vitro studies have shown that the G(-386) allele presented enhanced promoter activity compared to the T(-386) allele. A higher G(-386) allele frequency of TXAS gene has been demonstrated in Japanese patients with acute myocardial infarction than those with angina pectoris[53]. Moreover, 11 polymorphisms in human TXAS gene, including 8 missense mutations, have been recently identified[54]. However, the functional consequence of these variations of TXAS gene remains to be studied.

Pharmacological inhibition of TXAS causes the increase in the formation of PGE_2, $PGF_{2\alpha}$ and PGD_2 by activated platelets and PGI_2 by the vascular endothelium and blood leukocytes[55–57]. However, TXAS blockade is also associated with accumulation of PG endoperoxides (PGG_2 and PGH_2) that can occupy and activate platelet TXA_2 receptors (TPs). These complex biochemical changes transduce opposing signals, resulting in mild and inconsistent impairment of platelet aggregation[55]. Combined TXAS inhibitors and TP antagonists have theoretical advantages over existing antiplatelet agents by virtue of increasing vascular PGI_2

Table 25.2. Alteration of platelet TXA_2 biosynthesis in humans

Enhanced TXA2 biosynthesis		Reference number
Unstable angina		60–62
Acute cerebral ischemia and acute ischemic stroke		69, 70
Chronic phase after cerebral ischemia and intracerebral hemorrhage		71
Type IIa hypercholesterolemia		63
Diabetes mellitus, type I and II		64, 65
Homozygous homocystinuria		67
Smokers		68
Essential thrombocythemia		72
Polycythemia vera		73
Reduced TXA_2 biosynthesis	**Mechanism**	**Reference number**
Bleeding disorders	↓ AA release	74
	↓ COX-1 protein levels and COX-1 activity	75, 76
Uremia	↓ COX-1 activity	77
Liver cirrhosis	↓ Agonist-induced transmembrane signalling	78

biosynthesis and affecting the interaction of PGH_2 with the platelet TPs. Whether these theoretical advantages will translate into measurable improvements over existing antiplatelet agents remains to be tested in comparative clinical trials.

Alteration of platelet thromboxane biosynthesis in humans

The biosynthesis of platelet TXA_2 can be evaluated by the measurement of TXB_2 production in response to various agonists (e.g. ADP, collagen, arachidonate) added in vitro to washed platelets or platelet rich plasma (PRP). This is a measure of 'capacity', which indicates what platelets can do when challenged by rather intense stimuli in a closed artificial system. Measurement of TXB_2 production during whole blood clotting is also a capacity index related to virtually maximal conversion of platelet AA through the COX-1 pathway in response to endogenously formed thrombin[58]. The relevance of these capacity indexes to the actual occurrence of platelet activation in vivo is still unknown. In contrast, the measurement of urinary excretion of major enzymatic metabolites of TXB_2 is thought to be a reliable index of platelet function in vivo. In fact: (i) 11-dehydro-TXB_2 and 2,3-dinor-TXB_2 are excreted at low rates under physiological circumstances[26] (i.e. low background 'noise' unaffected by sampling-related artefacts), (ii) their excretion increases linearly with increased rates of entry of TXB_2 into the systemic circulation[26,27] and (iii) they are largely derived from platelet TXA_2 biosynthesis in vivo[29]. The contribution of platelets to enhanced urinary TXB_2 metabolite excretion, in different clinical conditions, can be verified by assessing the extent of its inhibition and the time of its recovery after the daily administration of low-dose aspirin for 5–7 consecutive days. An almost complete suppression of platelet COX-1 activity, as assessed by measuring serum TXB_2 production, by low-dose aspirin is associated with a 70–80% reduction of urinary 11-dehydro-TXB_2 and 2,3-dinor-TXB_2 excretion[29]; after discontinuing aspirin administration, urinary TXB_2 metabolite excretion returns to pre-drug levels within 10–14 days[29], which is consistent with platelet turnover.

Episodic increases in TXB_2 metabolite excretion have been detected in patients with unstable angina[59–62]. Platelet activation in this setting is not merely related to the presence of atherosclerotic lesions in the arterial wall, but is an acute process most likely triggered by sudden rupture of the plaque[59]. In fact, the levels of TXB_2 metabolites were unchanged in patients with chronic stable angina[60] and peripheral vascular disease[62]. In contrast, a relatively reproducible and persistent increase in TXB_2 metabolite excretion has been demonstrated in association with cardiovascular risk factors (i.e. hypercholesterolemia, diabetes mellitus, hypertension, homocystinuria or smoking)[63–68]. The results of these studies suggest that the occurrence of arterial disease *per se* is not a trigger of plate-

Cambridge Books Online © Cambridge University Press, 2009

let activation in vivo. Rather, the rate of TXA_2 biosynthesis appears to reflect the influence of coexisting disorders. Thus, it has been proposed that TXA_2-mediated amplification of platelet activation in response to plaque fissuring may represent a link between different risk factors and the occurrence of thrombotic complications[66]. In Table 25.2, different clinical conditions characterized by enhanced TXA_2 biosynthesis in vivo are listed.

Reduced biosynthesis of platelet TXA_2 in vitro has been found in patients with bleeding disorders (Table 25.2). The mechanism of this defect may involve an impaired release of AA from phospholipids[74] or a COX-1 deficiency, i.e. undetectable protein levels or impaired catalytic activity[75–77]. Moreover, platelets from patients with liver cirrhosis produce reduced levels of TXA_2 in response to thrombin and collagen as a consequence of an impairment of transmembrane signalling through a molecular mechanism not yet identified[78]. Mild to moderate bleeding disorders have been associated with defective Ca^{2+} ionophore A23187-induced platelet aggregation without impaired TXA_2 production[79]. A defective or reduced platelet aggregation and secretion in response to ADP, collagen, AA and stable TXA_2 (STA_2) has been also detected. The molecular mechanisms of these defects are independent on PKC activation, Ca^{2+} mobilization and myosin light chain (MLC) phosphorylation.

Endogenous modulation of platelet TXA_2 biosynthesis

Platelet TXA_2 biosynthesis is, presumably, turned off through two main mechanisms: (i) the decrease in TXA_2 synthesis for suicide inactivation of COX-1 and TXAS and (ii) the irreversible sticking of platelets associated with the release of their intracellular granules. COX-1 is a self-inactivating enzyme. Both the peroxidase and cyclooxygenase activities have a limited number of catalytic turnovers[8]. Based on the protective effect of various reducing cosubstrates, it has been proposed that active radical intermediates, formed during the peroxidase or cyclooxygenase catalysis, are involved in the irreversible loss of enzyme activity[80]. Similarly, TXAS undergoes suicide inactivation during catalysis, are involved presumably via two mechanisms: (i) a covalent modification of the enzyme due to a tight association with PGH_2 or with an intermediate product not yet identified and (ii) a modification or dissociation of the heme prosthetic group[81]. Moreover, both COX-1 and TXAS activities may be modulated by the cellular levels of lipid hydroperoxides and/or nitric oxide[8,82].

Counterregulatory mechanisms can be evoked by platelet activation[22]. For instance, platelets can induce the synthesis of PGI_2 in adjacent vascular endothelial cells by transcellular metabolism: (i) platelet-derived PGH_2 can be utilized by endothelial PGIS[83], (ii) platelet microparticles or fragments of plasma membrane may deliver their unmetabolized AA content to endothelial cells and induce COX-2 expression via a PKC/MAPK-dependent pathway[84] (Fig. 25.6). Alternatively, activated platelets can cause overexpression of endothelial COX-2 as a consequence of direct cell-cell interaction or growth factor secretion (Fig. 25.6).

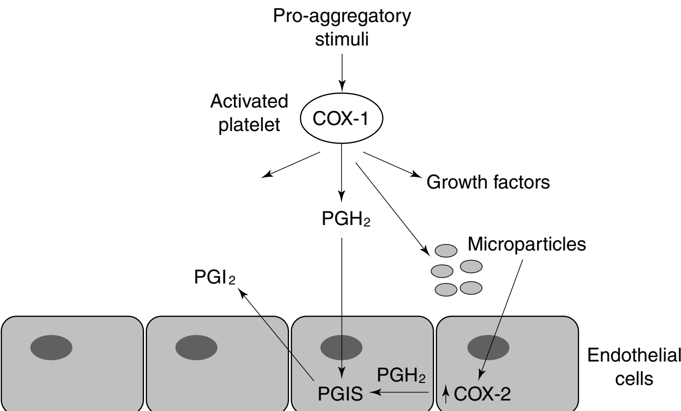

Fig. 25.6. Mechanisms involved in endothelial PGI_2 biosynthesis by activated platelets. PGI_2 synthase (PGIS) can utilize PGH_2, derived from platelet COX-1 and from endothelial COX-2, induced in response to platelet-derived growth factors and microparticles, to produce PGI_2.

PGI_2 has been proposed to be an atheroprotective mediator for its inhibitory effects on proliferation and contraction of vascular smooth muscle cells and platelet activation[85]. The involvement of PGI_2 in the control of platelet function in vivo is suggested by the finding that deletion of the PGI_2 receptor, the IP, results in an increased response to thrombotic stimuli in the mouse[86].

TXA_2 receptors (TPs)

TXA_2 acts on a receptor belonging to the heptahelical superfamily of G protein-coupled receptors[2]. TP purified from human platelets consists of a broad protein band of 57 kDa[87]. Although pharmacological studies, using different ligands, suggest heterogeneity of TPs[88], a single gene has been cloned from a placental library[89]. Deletion of this gene renders mouse platelets unresponsive to thromboxane analogues and abolishes the pressor response to infusion of TP agonists[90].

Two splice variants of TP have been identified, α and

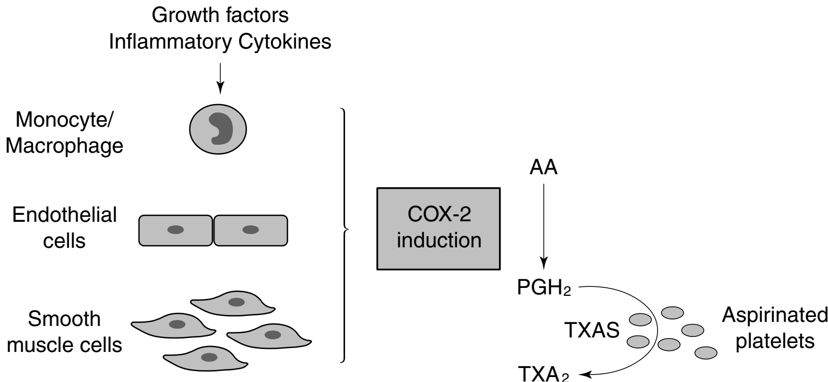

Fig. 25.7. Aspirin-treated platelets metabolize PGH_2 derived from vascular cells and macrophages into TXA_2. COX-2 induction in activated endothelial cells, smooth muscle cells and macrophages may contribute to TXA_2 biosynthesis by providing PGH_2 to the TXAS of aspirinated platelets.

β[89,91]. They differ only in the carboxyl-terminal tail. TPβ isoform has a longer carboxyl-terminal extension than TPα isoform. Although mRNA for both isoforms exists in platelets, only TPα protein has been detected[92]. In contrast, both isoforms are expressed in endothelial and vascular smooth muscle cells[93]. The two isoforms of the TP differ in their rates of agonist-induced desensitization and propensity to couple with G proteins[94,95]. Thus, TPβ, but not TPα, undergoes agonist-induced internalization in several different cell types, presumably, through phosphorylation in a region containing three serine residues of its C-tail. Activation of TP isoforms causes the increase of phosphoinositide-specific phospholipase C (PLC) activity via the coupling with pertussis-insensitive GTP binding protein, G_q[96]. In contrast, only TPα signals via G_h to induce PLC-dependent IP_3 formation[95].

Pharmacological studies using the ligand I-BOP have evidenced the presence of two binding sites (high and low affinity) on platelet membranes. The interaction with the low affinity binding site induces secretion and aggregation, whereas that with the high affinity binding site induces shape change[97]. Since only TPα has been detected in human platelets, these two binding sites seem to represent different states of the same TP isoform.

Impaired coupling of TP receptor to G protein, as a consequence of a single aminoacid substitution (Arg[60] to Leu) in the first cytoplasmatic loop of the receptor, has been associated with a dominantly inherited bleeding disorder[98]. In fact, ligand activation of mutant TP receptor, expressed in Chinese hamster ovary (CHO) cells, has been shown to cause a decreased formation of second messengers despite a normal binding affinity[98].

A newly synthesized TP antagonist, S18886, which is devoid of partial agonist activity, has been shown to retard atherogenesis in the apoE-knockout mouse[99]. Since aspirin is ineffective, the possible involvement of platelet TP blockade is, presumably, excluded. Thus, the antagonist may have interfered with the activation of TPs expressed in other cells relevant to atherosclerosis (i.e. vascular smooth muscle cells, macrophages). Moreover, the possible prevention of isoprostane-dependent TP activation by S18886 cannot be excluded. Isoprostanes are PG isomers formed by free-radical catalysed arachidonate peroxidation[100]. 8-iso-$PGF_{2\alpha}$, one of the most abundant F_2-isoprostanes formed in vivo in humans, has been shown to induce platelet and vascular smooth muscle cell activation through the interaction with TPs[101].

Aspirin-insensitive TXA_2 biosynthesis

Studies performed in vitro have demonstrated that aspirin-treated platelets restore their capacity to synthesize TXA_2 if they are incubated with thrombin-stimulated endothelial cells[47]. Since the extent of TXA_2 production was proportional to the amount of endothelial COX-2 expression, it has been suggested that COX-2-dependent PGH_2 can be utilized by the TXAS of aspirinated platelets to produce TXA_2 (Fig. 25.7). Differently from platelets, which are persistently inactivated by aspirin, endothelial cells can rapidly (2–4 h) recover the aspirin-dependent irreversible inhibition of COX-2 activity after treatment with phorbol esters or interleukin (IL)-1α, due to *de novo* synthesis of COX-2[47]. These in vitro findings suggest that after a single daily administration of the short-lived aspirin, extraplatelet TXA_2 biosynthesis can be restored through the induction of COX-2 in nucleated cells (i.e. vascular cells, monocytes/macrophages) in response to a local inflam-

Cambridge Books Online © Cambridge University Press, 2009

matory milieu (Fig. 25.7). This phenomenon may be operative in vivo. In fact, in a subset of patients with unstable angina treated with low-dose aspirin to almost completely block platelet COX-1 activity, enhanced TXA_2 biosynthesis in vivo, as reflected by the urinary excretion of 11-dehydro-TXB_2 and 2,3-dinor-TXB_2, has been demonstrated[62]. The involvement of extraplatelet sources, possibly expressing COX-2, has been suggested by the finding that indobufen, an antiplatelet drug that largely inhibits both platelet COX-1 and monocyte COX-2 at therapeutic plasma concentrations, causes a more profound reduction of TXA_2 biosynthesis than low-dose aspirin, a selective inhibitor of platelet COX-1, in this setting[102]. Thus, COX-2 induction in plaque monocyte/macrophages or activated vascular cells may contribute to aspirin-insensitive TXA_2 biosynthesis in patients with acute coronary syndromes by generating PGH_2 as a substrate for the TXAS of the same cell or by providing PGH_2 to the TXAS of aspirinated platelets (Fig. 25.7).

Conclusions

COX-1-dependent TXA_2 biosynthesis produced by platelets in response to other primary agonists plays an important role in the local amplification of cell activation. This is demonstrated by the results of randomized clinical trials with aspirin showing that the antithrombotic effect is saturable at doses (50–100 mg/day) causing a selective inhibition of platelet COX-1 activity[30].

Aspirin-insensitive thromboxane biosynthesis occurring episodically in patients with acute coronary syndromes may provide a mechanism for the formation of a potent agonist of platelet and vascular TP receptors, possibly contributing to a number of clinical aspirin failures. The availability of potent and long-lasting TP antagonists[103] and selective COX-2 inhibitors (coxibs)[104] offers the opportunity to test this hypothesis.

Platelet procoagulant activities: the amplification loops between platelets and the plasmatic clotting system

H. Cœnraad Hemker

Synapse b.v.; Cardiovascular Research Institute Maastricht, Maastricht, The Netherlands

Introduction

Before the early 1960s interaction between platelets and plasmatic thrombin or 'thromboplastin' generation was the subject of intensive study[1]. Since the introduction of the aggregation and adhesion methods, most studies on platelets are done under conditions where clotting is prevented, whereas blood coagulation is usually studied in the absence of platelets. In this way only indirect information (e.g. recognition of thrombin-receptors) is obtained on the interaction between platelet and plasma. Direct information on the platelet-clotting system reinforcement loops has been reappearing only recently.

In the body, platelet activation and thrombin generation are two intimately linked processes. Thrombin is a potent platelet activator and adequate thrombin formation is impossible without activated platelets. Because thrombin generation and platelet activation are mutually interdependent, each process requiring the product of the other for its full activity, the two are interlocked in positive feedback. Unlike the better known negative feedback that has regulatory properties, a positive feedback loop amplifies product formation explosively. Hemostasis is an intricate complex of positive and negative feedback loops. Here, we will focus on the amplification mechanism constituted by the platelet–clotting system interaction. The thrombin induced positive feedback loop has been known for over half a century (see fig. 26.1 from ref.1) but only recently has it again become a focus of wider interest.

Two questions are essential to the understanding of this loop: (a) what is the nature of the procoagulant activity of activated platelets? and (b) how do the products of the clotting process, i.e. thrombin and fibrin, bring about procoagulant activity in platelets?

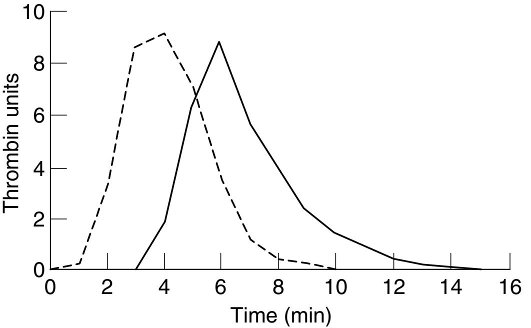

Fig. 26.1. Thrombin mediated feedback anno 1953. From ref. 1, p.97. The original legend reads: *The thrombin generation test was carried out on normal whole blood in glass tubes with and without the addition of thrombin to the blood. The presence of thrombin greatly shortens the delay phase before rapid thrombin formation occurs.*

Adhesion and aggregation are early events and make us focus on the start of plug formation. However, the role of platelets is not finished with the forming of an aggregate adhering to a lesion. Neither does clot formation mark the end of the activity of the clotting factor system. Over 97% of all thrombin appears after a clot has formed, in a mechanism that is critically dependent upon platelet function[2]. Such thrombin, among other things, determines the resistance of the clot to fibrinolysis[3] and the extent of the thrombotic reaction around a primary focus, brought about by the numerous actions of thrombin on the cells of the blood and the vessel wall. Clot retraction is another example of a late physiological reaction that is entirely dependent on platelets in a clot.

The importance of such late processes becomes apparent from clinical observation. Resistance to activated

protein C or heparin administration hardly influence the start of the haemostatic/thrombotic reaction triggered by tissue factor (TF). Neither are bleeding times or TF induced clotting times significantly influenced. The clinically observed pro- or antithrombotic state does, however, correlate well with the changes in the amount of thrombin formed after TF induced clotting.

Essentials of thrombin formation

When clotting is activated in blood or plasma, a dynamic situation builds up in which prothrombin is converted into thrombin and thrombin disappears by its interaction with antithrombins. Clotting occurs at the very beginning of the process, as soon as 5–10 nM of thrombin are formed. The peak of thrombin concentration is seen a few minutes later and, depending upon the reaction mixture, amounts to 50–250 nM. Normally only ~10% of all prothrombin remains unconverted.

The prothrombin converting complex (prothrombinase) consists of factor Xa and factor Va reversibly bound to the surface of a membrane containing coagulant phospholipids (CPL). Negatively charged or aminophospholipids, i.e. phosphatidylserine (PS) and/or phosphatidylethanolamine (PE) are essential components of CPL[4]. The factor X activating enzyme is either a complex of factor VIIa and (membrane bound) TF or it is 'tenase', a complex analogous to prothrombinase with factors IXa and VIIIa in the role of factors Xa and Va, respectively[5]. In prothrombinase, factor Va increases the rate of thrombin formation a thousand fold[6,7]. Factor Va is formed from plasmatic factor V by the action of (meizo-)thrombin[8]. The first traces of (meizo-) thrombin formed therefore tremendously increase thrombin formation. (Meizothrombin is a prothrombin activation intermediate that has retained the membrane binding properties of prothrombin but already has the proteolytic activities of thrombin). Thrombin also is essential in the activation of protein C and therefore entails factor Va breakdown in a later stage. Factor V activation and subsequent inactivation in this manner create a limited time lapse to which thrombin generation is confined.

The binding of prothrombinase and its substrate prothrombin (factor II) to CPL makes the proteins meet in the required juxtaposition and increases the local concentration of substrate around the enzyme, which kinetically translates into an upto one thousand fold decrease of Km. Not only the composition but also the size of the available surface influences the kinetic properties of the enzymes. A prothrombinase complex on a large CPL surface is more efficient (K_m decreases more) than that on a small aminophospholipid containing vesicle because the surface around the complex acts as a 'funnel' that guides prothrombin from free solution to the enzyme through lateral diffusion[9]. For the interpretation of experiments on clotting factor-platelet interaction it is essential to realise that mere changes in lipid availability and composition, as they occur during platelet activation, may profoundly change the binding and kinetic characteristics of the platelet membrane. This may be one of the reasons that a number of so far elusive clotting factor receptors have been postulated (see below).

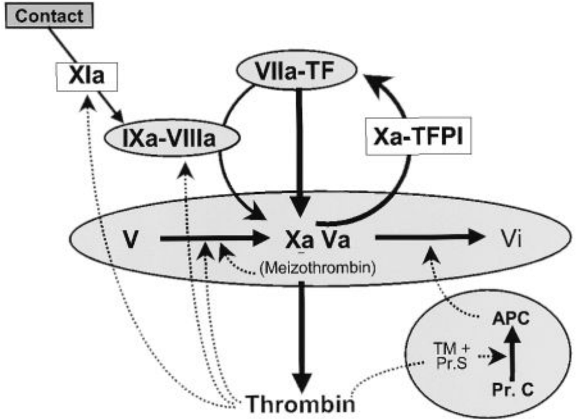

Fig. 26.2. A Coagulation Scheme for 2001. The main vertical axis is the cascade that ensures thrombin formation by sequential activation. The horizontal axis is the regulation dimension operating through activation of factor V (and VIII and XI) and subsequent inactivation of Va (and VIIIa) by APC.
TF: Tissue factor; TFPI: Tissue factor pathway inhibitor; TM: thrombomodulin; Pr.S: protein S; Pr.C: protein C; APC: activated protein C. suffix a: activated form, suffix i: inactivated form. The arrows indicate either chemical conversion sequential activation and the stippled ones, enzymatic activity. TFPI reacts stoichiometrically with Xa and the complex inactivates the TF-VIIa complex by binding to it.

As stated above, factor Xa is formed from factor X either by the TF – factor VIIa complex (the so called 'extrinsic' pathway) or by 'tenase' formed from factors IXa and VIIIa. Factor IXa is formed in the body by TF-VIIa and by (thrombin-activated) factor XIa. In the lab it forms via contact activation, notably during the determination of the activated partial thromboplastin time (aPTT), where a contact activator and CPL are added together with Ca^{2+} to start the so called 'intrinsic' reaction pathway. The clotting time in this case is the lag-time required for traces of thrombin to activate factor VIII that, in plasma, is bound to von Willebrand factor (vWF) and therefore, unlike factor V, will

Cambridge Books Online © Cambridge University Press, 2009

not adsorb upon the CPL surface before it is activated and hence cannot be activated by membrane-bound meizothrombin. It remains anybodies guess how far the situation changes when vWF, by binding to platelet receptors, brings factor VIII close to the platelet surface (see below).

TF occurs abundantly on perivascular connective tissue cells. These will express CPL only in so far as they are damaged. In a wound, contact establishes between TF and factor VII(a) from plasma. TF does not normally occur on circulating platelets but it is deposited on adherent platelets by leukocytes[10] (see below). It can thus be imagined that on damaged cells and platelets provided with TF the complete thrombin generation process can occur on the same surface. This is probably not the rule, however, otherwise the antithrombin–pentasaccharide complex, which acts on free factor Xa only, would not have an antithrombotic effect[11].

Means to study clotting factor – platelet interaction

The procoagulant properties of isolated platelets in suspension can be studied by measuring the conversion of added prothrombin and manipulating the concentration of the constituents of prothrombinase so that the one to be studied is rate limiting. The appearance of factor V(a) or CPL or other prothrombinase sustaining activity can thus be assessed. The property of Annexin V to bind to CPL only, can be conveniently used to inhibit CPL dependent processes or to spot CPL on cells in FACS-experiments[12,13]. On adherent platelets similar activity measurements in flow chambers can be combined with direct observation of morphological changes. The appearance of CPL can be observed directly by the binding of fluorescently labelled annexin V as well as the measurement of intracellular Ca^{2+} after loading the cells with a dye, the fluorescence of which is dependent upon the Ca^{2+} concentration.

In 1989 Béguin reintroduced measurement of thrombin generation (TG) in PRP[2]. Classical TG-experiments require inconvenient, frequent subsampling from recalcified PRP. Automated registration of the TG-curve with a fluorescent thrombin substrate, i.e. the thrombogram, circumvents this problem[14] (Fig. 26.3). In this type of experiment, the platelet-plus-plasma system is left intact as far as possible. It therefore allows direct investigation of their interaction under near to physiological conditions.

The appearance rate of thrombin is dependent upon the amount of prothrombin and on the activity of prothrombinase. The disappearance rate is proportional to the activity of the antithrombin present. This allows us to calculate the rate of conversion of prothrombin into thrombin[15]. At normal prothrombin- and antithrombin concentration and in the absence of heparin (-likes) that boost antithrombin action, this calculation is not necessary because the course of thrombin concentration directly reflects prothrombin conversion. So, in experiments such as those of Fig. 26.3 the differences between the thrombograms reflect the differences in the availability of the rate limiting component of prothrombinase.

In the extrinsic system thrombin formation immediately starts. In the intrinsic system and in PRP, thrombin generation is under normal detection limits for some time (= lag-time). Due to the fact that clotting occurs very early after the start of massive thrombin generation, this lag-time for all practical purposes equals the clotting time.

If no platelets are present (PPP), thrombin generation requires added CPL as well as Ca^{2+}. The trigger can be either TF or a contact activator (e.g. kaolin, ellagic acid). If the PPP is devoid of platelet remnants and a trigger is omitted, it may take an hour before thrombin will form after mere recalcification. Contrary to PPP, recalcification makes PRP clot without further triggering, after a lag-time that is dependent upon the degree of damage done to the platelet in obtaining the PRP. If the PRP is tested within one hour after a flawless venipuncture without suction and avoiding exposure to temperatures below 15 °C, the lag-time is 9 ± 2 min. The subtle damage brought about by washing or gel filtering already may reduce the lag time by several minutes. The closest approach to physiological conditions remains the study of blood directly from a venipuncture through a flow chamber[10]. The drawback is that, for all practical purposes, the observations remain restricted to histological and histochemical observation.

The role of platelets in thrombin formation

Because platelets stick to collagen and fibrin and expose their procoagulant properties after activation, they serve to localise thrombin generation in a wound or thrombus (Fig. 26.4). The enhancement of thrombin generation due to platelet collagen-interaction, acts via the receptors integrin $\alpha2\beta1$ and GP-VI[16,17]; see further[18].

Four types of procoagulant activity have been described for activated platelets: (a) release of clotting factors; (b) appearance of CPL; (c) activation of clotting factor receptors, and (d) a role in exposing TF from white blood cells.

(*a*) Activated platelets release factor V and von Willebrand factor (vWF) as well as fibrinogen[19–22]. Factor V is shed in unactivated form and activated by thrombin afterwards[23]. The physiological function of factor V release

is difficult to understand in terms of thrombin generation in plasma because, as is already known from the earliest studies on factor V, 10% or less of the normal plasma concentration of this factor is required for nearly normal thrombin generation. One can surmise that release serves a purpose for thrombin generation within a platelet aggregate. Adhesion and aggregation are the first steps in haemostasis but thrombin generation follows almost immediately and no stable thrombus or haemostatic plug will arise without it. The amount of plasma factors entrapped in the interstices of the aggregate is necessarily limited. In plasma, factor X is in 6–8 fold excess over factor V. For rapid and adequate thrombin formation it may therefore be required that more factor V is supplied via the release reaction. Recent results indeed suggest strongly that released factor V is preferably bound to the surface of procoagulant platelets[24].

Also factor IX, in plasma, is in excess over factor VIII (over 50-fold). There is no compelling evidence that factor VIII is released from platelets. This factor, however, is carried by vWF, the binding of which to GPIb and activated $\alpha_{IIb}\beta_3$ on the surface of platelets is well documented. Binding of vWF concentrates factor VIII near the platelet surface. As soon as some thrombin is generated on the platelet surface, this will activate this factor VIII. By making elegant use of the fact that human factor VIII binds to mouse vWF but human vWF hardly to mouse platelets, it could be shown that binding of factor VIII to the thrombus indeed has a prothrombotic effect[25]. This is corroborated by the observation that prothrombin consumption is decreased in patients with a congenital lack of GPIb and that this defect is corrected by addition of factor VIII[26]. This mechanism may explain the correlation between the level of factor VIII and thrombosis found in epidemiological studies[25].

Normally, during the clotting process, all fibrin is formed before 3% of prothrombin is converted but almost the totality of prothrombin available is consumed due to ongoing thrombin formation in the clot. As discussed in the introduction, this ‘excess’ amount of thrombin is an important determinant of the extent of the thrombotic/haemostatic reaction. Under low flow conditions, the thrombin generated in the aggregate/clot will act on

Cambridge Books Online © Cambridge University Press, 2009

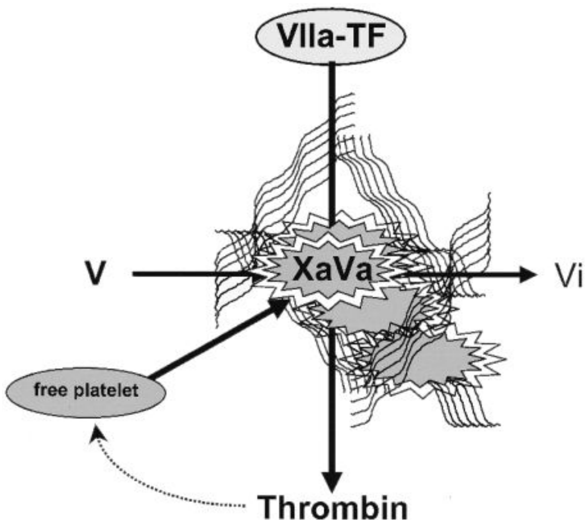

Fig. 26.4. The three-dimensions of thrombin generation. The first dimension (Y) is thrombin production through the cascade mechanism. The second one (X) ensures limitation in time through thrombin-governed positive and negative feedback. The third (Z) localizes thrombin generation on collagen or fibrin fibres through adhesion and aggregation and exposure of platelet CPL through these fibres and thrombin.

the surrounding blood and make it clot. At the fibrin–blood interface of that new clot more platelets will adhere (see below for the link: fibrin – vWF – GPIb – platelet) and become procoagulant, which starts the process again and makes the thrombus grow. The alternation of blood clot and platelet aggregates explains the striated aspect often observed in venous thrombi. Under high flow conditions thrombin that diffuses out of the aggregate/clot will be strongly diluted and washed away. Only a few fibrin fibres are to be found at the outside[27] and no erythrocytes will be entrapped. On this fibrin, to which active thrombin remains bound, new platelets may adhere and become procoagulant in their turn, by two mechanisms[28]: (*a*)activation by fibrin-bound thrombin, and (*b*) activation by fibrin-bound vWF, as discussed further.

(*a*) The amount of thrombin formed in a clot also determines the degree of activation of TAFI and therefore, indirectly, the resistance of the clot against fibrinolysis[3,29,30]. This may well explain the clinical observation that in deficiencies of factors FVIII, IX and XI loose clots form that are subject to easy lysis.

(*b*) Studies from the van Deenen group in the early 1970s had demonstrated that the phospholipid components of the cell membrane are not evenly distributed between the inner and the outer leaflet. PS and PE, essential for CPL-function, are to be found at the inside[31–35]. Therefore a cell membrane is not procoagulant unless wounded, apoptotic or otherwise disturbed (e.g. by hemoglobin crystals in depranocytosis). Platelets are the only known cells in which the loss of the normal asymmetry ('flip-flop') is induced as a part of their physiological function. In this way platelet activation brings about their power to facilitate blood coagulation[36]. How far the process is similar to membrane scrambling in apoptosis remains to be investigated.

Plateletmembranes scramble as a last stage in their activation after shape change, aggregation and release. This stage is only attained when they are activated by thrombin, by collagen and, as we will see later, by fibrin and vWF. Epinephrine, ADP, prostanoids etc. may modulate the scrambling response but will not, by themselves, bring it about.

The intra-membrane activity responsible for the break of asymmetry is attributed to three putative mechanisms (i) an inward-directed pump ('flippase') for PS and PE; (ii) an outward-directed pump ('floppase') and (iii) a lipid scramblase, which facilitates bidirectional migration across the bilayer of all phospholipid classes[37]. These activities await further description and definition in terms of protein entities. The precise intracellular events that activate the intramembrane mechanism remain largely obscure. It is clear that a rise in intracellular Ca^{2+} is required: any Ca^{2+}-ionophore is a potent inducer of flip-flop[18]. In the next section we will describe which platelet receptors may be involved in triggering the process.

Platelet activation goes hand in hand with extensive rearrangement of the cytoskeleton. In this process patches of the membrane bulge outward and pinch off ('blebbing')[38]. This causes minute vesicles (microparticles) to appear, the CPL activity of which can be demonstrated (e.g. by annexin V binding) and the platelet origin of which is clear from their containing integral platelet membrane proteins such as $\alpha_{IIb}\beta_3$ and P-selectin[39,40]. Calpain inhibitors, that inhibit cytoskeleton degradation[41] also inhibit blebbing and microparticle formation as well as thrombin generation in PRP (unpublished results). The microparticles can be demonstrated in the serum left after a thrombin generation experiment and their appearance is inhibited by antibodies against vWF, GPIb and against $\alpha_{IIb}\beta_3$; in the presence of fibrin, antibodies against GPIb/IX also inhibit (Keularts, publication in preparation). Microparticles bind to fibrin[42], so at least part of them remain normally in the emerging thrombus. It is not known whether they are shed in the bloodstream, but they have been found in the peripheral circulation in various pathological conditions[43–49].

(*c*) A number of receptors have been described that bind

Cambridge Books Online © Cambridge University Press, 2009

clotting factors to the platelet membrane. Confusingly, high affinity binding sites for clotting factors that arise from the exposure of CPL are sometimes called receptors. Here, we define receptors in the strict sense, as integral platelet membrane proteins that engage in a protein-protein interaction with clotting factors. Such receptors have been postulated for all known factors and rigorously demonstrated only for thrombin (see later).

Prothrombin

Zybacova and Plow have described that $\alpha_{IIb}\beta_3$ can act as a receptor for prothrombin[50]. A binding site that is shared with factor X has also been described[51].

Factor V(a)

Platelet receptor-dependent binding of factors Va and VIIIa has been described[52].

Factor X(a)

EPR-1, a receptor found and characterized on fibroblasts[53], is presumed to coordinate assembly of the prothrombinase complex. The site shared with prothrombin is described to have different properties[51].

Factor VIII(a)

A factor VIIIa receptor has been described[54] and it has also been surmised that GPIb, by virtue of its binding vWF, may serve to bring factor VIII in the vicinity of the platelet membrane[26]. It has been demonstrated that vWF binds to fibrin[55] and to the platelet surface in a thrombus and that this process leads to enrichment in factor VIII[25]. So vWF binding causes concentration of factor VIII near the platelet membrane.

Factor IX(a)

A factor IXa receptor on activated platelets has been postulated, that facilitates factor X activation[56–58].

Factor XI(a)

Through its apple 3 domain factor XI binds to a few high affinity sites on activated platelets[59] but also via high molecular weight kininogen.[60] The former facilitates FXI activation by thrombin on activated platelets[61,62]. In contrast, in fresh plasma from severely factor XI deficient patients, we found an essentially identical relation between the concentration of added factor XI and thrombin generation in PRP, in PPP supplemented with normal platelets and in PPP supplemented with 1 μM of synthetic CPL (Keularts, Zivellin, Béguin, Seligsohn and Hemker. Thrombosis Haemostasis, in press 2001), i.e. we found no evidence for a facilitating role of platelets in thrombin generation when factor XI is rate limiting.

Except for EPR-1 no specific protein receptors have been identified. In our opinion the evidence produced for the existence of most or all of these receptors is open for alternative interpretation. The observations might, for example, be brought about by changes in the lipid composition of the outer face of the platelet membrane. During platelet activation the composition and the size of the available CPL and therefore the kinetic characteristics of clotting factor binding and conversion increase considerably. This can mimic the effect of specific receptors. It may be extremely difficult to distinguish between a protein receptor for a clotting factor and a receptor that is instrumental in producing CPL with high affinity for a clotting factor.

The kinetic effects of platelets and of phospholipids extracted from platelets are of the same magnitude. Rigorous experimental proof would require the demonstration of thrombin formation in the absence of CPL, either by isolating the putative receptor to purity or by inhibiting CPL-dependent clotting factor activation completely. Such evidence to our knowledge has not been brought forward. As long as solid proof to the contrary has not been presented, we prefer not to multiply hypotheses beyond necessity and continue to explain the procoagulant phenomena on the surface of activated platelets in terms of CPL.

(*d*) When blood is led directly from a vein through a flow chamber in which collagen is exposed (either arterial media or purified collagen on glass), platelets adhere to the collagen. Such platelets pick up TF from leukocytes that roll over the surface of the aggregate; this TF is biologically active. In the free platelet no TF can be demonstrated. On the surface of the free leukocytes there is no active TF either, so TF is 'decrypted' in the process. The specific leukocyte membrane marker CD15, absent in circulating platelets, is present in adherent platelets that have been exposed to leukocytes, which shows that the leukocyte–platelet contact involves the carryover of pieces of leukocyte membrane. This process, together with the flip-flop induced by fibrin and by fibrin-bound thrombin, makes it possible that a plug or thrombus grows even though the collagen and perivascular TF-carrying cells are shielded from contact with flowing blood by the emerging thrombus/plug[10].

Which type of leukocyte is involved in these processes is still a matter of debate. Giesen et al. suggest that polymorphonuclear cells as well as monocytes contribute.

Cambridge Books Online © Cambridge University Press, 2009

Østerud et al.[63], in experiments in which TF synthesis is induced by lipopolysaccharides, conclude that only monocytes are able to synthesize TF but that platelets as well as granulocytes play a supporting role.

The role of thrombin and fibrin in provoking platelet procoagulant activity

The early effect of thrombin on the procoagulant capacity of platelets is triggering release (and subsequent activation) of, among many other substances, clotting factor V. At a later stage the platelet surface acquires procoagulant activities. The release reaction (see Chapter 24) can be provoked by a number of agents. The exposure of CPL is brought about by thrombin, collagen and vWF-fibrin only.

After recalcification of PRP, the burst of thrombin generation is preceded by the appearance of subnanomolar amounts (<0.1 U/ml) of thrombin, probably formed on traces of circulating procoagulant phospholipid or an occasional damaged platelet, possibly started by minute amounts of circulating TF or minimal contact activation. Adding such amounts of thrombin at zero time dramatically shortens the lag-time as already observed by Biggs and Macfarlane[1] (see Fig. 26.1) and similar amounts of a specific thrombin inhibitor like hirudin prolong it[2]. The lag phase can also be shortened by addition of synthetic CPL, through membrane scrambling by a Ca^{2+}- ionophore or by freeze–thawing. On the other hand, adding factor VIIIa does not abolish the lag phase unless CPL is available first. From these and similar observations we conclude that, in PRP, the availability of CPL is the rate-limiting component for thrombin generation and that thrombin or a thrombin product causes the platelets to produce it.

Which receptors are activated by thrombin may depend upon the amount of thrombin present. In PRP it may therefore be different during the lag-phase and thereafter. In washed platelets it has been shown[64] that blocking the PAR-1 receptor with a peptide (YFLLRNP), with bradykinin or with an antibody, blocks the appearance of CPL. Thrombin activating peptide (SFLLRN), although causing aggregation, does not provoke CPL but rather renders platelets insensitive to thrombin. Dörmann et al. also reported that CPL production in washed platelets is inhibited by antibodies against the thrombin binding site in GPIb and by glycocalicin. Unlike α-thrombin, γ-thrombin, which lacks the normal anionic exosite of α-thrombin, does not provoke CPL. These observations indicate a crucial involvement of thrombin-GPIb interaction and in all probability both PAR-1 and GPIb play a role.

Thrombin contact induces the activation of $\alpha_{IIb}\beta_3$ complex in the platelet membrane. Adding an antibody (abciximab) or another antagonist (MK383) to PRP partially inhibits thrombin generation[65–67,68]. So $\alpha_{IIb}\beta_3$ is part of a loop consisting of the sequence: thrombin $\rightarrow$ GPIb and/or PAR $\rightarrow$ $\alpha_{IIb}\beta_3$ $\rightarrow$ CPL $\rightarrow$ prothrombinase $\rightarrow$ thrombin. Inhibition via blocking $\alpha_{IIb}\beta_3$ is not complete, so the loop described is not likely to be the only pathway. If no fibrin(-ogen) is present, antibodies against GPIb will not inhibit thrombin generation but antibodies against vWF do[28,69,70]. This shows that (a) in PRP GPIb is not the only thrombin receptor involved and (b) vWF–$\alpha_{IIb}\beta_3$ interaction must play a role.

The addition of a fibrin clot after recalcification of PRP considerably shortens the lag phase[69]. This is partly due to fibrin bound thrombin that is able to activate platelets and other clotting factors. Also several other serum proteins (e.g. factor Xa) and platelet remnants[42] may be incorporated in a natural clot. When, however, purified fibrinogen is clotted with a snake venom enzyme that as such does not activate platelets, the pure fibrin clot that is obtained will still provoke platelet procoagulant activity[28], notably if $\alpha_{IIb}\beta_3$ is also blocked. This direct activation by fibrin can be observed via thrombin generation experiments but also in EM pictures, if care is taken to prevent thrombin playing a role (Fig. 26.5). Platelet–fibrin interaction can be inhibited by antibodies against GPIb and/or vWF. Preventing fibrin polymerization or removing fibrin as soon as it forms blocks this pathway. Our current hypothesis is that vWF adsorbs onto fibrin and thus undergoes the conformational change that makes it a ligand for GPIb. This constitutes a second feedback activation loop: thrombin $\rightarrow$ fibrin $\rightarrow$ fibrin-vWF $\rightarrow$ GPIb $\rightarrow$ CPL $\rightarrow$ prothrombinase $\rightarrow$ thrombin.

Because of the loop character of these sequences we cannot, in thrombin generation experiments, discern between the above sequence and a nested loop in which, e.g. thrombin and GPIb together are required for CPL formation. Experiments with platelets adherent to fibrin are in favour of this possibility (Briedé, manuscript in preparation). On the other hand, the platelet activation on fibrin is seen in EM pictures in which the possibility of thrombin generation was practically excluded (Fig. 26.5) and the polymerization of fibrinogen brought about by an otherwise inert snake venom enzyme enhances thrombin generation through GPIb-dependent platelet activation (unpublished results).

The fibrin–vWF–GPIb pathway of platelet activation remains active when $\alpha_{IIb}\beta_3$ is blocked with an antibody. The $\alpha_{IIb}\beta_3$ pathway remains active when GPIb is blocked or in the absence of polymerized fibrin. The two receptors

Cambridge Books Online © Cambridge University Press, 2009

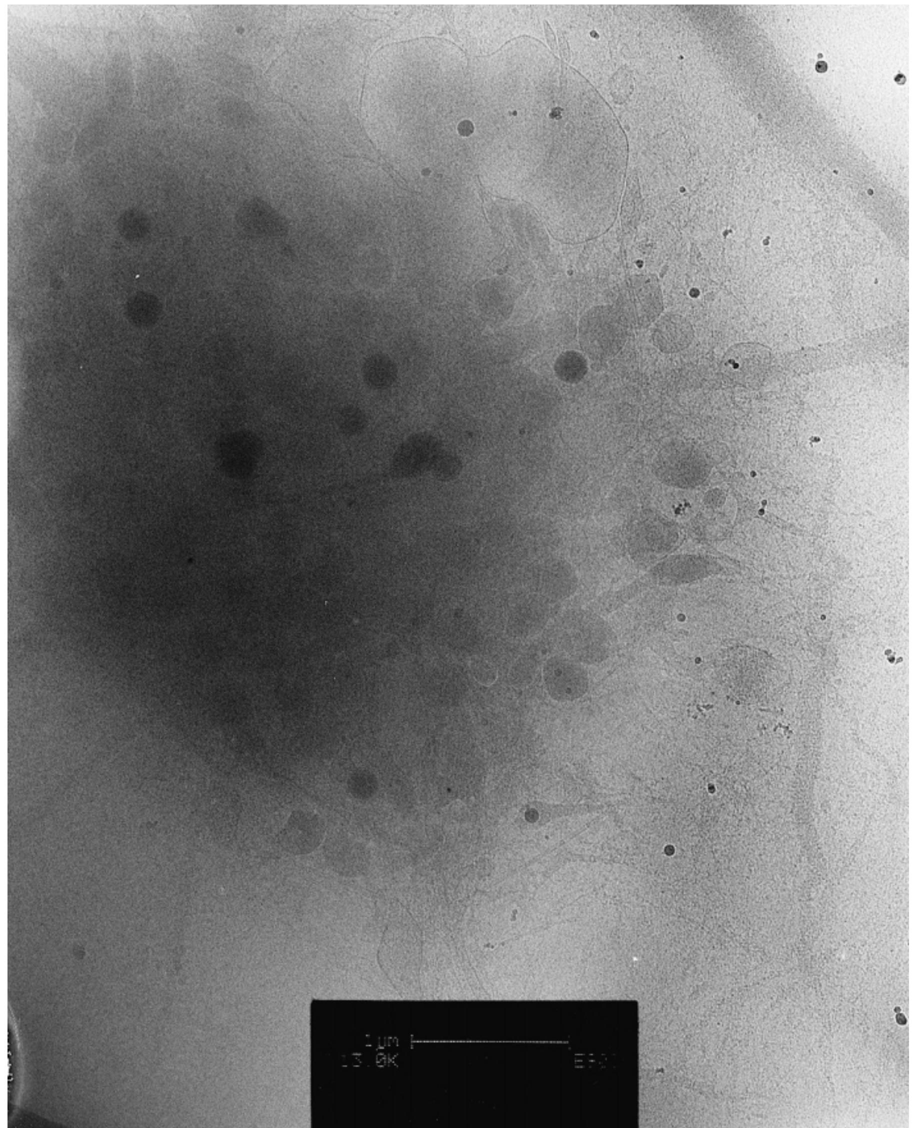

Fig. 26.5. Activated platelets on a fibrin mesh.
On a grid a fibrin mesh was made by clotting pure fibrinogen with a snake venom enzyme. Freshly drawn blood was collected on a mixture of hirudin (2 μM) and 0.5 mM of PPACK (both thrombin inhibitors). The grid was held in the anticoagulated PRP for 1 minute, washed in a saline solution, snap frozen and mounted for observation directly.

therefore seem to function on parallel pathways and both pathways are inhibited by lack of vWF or by vWF antibodies. Also in platelets adherent on fibrinogen, vWF has been shown to be required for CPL exposure[71].

The findings in PRP and with gel-filtered platelets are in accordance as to the involvement of the receptors GPIb and $\alpha_{IIb}\beta_3$[64]. Whereas the inhibition obtained by blocking these receptors in washed platelets is >90%, those in PRP do not exceed 50% which suggests that they are coupled in series in one condition and on parallel pathways in the other[70,71]. Also, in PRP, vWF is a compulsory factor but not in washed platelets. How these apparently contradictory observations may be reconciled is not clear at the moment. It must be kept in mind that the experimental conditions are significantly different, e.g. in the experiments with washed platelets fibrin polymerization is inhibited, which might prevent activation of vWF. The necessity to add polymerization inhibitors suggests that, at some stage, traces of thrombin arise.

Anyhow, in patients who lack vWF, thrombin generation

Cambridge Books Online © Cambridge University Press, 2009

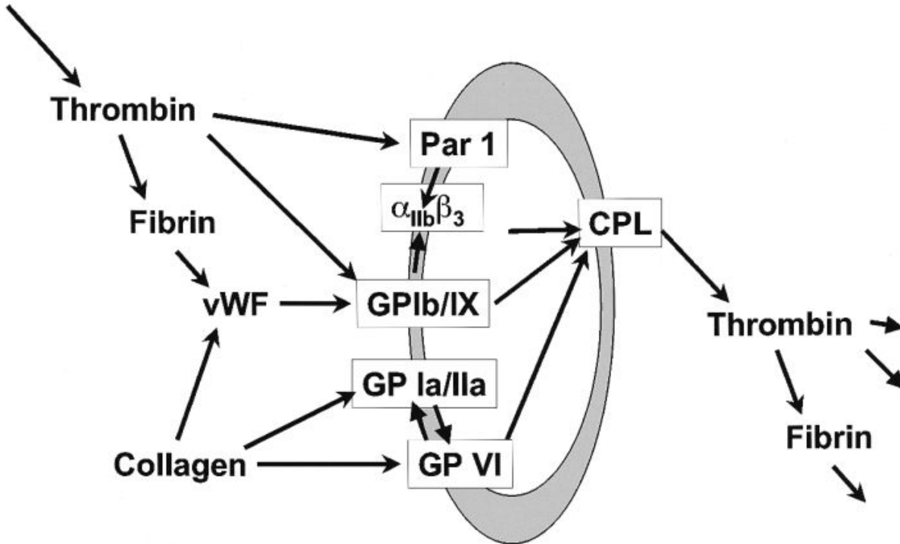

Fig. 26.6. The perpetuum model of thrombus formation. The arrows indicate activations, independent of the mechanism involved: binding, proteolysis or more complicated intraplatelet mechanisms.

in PRP is severely diminished, in a process that cannot be attributed to a lack of factor VIII[72]. Also, thrombin generation can be blocked over 75% with antibodies against vWF and such antibodies have an additional inhibitory power in the presence of antibodies against either of the two GPs involved (Keularts et al. publication in preparation). Under these conditions, and therefore presumably in vivo, vWF must play a role in both the $\alpha_{IIb}\beta_3$ and the GPIb dependent pathway. vWF, in PRP, is a clotting factor, in the sense that its presence is required for the generation of thrombin. This is explicitly not due to the fact that vWF carries factor VIII because the defect is not seen if sufficient CPL is present, i.e. in contact activated PPP with added CPL or in PRP where the platelet membrane is scrambled with a Ca^{2+}-ionophore.

In agreement with this proposed mechanism, Glanzmann's thrombasthenia as well as a- and hypofibrinogenemia and vWF deficiency cause a decreased thrombin generation in PRP (Fig. 26.6). Thrombin generation in PPP is normal in Glanzmann's disease and slightly increased in afibrinogenemia. In vWF disease thrombin-generation in PPP (intrinsic system) is normal as long as the factor VIII level is not below ~10%. Half normal thrombin generation in PRP is seen at a vWF level of ~40% (F.VIII 100%) and a F.VIII level of ~5% (vWF 100%)[73].

In conclusion, in PRP, the interaction between the plasmatic coagulation system and the platelet is close and mutually reinforcing. A minimal hypothesis requires two parallel, receptor dependent pathways for the appearance of CPL, that both need vWF: (a) via the $\alpha_{IIb}\beta_3$ heterodimer that originates upon the appearance of subnanomolar traces of thrombin; (b) via GPIb that interacts with vWF adsorbed onto formed fibrin. In the presence of collagen a third pathway, involving GP VI and $\alpha 2\beta 1$, plays a role.

Platelets and chemotaxis

Stefania Momi and Paolo Gresele

Division of Internal and Cardiovascular Medicine, Department of Internal Medicine, University of Perugia, Italy

Introduction

Platelets have been considered mostly for their role in hemostasis, thrombosis and vascular disease; however, many studies over the last few decades have provided an emerging body of evidence on their potential role in host defence reactions. This unconventional function of platelets is consistent with the theory that platelets may represent the phylogenetic vestige of the primitive hemocytes of lower organisms[1]. As hemocytes, which exert a central role both in defence against invading microorganisms and in repair of tissue injury, platelets maintain in many regards the function of inflammatory cells, able to activate complement, secrete proteases, alter vascular permeability and tone and express cytotoxic properties. For instance, platelets have been shown to participate in cytotoxicity against the parasites responsible for shistosomiasis, toxoplasmosis, and trypanosomiasis[2–6].

Although platelets are anucleated cells, they have an anatomical structure and biochemical properties in many aspects similar to leukocytes and it is thus conceivable that platelets may participate in the defence against infections and in other inflammatory responses. For instance, several observations have confirmed the involvement of platelets in allergic disease and in particular in the tissue inflammatory changes associated with allergic asthma[7]. However, given the role of paramount importance that platelets play in hemostasis and thrombosis and considering the complicacy of the mechanisms regulating these functions, which have absorbed much of the research efforts on these cells, little attention has been paid to the mechanisms regulating platelet inflammatory activities. This chapter will discuss functional activities of platelets related to chemotaxis, an important step in cell involvement in tissue inflammation.

Chemotaxis in eukaryotic cells

Cell migration plays a central role in a wide variety of biological phenomena, both physiologic and pathologic, going from embryogenesis to tumour metastatization[8].

In the inflammatory response, circulating leukocytes migrate by diapedesis across the wall of microvessels into the damaged area where they act as inflammatory cells displaying phagocytic and immune functions. The molecular components involved in cell migration are now largely identified and it is possible to make some generalizations across a wide spectrum of migrating cell types, including amoebae, leukocytes, fibroblasts, neurons and platelets, looking for similarities among physical mechanisms and biochemical characteristics[8].

The process can be sequenced in rolling on the endothelial monolayer, tight adhesion and transmigration, steps involving the active participation of both the transmigrating cells and the endothelium.

Migration of circulating cells begins with the capture or tethering of the cells from the flowing blood and their rolling along the vessel wall where, after appropriate stimuli, they become firmly adhered to the endothelium. Firm adhesion is the preliminary step necessary for cell migration into tissues and it involves the interaction with a number of adhesion molecules located on the migrating cell on one side and on the endothelium on the other.

In general, the adhesion processess leading to inflammation are mediated by different groups of adhesion molecules: the selectins, the integrin family, and the intercellular adhesion molecules.

Selectins mediate the process in which neutrophils roll or slow down prior to their adherence to endothelial cells[9]. Three classes of selectins have been identified: L-selectin, which has been identified on leukocytes; E-selectin, on the surface of activated endothelial cells; and P-selectin, found

on endothelial cells and platelets. Selectins function by binding to carbohydrate ligands present on the cognate cell. L-selectin is involved not only in the tethering and rolling of leukocytes on endothelium but also plays an important role in the activation of leukocytes: recently L-selectin has been established as a receptor capable of signal transduction[10].

P-selectin and E-selectin mediate PMN to endothelial cell adhesion. These selectins are expressed on endothelium only when appropriate inflammatory stimuli (e.g. complement products, oxygen-derived free radicals, cytokines) are generated. Moreover, binding of neutrophils to E-selectin can upregulate the adhesive activity of some integrins, particularly Mac-1[9]. P-selectin (GMP140, CD62P) is stored in Weibel–Palade bodies of endothelial cells and in α-granules of platelets[11]. Upon platelet, or endothelium, activation P-selectin is mobilized to the cell surface where it can interact with its ligand on PMNs, the P-selectin glycoprotein ligand-1 (PSGL-1, CD162). Monocytes and platelets also possess PSGL-1 and can thus bind to P-selectin present on activated endothelium. PSGL-1 consists of a disulfide-bound homodimer and is capable of binding two P-selectin ligands simultaneously[12].

The P-selectin to PSGL-1 interaction is short lived and reversible, unless additional adhesive events are soon evoked[13]. Following specific stimuli, P-selectin binding is followed by a fast redistribution of PSGL-1 to uropods on activated PMNs and may signal the transition from rolling to capture[14].

The second part of the adhesion process is tight binding mediated by integrins. Integrins are receptor molecules composed of two non-covalently associated heterodimers, α and β subunits, and are divided into different subfamilies according to β subunit expression[15].

α and β subunits together form an extracellular ligand binding site while the cytoplasmic tails of integrins provide phosphorylation sites and linkages to cytoskeletal proteins involved in signal transduction[16,17].

There are 8 different β-subunits (β1–β8) that associate with one of 16 α-subunits to form at least 23 known receptors in a variety of cells including lymphocytes, polymorphonuclear leukocytes and platelets[18]. Integrins mediate cell–cell binding and cell interactions with extracellular proteins such as laminin, fibronectin, vitronectin and fibrinogen.

The β1 very late antigen (VLA) integrins comprise a family of receptors that mediate cell adhesion to extracellular matrix (ECM) proteins such as collagen, fibronectin and laminin. They share a common β chain (β1, CD29) that is non-covalently linked to one of at least six different α-chains (α1–α6, CD49a–f) determining the binding properties of the receptor[19]. The VLA proteins are specialized transmembrane receptors allowing the attachment of cells to collagen (VLA-2), fibronectin (VLA-4 and –5) and laminin (VLA-6). Platelets, like megakaryocytes, contain VLA-5, VLA-2 and VLA-6[20] while VLA-4 is expressed on all leukocytes[21].

Recent observations indicate that extravasation of PMNs may be associated with up-regulation of β1 integrins on their cell surface[22]. Surface expression of the $\alpha2\beta1$ (VLA-2) integrin is induced in human and rat PMN on extravasation in vivo suggesting that PMNs locomotion and recruitment to extravascular tissue are critically dependent on $\alpha2\beta1$ integrin function[23].

The binding of PMNs to endothelial cells is mediated mainly by macrophage antigen-1 (Mac-1, CD11b/Cd18, $\alpha_M\beta_2$) and lymphocyte-associated function antigen-1 (LFA-1, $\alpha_L\beta_2$, CD11a/CD18). LFA-1 is the prevailing integrin involved in lymphocyte emigration[24]. In addition to mediating specific adherence, Mac-1 specifically participates in chemotaxis, in phagocytosis and in the production of reactive oxygen species. The ligand for Mac-1 is a cell surface protein found on endothelial cells, namely intercellular cell adhesion molecule-1 (ICAM-1)[25].

Integrins appear to exist in either an active or inactive state and the contact with activated endothelium may induce the appearance of activation epitopes on integrins thus favouring adhesion[17].

ICAM-1, ICAM-2 and VCAM-1 are the most important members of the intercellular adhesion molecules that are cell surface proteins involved in antigen recognition, complement binding or cellular firm adhesion[26]. They are characterized by a variable number of extracellular Ig-like domains with conserved cysteine sequences that form disulfide bonds to stabilize β sheets of the tertiary structure[27]. The Ig family of adhesive receptors bind a number of specific counterreceptors expressed on cells involved in the adhesive interactions. LFA-1 is the counterreceptor of ICAM-1 and ICAM-2 and is also expressed on activated platelets[28] while the physiological counterreceptor of VCAM-1 is VLA-4[21]. ICAM-1 and ICAM-2 bind also to Mac-1[29,30].

Once adhered to the endothelium, cells must undergo anatomical changes that allow them to move across the vessel wall. To this end, they must acquire a spatial asymmetry that allows them to translocate as a result of intracellular generated forces[8].

The locomotion of cells through tissue follows the sequential steps of morphological polarization, membrane extension, formation of cell-substratum attachment, contractile force, traction and release of attachment.

These events are mediated by cytoskeletal changes[31]. It is

Cambridge Books Online © Cambridge University Press, 2009

the polymerization and breakdown of F-actin that leads to the formation and retraction of lamellipodia which function like arms and legs of the migrating cell.

In addition, the actin cytoskeleton is a key mediator of cell polarization and of the directed migration of cells towards a chemoattractant. The two most prominent actin filament-containing structures found in migrating cells are stress fibres and lamellipodia.

Stress fibres are bundles of actin filaments associated with myosin II filaments and other proteins forming contractile fibres. They form sites of adhesion at the plasma membrane, called focal contacts or focal adhesions, where transmembrane integrins are clustered and associated with extracellular matrix proteins outside the cell and with a large number of proteins inside the cell[32]. Formation of such focal adhesions and reorganization of the actin cytoskeleton have been shown to be associated with the phosphorylation of components such as focal adhesion kinase (FAK), the adaptor protein p130 Cas, Crk and paxillin that are directly associated with cell migration[33,34].

Lamellipodia are broad, highly dynamic membrane protrusions that extend and retract through a combination of actin polymerization at the plasma membrane, depolymerization within the cytoplasm, and myosin-mediated rearward movements of the actin fibres[35].

Many signalling events have been identified as being involved in cell migration. Rho-like small GTPases, with their main representatives (Rho, Rac and Cdc42), have been recognized as key modulators of the signalling pathways that mediate the cytoskeletal changes required for both cellular motility and cell–cell adhesion[36]. An important action of Rho, Rac and Cdc42 is their ability to regulate the phosphorylation status of myosin light chain, a major regulator of the actin–myosin interaction[37].

Leukocyte-, but also fibroblast- and other cell type-, migration is largely controlled by soluble stimuli defined chemokines. Chemokines (chemotactic cytokines) are a small group of proteins with four conserved cysteines forming two essential disulfide bonds. CXC and CC chemokines are distinguished according to the position of the first two cysteines, which are either adjacent (CC or β chemokines) or separated by one amino acid (CXC or α chemokines)[38]. Recently, lymphotactin has been described, a chemokine with only two conserved cysteines (C), as well as chemokines with three amino acids between the first two cysteines (CX_3C motif)[38]. Most chemokines are produced under pathological conditions by tissue cells and infiltrating leukocytes. Stimulation of leukocyte suspensions with chemokines leads to a fast shape change that involves polymerization of actin filaments, formation of lamellipodia and activation of the integrins that mediate the adhesion to endothelial cells. Moreover, the activation of leukocytes by cytokines induces some other responses such as the rise in intracellular free calcium concentration, the production of oxygen radicals and bioactive lipids, the release of the content of cytoplasmic storage granules, such as proteases from neutrophils and monocytes, histamine from basophils[39], or cytotoxic proteins from eosinophils[40]. The effects of chemokines are mediated by seven transmembrane domain receptors coupled to GTP-binding proteins. Chemokines have two main sites of interaction with their receptors, one in the N-terminal region and the other within an exposed loop of the backbone that extends between the second and the third cysteine[41]. The N-terminal binding site is essential for the triggering of the receptor.

RANTES (regulated on activation, normal T-cell expressed and secreted) is the first chemokine identified as a potent eosinophil attractant and is released upon appropriate stimuli mainly by platelets but also by fibroblasts[42]. RANTES (ligand for CCR1, CCR3 and CCR9 receptors) has been identified in the bronchoalveolar lavage fluid (BAL) of asthmatics exposed to allergen challenge[43]. The observation that RANTES activates eosinophils and basophils, inducing chemotaxis and the release of histamine and leukotrienes, was the first proof that chemokines are involved in allergy[44].

Monocyte chemotactic proteins (MCPs) have been described in the past few years; they include MCP-1, MCP-2, MCP-3, MCP-4 and MCP-5, all ligands for the CCR2 receptor. MCP-3 acts as chemoattractant for eosinophils and can activate basophils[45].

Recently three peptides with eosinophilic chemotactic activity have been identified including eotaxin (CCL11), eotaxin-2 (CCL24) and eotaxin-3 (CCL26). Eotaxin is expressed in the lungs of animals with allergic asthma and in human tissues where eosinophils accumulate. The in vitro effects of eotaxin on eosinophils include chemotaxis, transendothelial migration, induction of the release of reactive oxygen species, induction of Ca^{2+} mobilization and actin polymerization, and induction of CD11b upregulation. In vivo, eotaxin cooperates with IL-5 to induce eosinophil recruitment and mast cell growth[46]. The specific receptor for eotaxin is CCR3 and it is present on eosinophils (40 000–400 000 receptors per cell), basophils, T-lymphocytes with T_{H2} helper properties[47] and platelets[48]. This receptor (CCR3) appears to mediate most of the actions of the CC chemokines, such as RANTES, MCP-2, MCP-3, MCP-4, and MIP-1α, on eosinophils[49].

Other chemokines involved in cell migration include macrophage inflammatory protein (MIP)-1α (ligand for

Cambridge Books Online © Cambridge University Press, 2009

CCR1, CCR5 and CCR6 receptors), MIP-1β (ligand for CCR5 and CCR8), macrophage-derived chemokine (MDC) (ligand for CCR4), thymus- and activation-regulated chemokine (TARC), stromal derived factor-1α (SDF-1α) (ligand for CXCR4) and some interleukins (like Il-8).

Human MIP-1α is a weak eosinophil attractant and has the ability to stimulate histamine release from basophils and mast cells while murine MIP-1α is a potent eosinophil attractant. MIP-1α is enhanced in bronchoalveolar lavage fluid of asthmatics[50].

MDC is a chemoattractant for monocytes, eosinophils and T_{H2} lymphocytes. In a murine model of lung inflammation, antibodies blocking MDC expression lead to a significant reduction of eosinophils in lung[51]. TARC is selectively expressed on the T_{H2} subset of lymphocytes and is of particular relevance for the recruitment and activation of eosinophils[52]. MDC and TARC are chromosome 16q13 chemokines[53] and are both ligands for CCR4.

A chemokine with potential involvement in lymphocyte maturation and other homeostatic functions is SDF-1α that attracts in vivo and in vitro resting lymphocytes with high affinity[54]. It is chemotactic for cells that express CXCR4 receptors, such as T lymphocytes, neutrophils and monocytes[55]; platelets too express the CXCR4 receptor[48]. Recently, a role for SDF-1α, and CXCR4 in transendothelial/stem cell migration and engraftment has been postulated[56].

Chemokines may be released by some cells involved in allergic reactions upon IgEs interaction with their receptor. The high affinity IgE receptor FcεRI (receptor for the Fc region of the ε-chain of IgE) is responsible for immediate hypersensitivity reactions: when a multivalent allergen associates with two or more FcεRI receptor-bound IgE molecules on the cell surface it cross-links receptors inducing degranulation of the cells and rapid release of stored mediators, such as histamine, and synthesis and secretion of cytokines that attract and activate inflammatory cells[57]. FcεRI is expressed on mast cells, basophils, eosinophils, platelets, monocytes and Langerhans cells[58–61]. The low affinity IgE receptor, FcεRII (CD23), is implicated in long-lasting IgE sensitivity. FcεRII is expressed on the surface of various inflammatory cells, such as eosinophils, lymphocytes, macrophages and platelets[62]. IgEs themselves close a negative feedback loop by switching off their own synthesis, through the interaction with FcεRII[57].

In addition to chemokines, a number of cytokines may also contribute to regulate chemotaxis. IL-1 is an important mediator of inflammation and fever[63]. IL-1 induces P-selectin and ICAM-1 expression on endothelial cells and shedding of L-selectin and expression of integrins on PMNs. Although IL-1 is not itself chemotactic for PMNs, its ability to activate endothelial cells causes the expression of selectins and integrins facilitating leukocyte transendothelial migration in vitro[18].

The actual consensus is that leukocyte transmigration requires mechanisms that open endothelial cell junctions to allow leukocyte passage, although another mechanism, transendothelial passage, has also been described in specific models[64]. The PMN to endothelial cell interaction, in the presence of a chemoattractant, induces a rise of intracellular calcium in endothelial cells[65] that results in the creation of gap junctions between adjacent cells through which neutrophils are able to pass[66]. Phosphorylation of myosin light chain kinase (MLCK) is a Ca^{2+}/calmodulin-dependent event and can regulate agonist and flow-stimulated Ca^{2+} influx in endothelial cells[67]. MLCK catalyzes myosin II filament formation and myosin-actin interactions and induces actin polymerization[68]. It was shown that actin filaments bind directly to the adherence junctions-associated protein, α-catenin[69], and that the tight junctions-associated protein ZO-1 binds directly to α-spectrin, a cross-linking protein of the actin filament[70]. On the other hand, actin polymerization can directly open these junctions[70]. Leukocytes may regulate MLCK activity in endothelial cells thus promoting their own transmigration. Some authors had earlier postulated that platelets too could pass through opened interendothelial cell junctions[71].

Recently, it was shown that transmigrating leukocytes cause a focal and reversible disruption of the vascular endothelial-specific cadherin (VE cadherin) complex[72].

Inflammatory cells transmigrate then through the basement membrane towards the site of inflammation using degrading proteinases. Matrix metalloproteinases (MMPs) comprise a family of zinc binding enzymes that degrade proteins of the extracellular matrix[73]. They are secreted by various inflammatory cells as proenzymes that are then activated by partial proteolytic cleavage. Lymphocytes use matrix metalloproteinase 9 (MMP-9 or gelatinase B) and MMP-2 (gelatinase A) to migrate through reconstituted basement membrane[74], neutrophils use MMP-9 and elastase[75] while eosinophils migrate by releasing and activating MMP-9 when activated by both PAF and IL-5[76]. Recently, it was shown that purified mature polyploid megakaryocytes produce and secrete MMP-9 and that MMP-9 is required for in vitro megakaryocyte migration through the components of the basement membrane in response to a chemoattractant stimulus, such as SDF-1α[77]. The enzymatic activity of matrix metalloproteinases is also necessary for megakaryocyte fragmentation and platelet release[77]. MMP-2 and MMP-9 have been reported to be

Table 27.1. Chemokines and platelets

Receptor or platelet	Chemokine ligand	Presence of the ligand in platelets (granules)	Responding cells
CCR1	MIP-1α, RANTES	Yes	Eosinophils, monocytes, activated T cells, dendritic cells, platelets
CCR3	Eotaxin, RANTES	Yes	Eosinophils, basophils, TH2 cells, platelets
CCR4	TARC, MDC	No	Activated T cells, dendritic cells, Th2 cells, platelets
CXCR4	SDF-1α	No	Dendritic cells, monocytes, resting T cells, platelets
Unknown	HRF	Yes	Basophils, mast cells
Unknown	βTG	Yes	Lymphocytes, monocytes, neutrophils, fibroblasts
Unknown	PF4	Yes	Lymphocytes, monocytes, neutrophils, fibroblasts, platelets (?)

secreted by collagen-stimulated platelets and active MMP-2 has been shown to play a role in platelet aggregation acting as a pro-aggregatory stimulus[78–80].

Structural characteristics of platelets that imply the ability to migrate

Platelets possess an anatomic and biochemical machinery under many aspects comparable to leukocytes and a series of structural characteristics that may be relevant to inflammation. Moreover, platelets are known to inherit several characteristics from their bone marrow progenitor cells, megakaryocytes, and these are provided with vivacious cell locomotion[81,82] (see Chapter 2).

Concerning the first step in cellular transmigration, i.e. adhesion to the endothelial monolayer, platelets possess and/or express a number of adhesive proteins or adhesive protein counterreceptors. Platelets contain P-selectin, stored in α-granules[83], and express its ligand PSGL-1 on their surface; although platelets can express P-selectin on their surface upon activation, this does not appear to regulate platelet rolling in vivo on activated endothelium[84] while it is probably involved in the crosstalk between platelets and leukocytes[85]. On the other hand, platelets interact with both P- and E-selectin exposed on activated endothelium[84,86] through their constitutively expressed PSGL-1 receptor[87]. Platelets have been observed while rolling in vivo on an activated endothelial surface in a manner which appears to be very similar to that observed for leukocytes: both cell types roll on stimulated vessel wall and for both this process is dependent on the expression of endothelial P-selectin[84].

The role of different platelet integrins in the adhesion process is a widely investigated and characterized process (see Chapters 5, 21 and 42).

Concerning the intracellular changes required to express cell locomotion, platelets have a cytoskeletal framework that allows cell motion (see Chapter 6).

In resting platelets the discoid shape is maintained by a network of actin filaments, spectrin and integrins, that together form the membrane skeleton, a submembranous structure that coats internally the cytoplasmic surface of platelets[88], and by actin gel filaments that link this structure to transmembrane proteins[89,90]. After stimulation, the activation of low molecular weight G proteins, such as Rac-1, induces the formation of focal complexes, very dynamic structures that, as the cells spread, are replaced by focal adhesions. Additional cytoskeletal changes lead to the formation of stress fibres, under the induction of RhoA[91], a member of the Rho family of low molecular weight GTPases. Stress fibres associate with focal adhesions allowing a contractile response to be exerted on the extracellular integrin-associated ligands. The continuous formation of filopodia and lamellipodia that leads to focal complexes is due to actin dynamic polymerization[92]. One of the signalling molecules that is activated as a consequence of integrin-induced signals is calpain. Platelets contain in their cytosol µ-calpain (one of the two major forms) that becomes activated when platelets aggregate in response to stimuli or when they spread on extracellular matrix proteins[89]. Calpain, by inducing Rac-1 and RhoA activation, provokes integrin-induced formation of focal adhesions and actin filament reorganization[89].

Concerning the soluble stimuli that control migration, recent reports have demonstrated the surface expression of different chemokine receptors on platelets (Table 27.1). The receptors for chemokines are seven transmembrane domain structures linked to G-proteins and mediate calcium flux upon activation[93,94]. Recently it was shown, by using flow cytometry, immunoprecipitation, Western blotting and reversible transcriptase polymerase chain reaction, that human platelets express CCR1, CCR3, CCR4 and CXCR4 chemokine receptors[48,95.] The effect of various

Cambridge Books Online © Cambridge University Press, 2009

cytokines and chemokines (IL-8, MCP-3, MCP-1, MIP-1α, eotaxin, RANTES, Thymus activation-regulated chemokine [TARC], MDC and SDF-1α), acting on different receptors, on Ca^{2+} levels in platelets was also tested. Most of the ligands tested gave clear calcium signals. A cellular response to MIP-1α and RANTES implicates the presence of the CCR1 receptor. A response to eotaxin and RANTES implicates the presence of CCR3, while a response to TARC and MDC implicates the existence of the CCR4. Finally, a response to SDF-1α implicates the expression of the CXCR4 receptor[48]. Although it is not yet clear what is the function of these chemokine receptors on platelets, reports have suggested that some chemokines may be able to activate platelets.

There is earlier evidence that PF4, an α-granule protein of platelets which is also a CXC chemokine[96], may bind to the platelet surface and may modulate platelet aggregation and secretion induced by low levels of platelet agonists[97] even though a specific receptor for PF4 has yet to be identified and no further data confirming this early report have appeared in the literature. Recently Abi-Younes and coworkers demonstrated that SDF-1α, a chemokine highly expressed in human atherosclerotic plaques, induces platelet aggregation and calcium signalling[98].

Most recently, MDC and TARC too, in addition to SDF-1α, were shown to induce platelet activation, in a rapid (less than 5 s) and maximal way under arterial flow conditions, by facilitating the agonistic activity of low doses of primary agonists such as ADP or thrombin. TARC, MDC and SDF-1α increase intracellular calcium concentration in the presence of ADP and their effects are insensitive to indomethacin, thus independent of cyclooxygenase[99]. The effects of MDC and TARC on platelets are mediated by their common receptor CCR4[100].

Challenge with SDF-1α or MDC also exposes P-selectin on the platelet surface[99].

Platelets themselves contain some of the chemokines that are ligands for CCR1 and CCR3, such as RANTES or MIP-1α[101,102], thus one role of the chemokines may be that of feeding back to receptors on the same or other platelets to amplify the response to stimuli. On the other hand, platelets do not contain either CCR4 (MDC, TARC) or CXCR4 (SDF-1α) agonists. Therefore, the role of these receptors may be to involve platelets in situations where these agonists are provided by other cells[48] and it can be hypothesized that they may be involved in platelet migration.

Activated platelets have been shown to exhibit membrane-bound IL-1 bioactivity. Using immunocytological and flow cytometric techniques IL-1α and IL-β were found in the cytoplasm of both resting and thrombin activated-platelets[103]; IL-1 is able to influence indirectly the transendothelial migration of leukocytes[18]. Moreover, flow cytometry studies have shown that the surface of platelets is able to express IL-1R and IL-8R (receptors for Il-1 and IL-8, respectively), the expression of which is significantly increased in inflammatory bowel disease[104].

It has already been mentioned that IgEs may induce the release of chemokines from inflammatory cells in allergic conditions[105,106]. Platelets of atopic individuals release RANTES and other chemokines stored in their α-granules in response to IgE[107]. Platelets can be activated by IgEs and are involved in IgE mediated effector mechanisms (see Chapter 54) and in IgE-mediated allergic disorders (see Chapter 56).

Concerning the passage of platelets through endothelium, it is interesting to observe that activated platelets can produce a rise of intracellular Ca^{2+} in endothelial cells[108], a condition favouring MLCK activation and the breakdown of intercellular junctions[68,72], thus allowing passage between endothelial cells. On the other hand, in a model of skin inflammation induced by fMLP injection, transendothelial cell migration[109], which does not require loosening of intercellular junctions, was also observed.

Finally, regarding the extracellular matrix degradation required for inflammatory cells to migrate through the basement membrane, platelets have been shown to contain and release MMPs (MMP-2 and MMP-9) in vitro and in vivo[78,80].

MMP-2 is secreted by platelets upon stimulation with natural agonists, such as collagen or thrombin, and active MMP-2 has been shown to play a role in platelet activation. MMP-2 is secreted as zymogen and is activated on the cell surface by MT-MMPs (membrane type matrix metalloproteinase), anchored at the cell membrane by transmembrane and intracellular domains[78]. Pro MMP-2 activation occurs through the formation of the trimolecular complex MT1MMP/TIMP2/MMP2 and recent studies have shown the existence of MT1–MMP and TIMP-2 (tissue inhibitor of MMP-2) in platelets and their role in aggregation[79]. In vivo release of MMP2 by platelets activated at a site of vessel wall damage in vivo in humans was recently reported[80].

Observations on platelet chemotaxis in vitro

It was only in the early 1970s that studies on platelet migration were reported. Before the publication of these results, platelets were considered simply passive elements in flowing blood and platelet motion in vitro, as observed under light microscopy, appeared to be a manifestation of Brownian movements[110]. Platelet migration in vitro has

Cambridge Books Online © Cambridge University Press, 2009

been studied for the first time by Lowenhaupt in 1972, by using a modification of the method used for studying macrophage migration in delayed hypersensitivity reactions[111,112], and her observations were confirmed by other laboratories in the following years. She used a capillary tube, closed by flame at one end and filled with platelet rich plasma. Each tube was centrifuged to obtain a platelet pellet, the capillaries were then broken 1–1.5 mm above the platelet pellet level and they were secured in a Petri-dish (migrating chamber), 20 mm in diameter and 3 mm deep, carefully filled with buffer medium and covered with a siliconized and sterilized cover glass. The chambers were then placed in a CO_2 incubator at 22 °C for 1 to 18 hours. After incubation the specimens were observed with a stereomicroscope and recorded photographically[113]. That platelet migration was not merely passive diffusion or Brownian motion but rather an active, energy requiring, process was shown by the demonstration that metabolic inhibitors, such as iodoacetamide acid, sodium fluoride and 2,4-dinitrophenol, inhibited platelet movement[114]. The study of cell migration in vitro was greatly facilitated by the introduction of the chamber of Boyden[115], a method initially developed for the study of leukocyte chemotaxis, and still largely employed to this end, which was adapted to the study of platelet migration by Valone and coworkers[116]. The method consists of the use of a perspex chamber, constituted by two compartments separated by an 8 μm micropore filter, 100 μm thick. A platelet suspension is added to the upper compartment while the lower compartment contains buffer medium. During the incubation period platelets migrate inside the filter. After 3 hours of incubation the filters are removed, washed, fixed in 10% formalin, stained and mounted on a glass slide. Migration into each filter is quantitated by counting the number of platelets at a fixed level (in the studies of Valone, 40–70 μM) from the surface of the filter where the platelet suspension was laying. Using this method it was shown that platelets not only migrate in a random fashion but also migrate specifically and directionally toward chemotactic stimuli such as collagen and PGE1[116]. Platelets are extremely susceptible to aggregation and thus the conditions for collection and handling were selected to minimize such a possibility.

Later, Lowenhaupt and coworkers developed a new method to study platelet migration by using gel-filtered platelets resuspended in autologous platelet free plasma radiolabelled with ^{111}In-oxine and were induced to migrate in a specially designed 7-compartment chamber[117]. This method allowed a more quantitative assay of platelet migration and thus a more precise comparison of the chemotactic properties of various substances, including soluble substances. With this method she demonstrated that collagen induces chemotaxis without the need for direct contact with platelets, since migration was observed when a filter was interposed between platelets and the stimulus. She postulated the existence of 'chemotaxins' produced by the interaction between collagen and plasma able to pass through the filter and to stimulate the migration of platelets toward collagen[118]. They also showed that different sources and forms of collagen have different chemotactic effects on platelets: rat-tail tendon collagen was a better inducer of platelet migration than bovine tendon collagen. Moreover, they showed that the structural features of collagen required for inducing aggregation are distinct from those required for inducing chemotaxis; fibrillar formation, needed to induce aggregation, was not necessary to induce chemotaxis[117].

Factors which were shown to influence blood platelet migration are: temperature, pH, anticoagulant, incubation time and buffer composition. Nathan[118] reported that platelet migration was maximal at 30 °C while Duquesnoy[119] observed a higher migration at 25 °C. Lowenhaupt observed little or no migration at 4 °C while, in her working conditions, migration was optimal at temperatures ranging from 22 to 37 °C[114]. On the basis of these data Lowenhaupt carried out her subsequent experiments at 22 °C. Valone observed maximal platelet migration between 30 to 37 °C and used 37 °C as the standard temperature for examining all the other variables in subsequent experiments[116].

In a pH-range curve of platelet migration, maximal migration was observed by Valone between pH 6 and 6.5 with then a plateau between 6.5 and 8.5[116]. Lowenhaupt noticed that no or little migration occurred at pH 6 while migration increased markedly from pH 6 to 7.4.

The effect of anticoagulants on platelet migration was studied by Duquesnoy and Lowenhaupt. Duquesnoy showed that the inhibitory effect of antiplatelet antibodies on migration was more evident when platelets were derived from citrated blood and based on this observation he chose to use sodium citrate for his experiments[119]. Lowenhaupt showed that migration was optimal in preparations containing sodium citrate or ACD while with other anticoagulants, such as EGTA, Na–EDTA, Mg–Na–EDTA and sodium oxalate, the migration rate was reduced and heparin consistently inhibited migration[114].

The effect of incubation time was tested by Valone, Nathan and Duquesnoy[116,118,119]. Valone showed that when platelets are incubated from 1 to 5 hours, maximal migration is observed at the longest incubation time[116]. For Nathan platelets migrate rapidly for the first 12 hours and then reach a plateau[118]. Duquesnoy observed a quick

Cambridge Books Online © Cambridge University Press, 2009

migration in platelets obtained from blood anticoagulated with EDTA, showing complete migration in the first 30 min while platelets obtained from citrated blood complete their migration in 12 hours[119].

Finally, the influence of the composition of the buffer used for platelet suspension on platelets' ability to migrate was assessed by Valone[116]. He found that platelet migration was optimal in the absence of added magnesium and calcium; the latter, when added at concentrations greater than 10^{-4}M, inhibited migration. The medium used by Valone contains thus only glucose and gelatin at concentrations (0.2 g/100 ml and 0.5 g/100 ml, respectively), inferred by dose-response curves, that favour maximal migration[116].

The ability of platelets to migrate in vitro is dependent on the contractile proteins of the cytoskeleton. Indeed, the incubation of platelets with cytochalasin B, which reversibily disrupts cellular actin microfilaments and reversibily stops cell movements, inhibits migration while the incubation with colchicine, which intereferes with the polymerization of microtubules, has no effect; therefore microtubules are not involved in the migration process[120].

While all the above studies have characterized the migration of platelets from healthy donors and the response to physiologic stimuli (collagen, prostaglandins)[117,121], no studies have explored platelet migration in disease and/or in response to pathological stimuli.

The studies carried out by Duquesnoy[119] were aimed at the detection of the platelet perturbing activity of antihuman leukocyte antigen (HLA) and antiplatelet antibodies[119] and used a test of inhibition of the migration of platelets from a capillary tube. This method, a modification of the migration test of Lowenhaupt[113], was as sensitive as the platelet lysis method and more sensitive than complement fixation, aggregometry and platelet factor-3 release for the detection of antiplatelet antibodies[119,122].

Based on observations suggesting the passage of platelets in the extravascular space in patients with allergic asthma (see below), we have studied the migration response of platelets from allergic asthmatics to in vitro stimulation with the specific sensitizing allergen by using the Boyden chamber system described by Valone[116]. Our data show that platelets from asthmatic subjects migrate in response to the specific allergen to which the patients are sensitized[123], but not in response to other allergens, and that IgEs play a role in this phenomenon. Monoclonal antihuman IgE antibodies, but not their Fab fragments, induced the migration of platelets from allergic asthmatics but not from healthy controls. Antihuman IgG antibodies were ineffective. The proposed mechanism is the following: in asthmatic subjects, IgEs produced following previous contacts with the allergen and bound to the platelet Fc IgE receptors, bind the allergen or the specific anti IgE MoAb. The binding process induces the cross-linking of contiguous receptors that activates the cell (personal unpublished observations) with a process already described for mast cells and basophils[124] (Fig. 27.1). Actually, the cross-linking of IgE receptors on platelets has been shown to induce other platelet activities, such as cytotoxicity against parasites[125], oxygen radical formation[126], and release of chemokines[107,127].

Observations on platelet chemotaxis in vivo

Studies in animals that imply the ability of platelets to migrate

Although very few direct studies on in vivo platelet migration exist, several observations imply the ability of platelets to migrate into tissues.

Degranulated platelets have been found extravascularly in the bronchial tissue, in close contact with contracted smooth muscle cells, in animals challenged with an allergen or with platelet activating factor (PAF)[128,129]. Moreover, platelets have been recovered in the broncho-alveolar lavage fluid of rabbits during the late-response after an allergen challenge[130]. The presence of platelets in these specimens does not appear to be the consequence of blood extravasation as no other blood cells were concomitantly found. The presence of platelets outside vessels, accompanied by neutrophils, was described also in rat skin after the intradermal injection of PAF[131].

Radiolabelled platelets localize in lungs after intravenous challenge with some platelet agonists, like ADP or collagen[132], or after challenge with allergen or PAF[132,133]. However, while they rapidly reenter the circulation with most of the agonists used, suggesting embolization and subsequent dissolution of the platelet microthrombi, a long-lasting retention is observed after PAF challenge, which suggests platelet diapedesis into bronchial tissue[134].

PAF- or allergen-challenge induce eosinophil infiltration in lungs of normal and allergic animals. Selective platelet depletion with an antiplatelet antiserum reduced PAF and antigen-induced eosinophil infiltration into the lungs suggesting that platelets are mediators in this phenomenon[135].

Recently, it was shown that injection of lipopolysaccharides (LPS) or endotoxin in mice and rats induced a slow accumulation of platelets in the sinusoidal and perisinusoidal Disse spaces of the liver. Considering that blood platelets of mice contain a large amount of 5HT, the

Cambridge Books Online © Cambridge University Press, 2009

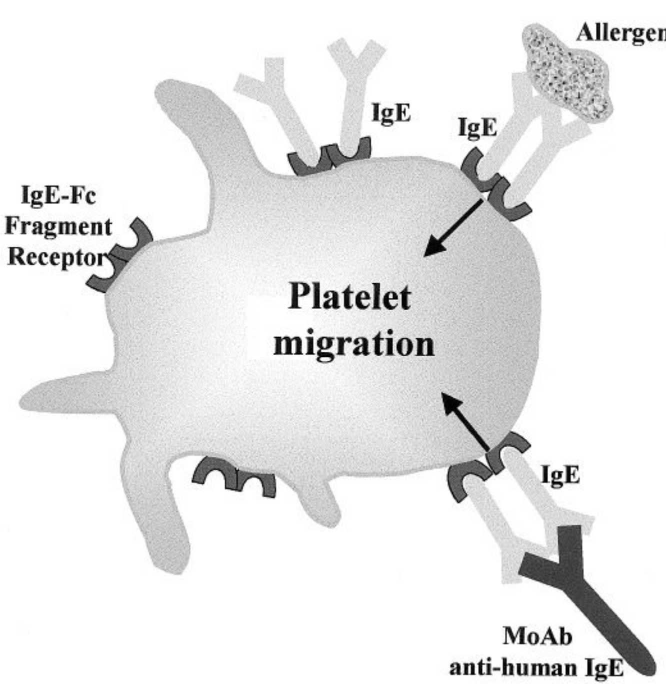

Fig. 27.1. Hypothetical mechanism of the allergen-induced chemotaxis of platelets from patients with allergic asthma. The cross-linking of adjacent, IgE-bound, IgEs receptors transduces a signal leading to chemotaxis. A complete monoclonal antibody antihuman IgE produces the same effect.

authors suggested that a sensitive measure of the diapedesis of platelets into tissues is the measurement of the local levels of 5HT[136]. Most of the platelets accumulated in these extravascular spaces still retained their intact structure. They also showed that the injection of chemokines TNF and IL-1 induce an accumulation of 5HT in the liver. The authors conclude that in response to IL-1, TNF or LPS platelets translocate into the liver in a way which is independent from aggregation and that some of them enter the hepatocytes[136].

Studies in animals showing platelet migration

The appearance of platelets outside blood vessels in acute inflammation is a classic observation[137,138] but little was known until recently about the mechanisms by which platelets extravasate. Recently, an interesting work of Feng et al.[109] has demonstrated active transendothelial migration of platelets by serial electron-microscopy of thin tissue sections from guinea pigs in which acute tissue inflammation was provoked by the skin injection of fMLP[64].

In this study it was shown that platelets in the vascular lumen extend pseudopods towards the luminal endothelial cell plasma membrane to provide their attachment: evidence that platelets participate actively in diapedesis.

In addition, it was observed that single platelets adhering to activated endothelium were completely enclosed within endothelial cytoplasmic vacuoles, generally located towards the periphery of the endothelial cells close to interendothelial cell junctions (Fig. 27.2). Platelets within endothelial cell cytoplasmic vacuoles extended pseudopod-like processes, again showing an active role in the process (Fig. 27.3). Subsequently, platelet-containing vacuoles opened to the endothelial cell ablumen whereupon platelets were discharged into the underlying basal lamina (Fig. 27.4)[105]. Following transmigration across the basal lamina, platelets passed into the dermal connective tissue where they were found free together with neutrophils and other white cells. Despite the close contact with matrix components, migrating platelets did not display the ultrastructural features of a classic release reaction[109].

The mechanism of transmigration observed with this model demonstrates that platelets cross undamaged the endothelium by a process similar to phagocytosis, a phenomenon not dissimilar to that observed for neutrophils with the same model[64]. However, the fact that platelets migrated in the extracellular space were not activated in this model must not necessarily apply to other conditions in which the inflammatory stimulus inducing diapedesis is different, like bacteria, allergens or other noxious agents.

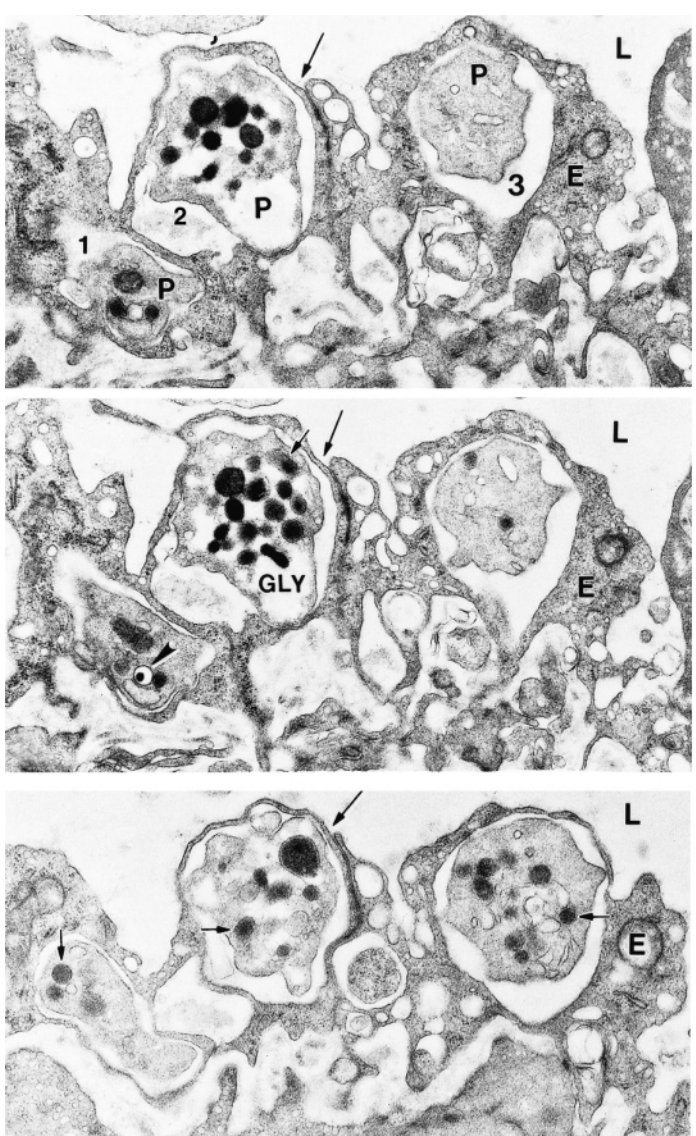

Fig. 27.2. Electron micrographs showing transcellular passage of three platelets across endothelial cells. 1, 2 and 3 are cytoplasmic endothelial vacuoles containing single platelets (P). Each platelet is entirely contained in the vacuole. The endothelium (E) shows no signs of injury. Each platelet presents intact α- and dense-granules. $\times$16 500. (Reproduced from ref. 109 with the permission of Professor Ann M. Dvorak.)

Actually, transendothelial migration too is not necessarily the only mechanism operating in vivo and active migration through interendothelial cell junctions may also take place[71,139].

Studies in humans

Platelet aggregates have been observed in the lamina propria of the microvasculature of lungs of asthmatic subjects during late-onset airway obstruction following allergen provocation[140]. Platelets were also found in the bronchoalveolar lavage fluid in asthmatics after allergen bronchoprovocation; some platelets were degranulated and free granules in the lavage were also observed[141]. Furthermore, platelets have been actually observed undergoing diapedesis in the lungs of asthmatics. Bioptic specimens taken from bronchi of subjects with asthma showed platelets passing through gap junctions between endothelial cells of postcapillary venules[139]. Moreover, platelet diapedesis has been observed towards the epithelial bronchial surfaces of symptomatic atopic asthmatics. Bronchial biopsy from these subjects showed platelets and electron-dense fibrils resembling fibrin, together with membranous debris, at the luminal edge from where surface epithelium was lost. All these observations suggest that, like leukocytes, platelets migrate into inflamed tissue. Platelets were often found near macrophages in bronchoalveolar lavage also after local antigen challenge into a subsegmental airway[130].

Another interesting observation concerns the early stages of the formation of atherosclerotic lesions during which monocytes, attached to inflamed endothelial cells and entering the subendothelial space by diapedesis, have been observed by immuno histochemical staining; interestingly, platelets adhering to the membrane of migrating monocytes were evident[142].

It may not come as a surprise that histologic observations on platelet migration in vivo are so scanty in the literature as the small dimensions of these cells and, especially, the lack of a nucleus which stains clearly in histologic specimens, render their detection rather difficult. Careful electron microscopic observation and/or special stainings are required and it is likely that, when applied on a larger scale, this will lead to a much more frequent detection of platelets in inflamed tissues.

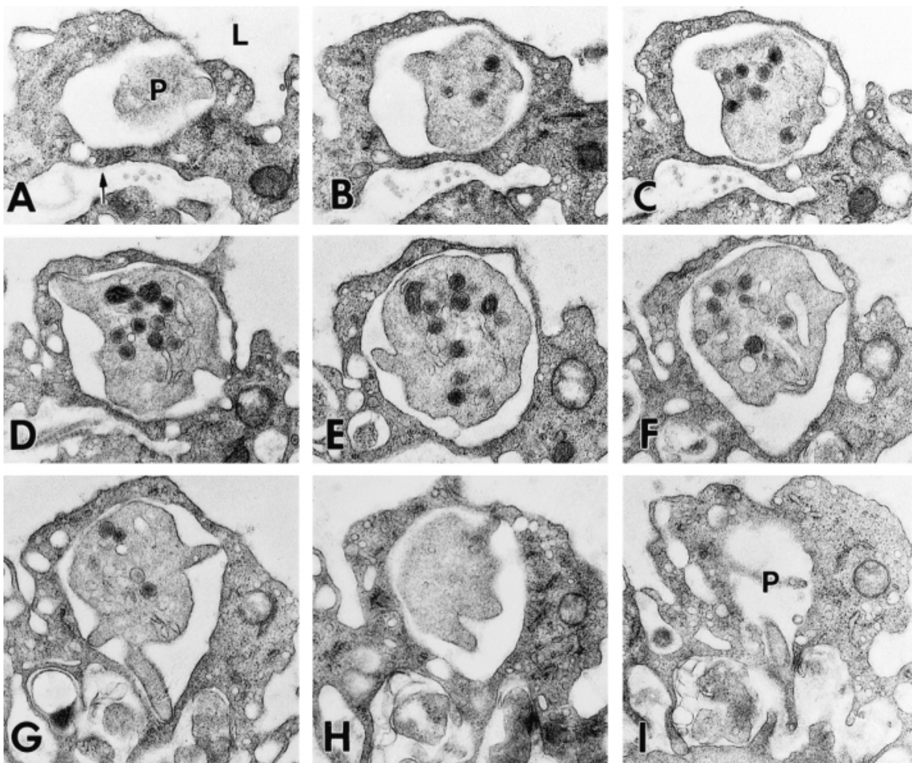

Fig. 27.3. Electron micrographs showing the active migration through the endothelium of one platelet contained in a endothelial cell vacuole. The platelet (P) in (*a*) is included in a cytoplasmic vacuole of the endothelial cell that is near the lumen (L). From (*b*) to (*g*) it is possible to see distinctly the granules inside the platelet. Extension of platelet pseudopods is evident. The centre of the cell recedes leaving a granule-free area (*h*) and a single process (P) visible in (*i*) × 16 500 (reproduced from ref. 109 with the permission of Professor Ann M. Dvorak).

Substances in platelets relevant to the chemotaxis of other cells

Besides their own ability to migrate, platelets may exert an important influence on the diapedesis of other cells. Upon activation platelets release several mediators, either stored in their granules or cytoplasm or synthesized after stimulation, that may participate in eliciting and maintaining the inflammatory reaction. Among these substances, a number of mediators of chemotaxis are present; moreover, platelets may directly, by cell contact, influence the migrating properties of other cells (Table 27.2).

Platelet δ granules store, among other substances, serotonin which is vasoactive, vasopermeabilizing and stimulating for fibroblasts and it is known to act as an inflammatory mediator[143]. In addition, serotonin enhances the chemotactic responsiveness of human monocytes and the chemotaxis of polymorphonuclear leukocytes[144]. Serotonin-stimulated human blood mononuclear cells secrete lymphocyte chemoattractant activity (IL-16) that may promote, via serotonin type 2 receptors, the recruitment of CD4+ T lymphocytes into an inflammatory focus[145].

Platelet α granules contain several proteins including PGDF, TGF-β, PF4, βTG, RANTES, MIP-1α, NAP-2 precursors and P-selectin, which may play a role in cell migration.

Platelets have also been shown to contain another chemokine of the CXC class: epithelial neutrophil-activating protein 78 (ENA-78)[95], which induces migration in neutrophils expressing the CXCR2 (IL-8RB) receptor on their surface[146].

PGDF and TGFβ are growth factors which display vasoactive and chemotactic properties on smooth muscle cells, macrophages, monocytes and fibroblasts[147,148]. Recently, PDGF and TNFβ released by aggregating platelets have been shown to act synergistically to induce the

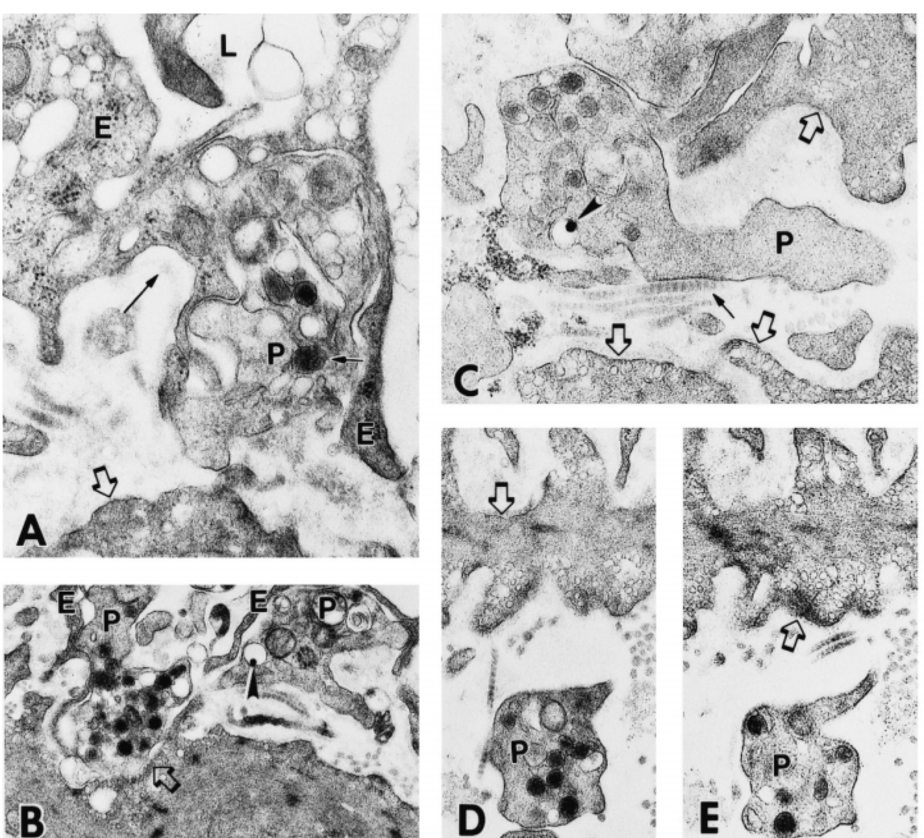

Fig. 27.4. Electron micrograph showing the later stages of platelets' transendothelial migration. (*a*) The platelet (P) has already crossed the overlying endothelial (E) cell and basal lamina (black arrow) and has come into contact with an underlying pericyte (open arrow). α-granules (small arrow) are evident in the platelet. (*b*) One platelet (P) beneath the endothelium is partially surrounded by thin endothelial cell processes and has indented an underlying pericyte (open arrow). A second platelet resides beneath the endothelial cell process and contains a granule with a dense core, characteristic of serotonin-containing platelet granules. The dense granule is indicated. (*c*) This platelet (P) also contains a single dense core granule and multiple α-granules. It lies beneath the endothelium close to pericyte processes (open arrows). Note that the elongated platelet process of this normally granulated platelet extends along a strand of interstitial collagen (closed arrow). (*d*), (*e*) Serial sections showing a platelet (P) that, after emerging through the endothelium, has migrated beneath the pericyte above it (open arrow). The platelet exhibits minor shape change and cytoplasmic extensions but granules are unaltered. (*a*) $\times$ 31 000; (*b*) $\times$ 14 000; (*c*) $\times$ 22 000; (*d*) $\times$ 18 000; (*e*) $\times$ 18 000. (Reproduced from ref. 109 with the permission of Professor Ann M. Dvorak.)

expression on smooth muscle cells of vascular endothelial growth factor (VEGF)[149], an endothelial mitogen and chemoattractant that is also able to induce endothelial cell migration[150].

PF4 is the major platelet α-chemokine. Purified PF4 lacks chemotactic activity for polymorphonuclear cells but in the presence of TNFα it stimulates these cells to undergo such functions as exocytosis of secondary granule markers or tight adhesion to different surfaces[151]. PF4 not only affects PMN, but it also mediates the release of histamine by basophils[152] and plays a role in eosinophil adhesion[153]. Beta-thromboglobulin (βTG) released from platelet α-granules exerts a chemotactic activity for neutrophils, monocytes, lymphocytes and fibroblasts[154,155].

RANTES and MIP-1α, 8 kDa peptides belonging to the CC chemokines, are potent chemotactic factors for basophils and eosinophils. RANTES is chemotactic also for memory T lymphocytes and for monocytes[42,157]. MIP-1α is less powerful in attracting basophils and eosinophils but is much more potent in inducing a transient intracellular Ca^{2+} elevation[158]. MIP-1α has also histamine-releasing activity on basophils and displays chemotactic properties for CD8 T lymphocytes[159].

RANTES is released from α granules of platelets after

Table 27.2. Substances in platelets that influence the migration of other cells

Substances released by platelets	Migratory responding cells
Serotonin	Monocyte, PMN leukocytes
PDGF	Endothelial cells
TNFβ	Endothelial cells
PF4	PMN leukocytes, basophils, eosinophils
RANTES	Basophils, eosinophils, memory T cells lymphocytes, monocytes
MIP-1α	Basophils, eosinophils, CD8 + lymphocytes
βTG Ag	PMN leukocytes
IL-8	PMN leukocytes
IL-1	Endothelial cells, smooth muscle cells
Histamine	PMN leukocytes, endothelial cells
Lysosomal enzymes	Fibroblasts, neutrophils
PAF	PMN leukocytes
PGE_2	Monocytes
TXA_2	Endothelial cells
PECAM-1	Neutrophils
CD40L	Endothelial cells

stimulation with thrombin[156]. MIP-1α is observed within cisterns of the open canalicular system and on the plasma membrane before its release from activated platelets[101].

RANTES has been found to be increased in the blood of patients with asthma during spontaneous attacks in a way that correlates with βTG rises suggesting a platelet source of the RANTES detected[160].

Platelet P-selectin, stored in α-granules and mobilized to the plasma membrane upon activation, mediates rolling and adhesion of leukocytes. In vitro neutrophils have been shown to roll on P-selectin of immobilized activated platelets[161].

Platelet λ-granules, the lysosomes, contain enzymes such as cathepsin, β-hexosoaminidase and heparinase, that are released in vitro upon strong stimulation[162,163]. Recently, platelet lysosome release has been demonstrated in vivo in humans at a localized site of vessel wall damage[162]. These acid hydrolases may participate in inflammation and cell diapedesis through their cytotoxic and tissue-degrading activity by remodelling the inflamed tissues.

Platelets contain in their cytoplasm other important mediators of inflammation such as histamine, IL-1 and CD40L, that may be released and can induce chemotaxis.

Histamine is released by platelets upon challenge with histamine releasing factors (HRF), upon aggregatory stimuli and by immunological stimuli in atopic subjects. Platelet histamine represents one of the most important pools of histamine in blood, after that of basophils and monocytes[164]. Histamine increases the number of PMNs migrating across the endothelial cells[165] by altering the endothelial cytoskeleton and increasing eicosanoid release[166].

IL-1, a central mediator in the cytokine cascade and a potent activator of vascular cytokine production, is contained in platelets and released upon activation[167–169] and it thus facilitates leukocyte and fibroblast transmigration.

CD40 ligand (CD40L, CD154), a transmembrane protein structurally related to TNFα originally identified in CD 4+ T cells, has now been identified also on the surface of activated platelets[170]. CD40L has been localized in the platelet cytoplasm by immunoprecipitation and Western blotting and it translocates to the cell surface within seconds of activation in vitro and in the process of thrombus formation in vivo[171]. CD40L induces endothelial cells to secrete chemokines and to express adhesion molecules like ICAM-1, VCAM-1 and E-selectin[26], thus modulating the leukocyte to endothelium interaction.

Platelet endothelial cell adhesion molecule-1 (PECAM-1) is a member of the Ig gene superfamily that is expressed on the surface of platelets, endothelial cells and certain leukocyte subsets. PECAM-1 may be an important mediator of leukocyte/endothelial cell interactions[172] and plays a role in leukocyte migration through the endothelium and the perivascular basement membrane[173].

In addition to the granule-stored substances, platelets release lipidic mediators upon activation, such as platelet activating factor (PAF) or arachidonate metabolites. PAF is an acetylated phosphoglyceride derived from the phospholipids of cell membranes and it is a potent proinflammatory mediator able to promote adhesive interactions between leukocytes and endothelial cells leading to transendothelial migration of leukocytes[174,175].

Activated platelets release some arachidonate metabolites, including thromboxane A2 (TxA2) or prostaglandin E2 (PGE2), that may also influence the migration of other cells. TxA2, a potent platelet activator and a vasoconstrictor[176], has a stimulatory activity on the proliferation of smooth muscle cells of the vessel wall[177] and the airways and it may stimulate endothelial cell migration[178]. Recently, it was shown that PGE2 inhibits the potential of monocytes to migrate in response to stimuli such as PAF and C5a and to adhere to endothelial cells. This inhibition is most probably due to a modulation of the chemokine receptor CCR5 and of the β2 integrin Mac-1[179].

Conclusions

Chemotaxis is a central phenomenon in the participation of cells to tissue inflammation, allowing the recruitment of inflammatory cells to the site of tissue damage and the local release of cytotoxic and vasoactive mediators. Platelets appear to display the ability to migrate and to influence the migration of a number of other cells involved in inflammation, a property regulated by mechanisms which are different from those involved in platelet aggregation. These functional properties of platelets, together with other findings, characterize the platelet as an inflammatory cell, besides its more studied function of haemostatic element.

A more intensive investigation on the mechanisms regulating this 'unconventional' functional activity of platelets as well as studies on platelet chemotaxis in disease may allow a deeper insight in the mechanisms leading to inflammation and allergy and may open new horizons in the search for drugs limiting these pathologic processes.

Platelet–leukocyte interaction: a tribute to Giulio Bizzozero

The interaction of blood platelets with leukocytes at the site of vascular injury was clearly described by Giulio Bizzozero, more than one century ago[1]:

> The blood platelets which are carried by the blood stream are arrested as soon as they reach the lesion of the arterial wall; at first one observes two to six platelets; very rapidly their number grows into hundreds. Usually, among these, a few white blood corpuscles are also arrested.
>
> Every time when a vascular wall is damaged . . . arrest of white blood corpuscles represents a secondary phenomenon and may, perhaps, be caused by increased adhesive properties of blood platelets whereby these cells react with white blood corpuscles which have been brought into contact with them by blood circulation (Fig. 28.1).

This was probably the first observation of the simultaneous involvement of platelets and leukocytes in hemostasis and thrombus formation.

Since then, the presence of leukocytes in hemostatic platelet plugs and arterial thrombi has been repeatedly observed by microscopy, but the general consensus was that these cells were only playing a passive role in thrombus formation being more likely involved in the subsequent repair process. In the past two decades, a number of studies have been performed looking for interactions between platelets and leukocytes to better understand their possible importance in the physiopathology of thrombosis.

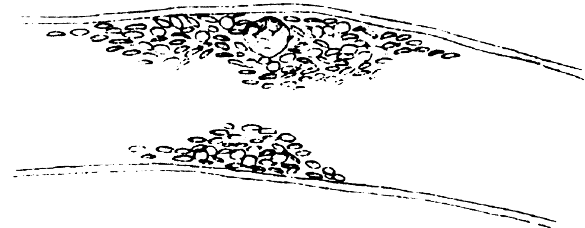

Fig. 28.1. 'Two small mural thrombi which have formed within a small artery of the omentum of a guinea pig. The larger one contains, among blood platelets, a white blood corpuscle.' This figure is reprinted from the original paper of Bizzozero[1], at the occasion of the first centennial anniversary of his death in Turin (April 8, 1901).

Mediators and mechanisms of platelet/leukocyte cross-talk

The broad range of interactions between platelets and leukocytes has been reviewed several times[2–9]. Results from in vitro studies indicate that the mutual modulation of platelet and leukocyte function is extremely complex. Both inhibitory and stimulatory effects have been described, suggesting the possibility of different in vivo physiopathological conditions.

Up-regulation of platelet function by leukocytes

Several leukocyte-derived products, such as hydrogen peroxide (H_2O_2), superoxide anion (O_2^-), oxygen radical species and the lipid mediator, platelet activating factor (PAF), are endowed with platelet stimulating activity[10–12].

The addition of the leukocyte specific agonist n-formyl-methionyl-leucyl-phenylalanine (fMLP) to human whole blood increases the number of P-selectin-expressing platelets. This increase is inhibited by a PAF antagonist, by the superoxide anion scavenger, superoxide dismutase, and by two different 5-lipoxygenase inhibitors, suggesting the involvement of PAF, superoxide anion and 5-lipoxygenase products in leukocyte-induced platelet activation[13].

Thromboxane (Tx) synthesized by monocytes potentiates ADP-stimulated platelet aggregation of autologous platelets through a fourfold increased binding of ^{125}I-fibrinogen to the platelet surface. Tx generation by monocytes is triggered by the interaction between fibrinogen and its monocyte membrane receptor[14]. Peripheral blood monocytes stimulated with arachidonic acid produce a platelet activating substance derived from cyclo- and lipoxygenase-dependent metabolism[15]; on the other hand, in vitro exposure of monocytes to lipopolysaccharide results in a dose-dependent increase in procoagulant activity and induction of platelet aggregation through thrombin generation[16].

A role for proteinases in PMN-dependent platelet aggregation was indicated by the observation that preincubation of platelets with chymotrypsin-like cationic proteins from human granulocytes resulted in enhanced platelet serotonin release initiated by thrombin or immune complexes[17]. Maria Kopec's group in Poland[18] first provided evidence that a neutral, chymotrypsin-like, serine proteinase purified from human leukocytes, stimulated platelet function. Marked platelet activation was also reported when mixed human platelet–polymorphonuclear (PMN) leukocyte suspensions were challenged with fMLP (or other PMN agonists) in the presence of cytochalasin B, which allows azurophilic granule discharge. Cell-free supernatants of fMLP-activated PMN also induced platelet activation, suggesting a secreted factor was involved[19,20].

Electron microscopic observation of aggregates from mixed cell suspensions showed both cell types closely intermingled: platelets were associated with each other as well as with PMN. Platelets and PMN appeared to interact by very close contact between their membranes (Fig. 28.2). In the aggregates from platelet samples stimulated by PMN-derived supernatant many platelets had lost their granules and were in an advanced stage of shape change, secretion and aggregation[21]. This platelet stimulating activity was identified as cathepsin G[21,22], a neutral serine proteinase contained in the PMN azurophilic granules and released upon activation. Elastase, another serine proteinase stored in the same granules that does not directly stimulate platelets, potentiates platelet activation induced by low concentrations of cathepsin G[23].

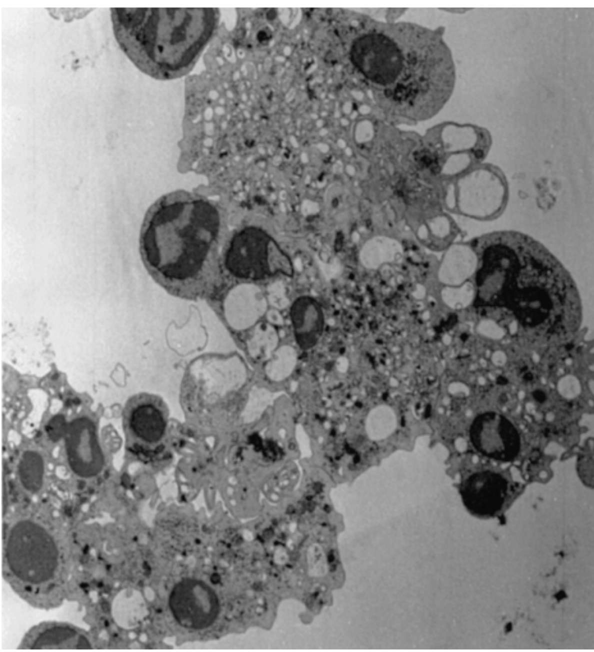

Fig. 28.2. Electron microscopic observation of aggregates from mixed platelet–PMN leukocyte suspensions stimulated with 1 μM fMLP. Both cell types appear closely intermingled: platelets are associated with each other as well as with PMN; platelets and PMN appear to interact by very close contact between their membranes. Original magnification × 9 600. (For more details[21]).

Platelet aggregation and signal transduction mechanisms induced by cathepsin G

Cathepsin G purified from human PMN induces platelet activation at concentrations comparable to those secreted by PMN upon fMLP activation in vitro. Concentration-dependent P-selectin expression[24], serotonin release and Tx formation occur in concomitance with platelet aggregation induced by purified cathepsin G or PMN-activated supernatant[22,25].

Like several other platelet agonists, cathepsin G induces a concentration-dependent (20–500 nM) increase in intraplatelet calcium levels, mainly through an influx across the plasma membrane[22,25]. The calcium increase started by cathepsin G does not depend on cyclooxygenase activation or on exposure of the membrane glycoprotein GpIIbIIIa. Both calcium-dependent and independent mechanisms of protein kinase C activation have been observed in platelets stimulated by cathepsin G[26].

Cathepsin G, thrombin receptors and platelet membrane glycoproteins

Cathepsin G shows saturable reversible binding to human platelets[27]. Since the proteolytic activity is essential for

Cambridge Books Online © Cambridge University Press, 2009

platelet activation by cathepsin G as well as by thrombin, it was suggested that cathepsin G would cause receptor activation by cleavage of the receptor itself. Following the discovery of Protease Activated Receptor 1 (PAR1), the first thrombin receptor cloned[28], attempts were made to determine whether cathepsin G and thrombin work through the same or different receptors. Selak[29] suggested that cathepsin G and thrombin act on different receptors since a monoclonal antibody directed against PAR1 did not block platelets' response to cathepsin G, while inhibiting the response to thrombin. Moreover cathepsin G does not evoke a calcium response in some cell types (human fibroblasts, human umbilical endothelial cells) that respond to thrombin[29,30], nor is cathepsin G able to induce a response in human PAR1-transfected cells[30]. The two enzymes, on the other hand, cross-desensitize[27].

Subsequent work has shown that cathepsin G induces N-terminal PAR1 cleavage at at least two sites: Phe[55]–Trp[56], deleting the tethered ligand domain, and after Arg[41], thus activating the thrombin receptor, when the distal site is altered or otherwise protected[30].

More recently, the platelet activating action of cathepsin G has been shown to be mediated by another protease-activated receptor, indicated as PAR4[31]. Cathepsin G triggered calcium mobilization in washed human platelets, PAR4-transfected fibroblasts and PAR4-expressing *Xenopus* oocytes. An antibody raised against the PAR4 thrombin cleavage site blocked platelet activation by cathepsin G but not by other agonists. Desensitisation with a PAR4 activating peptide had a similar effect. By contrast, inhibition of PAR1 function had no effect on platelet response to purified cathepsin G. PMN-dependent platelet activation was also blocked by the PAR4 antibody. These data show that a specific receptor mediates platelet responses to cathepsin G and increases the biological plausibility of the hypothesis that cathepsin G released from PMN induces platelet activation at sites of vascular injury or inflammation.

In addition to activating platelets, cathepsin G cleaves some platelet surface glycoproteins. As a consequence of platelet activation, cathepsin G increases the binding of antibodies directed at the GpIIbIIIa complex and at the fibrinogen binding site, and decreases the binding of an antibody recognizing the α chain of GpIb, while the binding of an antibody directed at the GpIX is only slightly affected[32–34]. The Leu[275]–Tyr[276] peptide bond has been indicated as the primary cleavage site for this proteinase from N-terminal sequencing of the cathepsin G-derived GpIbα fragment[34]. The increased proteolysis of GpIbα when platelets were inhibited by prostacyclin suggests there may be some cellular redistribution of the GpIbIX receptor during platelet activation by cathepsin G[34]. Actin polymerization and the cytoskeleton play a role in the redistribution of the remaining GpIbIX complex not cleaved by cathepsin G[33].

While the functional significance of the cleavage of GpIbα in the process of platelet activation by cathepsin G remains to be established, it has been clearly shown that this enzyme removes the von Willebrand factor binding site on the GpIb, while leaving the thrombin binding site unaffected. As a consequence, cathepsin G-treated platelets do not agglutinate in response to von Willebrand factor in the presence of ristocetin. Cathepsin G, while activating platelets, might reduce their in vivo reactivity to the subendothelium, through the removal of the von Willebrand factor binding site[32].

Also PMN-derived elastase, which does not cause platelet activation, cleaves GpIb and triggers the exposure of fibrinogen receptors through a proteolytic modification of the GpIIbIIIa[35,36].

Downregulation of platelet function by leukocytes

Early studies showed that the supernatant of apparently unstimulated PMN incubated at 37 °C for 30 minutes contained a platelet inhibitory activity that was compatible with thromboxane-synthase inhibition and/or thromboxane receptor antagonism[37,38]. Thereafter, several in vitro studies have shown that unstimulated PMN could inhibit platelet activation through a NO-like activity[39–43]. This is supported by the elevated levels of platelet cyclic GMP observed in the presence of PMN[40].

In addition to NO-mediated platelet inhibition, human PMN[38,44] and mononuclear leukocytes[45] may also control platelet reactivity via NO-independent mechanisms. Furthermore, unstimulated PMN inhibited activation and recruitment of thrombin- or collagen-stimulated platelets under conditions of close cell–cell contact[46]. The effects were not attributable to NO-like activity, but were modulated by lipoxygenase metabolites and enhanced by aspirin treatment[46]. Platelet ADP removal by ADPase activities expressed by PMN also contributes to down-regulation of platelet activation[47].

Finally, elastase or cathepsin G pretreatment reduces subsequent platelet adhesion to collagen, aggregation and release of granule content induced by thrombin or collagen, through the cleavage of GPIb[48,49].

Activation of leukocytes by platelets and platelet products

Platelet adhesion to the subendothelial matrix of a damaged vessel wall induces platelet activation and the

Cambridge Books Online © Cambridge University Press, 2009

release of substances able to cause the migration of circulating leukocytes toward the sites of injury. Platelet stimulation in whole blood induces oxidative burst in PMN, in conditions of intercellular contact[50]. Supernatants from stimulated platelets are chemotactic for eosinophils[51], induce a transient elevation of PMN intracellular calcium concentration[52], and increase degranulation[53] and superoxide anion generation of stimulated PMN[54,55]. Several platelet-released products endowed with PMN-stimulating activities have been described: Platelet Factor 4 (PF4) and platelet derived growth factor (PDGF), two proteins released by stimulated platelets, as well as arachidonic acid metabolites of the 12-lipoxygenase pathway induce PMN chemotaxis[56–58] and may favour PMN accumulation in vivo. PF4 induces PMN to undergo, through L-selectin and LFA-1, firm adhesion to endothelial cells and to release granule contents[59].

Platelet-dense granules are a relevant source of secreted ATP, which may represent an important mechanism of leukocyte activation: this nucleotide triggers leukocyte intracellular calcium increase and stimulates phosphoinositide breakdown, superoxide anion generation, granule exocytosis[60,61], and the increase of membrane expression of the β2-integrin Mac-1[62]. The identification and tissue distribution of the specific class of purinergic receptors, as well as their cloning and pharmacological characterization have been recently reviewed[63].

A neutrophil-activating peptide, called NAP-2, can be generated from platelet basic protein (PBP) and connective tissue-activating peptide III (CTAP-III), two inactive platelet products, through proteolytic processing operated by leukocyte proteases[64,65]. In addition, thrombin-activated human platelets release two NAP-2 variants, which are not generated outside the platelets by proteolytic processing, but are available already in the active form[66]. Similar results have been reported also with porcine platelets[67].

The synthesis of thrombospondin by monocytes is increased by platelet addition, an effect specific both for the cell type and the protein synthesized[68]. Platelet PF4 induces morphological changes in human monocytes toward a macrophage-like cell type[69], while platelets, or substances shed by activated platelets, enhance macrophage cholesteryl accumulation in conditions of close cell–cell association[70]. Altogether, these observations support the contribution of platelet–monocyte interaction to the progression of atherosclerotic lesion.

Finally, microparticles released from activated platelets enhance both leukocyte aggregation and accumulation of flowing leukocytes on a selectin substrate[71].

Downregulation of leukocytes by platelets

Unstimulated platelets may limit the effects of PMN activation by decreasing their capacity to synthesize PAF[72], to generate oxygen radicals[73], or to produce a cytotoxic effect[74]. Moreover, substances released upon platelet activation, such as TGF-β, the so-called 'adherence inhibiting factor', and P-selectin, which is rapidly lost by activated platelet surface[75], all inhibit PMN adhesion to endothelial cells[76–78]. Soluble P-selectin and PDGF may also reduce the generation of superoxide anion by activated PMN[79,80]. The platelet-derived precursors of NAP-2, CTAP-III and PBP, two CXC chemokines belonging to the subfamily of ELR^+, though lacking PMN-activating properties themselves, are able to down-regulate degranulation and chemotaxis induced by NAP-2 in neutrophils[81,82].

Platelet–monocyte interactions relevant to blood coagulation

A link between platelet–monocyte interactions and blood coagulation has long been established. In particular, generation of a platelet factor X activating activity, and a modulating role in monocyte tissue factor (TF) expression have been proposed.

Semeraro et al.[83], utilizing a system in which platelets were incubated with mononuclear cells in the presence of endotoxin (LPS), observed the development of a platelet coagulant activity of the factor X activator type. Platelets challenged with LPS in the absence of leukocytes were devoid of procoagulant activity, indicating a mediator role for mononuclear cells. Based on these findings a new cellular pathway of blood clotting initiation was proposed.

The first observation of the influence of platelets on mononuclear cell TF was provided by Niemetz and Marcus back in 1974[84]. TF is a 47 kD integral membrane glycoprotein associated with phospholipids, which, upon binding to factor VII and its active form VIIa, triggers blood coagulation leading to fibrin formation[85]. Under normal conditions monocytes do not express TF antigen or activity, but can be induced to do so by exposure to appropriate agonists, among which is LPS[86].

Platelets may influence monocyte TF expression in two different ways: they can induce TF activity in monocytes or enhance TF activity from LPS-stimulated monocytes[84,87,88]. The observation that TF activity correlated with the number of platelets, that arachidonic acid amplified TF expression, and that platelets from donors who had ingested acetylsalicylic acid were more effective, suggested a role for a platelet-derived lipoxygenase pathway metabolite[89]. Indeed, platelet-derived 12-hydroxyeicosatetraenoic

Cambridge Books Online © Cambridge University Press, 2009

acid (12-HETE), the end product of the 12-lipoxygenase-mediated pathway of arachidonic acid, enhanced TF expression in LPS-stimulated mononuclear cells[89]. In addition to 12-HETE, PF4, another platelet-derived mediator, was later reported to increase TF activity in stimulated monocytes[90].

Close contact between platelets and monocytes is required in order to induce TF expression in monocytes (R. Lorenzet, unpublished data), suggesting a role for adhesion molecules, P-selectin being a candidate. An in vivo role for P-selectin in blood clotting activation had been proposed by experiments in a baboon model[91]. The accumulation of leukocytes on activated platelets and fibrin formation, observed within an artificial graft, were greatly reduced by pretreatment of the baboon with anti-P-selectin monoclonal antibodies. This finding indicated that P-selectin in vivo was responsible for platelet–leukocyte binding within the thrombus, and that these leukocytes promoted fibrin formation. Taken together, these observations suggested the possibility that binding of monocytes to activated platelets could affect monocyte procoagulant activity. Indeed, it was shown that purified P-selectin upregulated monocyte TF expression[92]. In addition to P-selectin in the fluid phase, also Chinese hamster ovary cells (CHO) transfected with the P-selectin cDNA, but not with E-selectin, induced TF expression in monocytes.

The inducing effect of P-selectin was later confirmed: in a whole blood model, monocyte TF expression was markedly increased by adding collagen, and was abolished by anti-P-selectin antibodies[93]. A role for P-selectin in mediating the stimulatory effect of platelets and granulocytes on LPS-induced TF activity in monocytes was also shown[94].

12-HETE, similarly to what was observed with LPS-stimulated monocytes, greatly potentiated TF expression by P-selectin-exposed monocytes[95].

Since activated platelets, which express P-selectin on their surface, colocalize with monocytes at sites of vascular injury and thrombosis, signalling for *de novo* monocyte TF synthesis would be important for the maintenance of the local activation of blood coagulation in order to prevent further blood loss.

Lately, it was shown that in mice expressing P-selectin without the cytoplasmic tail an increase in plasma P-selectin was detected; these elevated amounts of plasma P-selectin enhanced the generation of leukocyte-derived microparticles, some of which expressed TF[96].

Finally, a new type of interaction between platelets and leukocytes has been proposed, namely the transfer of TF microparticles from monocytes and, possibly, granulocytes to platelets during thrombus formation[97]. In an in vitro model, the transfer was mediated by TF itself and by the interaction of CD15, the P-selectin counter-receptor (also known as PSGL-1, see below), with platelets. If confirmed, this finding would be of great relevance, since platelets, acquiring TF activity, would be directly capable of triggering and propagating thrombosis.

Transcellular metabolism of arachidonic acid in platelet–leukocyte interaction

The platelet–PMN interaction includes cell–cell co-operation in the arachidonic acid metabolism, which has been defined as transcellular metabolism[3]. Platelets are devoid of 5-lipoxygenase and are thus unable *per se* to synthesise leukotrienes, but platelet-PMN transcellular metabolism of arachidonic acid results in increased leukotriene production, as activated platelets provide free arachidonic acid to activated PMN[98–101]. Platelets may also contribute to LTC4 and lipoxin production by metabolizing PMN-derived LTA4[100,102,103]. PMN, on the other hand, may provide free arachidonic acid to activated platelets, thus increasing the synthesis of cyclooxygenase[104] and 12-lipoxygenase[105] products.

Palmantier and Borgeat[106] first suggested that direct cell–cell contact through specific adhesion molecules may facilitate arachidonic acid transcellular metabolism between platelets and PMN.

Following the observation that L-selectin-mediated PMN–endothelial cell interaction promotes transcellular leukotriene biosynthesis[107], P-selectin-dependent platelet–PMN adhesion has been shown to facilitate the transcellular metabolism of arachidonic acid, resulting in increased production of both TxB2 and LTC4[24].

Adhesive mechanisms

The role of P-selectin and the β2-integrin CD11b/CD18 (Mac-1)

A selective binding of thrombin-stimulated platelets to human monocytes, PMN and related cell lines was shown more than a decade ago[108] and subsequently demonstrated to be primarily mediated by P-selectin[109,110]. P-selectin is a type-1 membrane glycoprotein with a 'C-type' lectin domain, stored in the α-granules of platelets and in the Weibel Palade bodies of endothelial cells (for review see [111,112]). This glycoprotein is exposed on the external surface after cell activation and recognises sialylated fucosylated lactosamines as critical components of specific ligands on different classes of leukocytes. P-selectin glycoprotein ligand-1 (PSGL-1) is a glycoprotein, endowed with high

Cambridge Books Online © Cambridge University Press, 2009

affinity and biologically relevant bonds with P-selectin (for review see [111–114]). In conditions of flow, P-selectin tethers flowing leukocytes and supports subsequent rolling interaction[115], thanks to its ability to bind the PSGL-1 counter-receptor on PMN leukocytes with rapid association and dissociation rates[116,117]. High resolution, high speed imaging under flow allowed direct observation of membrane tethers formed during neutrophil attachment to platelets or P-selectin under physiological flow[118]. Based on the absence of rolling and the severe inflammatory defect reported in E- and P-selectin double-deficient mice[119,120], P-selectin is considered to be an essential requirement for PMN rolling[121]. It is also a prerequisite for β2-integrin-mediated arrest on immobilized platelets following PMN activation by an exogenous chemotactic peptide[122,123].

In a pioneering study performed under physiological shear, Yeo et al.[124] had observed spontaneous conversion from rolling to firm adhesion of PMN on platelets in the absence of exogenous stimuli. Co-operation between P-selectin and the β2-integrin Mac-1 was demonstrated in mixed platelet–PMN suspensions subjected to high speed rotatory motion, a condition emphasizing high affinity adhesive cell-cell interactions not easily disrupted at moderate or high shear forces[125]. In the absence of exogenous stimuli for PMN, activated platelets rapidly formed with them mixed cell conjugates. These were prevented not only, as expected, by anti-P-selectin antibodies, but also by anti-CD18 or anti-CD11b antibodies. Adhesion of pre-activated platelets to PMN resulted in binding to PMN of a monoclonal antibody recognizing an activation and ligand-induced neoepitope on the α-chain of the β2-integrins[126].

More recent observations, obtained in whole blood exposed to hydrodynamic shear comparable to that of venous circulation, indicated that platelet adherence to PMN, via P-selectin binding to PSGL-1, induced Mac-1-dependent platelet–PMN and PMN–PMN aggregation[127]. This confirms the relevance of the molecular mechanisms mentioned above in platelet–PMN interaction in a physiological milieu.

Thus platelets either immobilized on a surface[128] or activated in suspension[125] express a complete machinery to catch flowing PMN: (a) P-selectin mediating the first contact, (b) one or more signalling molecules, relevant for CD11b/CD18 activation and (c) the counter-receptor(s) of the β2-integrin (Fig. 28.3). The latter include the constitutively expressed ICAM-2[129,130], fibrinogen[130,131] bound to GpIIbIIIa[132], GpIbα[133] and probably other not yet characterized receptors[125].

At variance with the adhesive molecules involved in the rolling step that do not require an activation signal to recognize their ligand, β2-integrins require a functional upregulation to become competent to bind their counter-receptor[134]. This implies that an intermediate β2-integrin-activating signal is delivered from the platelet surface to PMN in the few seconds between rolling movement and firm attachment.

To explain this signalling, two possible mechanisms probably cooperating with each other have been proposed[135]: the first assumes that selectin-mediated rolling slows down leukocytes and therefore facilitates PMN and β2-integrin activation by agonists coexpressed with P-selectin on the platelet surface, such as PAF and CXC chemokines[130]. The second possibility is that selectin binding to PMN itself induces a signal enabling β2-integrin adhesiveness.

In the context of the latter hypothesis, Lawrence and Springer[115], using lipid bilayers containing purified selectin and ICAM-1, reported that in flow conditions P-selectin itself does not activate integrins on rolling PMN leukocytes. A similar conclusion was reached by Lorant et al.[136], showing that although soluble P-selectin does not directly induce β2-integrin adhesiveness, it potentiates the β2-integrin-dependent adhesive response to PAF. More recently, however, evidence was provided supporting a direct role for P-selectin in influencing β2-integrin function: indeed purified P-selectin was able to increase the PMN phagocytosis of unopsonized zymosan, which is a recognized Mac-1-dependent function[137], and to stimulate Mac-1-dependent homotypic aggregation of human PMN[138] and LFA-1-, Mac-1-dependent adhesion of mouse PMN to ICAM-1[139].

The role of PSGL-1 and of protein tyrosine phosphorylation as signalling molecules

As already mentioned, an important role in transmitting the P-selectin-induced signal is played by PSGL-1[138,139]; engagement of PSGL-1 by P-selectin or by specific monoclonal antibodies induces protein tyrosine phosphorylation[138,140] and activates mitogen-activated protein (MAP) kinases in human PMN leukocytes[140]. Consistently, tyrosine kinase inhibitors prevented Mac-1 adhesion[125], as well as IL-8 production triggered by P-selectin or PSGL-1 engagement by monoclonal antibodies.

Among different families of protein tyrosine kinases present in leukocytes, those belonging to the family of SRC play a major role in β2-integrin adhesive function triggered by P-selectin[141]. Specific inhibitors of SRC tyrosine kinases were found to inhibit PMN adhesion to activated platelets or to P-selectin expressing CHO (CHO-P) cells as well as protein tyrosine phosphorylation in PMN. Adhesion of

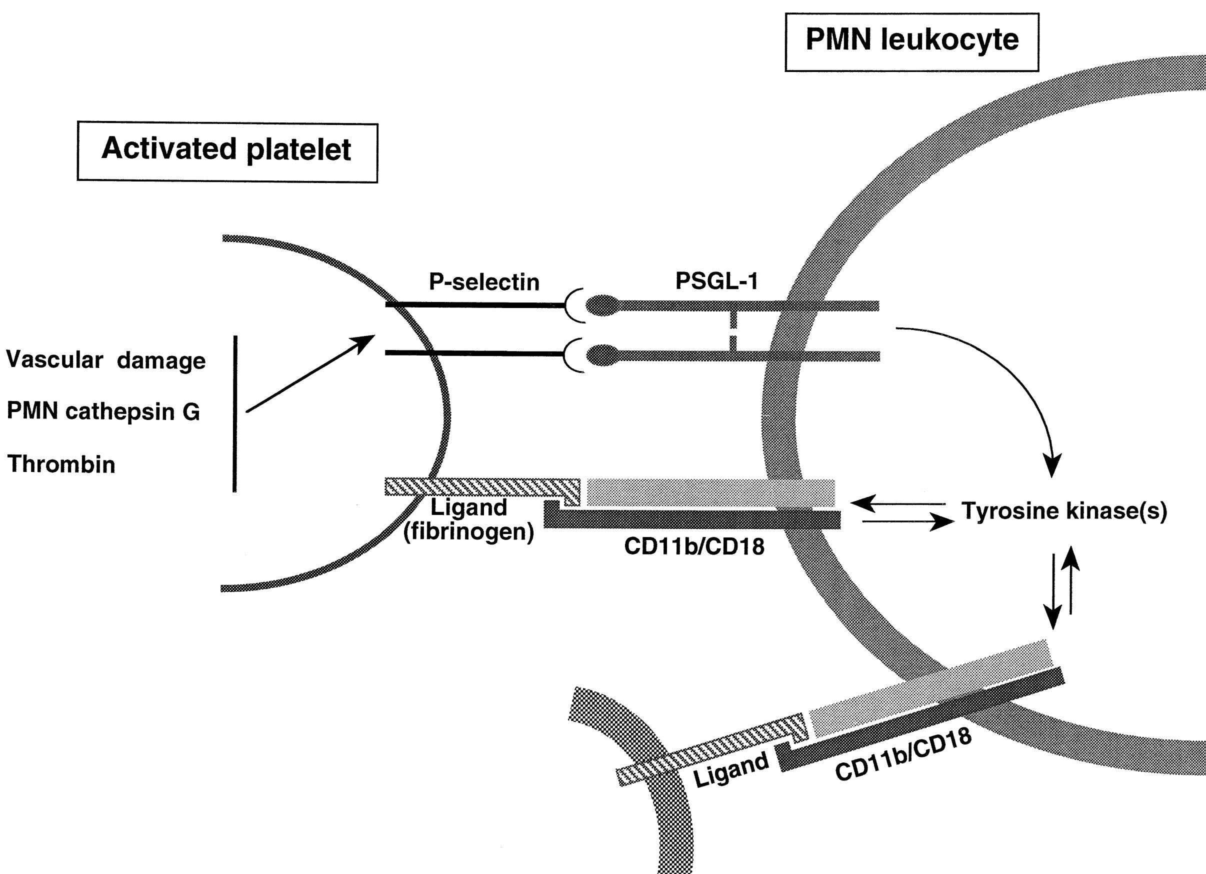

Fig. 28.3. Schematic sequence of the molecular events following platelet activation by different means. P-selectin expressed on activated platelet surface binds to PSGL-1 on PMN leukocytes, thus establishing a rapidly reversible tethering. PSGL-1 engagement starts a signalling mechanism, involving protein tyrosine phosphorylation. The latter is followed by activation of the β2-integrin Mac-1, which becomes able to bind to platelet counter-receptors (including fibrinogen) or to other β2-integrin ligands that allow multicellular interactions, as in Fig. 28.7. At this moment the interaction between platelets and PMN leukocytes becomes stable. (This figure is reprinted[8], with permission.)

PMN to activated platelets or to CHO-P cells stimulated the activity of LYN and HCK, two SRC kinases, while monoclonal antibody blockade of P-selectin or β2-integrins reduced the activation of both kinases. In PMN, either adherent to platelets or aggregated by P-selectin-IgG chimera or by anti-PSGL-1 antibodies, Mac-1 was rapidly redistributed to the Triton X-100-insoluble cytoskeletal fraction and large clusters of this β2-integrin colocalized with patches of F-actin at the site of cell-cell contact[141] (Fig. 28.4, see colour plate). In PMN stimulated by P-selectin-IgG chimera, SRC kinase inhibition impaired Mac-1 clustering and F-actin accumulation and CD18 redistribution to the cytoskeleton. Conversely, disruption of actin filament network by cytochalasin D prevented PMN-platelet adhesion and P-

selectin-induced PMN aggregation and impaired clustering of Mac-1. In agreement with the requirement for the β2-integrin in the functional upregulation of LYN and HCK, integrin blockade by monoclonal antibodies resulted in a complete inhibition of Mac-1 clustering and F-actin accumulation in P-selectin-challenged PMN[141]. These results indicate that, after the initial β2-integrin interaction with its ligand, SRC kinases are activated and allow the remodelling of cytoskeleton–β2-integrin linkages and clustering that finally strengthen cell–cell adhesion. This model highlights a new role for SRC kinases in a regulatory loop by which Mac-1 promotes its own adhesive function, but leaves open the question about the initial signal triggered by P-selectin that upregulates β2-integrin[141].

The contributory role of platelet–leukocyte interaction in vascular damage and thrombosis

Evidence from experimental animal models

Evidence of platelet–leukocyte interaction and leukocyte incorporation into and/or onto thrombi has been found in different experimental models (for reviews see refs[5,7,9]). On the one hand, thrombocytopenia decreases leukocyte recruitment after vascular injury in a porcine model[142], on the other platelet accumulation in experimental myocardial infarction is reduced by PMN depletion[143]. Activated PMN produce and release reactive oxygen species, inflammatory leukotrienes and proteolytic lysosomal enzymes, which can directly induce vascular damage and influence the activation state of both platelets and endothelial cells[7]. In animal models of myocardial infarction, PMN depletion, pharmacological suppression of PMN activation, as well as inhibition of PMN–endothelial cell adhesion reduced the extent of acute tissue injury and mortality following ischemia and reperfusion[143–146].

Mixed masses of PMN and platelets have been observed in the lungs of experimental animals subjected to hemorrhagic shock[147] or anaphylatoxin instillation[148] or following intradermal or intravenous infusion of fMLP[149,150], or in rat glomeruli in a model of immune complex nephritis[151].

The classical observations of leukocyte accumulation at the site of platelet thrombus have already been mentioned[1,91]. Platelet–leukocyte interaction in circulating blood was also observed after injection of oxidised lipoproteins in vivo[152]. When native whole blood was perfused over a collagen-coated surface, the platelet thrombi were coated with a layer of leukocytes[153]. The pathogenesis of the adult respiratory distress syndrome also appears to involve activation of both platelets and PMN[154]. Platelets and PMN leukocytes act synergistically in provoking post-reperfusion cardiac dysfunction in rats[155] or vasoconstriction after deep carotid arterial injury by angioplasty in pigs[156].

The transcellular biosynthesis of sulphidopeptide leukotrienes is accompanied by morphological changes and coronary vasospasm in isolated rabbit heart preparations perfused with activated human PMN[157]. Pretreatment with leukotriene synthesis inhibitors prevented morphological alterations and protected against the increase in coronary perfusion pressure[157,158]. In experiments of permanent coronary artery ligature in vivo a leukotriene synthesis inhibitor reduced the mortality rate and protected the rabbits against the marked electrocardiogram derangement induced by ligation[158]. A monoclonal anti-CD18 antibody prevented transcellular biosynthesis of cysteinyl leukotrienes in vitro and in vivo and protected against LT-dependent increase in coronary resistance[159].

Intravenous infusion of the inflammatory chemotactic agent fMLP in the rabbit induced a dramatic fall in circulating leukocytes and platelets; the latter were activated and aggregated together with leukocytes in the capillaries and venules of the lungs[150]. The concomitant synthesis of eicosanoids and ischemic electrocardiographic changes were prevented by treatment with thromboxane inhibitors, supporting platelet involvement in this model of primary leukocyte activation[160,161] (Fig. 28.5).

Altogether these data provide experimental support to the hypothesis that inflammation is an intermediate mechanism relevant in acute coronary syndromes that can be sustained by platelet–leukocyte interaction.

Experimental evidence also supports the contribution of platelet–leukocyte interactions to the intimal hyperplasia, caused by vascular injury. Transluminal wire injury to the mouse femoral artery induces abundant intimal hyperplasia formation within 2–4 weeks, but already one hour after injury the denuded surface was covered with platelets and leukocytes, predominantly neutrophils, and associated with the accumulation of the adhesion molecules P-selectin, VCAM-1 and ICAM-1[162]. In a balloon-injury model of rat carotid artery, inhibition of P-selectin-mediated leukocyte recruitment prevented the development of neointimal formation, adventitial inflammation, and vascular shrinking, and promoted pseudo-endothelialization by luminal smooth muscle cells[163]. P-selectin-deficient mice are protected from developing intimal hyperplasia after ligating the carotid artery[164], and have defects in leukocyte rolling in the absence of inflammation and in the early recruitment of PMN in the presence of inflammation[165]. P-selectin-deficient mice also show significant protection from reperfusion injury in different vascular districts[166–171].

Cambridge Books Online © Cambridge University Press, 2009

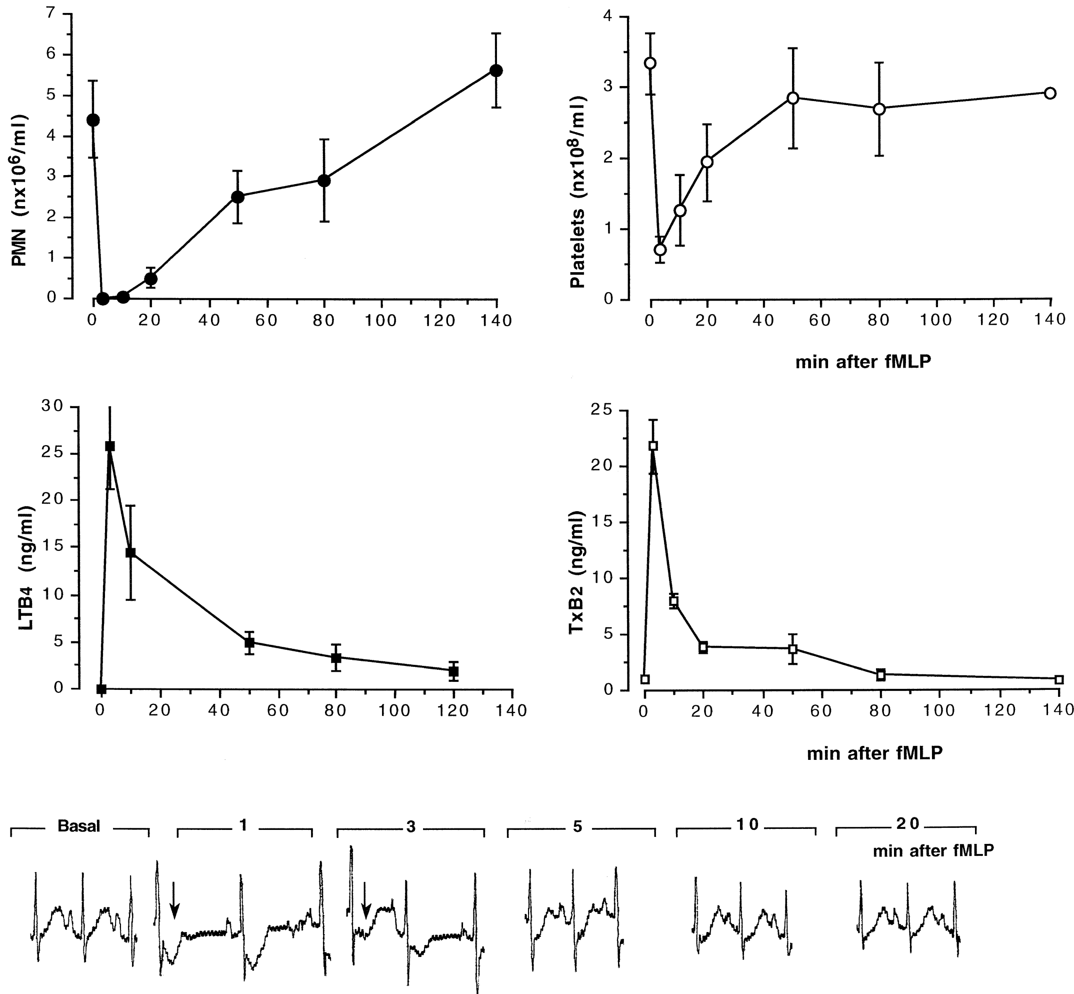

Fig. 28.5. Effect of intravenous infusion of fMLP in rabbits on PMN and platelet count, eicosanoid production (LTB4 and TxB2) and an electrocardiographic tracing showing signs of acute reversible ischemia (indicated by the arrows). (For more details[160,161].)

A recent study tested the hypothesis that the absence of either P-selectin or ICAM-1 inhibits macrophage recruitment into the vessel wall and protects against neointimal formation after arterial denudation in atherosclerosis-prone apolipoprotein E-deficient mice. The results indicate that the complete absence of P-selectin, but not ICAM-1, markedly reduces plaque area and suggest that P-selectin is critical for monocyte recruitment to sites of neointima formation after arterial injury[172].

In addition, anti-Mac-1 antibodies inhibited intimal hyperplasia in a rabbit model[173], and Mac-1-deficient mice were protected from developing neointimal thickening following injury to the carotid vasculature[174]. The role of P-selectin in the development of intimal hyperplasia was recently confirmed in P-selectin-deficient mice after endothelial injury; interestingly enough, β3-integrin-deficient mice were not protected[175].

Most recently, infiltration of PMN into the media of blood vessels was observed in the rabbit within a few hours after injury, and a correlation was found between early PMN transmigration and subsequent smooth muscle cell proliferation[176].

From these experimental studies it appears that P-selectin and Mac-1 are the major mediators responsible for PMN recruitment in an injured vessel covered by platelets.

Evidence from epidemiological and clinical studies

Epidemiological evidence suggests a positive correlation between the number of leukocytes, PMN in particular, and the risk of ischemic vascular disease (for review see [177–179]). Indeed high PMN count was associated with an increased risk of acute myocardial infarction[177] and its recurrence[180] or of transient cerebral ischemic attacks[181]. Further studies

Cambridge Books Online © Cambridge University Press, 2009

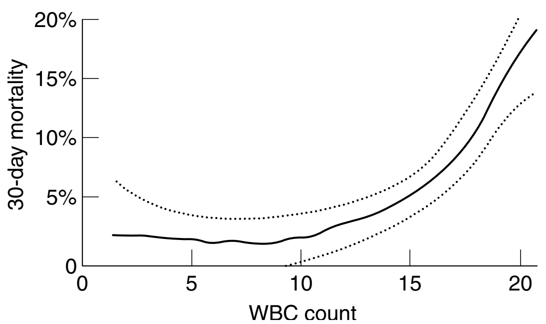

Fig. 28.6. Association of baseline white blood cell count ($\times 10^3/\mu l$) with increased 30-day mortality in acute myocardial infarction and unstable angina patients. (This figure is reprinted[184], with permission from Excerpta Medica Inc.)

reported increased ex vivo functional responsiveness as well as in vivo PMN activation and platelet–leukocyte interaction in different clinical manifestations of ischemic heart disease and suggested an active role for these cells in the progression of vascular occlusion[182,183]. Recently, association of white blood cell count with increased mortality in acute myocardial infarction and unstable angina has been reported[184] (Fig. 28.6).

Elevated levels of soluble P-selectin have been found in atherosclerotic, hyperlipidemic and hypertensive patients[185–190]. Recently, elevated baseline levels of soluble P-selectin were found to be associated with increasing risk of future myocardial infarction, stroke, coronary revascularization and cardiovascular death in a large scale prospective study of apparently healthy women. This association was independent of traditional risk factors[191].

Although most platelet–leukocyte aggregates have probably a short intravascular survival time, so that only a small fraction of the formed aggregates are present in the systemic circulation at any time, platelet–leukocyte conjugates have been observed in peripheral blood from patients with unstable angina[192]. Cell–cell interaction might trigger PMN activation in this clinical condition[182], as originally reported by Mazzone et al[183]. On the other hand, the formation of platelet–PMN conjugates following percutaneous coronary interventions was considered a predictive index of acute reocclusion[192,193]. Circulating monocyte–platelet aggregates have been identified in patients with stable coronary artery disease[194].

Activated leukocytes, as judged by increased surface expression of Mac-1, have been reported in the systemic circulation of patients admitted to hospital with chest pain[195], in patients after myocardial infarction[196] or after coronary angioplasty[197] and in the coronary sinus blood of patients with unstable (but not stable) angina[183,198]. On the other hand, monocytes with attached platelets from patients undergoing stenting for acute myocardial infarction express more Mac-1 than monocytes without attached platelets[199]. In patients with unstable angina, increased Mac-1 expression was measured on leukocytes from coronary sinus blood compared to blood from either the coronary ostium or the coronary artery just distal to the culprit lesion, suggesting that leukocyte activation occurs within the microcirculation of the myocardium[200].

Induction of cytokine expression in PMN leukocytes by binding of thrombin-stimulated platelets was observed in patients with unstable angina or myocardial infarction[201].

Pharmacology of the platelet–leukocyte interactions

As the intensity of the platelet response is directly related to the degree of PMN activation, substances inhibiting PMN stimulation may prevent the platelet–PMN interaction. This is the case with serine proteinase inhibitors such as α1-proteinase inhibitor, secretory leukocyte proteinase inhibitor, or its truncated form, and eglin C[202–204]. However, cathepsin G discharged from stimulated PMN on strictly adherent platelets may be protected from these antiproteinases[21,205].

Heparin, one of the most widely used drugs for prevention and treatment of thrombosis, has three effects which may be relevant to pharmacological modulation of the platelet–PMN interaction. First, heparin may interfere with P-selectin-dependent platelet–PMN adhesion[206]; secondly, it prevents platelet activation induced by stimulated PMN by acting on cathepsin G, possibly through an ionic interaction between differently charged molecules[203,207,208]. Heparin, as an adhesive ligand for Mac-1[209,210], may interfere with cell adhesion, thus avoiding the formation of a protected microenvironment, at the same time preventing the effect of cathepsin G on platelets. The effect of heparin, independent of its polyanionic and its anticoagulant activity has been recently confirmed by studying the adhesion of human PMN to vascular endothelium[211]. Other glycosaminoglycans, such as sulodexide, low-molecular-weight dermatansulfate and heparins with different degrees and types of sulfation have also been shown to inhibit platelet aggregation induced by cathepsin G and its catalytic activity[212]. Thirdly, heparin and other glycosaminoglycans inhibited lysosomal enzyme release and superoxide production by activated PMN[208,212]. In the already mentioned rabbit model of stent-induced arterial injury, heparin was shown to inhibit early neutrophil infiltration in the media, smooth muscle cell proliferation and neointimal growth at 7–14 days[176].

These observations may help establish whether

Cambridge Books Online © Cambridge University Press, 2009

mechanism(s) of action other than anticoagulation may contribute to the antithrombotic activity of heparin and related compounds. Like heparin, defibrotide, a polydeoxyribonucleotide with antithrombotic effects in experimental models, inhibits platelet activation by stimulated PMN, through inactivation of cathepsin G catalytic activity. Defibrotide is inactive on thrombin[213].

Several compounds known to affect platelet response have also been tested for their ability to modify platelet–PMN interaction in vitro. As already observed on platelets challenged with thrombin, aspirin, even at high concentrations, did not prevent platelet activation induced by PMN or cathepsin G, although it completely suppressed TxB2 generation[19,20,25]. Thus aspirin treatment of patients with ischemic events may not reduce platelet activation at sites of PMN accumulation such as myocardial infarction areas. The reported efficacy of dipyridamole in preventing PMN-dependent platelet activation, as well as PMN oxygen radical generation when triggered by LTB4[20,214] is of interest, but remains to be confirmed.

Iloprost, a stable prostacyclin analogue, appears to be active at nanomolar concentrations on PMN–platelet interaction and at micromolar concentrations on PMN activation. Iloprost reportedly helped the healing of cutaneous ulcers and reduced amputation in patients with critical leg ischemia, where leukocyte–platelet activation may have pathogenic relevance[215].

While β-adrenergic blocking agents appear to enhance leukocyte function, no data are available on a possible consequent increase of platelet activation. Similarly, it is not known whether the inhibitory effect of calcium antagonists and nitrates on PMN function has any consequence on platelet–PMN interaction[216].

Preliminary data show that in patients undergoing coronary interventions, treatment with abciximab, an antiGpIIbIIIa chimeric monoclonal antibody, not only prevents the increase in PMN and monocyte Mac-1 expression that occurs postangioplasty, but actually results in an absolute decrease in Mac-1 expression on both cell types[197]. A study in which human platelets, leukocytes, and fibrinogen were infused into isolated guinea pig hearts after 15 min of ischemia and 2 min of reperfusion, indicated that abciximab treatment not only prevented the transcoronary increase in neutrophil Mac-1 and the development of platelet-PMN aggregates, but also facilitated postischemic recovery[217]. A recent study in patients undergoing coronary angioplasty[218] demonstrates that, although abciximab treatment decreases the percentage of circulating platelet–leukocyte aggregates, it promotes P-selectin-mediated platelet–leukocyte interaction on a collagen-von Willebrand factor surface. On the other hand, platelet–monocyte interaction decreased after abciximab treatment in patients with acute myocardial infarction, mainly due to a reduction in platelet mass attached to monocytes, as it did not affect the percentage of monocytes with adherent platelets[199].
