TERMS OF USE

This is a copyrighted work and The McGraw-Hill Companies, Inc. (“McGraw-Hill”) and its licensors reserve all rights in and to the work. Use of this work is subject to these terms. Except as permitted under the Copyright Act of 1976 and the right to store and retrieve one copy of the work, you may not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill’s prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

THE WORK IS PROVIDED “AS IS.” MCGRAW-HILL AND ITS LICENSORS MAKE NO GUARANTEES OR WARRANTIES AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

To my wife, Melissa, my children, Isaac and Jackson, my mother, Rose, and my late father, Edward Brunicardi, for their love and support

FCB

To my wife, Cindy, and my children, Ashley, Lauren, Kathryn, Thomas, and Olivia

DKA

To Edith, Isabel and Alex

TRB

To my wife, Kelli, for all of her support of my career and academic endeavors, and my children, Michael, Evelyn, Julia, and Edward

DLD

To my wife, Laura, my children, Sarah, Sam, and Jillian, and the residents, fellows, and surgical faculty at OSHU who have created a community of health, collegiality, and open-minded intellectual rigor

JGH

Preface xxiii

PART I BASIC CONSIDERATIONS

- 1 Systemic Response to Injury and Metabolic Support **3**
*J. Martin Perez, Edward Lim, Steven E. Calvano,
and Stephen F. Lowry*
- 2 Fluid and Electrolyte Management of the
Surgical Patient **32**
Rosemary A. Kozar and Frederick A. Moore
- 3 Hemostasis, Surgical Bleeding, and Transfusion **46**
Seymour I. Schwartz
- 4 Shock **56**
*Andrew B. Peitzman, Brian G. Harbrecht,
and Timothy R. Billiar*
- 5 Surgical Infections **78**
Gregory J. Beilman and David L. Dunn
- 6 Trauma **97**
*John M. Burch, Reginald J. Franciose,
and Ernest E. Moore*
- 7 Burns **138**
James H. Holmes and David M. Heimbach
- 8 Wound Healing **165**
Adrian Barbul
- 9 Oncology **183**
*Funda Meric-Bernstam and Raphael
E. Pollock*
- 10 Transplantation **216**
Abhinav Humar and David L. Dunn
- 11 Patient Safety, Errors, and Complications in Surgery **245**
Mark L. Shapiro and Peter B. Angood
- 12 Physiologic Monitoring of the Surgical Patient **275**
Louis H. Alarcon and Mitchell P. Fink

- 13 Minimally Invasive Surgery **293**
Blair A. Jobe and John G. Hunter
- 14 Cell, Genomics, and Molecular Surgery **309**
*Xin-Hua Feng, Jeffrey B. Matthews, Xia Lin, and
 F. Charles Brunicaudi*

PART II SPECIFIC CONSIDERATIONS

- 15 Skin and Subcutaneous Tissue **329**
*Scott L. Hansen, Stephen J. Mathes, and
 David M. Young*
- 16 The Breast **344**
*Kirby I. Bland, Samuel W. Beenken, and
 Edward E. Copeland, III*
- 17 Disorders of the Head and Neck **369**
*Richard O. Wein, Rakesh K. Chandra, and
 Randal S. Weber*
- 18 Chest Wall, Lung, Mediastinum, and Pleura **396**
*Michael A. Maddaus and
 James D. Luketich*
- 19 Congenital Heart Disease **436**
*Tara B. Karamlou, Irving Shen, and
 Ross M. Ungerleider*
- 20 Acquired Heart Disease **458**
*Charles F. Schwartz, Aubrey C. Galloway, Ram
 Sharony, Paul C. Saunders, Eugene A. Grossi, and
 Stephen B. Colvin*
- 21 Thoracic Aortic Aneurysms and Aortic Dissection **496**
Joseph S. Coselli and Scott A. LeMaire
- 22 Arterial Disease **515**
*Alan B. Lumsden, Peter H. Lin, Ruth L. Bush, and
 Changyi Chen*
- 23 Venous and Lymphatic Disease **556**
Gregory L. Moneta
- 24 Esophagus and Diaphragmatic Hernia **573**
Jeffrey H. Peters and Tom R. DeMeester
- 25 Stomach **650**
Daniel T. Dempsey
- 26 The Surgical Management of Obesity **685**
*Philip R. Schauer and
 Bruce David Schirmer*

- 27 Small Intestine **702**
Edward E. Whang, Stanley W. Ashley, and Michael J. Zinner
- 28 Colon, Rectum, and Anus **732**
Kelli M. Bullard and David A. Rothenberger
- 29 The Appendix **784**
David H. Berger and Bernard M. Jaffe
- 30 Liver **800**
Steven A. Curley and Timothy D. Sietlaff
- 31 Gallbladder and Extrahepatic Biliary System **821**
Margrét Oddsdóttir and John G. Hunter
- 32 Pancreas **845**
William E. Fisher, Dana K. Anderson, Richard H. Bell, Jr., Ashok K. Saluja, and F. Charles Brunicaudi
- 33 Spleen **879**
Adrian E. Park and Rodrick McKinlay
- 34 Abdominal Wall, Omentum, Mesentery, and Retroperitoneum **897**
Robert L. Bell and Neal E. Seymour
- 35 Soft Tissue Sarcomas **906**
Janice N. Cormier and Raphael E. Pollock
- 36 Inguinal Hernias **920**
Robert J. Fitzgibbons, Jr. and Hardeep S. Ahluwalia
- 37 Thyroid, Parathyroid, and Adrenal **943**
Geeta Lal and Orlo H. Clark
- 38 Pediatric Surgery **989**
David J. Hackam, Kurt Newman, and Henri R. Ford
- 39 Urology **1036**
Hyung L. Kim and Arie Belldgrun
- 40 Gynecology **1061**
Gregory P. Sutton, Robert E. Rogers, William W. Hurd, and Martina F. Mutone
- 41 Neurosurgery **1102**
Michael L. Smith and M. Sean Grady
- 42 Orthopaedics **1130**
Dempsey Springfield
- 43 Plastic and Reconstructive Surgery **1169**
Saleh M. Shenaq, John Y.S. Kim, Alan Bienstock, Forrest S. Roth, and Eser Yuksel
- 44 Surgical Considerations in Older Adults **1188**
Rosemarie E. Hardin and Michael E. Zenilman

45	Anesthesia of the Surgical Patient	1201
	<i>Robert S. Dorian</i>	
46	ACGME Core Competencies	1223
	<i>Liz Nguyen, Mary L. Brandt, Samir S. Awad, Ruth Bush, David H. Berger, and F. Charles Brunickardi</i>

Contributors

Hardeep S. Ahluwalia, MD
Medical Dean, Housestaff
Department of Surgery
Creighton University Medical
Center
Omaha, Nebraska
Chapter 36: Inguinal Hernias

Louis H. Alarcon, MD
Assistant Professor
Departments of Surgery and Critical
Care Medicine
University of Pittsburgh School of
Medicine
Pittsburgh, Pennsylvania
*Chapter 12: Physiologic Monitoring
of the Surgical Patient*

Dana K. Andersen, MS, FACS
Professor and Vice-Chair
Department of Surgery
Johns Hopkins School of Medicine
Surgeon-in-Chief
Johns Hopkins Bayview Medical
Center
Baltimore, Maryland
Chapter 32: Pancreas

**Peter B. Angood, MD, FACS,
FCCM**
Professor of Surgery Anesthesia and
Emergency Medicine
Chief, Division of Trauma and
Critical Care
University of Massachusetts
Medical School and
University of Massachusetts—
Memorial Health Care System
Worcester, Massachusetts
*Chapter 11: Patient Safety, Errors,
and Complications in Surgery*

Stanley W. Ashley, MD
Professor and Vice Chairman

Department of Surgery
Brigham and Women's
Hospital/Harvard Medical School
Boston, Massachusetts
Chapter 27: Small Intestine

Samir S. Awad, MD
Associate Professor of Surgery
Chief, Section of Critical Care
Michael E. DeBakey Department
of Surgery
Baylor College of Medicine
Medical Director SICU
Michael E. DeBakey Veterans
Affairs Medical Center
Houston, Texas
*Chapter 46: ACGME Core
Competencies*

Adrian Barbul, MD, FACS
Surgeon-in-Chief, Sinai Hospital
of Baltimore and
Professor and Vice-Chairman,
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Chapter 8: Wound Healing

**Samuel W. Beenken, MD,
FRCS(C), FACS**
Professor of Surgery
The University of Alabama at
Birmingham
Birmingham, Alabama
Chapter 16: The Breast

Gregory J. Beilman, MD, FACS
Associate Professor of Surgery and
Anesthesia
University of Minnesota Medical
School
Minneapolis, Minnesota
Chapter 5: Surgical Infections

Richard H. Bell, Jr., MD, FACS

Loyal and Edith Davis Professor and
Chair

Department of Surgery
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Chapter 32: Pancreas

Robert L. Bell, MD, MA

Assistant Professor
Department of Surgery
Yale University School of Medicine
New Haven, Connecticut

*Chapter 34: Abdominal Wall,
Omentum, Mesentery, and
Retroperitoneum*

Arie Beldegrun, MD, FACS

Roy and Carol Doumani Chair in

Urologic Oncology
Professor of Urology
Chief, Division of Urologic Oncology
David Geffen School of Medicine at
University of California, Los
Angeles

Los Angeles, California

Chapter 39: Urology

David H. Berger, MD, FACS

Associate Professor and Vice Chair
Michael E. DeBakey Department of
Surgery

Baylor College of Medicine
Operative Care Line Executive
Chief, Surgical Services
Michael E. DeBakey Veterans
Affairs Medical Center
Houston, Texas

Chapter 29: The Appendix

Chapter 46: ACGME Core

Competencies

Alan Bienstock, MD, BS

Resident

Division of Plastic Surgery

Michael E. DeBakey Department of
Surgery

Baylor College of Medicine

Houston, Texas

*Chapter 43: Plastic and
Reconstructive Surgery*

Timothy R. Billiar, MD

George Vance Foster
Professor and Chairman

Department of Surgery
University of Pittsburgh School of
Medicine

Pittsburgh, Pennsylvania

Chapter 4: Shock

Kirby I. Bland, MD, FACS

Fay Fletcher Kerner Professor and
Chairman

Deputy Director, UAB
Comprehensive Cancer Center

Department of Surgery
University of Alabama at
Birmingham

Birmingham, Alabama

Chapter 16: The Breast

Mary L. Brandt, MD

Chief, Colorectal Clinic and Chief,
Pediatric Surgery Clinic

Texas Children's Hospital, Houston,
Texas

Professor of Surgery, Michael E.

DeBakey Department of

Surgery

Professor of Pediatrics, Baylor

College of Medicine

Houston, Texas

Chapter 46: ACGME Core

Competencies

F. Charles Brunicaudi, MD, FACS

DeBakey/Bard Professor and
Chairman

Michael E. DeBakey Department of
Surgery

Baylor College of Medicine

Houston, Texas

*Chapter 14: Cell, Genomics, and
Molecular Surgery*

Chapter 32: Pancreas

Chapter 46: ACGME Core

Competencies

Kelli M. Bullard, MD, FACS

Assistant Professor of Surgery and

Laboratory Medicine and

Pathology

University of Minnesota

Minneapolis, Minnesota
*Chapter 28: Colon, Rectum,
 and Anus*

John M. Burch, MD

Professor of Surgery
 University of Colorado Health
 Sciences Center

Chief of General and Vascular
 Surgery

Denver Health Medical Center
 Denver, Colorado

Chapter 6: Trauma

Ruth L. Bush, MD

Assistant Professor of Surgery
 Division of Vascular Surgery and
 Endovascular Therapy

Michael E. DeBakey Department of
 Surgery

Baylor College of Medicine
 Houston, Texas

Chapter 22: Arterial Disease

Chapter 46: ACGME Core

Competencies

Steven E. Calvano, PhD

Associate Professor
 Division of Surgical Sciences

Department of Surgery

University of Medicine and
 Dentistry of New Jersey—Robert
 Wood Johnson Medical School

New Brunswick, New Jersey

*Chapter 1: Systemic Response to
 Injury and Metabolic Support*

Rakesh K. Chandra, MD

Assistant Professor

Director, Division of Nasal and
 Sinus Disorders

Residency Program Director

Department of Otolaryngology—
 Head and Neck Surgery

University of Tennessee Health
 Science Center

Memphis, Tennessee

*Chapter 17: Disorders of the Head
 and Neck*

Changyi Chen, MD, PhD

Professor of Surgery

Division of Vascular Surgery and
 Endovascular Therapy

Michael E. DeBakey Department of
 Surgery

Baylor College of Medicine

Houston, Texas

Chapter 22: Arterial Disease

Orlo H. Clark, MD

Professor of Surgery

University of California, San
 Francisco/Mt. Zion Medical
 Center

Department of Surgery

San Francisco, California

*Chapter 37: Thyroid, Parathyroid,
 and Adrenal*

Stephen B. Colvin, MD

Chief, Cardiothoracic Surgery

New York University School of
 Medicine

New York, New York

*Chapter 20: Acquired Heart
 Disease*

Edward E. Copeland, III, MD

Distinguished Professor of
 Surgery

University of Florida College of
 Medicine

Gainesville, Florida

Chapter 16: The Breast

Janice N. Cormier, MD, MPH

Assistant Professor of Surgery
 Department of Surgical Oncology

The University of Texas M. D.

Anderson Cancer Center

Houston, Texas

Chapter 35: Soft Tissue Sarcomas

Joseph C. Coselli, MD

Professor and Chief

Division of Cardiothoracic
 Surgery

Michael E. DeBakey Department of
 Surgery

Baylor College of Medicine

Houston, Texas

*Chapter 21: Thoracic Aortic
 Aneurysms and Aortic Dissection*

Steven A. Curley, MD, FACS

Professor, Department of Surgical
Oncology
Chief, Gastrointestinal Tumor
Surgery
The University of Texas M.D.
Anderson Cancer Center
Houston, Texas
Chapter 30: Liver

Tom R. DeMeester, MD

The Jeffrey P. Smith Professor of
General and Thoracic Surgery
Chairman, Department of Surgery
Keck School of Medicine,
University of Southern California
Los Angeles, California
*Chapter 24: Esophagus and
Diaphragmatic Hernia*

Daniel T. Dempsey, MD, FACS

Professor and Chairman of
Surgery
Temple University School of
Medicine
Philadelphia, Pennsylvania
Chapter 25: Stomach

Robert S. Dorian, MD

Chairman and Program Director
Department of Anesthesiology
Saint Barnabas Medical Center
Livingston, New Jersey
*Chapter 45: Anesthesia of the
Surgical Patient*

David L. Dunn, MD, PhD

Vice President for Health Sciences
University at Buffalo/SUNY
Buffalo, New York
*Chapter 5: Surgical Infections
Chapter 10: Transplantation*

Xin-Hua Feng, PhD

Associate Professor of Surgery
Division of General Surgery
Michael E. DeBakey Department of
Surgery
Baylor College of Medicine
Houston, Texas
*Chapter 14: Cell, Genomics, and
Molecular Surgery*

Mitchell P. Fink, MD

Professor and Chairman
Department of Critical Care
Medicine
Watson Chair in Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
*Chapter 12: Physiologic Monitoring
of the Surgical Patient*

William E. Fisher, MD, FACS

Associate Professor of Surgery
Michael E. DeBakey Department of
Surgery
Baylor College of Medicine
Houston, Texas
Chapter 32: Pancreas

Robert J. Fitzgibbons, Jr., MD

Harry E. Stuckenhoff Professor of
Surgery
Department of Surgery
Creighton University School of
Medicine
Omaha, Nebraska
Chapter 36: Inguinal Hernias

Henri R. Ford, MD

Benjamin R. Fisher Chair
Professor and Chief
Division of Pediatric Surgery
Children's Hospital of
Pittsburgh
University of Pittsburgh School of
Medicine
Pittsburgh, Pennsylvania
Chapter 38: Pediatric Surgery

Reginald J. Franciose, MD

Assistant Professor of Surgery
University of Colorado Health
Sciences Center
Attending Surgeon
Denver Health Medical Center
Denver, Colorado
Chapter 6: Trauma

Aubrey C. Galloway, MD

Professor of Surgery, Cardiothoracic
Surgery
Director, Cardiac Surgical
Research

New York University School of
Medicine
New York, New York
*Chapter 20: Acquired Heart
Disease*

M. Sean Grady, MD, FACS
Charles Harrison Frazier Professor
and Chairman
Department of Neurosurgery
University of Pennsylvania School
of Medicine
Philadelphia, Pennsylvania
Chapter 41: Neurosurgery

Eugene A. Grossi, MD
Professor of Surgery, Cardiothoracic
Surgery
New York University School of
Medicine
New York, New York
*Chapter 20: Acquired Heart
Disease*

David J. Hackam, MD, PhD
Assistant Professor of Surgery, Cell
Biology and Physiology
University of Pittsburgh School of
Medicine
Attending Pediatric Surgeon
Co-Director, Fetal Diagnosis and
Treatment Center
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 38: Pediatric Surgery

Scott L. Hansen, MD
Resident, Plastic and Reconstructive
Surgery
University of California, San
Francisco
San Francisco, California
*Chapter 15: Skin and Subcutaneous
Tissue*

Brain G. Harbrecht, MD, FACS
Associate Professor of
Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 4: Shock

Rosemarie E. Hardin, MD
Resident
Department of Surgery
State University of New York Health
Science Medical Center
Brooklyn, New York
*Chapter 44: Surgical
Considerations in the
Elderly*

David M. Heimbach, MD, FACS
Professor of Surgery
University of Washington Burn
Center
Harborview Medical Center
Seattle, Washington
Chapter 7: Burns

James H. Holmes, MD
Burn Fellow & Acting Instructor in
Surgery
Harborview Medical Center—
University of Washington
Seattle, Washington
Chapter 7: Burns

Abhinav Humar, MD, FRCS (Can)
Associate Professor
Department of Surgery
University of Minnesota
Minneapolis, Minnesota
Chapter 10: Transplantation

John G. Hunter, MD, FACS
Mackenzie Professor and Chairman
of Surgery
Department of Surgery
Oregon Health and Science
University
Portland, Oregon
*Chapter 13: Minimally-Invasive
Surgery*
*Chapter 31: Gallbladder and
Extrahepatic Biliary
System*

**William W. Hurd, MD, FACOG,
FACS**
Nicholas J. Thompson Professor and
Chair
Department of Obstetrics and
Gynecology

Wright State University School of
Medicine
Dayton, Ohio
Chapter 40: Gynecology

Bernard M. Jaffe, MD
Professor of Surgery
Tulane University School of
Medicine
New Orleans, Louisiana
Chapter 29: The Appendix

Blair A. Jobe, MD
Assistant Professor
Department of Surgery
Oregon Health and Science
University
Portland, Oregon
*Chapter 13: Minimally-Invasive
Surgery*

Tara B. Karamlou, MD
Senior Research Fellow
Division of Cardiothoracic Surgery
Oregon Health and Science
University
Portland, Oregon
*Chapter 19: Congenital heart
Disease*

Hyung L. Kim, MD
Assistant Professor
Department of Urology
Department of Cellular Stress
Biology
Roswell Park Cancer Institute
Buffalo, New York
Chapter 39: Urology

John Y. S. Kim, MD
Assistant Professor, Division of
Plastic Surgery
Department of Surgery
Northwestern University School of
Medicine
Chicago, Illinois
*Chapter 43: Plastic and
Reconstructive Surgery*

Rosemary A. Kozar, MD, PhD
Associate Professor of Surgery
University of Texas-Houston

Houston, Texas
*Chapter 2: Fluid and Electrolyte
Management of the Surgical
Patient*

Greeta Lal, MD
Assistant Professor of Surgery
Surgical Oncology and Endocrine
Surgery
University of Iowa Hospital and
Clinics
Iowa City, Iowa
*Chapter 37: Thyroid, Parathyroid,
and Adrenal*

Scott A. LeMaire, MD
Assistant Professor
Division of Cardiothoracic Surgery
Baylor College of Medicine
The Methodist DeBakey Heart
Center
Houston, Texas
*Chapter 21: Thoracic Aortic
Aneurysms and Aortic
Dissection*

Edward Lin, DO, CNSP
Assistant Professor of Surgery
Division of Gastrointestinal and
General Surgery
Surgical Metabolism Laboratory
Emory University School of
Medicine
Atlanta, Georgia
*Chapter 1: Systemic Response to
Injury and Metabolic Support*

Peter H. Lin, MD
Associate Professor of Surgery
Division of Vascular Surgery and
Endovascular Therapy
Michael E. DeBakey Department of
Surgery
Baylor College of Medicine
Houston, Texas
Chapter 22: Arterial Disease

Xia Lin, PhD
Assistant Professor of Surgery
Division of General Surgery
Michael E. DeBakey Department of
Surgery

Baylor College of Medicine
Houston, Texas
*Chapter 14: Cell, Genomics, and
Molecular Surgery*

Steven F. Lowry, MD, FACS
Professor and Chairman
Department of Surgery
UMDNJ - Robert Wood Johnson
Medical School
New Brunswick, New Jersey
*Chapter 1: Systemic Response to
Injury and Metabolic
Support*

James D. Luketich, MD
Professor and Chief, Division of
Thoracic and Foregut
Surgery
University of Pittsburgh Medical
Center
Pittsburgh, Pennsylvania
*Chapter 18: Chest Wall, Lung,
Mediastinum, and Pleura*

Alan B. Lumsden, MD
Professor of Surgery
Division of Vascular Surgery and
Endovascular Therapy
Michael E. DeBakey Department of
Surgery
Baylor College of Medicine
Houston, Texas
Chapter 22: Arterial Disease

Michael A. Maddaus, MD, FACS
Professor and Head, Section of
General Thoracic Surgery
Garamella-Lynch-Jensen Chair in
Thoracic and Cardiovascular
Surgery
Co-Director, Minimally Invasive
Surgery Center
University of Minnesota
Minneapolis, Minnesota
*Chapter 18: Chest Wall, Lung,
Mediastinum, and Pleura*

Stephen J. Mathes, MD
Professor of Surgery
Chief, Division of Plastic and
Reconstructive Surgery

University of California, San
Francisco
San Francisco, California
*Chapter 15: Skin and Subcutaneous
Tissue*

Jeffrey B. Matthews, MD, FACS
Christian R. Holmes Professor and
Chairman
Department of Surgery
University of Cincinnati
Cincinnati, Ohio
*Chapter 14: Cell, Genomics,
and Molecular Surgery*

Rodrick McKinlay, MD
Gastrointestinal and Minimally
Invasive Surgery
Rocky Mountain Associated
Physicians
Salt Lake City, Utah
Chapter 33: Spleen

**Funda Meric-Bernstam, MD,
FACS**
Assistant Professor
Department of Surgical Oncology
University of Texas M. D. Anderson
Cancer Center
Houston, Texas
Chapter 9: Oncology

Gregory L. Moneta, MD
Professor and Chief Vascular
Surgery
Oregon Health and Science
University
Portland, Oregon
*Chapter 23: Venous and Lymphatic
Disease*

Ernest E. Moore, MD, FACS
Professor and Vice Chairman,
Department of Surgery
University of Colorado Health
Sciences Center
Chief of Surgery and Trauma
Services
Denver Health Medical
Center
Denver, Colorado
Chapter 6: Trauma

Frederick A. Moore, MD

James H. "Red" Duke, Jr. Professor
& Vice Chairman

Department of Surgery
The University of Texas Houston
Medical School
Houston, Texas

*Chapter 2: Fluid and Electrolyte
Management of the Surgical
Patient*

Martina F. Mutone, MD

Clinical Assistant Professor
Indiana University/Methodist
Hospital
St. Vincent Hospitals and Health
Services

Indianapolis, Indiana
Chapter 40: Gynecology

Kurt Newman, MD, FACS

Executive Director and Surgeon in
Chief

Joseph E. Robert, Jr. Center for
Surgical Care
Children's National Medical
Center

Professor of Surgery and
Pediatrics
George Washington University
School of Medicine
Washington, D.C.
Chapter 38: Pediatric Surgery

Liz Nguyen, MD

Surgery Resident
Baylor College of Medicine
Houston, Texas
*Chapter 46: ACGME Core
Competencies*

Margrét Oddsdóttir, MD

Professor of Surgery
Chief of General Surgery
Landspítali-University
Hospital
Hringbraut
Reykjavik, Iceland
*Chapter 31: Gallbladder and the
Extrahepatic Biliary
System*

**Adrian E. Park, MD, FRCS(C),
FACS**

Campbell and Jeanette Plugge
Professor of Surgery
Chief, Division of General Surgery,
Department of Surgery, University
of Maryland Medical Center
Baltimore, Maryland
Chapter 33: Spleen

Andre B. Peitzman, MD, FACS

Professor and Vice-Chairman,
Department of Surgery
University of Pittsburgh Medical
Center
Pittsburgh, Pennsylvania
Chapter 4: Shock

J. Martin Perez MD

Assistant Professor of Surgery
Trauma and Surgical Critical
Care
University of Medicine and
Dentistry of New Jersey
New Brunswick, New Jersey
*Chapter 1: Systemic Response to
Injury and Metabolic Support*

Jeffrey H. Peters, MD, FACS

Seymour I. Schwartz Professor and
Chairman
University of Rochester School of
Medicine and Dentistry
Surgeon-in-Chief Strong Memorial
Hospital
Department of Surgery
Rochester, New York
*Chapter 24: Esophagus and
Diaphragmatic Hernia*

**Raphael E. Pollock, MD, PhD,
FACS**

Head, Division of Surgery
Professor and Chairman
Department of Surgical Oncology
Senator A.M. Aiken, Jr.,
Distinguished Chair
The University of Texas M. D.
Anderson Cancer Center
Houston, Texas
*Chapter 9: Oncology
Chapter 35: Soft Tissue Sarcomas*

Robert E. Rogers, MD

Emeritus Professor, Obstetrics and
Gynecology
Indiana University School of
Medicine
Indianapolis, Indiana
Chapter 40: Gynecology

Forrest S. Roth, MD

Fellow in Plastic Reconstructive and
Microsurgery
Division of Plastic and

Preface

This manual, crafted for easy portability and convenient reference by surgical students and house officers, is intended as a supplement to the eighth edition of *Schwartz's Principles of Surgery*. These condensed chapters, edited by their original authors, provide a concise synopsis of each chapter and are meant as a companion to the main text. I am grateful for the efforts of all whom contributed and their willingness and dedication to further the education of students of surgery.

I also express my deep appreciation to Katie Elsbury, who worked with the contributors, the publisher, and with me in every step of the production of this book.

F. Charles Brunickardi, MD, FACS

PART I | BASIC CONSIDERATIONS

This page intentionally left blank

Systemic Response to Injury and Metabolic Support

*J. Martin Perez, Edward Lim, Steven E. Calvano,
and Stephen F. Lowry*

The inflammatory response to injury is designed to restore tissue function and eradicate invading microorganisms. Injuries of limited duration are usually followed by functional restoration with minimal intervention. By contrast, major insults to the host are associated with an overwhelming inflammatory response that, without appropriate and timely intervention, can lead to multiple-organ failure and adversely impact patient survival. Therefore, understanding how the inflammatory response is mobilized and controlled provides a functional framework on which interventions and therapeutics are formulated for the surgical patient.

This chapter addresses the hormonal, immunologic, and cellular responses to injury. Alterations of metabolism and nutrition in injury states are discussed in continuum because the utilization of fuel substrates during injury also is subject to the influences of hormonal and inflammatory mediators.

THE SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

The systemic response to injury can be broadly compartmentalized into two phases: (1) a proinflammatory phase characterized by activation of cellular processes designed to restore tissue function and eradicate invading microorganisms, and (2) an antiinflammatory (*counterregulatory* phase) that is important for preventing excessive proinflammatory activities and restoring homeostasis in the individual (Table 1-1).

CENTRAL NERVOUS SYSTEM REGULATION OF INFLAMMATION

Reflex Inhibition of Inflammation

The central nervous system (CNS), via autonomic signaling, has an integral role in regulating the inflammatory response that is primarily involuntary. The autonomic system regulates heart rate, blood pressure, respiratory rate, gastrointestinal (GI) motility, and body temperature. The autonomic nervous system also regulates inflammation in a reflex manner, much like the patellar tendon reflex. The site of inflammation sends afferent signals to the hypothalamus, which in turn rapidly relays opposing antiinflammatory messages to reduce inflammatory mediator release by immunocytes.

Afferent Signals to the Brain

The CNS receives immunologic input from both the circulation and neural pathways. Areas of the CNS devoid of blood-brain barrier admit the passage of inflammatory mediators such as tumor necrosis factor (TNF)- α . Fevers, anorexia, and depression in illness are attributed to the humoral (circulatory) route of inflammatory signaling. Although the mechanism for vagal sensory input is not fully understood, it has been demonstrated that afferent stimuli

TABLE 1-1 Clinical Spectrum of Infection and Systemic Inflammatory Response Syndrome (SIRS)

Term	Definition
Infection	Identifiable source of microbial insult
SIRS	Two or more of following criteria Temperature $\geq 38^{\circ}\text{C}$ or $\leq 36^{\circ}\text{C}$ Heart rate ≥ 90 beats/min Respiratory rate ≥ 20 breaths/min or $\text{Paco}_2 \leq 32$ mm Hg or mechanical ventilation White blood cell count $\geq 12,000/\mu\text{L}$ or $\leq 4000/\mu\text{L}$ or $\geq 10\%$ band forms
Sepsis	Identifiable source of infection + SIRS
Severe sepsis	Sepsis + organ dysfunction
Septic shock	Sepsis + cardiovascular collapse (requiring vasopressor support)

to the vagus nerve include cytokines (e.g., $\text{TNF-}\alpha$ and interleukin [IL]-1), baroreceptors, chemoreceptors, and thermoreceptors originating from the site of injury.

Cholinergic Antiinflammatory Pathways

Acetylcholine, the primary neurotransmitter of the parasympathetic system, reduces tissue macrophage activation. Furthermore, cholinergic stimulation directly reduces tissue macrophage release of the proinflammatory mediators $\text{TNF-}\alpha$, IL-1, IL-18, and high mobility group protein (HMG-1), but not the antiinflammatory cytokine IL-10. The attenuated inflammatory response induced by cholinergic stimuli was further validated by the identification of acetylcholine (nicotinic) receptors on tissue macrophages.

In summary, vagal stimulation reduces heart rate, increases gut motility, dilates arterioles, and causes pupil constriction, and regulates inflammation. Unlike the humoral antiinflammatory mediators, signals discharged from the vagus nerve are targeted at the site of injury or infection. Moreover, this cholinergic signaling occurs rapidly in real time.

HORMONAL RESPONSE TO INJURY

Hormone Signaling Pathways

Hormones are chemically classified as *polypeptides* (e.g., cytokines, glucagon, and insulin), *amino acids* (e.g., epinephrine, serotonin, and histamine), or *fatty acids* (e.g., glucocorticoids, prostaglandins, and leukotrienes [LT]). Most hormone receptors generate signals by one of three major overlapping pathways: (1) *receptor kinases* such as insulin and insulin-like growth factor receptors, (2) *guanine nucleotide-binding or G-protein receptors* such as neurotransmitter and prostaglandin receptors, (3) *ligand-gated ion channels*, which permit ion transport when activated. Membrane receptor activation leads to amplification via secondary signaling pathways. Hormone signals are further mediated by intracellular receptors with binding affinities for both the hormone itself, and for the targeted gene sequence on the deoxyribonucleic acid (DNA). The classic example of a cytosolic hormonal receptor is the glucocorticoid (GC) receptor.

TABLE 1-2 Hormones Regulated by the Hypothalamus, Pituitary, and Autonomic System

Hypothalamic Regulation

Corticotropin-releasing hormone
 Thyrotropin-releasing hormone
 Growth hormone-releasing hormone
 Luteinizing hormone-releasing hormone

Anterior Pituitary Regulation

Adrenocorticotrophic hormone
 Cortisol
 Thyroid-stimulating hormone
 Thyroxine
 Triiodothyronine
 Growth hormone
 Gonadotrophins
 Sex hormones
 Insulin-like growth factor
 Somatostatin
 Prolactin
 Endorphins

Posterior Pituitary Regulation

Vasopressin
 Oxytocin

Autonomic System

Norepinephrine
 Epinephrine
 Aldosterone
 Renin-angiotensin system
 Insulin
 Glucagon
 Enkephalins

Hormones of the hypothalamic-pituitary-adrenal (HPA) axis influences the physiologic response to injury and stress (Table 1-2), but some with direct influence on the inflammatory response or immediate clinical impact will be highlighted.

Adrenocorticotrophic Hormone

Adrenocorticotrophic hormone (ACTH) is synthesized and released by the anterior pituitary. In healthy humans, ACTH release is regulated by circadian signals with high levels of ACTH occurring late at night until the hours immediately before sunrise. During injury, this pattern is dramatically altered. Elevations in corticotropin-releasing hormone and ACTH are typically proportional to the severity of injury. Pain, anxiety, vasopressin, angiotensin II, cholecystokinin, vasoactive intestinal polypeptide (VIP), catecholamines, and proinflammatory cytokines are all prominent mediators of ACTH release in the injured patient.

Cortisol and Glucocorticoids

Cortisol is the major glucocorticoid in humans and is essential for survival during significant physiologic stress. Following injury, the degree of cortisol elevation is dependent on the degree of systemic stress. For example, burn

patients have elevated circulating cortisol levels for up to 4 weeks, whereas lesser injuries may exhibit shorter periods of cortisol elevation.

Cortisol potentiates the actions of glucagon and epinephrine that manifest as hyperglycemia. Cortisol stimulates gluconeogenesis, but induces insulin resistance in muscles and adipose tissue. In skeletal muscle, cortisol induces protein degradation and the release of lactate that serve as substrates for hepatic gluconeogenesis. During injury, cortisol potentiates the release of free fatty acids, triglycerides, and glycerol from adipose tissue providing additional energy sources.

Acute adrenal insufficiency (AAI) secondary to exogenous glucocorticoid administration can be a life-threatening complication most commonly seen in acutely ill patients. These patients present with weakness, nausea, vomiting, fever, and hypotension. Objective findings include hypoglycemia from decreased gluconeogenesis, hyponatremia, and hyperkalemia. Insufficient mineralocorticoid (aldosterone) activity also contributes to hyponatremia and hyperkalemia.

Glucocorticoids have long been employed as immunosuppressive agents. Immunologic changes associated with glucocorticoid administration include thymic involution, depressed cell-mediated immune responses reflected by decreases in T-killer and natural killer cell functions, T-lymphocyte blastogenesis, mixed lymphocyte responsiveness, graft-versus-host reactions, and delayed hypersensitivity responses. With glucocorticoid administration, monocytes lose the capacity for intracellular killing but appear to maintain normal chemotactic and phagocytic properties. For neutrophils, glucocorticoids inhibit intracellular superoxide reactivity, suppress chemotaxis, and normalize apoptosis signaling mechanisms. However, neutrophil phagocytosis function remains unchanged. Clinically, glucocorticoids has been associated with modest reductions in proinflammatory response in septic shock, surgical trauma, and coronary artery bypass surgery. However, the appropriate dosing, timing, and duration of glucocorticoid administration have not been validated.

Macrophage Inhibitory Factor

Macrophage inhibitory factor (MIF) is a glucocorticoid antagonist produced by the anterior pituitary that potentially reverses the immunosuppressive effects of glucocorticoids. MIF can be secreted systemically from the anterior pituitary and by T lymphocytes situated at the sites of inflammation. MIF is a proinflammatory mediator that potentiates gram-negative and gram-positive septic shock.

Growth Hormones and Insulin-Like Growth Factors

During periods of stress, growth hormone (GH), mediated in part by the secondary release of insulin-like growth factor-1 (IGF-1), promotes protein synthesis and enhances the mobilization of fat stores. IGF, formerly called somatomedin C, circulates predominantly in bound form and promotes amino acid incorporation, cellular proliferation, skeletal growth, and attenuates proteolysis. In the liver, IGFs are mediators of protein synthesis and glycogenesis. In adipose tissue, IGF increases glucose uptake and fat utilization. In skeletal muscles, IGF increases glucose uptake and protein synthesis. The decrease in protein synthesis and observed negative nitrogen balance following injury is attributed in part to a reduction in IGF-1 levels. GH administration has improved

the clinical course of pediatric burn patients. Its use in injured adult patients remains unproven.

Catecholamines

The hypermetabolic state observed following severe injury is attributed to activation of the adrenergic system. Norepinephrine (NE) and epinephrine (EPI) are increased 3- to 4-fold in plasma immediately following injury, with elevations lasting 24–48 hours before returning toward baseline levels.

In the liver, EPI promotes glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis. It also causes decreased insulin release, but increases glucagon secretion. Peripherally, EPI increases lipolysis in adipose tissues and induces insulin resistance in skeletal muscle. These collectively manifest as stress-induced hyperglycemia, not unlike the effects of cortisol on blood sugar.

Like cortisol, EPI enhances leukocyte demargination with resultant neutrophilia and lymphocytosis. However, EPI occupation of β receptors present on leukocytes ultimately decreases lymphocyte responsiveness to mitogens.

In noncardiac surgical patients with heart disease, perioperative β -receptor blockade also reduced sympathetic activation and cardiac oxygen demand with significant reductions in cardiac-related deaths.

Aldosterone

The mineralocorticoid aldosterone is synthesized, stored, and released, via ACTH stimulation, in the adrenal zona glomerulosa. The major function of aldosterone is to maintain intravascular volume by conserving sodium and eliminating potassium and hydrogen ions in the early distal convoluted tubules of the nephrons.

Patients with aldosterone deficiency develop hypotension and hyperkalemia, whereas patients with aldosterone excess develop edema, hypertension, hypokalemia, and metabolic alkalosis.

Insulin

Hormones and inflammatory mediators associated with stress response inhibit insulin release. In conjunction with peripheral insulin resistance following injury, this results in stress-induced hyperglycemia and is in keeping with the general catabolic state immediately following major injury.

In the healthy individual, insulin exerts a global anabolic effect by promoting hepatic glycogenesis and glycolysis, glucose transport into cells, adipose tissue lipogenesis, and protein synthesis. During injury, insulin release is initially suppressed followed by normal or excessive insulin production despite hyperglycemia.

Activated lymphocytes express insulin receptors, and activation enhances T-cell proliferation and cytotoxicity. Tight control of glucose levels in the critically ill has been associated with significant reductions in morbidity and mortality.

Acute Phase Proteins

The acute phase proteins are nonspecific biochemical markers produced by hepatocytes in response to tissue injury, infection, or inflammation. IL-6 is a potent inducer of acute phase proteins that can include proteinase inhibitors, coagulation and complement proteins, and transport proteins. Only C-reactive

protein (CRP) has been consistently used as a marker of injury response because of its dynamic reflection of inflammation. The accuracy of CRP appears to surpass that of the erythrocyte sedimentation rate.

MEDIATORS OF INFLAMMATION

Cytokines

Cytokines are the most potent mediators of the inflammatory response. When functioning locally at the site of injury or infection, cytokines eradicate invading microorganisms and promote wound healing. Overwhelming production of proinflammatory cytokines in response to injury can cause hemodynamic instability (e.g., septic shock) or metabolic derangements (e.g., muscle wasting). If uncontrolled, the outcome of these exaggerated responses is end-organ failure and death. The production of antiinflammatory cytokines serves to oppose the actions of proinflammatory cytokines. To view cytokines merely as proinflammatory or antiinflammatory oversimplifies their functions, and overlapping bioactivity is the rule (Table 1-3).

Heat Shock Proteins

Hypoxia, trauma, heavy metals, local trauma, and hemorrhage all induce the production of intracellular heat shock proteins (HSPs). HSPs are intracellular protein modifiers and transporters that are presumed to protect cells from the deleterious effects of traumatic stress. The formation of HSPs requires gene induction by the heat shock transcription factor.

Reactive Oxygen Metabolites

Reactive oxygen metabolites are short-lived, highly reactive molecular oxygen species with an unpaired outer orbit. Tissue injury is caused by oxidation of unsaturated fatty acids within cell membranes. Activated leukocytes are potent generators of reactive oxygen metabolites. Furthermore, ischemia with reperfusion also generates reactive oxygen metabolites.

Oxygen radicals are produced by complex processes that involve anaerobic glucose oxidation coupled with the reduction of oxygen to superoxide anion. Superoxide anion is an oxygen metabolite that is further metabolized to other reactive species such as hydrogen peroxide and hydroxyl radicals. Cells are generally protected by oxygen scavengers that include glutathione and catalases.

Eicosanoids

The eicosanoid class of mediators, which encompasses prostaglandins (PGs), thromboxanes (TXs), LTs, hydroxy-icosatetraenoic acids (HETEs), and lipoxins (LXs), are oxidation derivatives of the membrane phospholipid arachidonic acid (eicosatetraenoic acid). Eicosanoids are secreted by virtually all nucleated cells except lymphocytes. Products of the cyclooxygenase pathway include all of the prostaglandins and thromboxanes. The lipoxygenase pathway generates the LT and HETE.

Eicosanoids are synthesized rapidly on stimulation by hypoxic injury, direct tissue injury, endotoxin, NE, vasopressin, angiotensin II, bradykinin, serotonin, acetylcholine, cytokines, and histamine. COX-2, a second cyclooxygenase enzyme, converts arachidonate to prostaglandin E₂ (PGE₂). PGE₂ increases

TABLE 1-3 Cytokines and Their Sources

Cytokine	Source	Comment
TNF- α	<i>Macrophages/monocytes</i> Kupffer cells Neutrophils NK cells Astrocytes Endothelial cells T lymphocytes Adrenal cortical cells Adipocytes Keratinocytes Osteoblasts Mast cells Dendritic cells	Among earliest responders following injury; half-life <20 min; activates TNF-receptor-1 and -2; induces significant shock and catabolism
IL-1	<i>Macrophages/monocytes</i> B and T lymphocytes NK cells Endothelial cells Epithelial cells Keratinocytes Fibroblasts Osteoblasts Dendritic cells Astrocytes Adrenal cortical cells Megakaryocytes Platelets Neutrophils Neuronal cells	Two forms (IL- α and IL- β); similar physiologic effects as TNF- α ; induces fevers through prostaglandin activity in anterior hypothalamus; promotes β -endorphin release from pituitary; half-life <6 min
IL-2	<i>T lymphocytes</i>	Promotes lymphocyte proliferation, immunoglobulin production, gut barrier integrity; half-life <10 min; attenuated production following major blood loss leads to immunocompromise; regulates lymphocyte apoptosis
IL-3	<i>T lymphocytes</i> Macrophages Eosinophils Mast cells	
IL-4	<i>T lymphocytes</i> Mast cells Basophils Macrophages B lymphocytes Eosinophils Stromal cells	Induces B-lymphocyte production of IgG4 and IgE, mediators of allergic and anthelmintic response; downregulates TNF- α , IL-1, IL-6, IL-8
IL-5	<i>T lymphocytes</i> Eosinophils Mast cells Basophils	Promotes eosinophil proliferation and airway inflammation
IL-6	<i>Macrophages</i> B lymphocytes Neutrophils Basophils Mast cells Fibroblasts	Elicited by virtually all immunogenic cells; long half-life; circulating levels proportional to injury severity; prolongs activated neutrophil survival

(continued)

TABLE 1-3 *Continued*

Cytokine	Source	Comment
	Endothelial cells Astrocytes Synovial cells Adipocytes Osteoblasts Megakaryocytes Chromaffin cells Keratinocytes	
IL-8	<i>Macrophages/monocytes</i> T lymphocytes Basophils Mast cells Epithelial cells Platelets	Chemoattractant for neutrophils, basophils, eosinophils, lymphocytes
IL-10	<i>T lymphocytes</i> B lymphocytes Macrophages Basophils Mast cells Keratinocytes	Prominent anti-inflammatory cytokine; reduces mortality in animal sepsis and ARDS models
IL-12	<i>Macrophages/monocytes</i> Neutrophils Keratinocytes Dendritic cells B lymphocytes	Promotes T _H 1 differentiation; synergistic activity with IL-2
IL-13	<i>T lymphocytes</i>	Promotes B-lymphocyte function; structurally similar to IL-4; inhibits nitric oxide and endothelial activation
IL-15	<i>Macrophages/monocytes</i> Epithelial cells	Anti-inflammatory effect; promotes lymphocyte activation; promotes neutrophil phagocytosis in fungal infections
IL-18	<i>Macrophages</i> Kupffer cells Keratinocytes Adrenal cortical cells Osteoblasts	Similar to IL-12 in function; elevated in sepsis, particularly gram-positive infections; high levels found in cardiac deaths
IFN- γ	<i>T lymphocytes</i> NK cells Macrophages	Mediates IL-12 and IL-18 function; half-life, days; found in wounds 5–7 days after injury; promotes ARDS
GM-CSF	<i>T lymphocytes</i> Fibroblasts Endothelial cells Stromal cells	Promotes wound healing and inflammation through activation of leukocytes
IL-21	<i>T lymphocytes</i>	Preferentially secreted by T _H 2 cells; structurally similar to IL-2 and IL-15; activates NK cells, B and T lymphocytes; influences adaptive immunity
HMGB-1	<i>Monocytes/lymphocytes</i>	High mobility group box chromosomal protein; DNA transcription factor; late (downstream) mediator of inflammation (ARDS, gut barrier disruption); induces “sickness behavior”

ARDS = acute respiratory distress syndrome; GM-CSF = granulocyte-macrophage colony-stimulating factor; IFN = interferon; IgE = immunoglobulin E; IgG = immunoglobulin G; IL = interleukin; NK = natural killer; T_H1 = T helper subset cell 1; T_H2 = T helper subset cell 2; TNF = tumor necrosis factor.

fluid leakage from blood vessels, but a rising PGE₂ level over several hours eventually feeds back to COX-2 and induces the formation of the antiinflammatory lipoxin from neutrophils. Nonsteroidal antiinflammatory drugs (NSAIDs) reduce the PGE₂ levels by COX-2 acetylation and increases lipoxin production. COX-2 activity also can be inhibited by glucocorticoids.

Eicosanoids have diverse effects systemically on endocrine and immune function, neurotransmission, and vasomotor regulation. Eicosanoids are implicated in acute lung injury, pancreatitis, and renal failure. LT are effective promoters of leukocyte adherence, neutrophil activation, bronchoconstriction, and vasoconstriction.

Eicosanoids are involved in the regulation of glucose, with the products of the cyclooxygenase pathway inhibiting pancreatic β -cell release of insulin, whereas products of the lipoxygenase pathway promote β -cell activity. Hepatocyte PGE₂ receptors, when activated, inhibit gluconeogenesis. PGE₂ also can inhibit hormone-stimulated lipolysis.

Fatty Acid Metabolites

Fatty acid metabolism potentially has a role in the inflammatory response. Omega-6 fatty acids, most commonly the primary lipid source in enteral nutrition formulas, also serve as precursors of inflammatory mediators, such as the eicosanoids, and are associated with injury and the stress response. Animal studies substituting omega-3 for omega-6 fatty acids have demonstrated attenuated inflammatory response in hepatic Kupffer cells as measured by TNF and IL-1 release and PGE₂ production.

Kallikrein-Kinin System

Bradykinins are potent vasodilators that are produced through kininogen degradation by the serine protease kallikrein. Kinins increase capillary permeability and tissue edema, evoke pain, inhibit gluconeogenesis, and increase bronchoconstriction. An increase in renin secondary to reduced renal perfusion promotes sodium and water retention via the renin-angiotensin system.

Increased bradykinin levels are observed following hypoxia, reperfusion, hemorrhage, sepsis, endotoxemia, and tissue injury. These elevations are proportional to the magnitude of injury and mortality. Clinically, bradykinin antagonists in septic shock studies have only demonstrated modest reversal in gram-negative sepsis, but no overall improvement in survival.

Serotonin

The neurotransmitter serotonin (5-hydroxytryptamine, 5-HT) is a tryptophan derivative that is found in chromaffin cells of the intestine and in platelets. Serotonin stimulates vasoconstriction, bronchoconstriction, and platelet aggregation. Although serotonin is clearly released at sites of injury, its role in the inflammatory response is unclear.

Histamine

Histamine is derived from histidine and stored in neurons, skin, gastric mucosa, mast cells, basophils, and platelets. There are two receptor types (H₁ and H₂) for histamine binding. H₁ receptor binding stimulates bronchoconstriction, intestinal motility, and myocardial contractility. H₂ receptor binding inhibits histamine release. Both H₁ and H₂ receptor activation induce

hypotension, peripheral pooling of blood, increased capillary permeability, decreased venous return, and myocardial failure. The rise in histamine levels has been documented in hemorrhagic shock, trauma, thermal injury, endotoxemia, and sepsis.

CYTOKINE RESPONSE TO INJURY

Tumor Necrosis Factor

TNF- α is among the earliest and most potent mediators of the inflammatory host responses. TNF- α synthesis occurs in monocytes/macrophages and T cells, which are abundant in the peritoneum, splanchnic tissues, and liver (Kupffer cells). Although the half-life of TNF- α is less than 20 minutes, this is sufficient to evoke marked muscle catabolism and cachexia during stress, hemodynamic changes, and activate mediators distally in the cytokine cascade. TNF- α also promotes coagulation activation, the expression or release of adhesion molecules, prostaglandin E₂, platelet-activating factor (PAF), glucocorticoids, and eicosanoids.

Soluble TNF receptors (sTNFRs) are proteolytically cleaved extracellular domains of membrane-associated TNFRs that are elevated and readily detectable in acute inflammation. sTNFRs retain their affinity for the binding of TNF- α and therefore compete with the cellular receptors for the binding of free TNF- α . This may represent a counterregulatory response to excessive systemic TNF- α activity or serve as a carrier of bioactive TNF- α .

Interleukin-1

IL-1 (IL-1 α and IL-1 β) is primarily released by activated macrophages and endothelial cells. IL-1 α is predominantly cell membrane-associated and exerts its influence via cellular contacts. IL-1 β is more readily detectable in the circulation and is similar in its effects to TNF- α . High doses of either IL-1 or TNF- α initiate a state of hemodynamic decompensation. At low doses, they can produce the same response only if administered simultaneously. TNF- α and IL-1 appear to have synergy in the inflammatory response. IL-1 is predominantly a local mediator with a half-life of approximately 6 minutes. IL-1 induces the febrile response to injury by stimulating local prostaglandin activity in the anterior hypothalamus.

Endogenous IL-1 receptor antagonists (IL-1ra) also are released during injury and serve as an endogenous auto-regulator of IL-1 activity.

Interleukin-2

IL-2 is a primary promoter of T-lymphocyte proliferation, immunoglobulin production, and gut barrier integrity. Partly because of its circulation half-life of less than 10 minutes, IL-2 has not been readily detectable following acute injury. Attenuated IL-2 expression associated with major injuries or perioperative blood transfusions potentially contribute to the transient immunocompromised state of the surgical patient.

Interleukin-4

IL-4 is produced by activated type 2 T-helper (T_H2) lymphocytes and is particularly important in antibody-mediated immunity and in antigen presentation. IL-4 also induces class switching in differentiating B lymphocytes to produce

predominantly IgG₄ and IgE, which are important immunoglobulins in allergic and anthelmintic responses. IL-4 has potent antiinflammatory properties against activated macrophages by downregulating the effects of IL-1, TNF- α , IL-6, and IL-8, and oxygen radical production. IL-4 also appears to increase macrophage susceptibility to the antiinflammatory effects of glucocorticoids.

Interleukin-6

TNF- α and IL-1 are potent inducers of IL-6 production from virtually all cells and tissues, including the gut. Circulating IL-6 levels appear to be proportional to the extent of tissue injury during an operation, more so than the duration of the surgical procedure itself. Recent evidence has demonstrated both a proinflammatory role and an antiinflammatory role for IL-6. IL-6 is an important mediator of the hepatic acute phase response during injury and convalescence, induces neutrophils activation, and paradoxically delays the disposal of activated neutrophils.

Interleukin-8

IL-8 is a chemoattractant and a potent activator of neutrophils. Expression and activity is similar to that of IL-6 after injury and has been proposed as an additional biomarker for the risk of multiple-organ failure. IL-8 does not produce the hemodynamic instability characteristic of TNF- α and IL-1.

Interleukin-10

IL-10 has emerged as a modulator of TNF- α activity. Experimental evidence has demonstrated that neutralization of IL-10 during endotoxemia increases monocyte TNF- α production and mortality, but restitution of IL-10 reduces TNF- α levels and the associated deleterious effects.

Interferon- γ

Human T-helper lymphocytes activated by bacterial antigens and interleukins readily produce IFN- γ . When released into the circulation, IFN- γ is detectable in vivo by 6 hours and may be persistently elevated for as long as 8 days. Injured tissues, such as operative wounds, also demonstrate the presence of IFN- γ production 5–7 days after injury. IFN- γ has important roles in activating circulating and tissue macrophages. Alveolar macrophage activation mediated by IFN- γ may induce acute lung inflammation after major surgery or trauma.

Granulocyte-Macrophage Colony-Stimulating Factor

Granulocyte-macrophage colony-stimulating factor (GM-CSF) delays apoptosis (programmed cell death) of macrophages and neutrophils. This growth factor is effective in promoting the maturation and recruitment of functional leukocytes necessary for normal inflammatory cytokine response, and potentially in wound healing. The delay in apoptosis may contribute to organ injury such as that found in acute respiratory distress syndrome (ARDS).

High Mobility Group Box-1

DNA transcription factor, HMGB-1, is released 24–48 hours after the onset of sepsis. The appearance of HMGB-1 is contrast to the early appearances of TNF- α , IL-1, IL-6, and IL-8. Clinically, HMGB-1 peak levels are associated

with ARDS and mortality. As a late mediator of the inflammatory response, anti-HMGB-1 strategies may be utilized to modify the inflammatory response.

CELLULAR RESPONSE TO INJURY

Gene Expression and Regulation

In the inflammatory response, cytokine production involves rapid ribonucleic acid (RNA) transcription and translation or protein synthesis. These proteins can further be modified in the cytosol for specific functions. In essence, these cytosolic modifications supplement the primary regulatory mechanisms within the nucleus.

How a particular gene is activated depends on the orderly assemblage of transcription factors to specific DNA sequences immediately upstream to the target gene, known as the *promoter region*. The DNA binding sites are the *enhancer sequences*, and proteins that inhibit the initiation of transcription are *repressors*. Transcription factors become important during the inflammatory response because the ability to control the pathways leading to their activation means the ability to regulate the manner and magnitude by which a cell can respond to an injury stimulus.

Cell Signaling Pathways

Heat Shock Proteins

HSPs, also known as stress proteins, are produced by cells in response to injury or tissue ischemia. HSPs are essential for the ability of cells to overcome stress. HSPs' primary role are to attenuate the inflammatory response by reducing oxygen metabolites, promoting T_H2 cell proliferation, and inhibiting nuclear factor (NF)- κ B activation.

G-Protein Receptors

Guanosine-5'-triphosphate (GTP)-binding proteins (G-proteins), with activation of an adjacent effector protein, are the largest family of signaling receptors for cells and include many of the pathways associated with the inflammatory response. The two major second messengers of the G-protein pathway are (a) formation of cyclic adenosine monophosphate (cAMP), and (b) calcium, released from the endoplasmic reticulum. An increase in cellular cAMP can activate gene transcription.

G-protein/calcium activation requires activation of the effector phospholipase C and phosphoinositols. G-protein signaling activates protein kinase C (PKC), which can in turn activate NF- κ B and other transcription factors.

Ligand-Gated Ion Channels

These receptor channels, when activated by a ligand, permit rapid flux of ions across the cell membrane. Neurotransmitters function by this pathway, and an example of such a receptor is the nicotinic acetylcholine receptor.

Receptor Tyrosine Kinases

Receptor tyrosine kinases have significant intracellular tyrosine kinase domains. Examples of these receptors include insulin and various hormone growth factors (e.g., platelet-derived growth factor [PDGF], IGF-1, epidermal growth factor [EGF], and vascular endothelial growth factor [VEGF]).

Activation of protein kinase receptors is important for gene transcription and cell proliferation.

Janus Kinase/Signal Transduction and Activator of Transcription (STAT) Signaling

Janus kinase (JAK) is the receptor for many cytokines. Ligand receptor interaction leads to receptor dimerization and enzymatic activation results in propagation through the JAK domains of the receptors. JAK mediated signaling via STAT mediated transcription can activate different T-cell responses during injury and inflammation.

Suppressors of Cytokine Signaling

Suppressors of cytokine signaling (SOCS) specifically block JAK and STAT activation and regulate the signaling of certain cytokines. A deficiency of SOCS activity may render a cell hypersensitive to certain stimuli such as inflammatory cytokines and growth hormones.

Mitogen-Activated Protein Kinases

The mitogen-activated protein kinase (MAPK) pathway is a major cellular inflammatory signaling pathway with regulatory roles over cell proliferation and cell death. The three major isoforms are the JNK (c-Jun NH₂-terminal kinase), ERK (extracellular regulatory protein kinase), and p38 kinase. The JNK pathway has clear links, via TNF- α and IL-1, to the inflammatory response with a regulatory role in apoptosis. The p38 kinase is activated in response to endotoxin, viruses, interleukins, TNF- α , and transforming growth factor (TGF)- β . P38-kinase activation triggers the recruitment and activation of leukocytes. MAPK isoforms exhibit appreciable "cross-talk," which can modulate the inflammatory response.

Nuclear Factor- κ B

NF- κ B activates genes important for the activation of proinflammatory cytokines and acute phase proteins. NF- κ B is really a complex of smaller proteins, and the p50-p65 heterodimer complex is the most widely studied. Cytosolic NF- κ B is maintained by binding to the inhibitor protein I- κ B. When a cell is exposed to an inflammatory stimulus (TNF- α or IL- β), a series of phosphorylation events leads to I- κ B degradation. Low intracellular I- κ B appears to prolong the inflammatory response and enhanced activity of NF- κ B appears to delay the apoptosis of activated immune cells.

Toll-Like Receptors and CD14

Lipopolysaccharide (LPS), an endotoxin, is an important mediator of gram-negative sepsis syndrome. LPS recognition and activation of the inflammatory response by immune cells occurs primarily by the toll-like receptor-4 (TLR4) mechanism. LPS-binding proteins (LBPs) carry LPS to the CD14/TLR4 complex, which sets into motion cellular mechanisms that activate MAPK, NF- κ B, and cytokine gene promoters. TLR4 is primarily the receptor for gram-negative endotoxins and TLR2 is the counterpart for gram-positive sepsis. The fact that some patient populations are more susceptible to infectious complications than others recently has been associated with specific point mutations in the TLR gene.

Tumor Necrosis Factor and CD95-Induced Apoptosis

Apoptosis is the principal mechanism by which senescent or dysfunctional cells, including macrophages and neutrophils, are systematically disposed of without activating other immunocytes or inducing an inflammatory response. The cellular environment created by systemic inflammation disrupts the normal apoptotic machinery in activated immunocytes, consequently prolonging the inflammatory response.

Several proinflammatory cytokines (e.g., TNF- α , IL-1, IL-3, IL-6, GM-CSF, granulocyte colony-stimulating factor [G-CSF], and IFN- γ) and bacterial products (e.g., endotoxin) have been shown to delay macrophage and neutrophil apoptosis *in vitro*, whereas IL-4 and IL-10 accelerate apoptosis in activated monocytes.

In acute inflammation, the response of the immunocyte to TNF- α is perhaps the most widely investigated. This cytokine exerts its biologic effects by binding to specific cellular receptors, tumor necrosis factor receptor (TNFR)-1 (55 kDa) and TNFR-2 (75 kDa). When TNFR-1 is exclusively activated, it precipitates circulatory shock reminiscent of severe sepsis. However, exclusive activation of TNFR-2 fails to induce any inflammatory responses or shock.

The activation of NF- κ B and JNK is believed to be the major antiapoptotic, and therefore proinflammatory, factor; it is signal induced by TNFR-1 and TNFR-2. It is well known that TNF- α -induced NF- κ B activation delays cell death and is associated with the activation of diverse genes that include proinflammatory mediators. Exaggerated peripheral blood monocyte NF- κ B activation has been associated with higher mortality rates in patients with septic shock.

The CD95 (Fas) receptor shares much of its intracellular structure with TNFR-1. Unlike TNFR-1, the only known function of CD95 is to initiate programmed cell death. Neutrophils and macrophages express CD95, and this expression may have important implications in the cellular contribution to the inflammatory response. In fact, both clinical sepsis and experimental endotoxemia have demonstrated prolonged survival of neutrophils and diminished responsiveness to CD95 stimuli.

Cell-Mediated Inflammatory Response

Platelets

Clot formation at the site of injury releases inflammatory mediators and serves as the principal chemoattractant for neutrophils and monocytes. The migration of platelets and neutrophils through the vascular endothelium occurs within 3 hours of injury and is mediated by serotonin release, platelet-activating factor, and prostaglandin E₂. Platelets can enhance or reduce neutrophil-mediated tissue injury by modulating neutrophil adherence to the endothelium and subsequent respiratory burst. Platelets are an important source of eicosanoids and vasoactive mediators. NSAIDs irreversibly inhibit thromboxane production.

Lymphocytes and T-Cell Immunity

Injury, surgical or traumatic, is associated with acute impairment of cell-mediated immunity and macrophage function. T-helper lymphocytes are functionally divided into two subgroups, referred to as T_H1 and T_H2. In severe infections and injury, there appears to be a reduction in T_H1 (cell-mediated immunity) cytokine production, with a lymphocyte population shift toward the

T_H2 response and its associated immunosuppressive effects. In patients with major burns, a shift to a T_H2 cytokine response has been a predictor of infectious complications. However, studies in patients undergoing major surgery have demonstrated a postoperative reduction in T_H1 cytokine production that is not necessarily associated with increased T_H2 response. Nevertheless, depressed T_H1 response and systemic immunosuppression following major insults to the host may be a useful paradigm in predicting the subset of patients who are prone to infectious complications and poor outcome.

Eosinophils

Eosinophils are characteristically similar to neutrophils in that they migrate to inflamed endothelium and release cytoplasmic granules that are cytotoxic. Eosinophils preferentially migrate to sites of parasitic infection and allergen challenge. Major activators of eosinophils include IL-3, GM-CSF, IL-5, platelet-activating factor, and complement anaphylatoxins C3a and C5a.

Mast Cells

Tissue resident mast cells are important as first-responders to sites of injury. Activated mast cells produce histamine, cytokines, eicosanoids, proteases, and chemokines. The immediate results are vasodilation, recruitment of other immunocytes, and capillary leakage. $TNF-\alpha$ is secreted rapidly by mast cells because of the abundant stores within granules. Mast cells also can synthesize a variety of cytokines and migration-inhibitory factor (MIF).

Monocytes

In clinical sepsis, nonsurviving patients with severe sepsis have an immediate reduction in monocyte surface TNFR expression with failure to recover, whereas surviving patients have normal or near-normal receptor levels from the onset of clinically defined sepsis.

Thus, TNFR expression potentially can be used as a prognostic indicator of outcome in patients with systemic inflammation. There is also decreased CD95 expression following experimental endotoxemia in humans, which correlates with diminished CD95-mediated apoptosis. Taken together, the reduced receptor expression and delayed apoptosis may be a mechanism for prolonging the inflammatory response during injury or infection.

Neutrophils

Neutrophils mediate important functions in every form of acute inflammation, including acute lung injury, ischemia/reperfusion injury, and inflammatory bowel disease. G-CSF is the primary stimulus for neutrophil maturation. Inflammatory mediators from a site of injury induce neutrophil adherence to the vascular endothelium and promote eventual cell migration into the injured tissue. Neutrophil function is mediated by a vast array of intracellular granules that are chemotactic or cytotoxic to local tissue and invading microorganisms.

ENDOTHELIUM-MEDIATED INJURY

Neutrophil-Endothelium Interaction

Increased vascular permeability during inflammation is intended to facilitate oxygen delivery and immunocyte migration to the sites of injury. However,

neutrophils migration and activation at sites of injury may contribute to the cytotoxicity of vital tissues and result in organ dysfunction. Ischemia/reperfusion (I/R) injury potentiates this response by unleashing oxygen metabolites, lysosomal enzymes that degrade tissue basal membranes, cause microvascular thrombosis, and activate myeloperoxidases. The recruitment of circulating neutrophils to endothelial surfaces is mediated by concerted actions of adhesion molecules referred to as selectins that are elaborated on cell surfaces.

Nitric Oxide

Nitric oxide (NO) is derived from endothelial surfaces in response to acetylcholine stimulation, hypoxia, endotoxin, cellular injury, or mechanical shear stress from circulating blood. NO promotes vascular smooth muscle relaxation, reduces microthrombosis, and mediates protein synthesis in hepatocytes. NO is formed from oxidation of L-arginine, a process catalyzed by nitric oxide synthase (NOS). NO is a readily diffusible substance with a half-life of a few seconds. NO spontaneously decomposes into nitrate and nitrite.

In addition to the endothelium, NO formation also occurs in neutrophils, monocytes, renal cells, Kupffer cells, and cerebellar neurons.

Prostacyclin

Although it is an arachidonate product, prostacyclin (PGI_2) is another important endothelium-derived vasodilator synthesized in response to vascular shear stress and hypoxia. PGI_2 shares similar functions with NO, inducing vasorelaxation and platelet deactivation by increasing cAMP. Clinically, it has been used to reduce pulmonary hypertension, particularly in the pediatric population.

Endothelins

Endothelins (ETs) are elaborated by vascular endothelial cells in response to injury, thrombin, transforming growth factor- β (TGF- β), IL-1, angiotensin II, vasopressin, catecholamines, and anoxia. ET is a 21-amino-acid peptide with potent vasoconstricting properties. Of the peptides in this family (e.g., ET-1, ET-2, and ET-3), endothelial cells appear to exclusively produce ET-1. ET-1 appears to be the most biologically active and the most potent known vasoconstrictor. It is estimated to be 10 times more potent than angiotensin II. The maintenance of physiologic tone in vascular smooth muscle depends on the balance between NO and ET production. Increased serum levels of ETs correlate with the severity of injury following major trauma, major surgical procedures, and in cardiogenic or septic shock.

Platelet-Activating Factor

Platelet-activating factor (PAF), an endothelial-derived product, is a natural phospholipid constituent of cell membranes, which under normal physiologic conditions is minimally expressed. During acute inflammation, PAF is released by neutrophils, platelets, mast cells, and monocytes, and is expressed at the outer leaflet of endothelial cells. PAF can further activate neutrophils and platelets and increase vascular permeability. Human sepsis is associated with a reduction in PAF-acetylhydrolase levels, which is the endogenous inactivator of PAF. Indeed, PAF-acetylhydrolase administration in patients with severe sepsis has shown some reduction in multiple organ dysfunction and mortality.

Atrial Natriuretic Peptides

Atrial natriuretic peptides (ANPs) are a family of peptides released primarily by atrial tissue, but are also synthesized by the gut, kidney, brain, adrenal glands, and endothelium. They induce vasodilation and fluid and electrolyte excretion. ANPs are potent inhibitors of aldosterone secretion and prevent reabsorption of sodium.

SURGICAL METABOLISM

The initial hours following surgical or traumatic injury are metabolically associated with a reduced total body energy expenditure and urinary nitrogen wasting. Following resuscitation and stabilization of the injured patient, a reprioritization of substrate utilization ensues to preserve vital organ function and for the repair of injured tissue. This phase of recovery also is characterized by augmented metabolic rates and oxygen consumption, enzymatic preference for readily oxidizable substrates such as glucose, and stimulation of the immune system.

Understanding the collective alterations, as a consequence of the inflammatory response, in amino acid (protein), carbohydrate, and lipid metabolism lays the foundation on which clinical metabolic and nutritional support can be implemented.

Metabolism Following Injury

Injuries or infections induce unique neuroendocrine and immunologic responses that differentiate injury metabolism from that of unstressed fasting. The magnitude of metabolic expenditure appears to be directly proportional to the severity of insult, with thermal injuries and severe infections having the highest energy demands. The increase in energy expenditure is mediated in part by sympathetic activation and catecholamine release.

Lipid Metabolism Following Injury

Lipids serve as a nonprotein and noncarbohydrate fuel sources that minimize protein catabolism in the injured patient, and lipid metabolism potentially influences the structural integrity of cell membranes and the immune response during systemic inflammation. Fat mobilization (lipolysis) occurs mainly in response to catecholamine stimulus of the hormone-sensitive triglyceride lipase. Other hormonal influences on lipolysis include adrenocorticotrophic hormone, catecholamines, thyroid hormone, cortisol, glucagon, growth hormone release, reduction in insulin levels, and increased sympathetic stimulus.

Lipid absorption. Adipose tissue provides fuel for the host in the form of free fatty acids and glycerol during critical illness and injury. Oxidation of 1 g of fat yields approximately 9 kcal of energy. Although the liver is capable of synthesizing triglycerides from carbohydrates and amino acids, dietary and exogenous sources provide the major source of triglycerides. Dietary lipids are not readily absorbable in the gut, but require pancreatic lipase and phospholipase within the duodenum to hydrolyze the triglycerides into free fatty acids and monoglycerides. The free fatty acids and monoglycerides are then readily absorbed by gut enterocytes, which resynthesize triglycerides by esterification of the monoglycerides with fatty acylcoenzyme A (acyl-CoA). Long-chain triglycerides (LCTs), defined as those with 12 carbons or more,

undergo esterification and enter the circulation through the lymphatic system as chylomicrons. Shorter fatty acid chains directly enter the portal circulation and are transported to the liver by albumin carriers. Hepatocytes use free fatty acids as a fuel source during stress states, but can also synthesize phospholipids or triglycerides (very-low-density lipoproteins) during fed states. Systemic tissue (e.g., muscle and the heart) can use chylomicrons and triglycerides as fuel by hydrolysis with lipoprotein lipase at the luminal surface of capillary endothelium. Trauma or sepsis suppresses lipoprotein lipase activity in both adipose tissue and muscle, presumably mediated by $\text{TNF-}\alpha$.

Lipolysis and fatty acid oxidation. Periods of energy demand are accompanied by free fatty acid mobilization from adipose stores. In adipose tissues, triglyceride lipase hydrolyzes triglycerides into free fatty acids and glycerol. Free fatty acids enter the capillary circulation and are transported by albumin to tissues requiring this fuel source (e.g., heart and skeletal muscle). Insulin inhibits lipolysis and favors triglyceride synthesis by augmenting lipoprotein lipase activity and intracellular levels of glycerol-3-phosphate. The use of glycerol for fuel depends on the availability of tissue glycerokinase, which is abundant in the liver and kidneys.

Free fatty acids absorbed by cells is conjugated with acyl-CoA within the cytoplasm and transported across membranes by the carnitine shuttle. Medium-chain triglycerides (MCTs), defined as those 6 to 12 carbons in length, bypass the carnitine shuttle and readily cross the mitochondrial membranes. This accounts in part for why MCTs are more efficiently oxidized than LCTs. Ideally, the rapid oxidation of MCTs makes them less prone to fat deposition, particularly within immune cells and the reticuloendothelial system—a common finding with lipid infusion in parenteral nutrition. However, in animal studies, exclusive use of MCTs as fuel is associated with higher metabolic demands and toxicity, as well as essential fatty acid deficiency.

Fatty acyl-CoA undergoes mitochondrial β -oxidation, which produces acetyl-CoA. Each acetyl-CoA molecule subsequently enters the tricarboxylic acid (TCA) cycle for further oxidation to yield 12 adenosine triphosphate (ATP) molecules, carbon dioxide, and water. Excess acetyl-CoA molecules serve as precursors for ketogenesis. Unlike glucose metabolism, oxidation of fatty acids requires proportionally less oxygen and produces less carbon dioxide. This is frequently quantified as the ratio of carbon dioxide produced to oxygen consumed for the reaction, and is known as the *respiratory quotient* (RQ). An RQ of 0.7 would imply greater fatty acid oxidation for fuel, whereas an RQ of 1 indicates greater carbohydrate oxidation (*overfeeding*). An RQ of 0.85 suggests the oxidation of equal amounts of fatty acids and glucose.

Ketogenesis. Carbohydrate depletion slows acetyl-CoA entry into the TCA cycle secondary to depleted TCA intermediates and enzyme activity. Increased lipolysis and reduced systemic carbohydrate availability during starvation diverts excess acetyl-CoA toward hepatic ketogenesis. A number of extrahepatic tissues, but not the liver itself, are capable of utilizing ketones for fuel. Ketosis represents a state in which hepatic ketone production exceeds extrahepatic ketone use.

The rate of ketogenesis appears to be inversely related to the severity of injury. Major trauma, severe shock, and sepsis attenuate ketogenesis by increasing insulin levels and by rapid tissue oxidation of free fatty acids.

Carbohydrate Metabolism

Ingested and enteral carbohydrates are primarily digested in the small intestine, in which pancreatic and intestinal enzymes reduce the complex carbohydrates to dimeric units. Disaccharidases are further broken down into hexose units such as glucose and galactose, which require energy dependent transport for primary absorption.

Carbohydrate metabolism primarily refers to the utilization of glucose. The oxidation of 1 g of carbohydrate yields 4 kcal, but administered sugar solutions such as that found in intravenous fluids or parenteral nutrition provides only 3.4 kcal/g of dextrose. The primary goal for maintenance glucose administration in surgical patients serves to minimize muscle wasting. The exogenous administration of small amounts of glucose (approximately 50 g/d) facilitates fat entry into the TCA cycle and reduces ketosis. Studies providing exogenous glucose to septic and trauma patients never have been shown to fully suppress amino acid degradation for gluconeogenesis. This suggests that during periods of stress, other hormonal and proinflammatory mediators have profound influence on the rate of protein degradation and that some degree of muscle wasting is inevitable. Insulin has been shown to reverse protein catabolism during severe stress by stimulating protein synthesis in skeletal muscles and inhibits hepatocyte protein degradation.

In cells, glucose is phosphorylated to form glucose-6-phosphate (G6P). G6P can be polymerized during glycogenesis or catabolized in glycogenolysis. Glucose catabolism occurs by cleavage to pyruvate or lactate (pyruvic acid pathway) or by decarboxylation to pentoses (pentose shunt).

Excess glucose from overfeeding, as reflected by RQs greater than 1.0, can result in conditions such as glucosuria, thermogenesis, and conversion to fat (lipogenesis). Excessive glucose administration results in elevated carbon dioxide production, which may be deleterious in patients with suboptimal pulmonary function.

Injury and severe infections acutely induce a state of peripheral glucose intolerance, despite ample insulin production several-fold above baseline. This may occur in part because of reduced skeletal muscle pyruvate dehydrogenase activity following injury, which diminishes the conversion of pyruvate to acetyl-CoA and subsequent entry into the TCA cycle. The consequent accumulation of 3-carbon structures (e.g., pyruvate and lactate) is shunted to the liver as substrate for gluconeogenesis. Unlike the nonstressed subject, the hepatic gluconeogenic response to injury or sepsis cannot be suppressed by exogenous or excess glucose administration, but rather persists in the hypermetabolic, critically ill patient. Hepatic gluconeogenesis, arising primarily from alanine and glutamine catabolism, provides a ready fuel source for tissues such as those of the nervous system, wounds, and erythrocytes, which do not require insulin for glucose transport. The elevated glucose concentrations also provide a necessary energy source for leukocytes in inflamed tissues and in sites of microbial invasions. Glycogen stores within skeletal muscles can be mobilized as a ready fuel source by epinephrine activation of β -adrenergic receptors.

PROTEIN AND AMINO ACID METABOLISM

The average protein intake in healthy, young adults ranges from 80 to 120 g/d, and every 6 g of protein yields approximately 1 g of nitrogen. The degradation of 1 g of protein yields approximately 4 kcal of energy, almost the same as for carbohydrates.

Following injury the initial systemic proteolysis, mediated primarily by glucocorticoids, increases urinary nitrogen excretion to levels in excess of 30 g/day, which roughly corresponds to a loss in lean body mass of 1.5 percent per day. An injured individual who does not receive nutrition for 10 days can theoretically lose 15 percent lean body mass. Therefore amino acids cannot be considered a long-term fuel reserve, and indeed excessive protein depletion (25–30 percent of lean body weight) is not compatible with sustaining life.

Protein catabolism following injury provides substrates for gluconeogenesis and for the synthesis of acute phase proteins. Radiolabeled amino acid incorporation studies and protein analyses confirm that skeletal muscles are preferentially depleted acutely following injury, whereas visceral tissues (e.g., the liver and kidney) remain relatively preserved. The accelerated urea excretion following injury is also associated with the excretion of intracellular elements such as sulfur, phosphorus, potassium, magnesium, and creatinine. Conversely, the rapid use of elements such as potassium and magnesium during recovery from major injury may indicate a period of tissue healing.

The net changes in protein catabolism and synthesis correspond to the severity and duration of injury. The rise in urinary nitrogen and negative nitrogen balance can be detected early following injury and peak by 7 days. This state of protein catabolism may persist for as long as 3–7 weeks. The patient's prior physical status and age appear to influence the degree of proteolysis following injury or sepsis.

NUTRITION IN THE SURGICAL PATIENT

The goal of nutritional support in the surgical patient is to prevent or reverse the catabolic effects of disease or injury. Although several important biologic parameters have been used to measure the efficacy of nutrition regimens, the ultimate validation for nutritional support should be improvement in clinical outcome and restoration of function.

Estimating Energy Requirements

Nutritional assessment determines the severity of nutrient deficiencies or excess and aids in predicting nutritional requirements. Elements of nutritional assessment include weight loss, chronic illnesses, or dietary habits that influence the quantity and quality of food intake. Social habits predisposing to malnutrition and the use of medications that may influence food intake or urination should also be investigated. Physical examination seeks to assess loss of muscle and adipose tissues, organ dysfunction, and subtle changes in skin, hair, or neuromuscular function reflecting frank or impending nutritional deficiency. Anthropometric data including weight change, skinfold thickness, and arm circumference muscle area and biochemical determinations (i.e., creatinine excretion, albumin, prealbumin, total lymphocyte count, and transferrin) may be used to substantiate the patient's history and physical findings. Nutritional assessment remains an imprecise method for the detection of malnutrition and prediction of patient outcome. Appreciation for the stresses and natural history of the disease process, in combination with nutritional assessment, remains the basis for identifying patients in acute or anticipated need of nutritional support.

A fundamental goal of nutritional support is to meet the energy requirements for metabolic processes, core temperature maintenance, and tissue repair. The requirement for energy may be measured by indirect calorimetry or estimated

from urinary nitrogen excretion, which is proportional to resting energy expenditure. However, the use of indirect calorimetry, particularly in the critically ill patient, is labor-intensive and often leads to overestimation of caloric requirements.

Basal energy expenditure (BEE) may also be estimated using the Harris-Benedict equations:

$$\text{BEE (men)} = 66.47 + 13.75 (W) + 5.0 (H) - 6.76 (A) \text{ kcal/d}$$

$$\text{BEE (women)} = 655.1 + 9.56 (W) + 1.85 (H) - 4.68 (A) \text{ kcal/d}$$

where W = weight in kilograms, H = height in centimeters, and A = age in years.

These equations, adjusted for the type of surgical stress, are suitable for estimating energy requirements in over 80 percent of hospitalized patients. It has been demonstrated that the provision of 30 kcal/kg per day will adequately meet energy requirements in most postsurgical patients, with low risk of overfeeding. Following trauma or sepsis, energy substrate demands are increased, necessitating greater nonprotein calories beyond calculated energy expenditure. These additional nonprotein calories provided after injury are usually 1.2 to 2.0 times greater than calculated resting energy expenditure (REE), depending on the type of injury. It is seldom appropriate to exceed this level of nonprotein energy intake during the height of the catabolic phase.

The second objective of nutritional support is to meet the substrate requirements for protein synthesis. An appropriate nonprotein calorie-to-nitrogen ratio of 150:1 (e.g., 1 g N = 6.25 g protein) should be maintained, which is the basal calorie requirement provided to prevent use of protein as an energy source. There is now greater evidence suggesting that increased protein intake, and a lower calorie-to-nitrogen ratio of 80:1 to 100:1, may benefit healing in selected hypermetabolic or critically ill patients. In the absence of severe renal or hepatic dysfunction precluding the use of standard nutritional regimens, approximately 0.25 to 0.35 g of nitrogen per kilogram of body weight should be provided daily.

Vitamins and Minerals

The requirements for vitamins and essential trace minerals usually can be easily met in the average patient with an uncomplicated postoperative course. Therefore vitamins are usually not given in the absence of preoperative deficiencies. Patients maintained on elemental diets or parenteral hyperalimentation require complete vitamin and mineral supplementation. Essential fatty acid supplementation may also be necessary, especially in patients with depletion of adipose stores.

Overfeeding

Overfeeding usually results from overestimation of caloric needs, as occurs when actual body weight is used to calculate the BEE in such patient populations as the critically ill with significant fluid overload and the obese. Indirect calorimetry can be used to quantify energy requirements, but frequently overestimates BEE by 10–15 percent in stressed patients, particularly if they are on a ventilator. In these instances, estimated dry weight should be obtained from preinjury records or family members.

Adjusted lean body weight also can be calculated. Clinically, increased oxygen consumption, increased CO₂ production, fatty liver, suppression of leukocyte function, and increased infectious risks have all been documented with overfeeding.

ENTERAL NUTRITION

Rationale for Enteral Nutrition

Enteral nutrition generally is preferred over parenteral nutrition based on reduced cost and associated risks of the intravenous route. Laboratory models have long demonstrated that luminal nutrient contact reduces intestinal mucosal atrophy when compared with parenteral or no nutritional support. Studies comparing postoperative enteral and parenteral nutrition in patients undergoing GI surgery have demonstrated reduced infection complications and acute phase protein production when fed by the enteral route. Yet, prospectively randomized studies for patients with adequate nutritional status (albumin ≥ 4 g/dL) undergoing GI surgery demonstrate no differences in outcome and complications when administered enteral nutrition compared to maintenance intravenous fluids alone in the initial days following surgery. At the other extreme, recent meta-analysis for critically ill patients demonstrates a 44 percent reduction in infectious complications in those receiving enteral nutritional support over those receiving parenteral nutrition. Most prospectively randomized studies for severe abdominal and thoracic trauma demonstrate significant reductions in infectious complications for patients given early enteral nutrition when compared with those who are unfed or receiving parenteral nutrition.

Recommendations for instituting early *enteral* nutrition to surgical patients with moderate malnutrition (albumin = 2.9 to 3.5 g/dL) can only be made by inferences because of a lack of data directly pertaining to this population. It is prudent to offer enteral nutrition based on measured energy expenditure of the recovering patient, or if complications arise that may alter the anticipated course of recovery (e.g., anastomotic leaks, return to surgery, sepsis, or failure to wean from the ventilator). Other clinical scenarios with substantiated benefits from enteral nutritional support include permanent neurologic impairment, oropharyngeal dysfunction, short-bowel syndrome, and bone marrow transplantation patients.

Data support the use of early enteral nutritional support following major trauma and in patients who are anticipated to have prolonged recovery after surgery. Healthy patients without malnutrition undergoing uncomplicated surgery can tolerate 10 days of partial starvation (with maintenance intravenous fluids only) before any significant protein catabolism occurs. Earlier intervention is likely indicated in patients with poorer preoperative nutritional status.

Initiation of enteral nutrition should occur immediately after adequate resuscitation, most readily determined by adequate urine output. Presence of bowel sounds and the passage of flatus or stool are not absolute requisites for initiating enteral nutrition, but feedings in the setting of gastroparesis should be administered distal to the pylorus. Enteral feeding should also be offered to patients with short-bowel syndrome or clinical malabsorption, but caloric needs, essential minerals, and vitamins should be supplemented with parenteral modalities.

Enteral Formulas

The functional status of the GI tract determines the type of enteral solutions to be used. Patients with an intact GI tract will tolerate complex enteral solutions. In patients with malabsorption such as in inflammatory bowel diseases, absorption may be improved by provision of dipeptides, tripeptides, and MCTs. However, MCTs are deficient in essential fatty acids, which necessitates supplementation with some LCT.

In general, factors that influence the choice of enteral formula include the extent of organ dysfunction (e.g., renal, pulmonary, hepatic, or GI), the nutrient needs to restore optimal function and healing, and the cost of specific products.

Immune-enhancing formulas. These formulas are fortified with special nutrients that are purported to enhance various aspects of immune or solid organ function. Such additives include glutamine, arginine, branched-chain amino acids, omega-3 fatty acids, nucleotides, and beta-carotene. Although several trials have proposed that one or more of these additives reduce surgical complications and improve outcome, these results have not been uniformly corroborated by other trials. The addition of amino acids to these formulas generally doubles the amount of protein (nitrogen) found in standard formula; however, their use can be cost-prohibitive.

High-protein formulas. High-protein formulas are available in isotonic and nonisotonic mixtures and are proposed for critically ill or trauma patients with high protein requirements. These formulas comprise nonprotein calorie-to-nitrogen ratios between 80:1 and 120:1.

Elemental formulas. These formulas contain predigested nutrients and provide proteins in the form of small peptides. Complex carbohydrates are limited, and fat content, in the form of MCTs and LCTs, is minimal. The primary advantage of such a formula is ease of absorption, but the inherent scarcity of fat, associated vitamins, and trace elements limits its long-term use as a primary source of nutrients. Because of its high osmolarity, dilution or slow infusion rates are usually necessary, particularly in critically ill patients. These formulas have been used frequently in patients with malabsorption, gut impairment, and pancreatitis, but their cost is significantly higher than that of standard formulas.

Renal-failure formulas. The primary benefits of the renal formula are the lower fluid volume and concentrations of potassium, phosphorus, and magnesium needed to meet daily calorie requirements. This formulation almost exclusively contains essential amino acids and has a high nonprotein-to-calorie ratio; however, it does not contain trace elements or vitamins.

Pulmonary-failure formulas. In these formulas, fat content is usually increased to 50 percent of the total calories, with a corresponding reduction in carbohydrate content. The goal is to reduce CO₂ production and alleviate ventilation burden for failing lungs.

Access for Enteral Nutritional Support

The available techniques and repertoire for enteral access have provided multiple options for feeding the gut. Table 1-4 summarizes the presently used methods and preferred indications.

TABLE 1-4 Options for Enteral Feeding Access

Access option	Comments
Nasogastric tube	Short-term use only; aspiration risks; nasopharyngeal trauma; frequent dislodgment
Nasoduodenal/nasojejunal	Short-term use; lower aspiration risks in jejunum; placement challenges (radiographic assistance often necessary)
Percutaneous endoscopic gastrostomy (PEG)	Endoscopy skills required; may be used for gastric decompression or bolus feeds; aspiration risks; can last 12–24 months; slightly higher complication rates with placement and site leaks
Surgical gastrostomy	Requires general anesthesia and small laparotomy; may allow placement of extended duodenal/jejunal feeding ports; laparoscopic placement possible
Fluoroscopic gastrostomy	Blind placement using needle and T-prongs to anchor to stomach; can thread smaller catheter through gastrostomy into duodenum/jejunum under fluoroscopy
PEG-jejunal tube	Jejunal placement with regular endoscope is operator dependent; jejunal tube often dislodges retrograde; two-stage procedure with PEG placement, followed by fluoroscopic conversion with jejunal feeding tube through PEG
Direct percutaneous endoscopic jejunostomy (DPEJ)	Direct endoscopic placement with enteroscope; placement challenges; greater injury risks
Surgical jejunostomy	Commonly applied during laparotomy; general anesthesia; laparoscopic placement usually requires assistant to thread catheter; laparoscopy offers direct visualization of catheter placement
Fluoroscopic jejunostomy	Difficult approach with injury risks; not commonly done

Nasoenteric tubes. Nasogastric feeding should be reserved for those with intact mental status and protective laryngeal reflexes to minimize risks of aspiration. Even in intubated patients, nasogastric feedings can often be recovered from tracheal suction. Nasojejunal feedings are associated with fewer pulmonary complications, but access past the pylorus requires greater effort to accomplish. Blind insertion of nasogastric feeding tubes is fraught with misplacement, and air instillation with auscultation is inaccurate for ascertaining proper positioning. Radiographic confirmation is usually required to verify the position of the nasogastric feeding tube.

Small bowel feeding is more reliable for delivering nutrition than nasogastric feeding. Furthermore, the risks of aspiration pneumonia can be reduced by 25 percent with small bowel feeding when compared with nasogastric feeding. The disadvantages of nasoenteric feeding tubes are clogging, kinking, inadvertent displacement or removal, and nasopharyngeal complications. If

nasoenteric feeding will be required for longer than 30 days, access should be converted to a percutaneous one.

Percutaneous endoscopic gastrostomy. The most common indications for percutaneous endoscopic gastrostomy (PEG) placement include impaired swallowing mechanisms, oropharyngeal or esophageal obstruction, and major facial trauma. It is frequently utilized for debilitated patients requiring caloric supplementation, hydration, or frequent medication dosing. It is also appropriate for patients requiring passive gastric decompression. Relative contraindications for PEG placement include ascites, coagulopathy, gastric varices, gastric neoplasm, and lack of a suitable abdominal site.

If endoscopy is not available or technical obstacles preclude PEG placement, the interventional radiologist can attempt the procedure percutaneously under fluoroscopic guidance. If this is also unsuccessful, surgical gastrostomy or small-bowel tube placement can be considered.

Although PEG tubes enhance nutritional delivery, facilitate nursing care, and are superior to nasogastric tubes, serious complications can occur in approximately 3 percent of patients. These complications include wound infection, necrotizing fasciitis, peritonitis, aspiration, leaks, dislodgment, bowel perforation, enteric fistulas, bleeding, and aspiration pneumonia. For patients with significant gastroparesis or gastric outlet obstruction, feedings through PEG tubes are hazardous. In this instance, the PEG tube can be used for decompression and to allow access for converting the PEG tube to a transpyloric feeding tube.

Surgical gastrostomy and jejunostomy. In a patient undergoing complex abdominal or trauma surgery, thought should be given during surgery to the possible routes for subsequent nutritional support, because laparotomy affords direct access to the stomach or small bowel. The only absolute contraindication to feeding jejunostomy is distal intestinal obstruction. Relative contraindications include severe edema of the intestinal wall, radiation enteritis, inflammatory bowel disease, ascites, severe immunodeficiency, and bowel ischemia. Needle-catheter jejunostomies can also be done with a minimal learning curve. The biggest drawback is usually related to clogging and knotting of the 6F catheter.

Abdominal distention and cramps are common adverse effects of early enteral nutrition and usually managed by temporarily discontinuing feeds and resuming at a lower infusion rate.

Pneumatosis intestinalis and small bowel necrosis are infrequent but significant problems associated with patients receiving jejunal tube feedings. Several contributing factors have been proposed, including the hyperosmolar consistency of enteral solutions, bacterial overgrowth, fermentation, and metabolic breakdown products. The common pathophysiology is believed to be bowel distention and consequent reduction in bowel wall perfusion. Risk factors for these complications include cardiogenic and circulatory shock, vasopressor use, diabetes mellitus, and chronic obstructive pulmonary disease. Therefore, enteral feedings in the critically ill patient should be delayed until adequate resuscitation has been achieved.

PARENTERAL NUTRITION

Parenteral nutrition involves the continuous infusion of a hyperosmolar solution containing carbohydrates, proteins, fat, and other necessary nutrients through an indwelling catheter inserted into the superior vena cava. To

obtain the maximum benefit, the ratio of calories to nitrogen must be adequate (at least 100 to 150 kcal/g nitrogen), and both carbohydrates and proteins must be infused simultaneously. When the sources of calories and nitrogen are given at different times, there is a significant decrease in nitrogen utilization. These nutrients can be given in quantities considerably greater than the basic caloric and nitrogen requirements. Clinical trials and meta-analysis of parenteral feeding in the perioperative period have suggested that preoperative nutritional support may benefit some surgical patients, particularly those with extensive malnutrition. Short-term use of parenteral nutrition in critically ill patients (i.e., duration <7 days) when enteral nutrition may have been instituted is associated with higher rates of infectious complications. Following severe injury, parenteral nutrition is associated with higher rates of infectious risks when compared with enteral feeding. However, parenteral feeding still has fewer infectious complications compared with no feeding at all.

Rationale for Parenteral Nutrition

The principal indications for parenteral nutrition are found in seriously ill patients suffering from malnutrition, sepsis, or surgical or accidental trauma, when use of the GI tract for feedings is not possible. In some instances, intravenous nutrition may be used to supplement inadequate oral intake. The safe and successful use of parenteral nutrition requires proper selection of patients with specific nutritional needs, experience with the technique, and an awareness of the associated complications. As with enteral nutrition, the fundamental goals are to provide sufficient calories and nitrogen substrate to promote tissue repair and to maintain the integrity or growth of lean tissue mass. Listed below are situations in which parenteral nutrition has been used in an effort to achieve these goals:

1. Newborn infants with catastrophic GI anomalies, such as tracheoesophageal fistula, gastroschisis, omphalocele, or massive intestinal atresia.
2. Infants who fail to thrive because of GI insufficiency associated with short-bowel syndrome, malabsorption, enzyme deficiency, meconium ileus, or idiopathic diarrhea.
3. Adult patients with short-bowel syndrome secondary to massive small bowel resection (<100 cm without colon or ileocecal valve, or <50 cm with intact ileocecal valve and colon).
4. Enteroenteric, enterocolic, enterovesical, or high-output enterocutaneous fistulas (>500 mL/d).
5. Surgical patients with prolonged paralytic ileus following major operations (>7–10 days), multiple injuries, blunt or open abdominal trauma, or patients with reflex ileus complicating various medical diseases.
6. Patients with normal bowel length but with malabsorption secondary to sprue, hypoproteinemia, enzyme or pancreatic insufficiency, regional enteritis, or ulcerative colitis.
7. Adult patients with functional GI disorders such as esophageal dyskinetia following cerebrovascular accident, idiopathic diarrhea, psychogenic vomiting, or anorexia nervosa.
8. Patients with granulomatous colitis, ulcerative colitis, and tuberculous enteritis, in which major portions of the absorptive mucosa are diseased.
9. Patients with malignancy, with or without cachexia, in whom malnutrition might jeopardize successful delivery of a therapeutic option.

10. Failed attempts to provide adequate calories by enteral tube feedings or high residuals.
11. Critically ill patients who are hypermetabolic for more than 5 days or when enteral nutrition is not feasible.

Conditions *contraindicating* hyperalimentation include the following:

1. Lack of a specific goal for patient management, or in cases in which instead of extending a meaningful life, inevitable dying is delayed.
2. Periods of hemodynamic instability or severe metabolic derangement (e.g., severe hyperglycemia, azotemia, encephalopathy, hyperosmolality, and fluid-electrolyte disturbances) requiring control or correction before attempting hypertonic intravenous feeding.
3. Feasible GI tract feeding; in the vast majority of instances, this is the best route by which to provide nutrition.
4. Patients with good nutritional status.
5. Infants with less than 8 cm of small bowel, because virtually all have been unable to adapt sufficiently despite prolonged periods of parenteral nutrition.

Total Parenteral Nutrition

Total parenteral nutrition (TPN), also referred to as central parenteral nutrition, requires access to a large-diameter vein to deliver the entire nutritional requirements of the individual. Dextrose content is high (15–25 percent) and all other macro- and micronutrients are deliverable by this route.

Peripheral Parenteral Nutrition

The lower osmolality of the solution used for peripheral parenteral nutrition (PPN), secondary to reduced dextrose (5–10 percent) and protein (3 percent) levels, allows for its administration via peripheral veins. Some nutrients cannot be supplemented because of inability to concentrate them into small volumes. Therefore PPN is not appropriate for repleting patients with severe malnutrition. It can be considered if central routes are not available or if supplemental nutritional support is required. Typically, PPN is used for short periods (< 2 weeks).

Intravenous Access Methods

Temporary or short-term access can be achieved with a 16-gauge, percutaneous catheter inserted into a subclavian or internal jugular vein and threaded into the superior vena cava. More permanent access, with the intention of providing long-term or home parenteral nutrition, can be achieved by placement of a catheter with a subcutaneous port for access, by tunneling a catheter with a substantial subcutaneous length, or threading a long catheter through the basilic or cephalic vein into the superior vena cava.

COMPLICATIONS OF PARENTERAL NUTRITION

Technical Complications

One of the more common and serious complications associated with long-term parenteral feeding is sepsis secondary to contamination of the central venous catheter. Complications related to catheter insertion such as pneumothorax, hemothorax, subclavian artery injury, thoracic duct injury, cardiac arrhythmia, air embolism, catheter embolism, and cardiac perforation with tamponade have

also been described. Contamination of solutions should be considered, but is rare when proper pharmacy protocols have been followed. This problem occurs more frequently in patients with systemic sepsis, and in many cases is because of hematogenous seeding of the catheter with bacteria. It is prudent to delay reinserting the catheter by 12–24 hours, especially if bacteremia is present.

Metabolic Complications

Hyperglycemia may develop with normal rates of infusion in patients with impaired glucose tolerance or in any patient if the hypertonic solutions are administered too rapidly. This is a particularly common complication in latent diabetics and in patients subjected to severe surgical stress or trauma. Treatment of the condition consists of volume replacement with correction of electrolyte abnormalities and the administration of insulin. This complication can be avoided with careful attention to daily fluid balance and frequent monitoring of blood sugar levels and serum electrolytes.

Increasing experience has emphasized the importance of not overfeeding the parenterally nourished patient. This is particularly true of the depleted patient in whom excess calorie infusion may result in carbon dioxide retention and respiratory insufficiency. Additionally, excess feeding also has been related to the development of hepatic steatosis or marked glycogen deposition in selected patients. Cholestasis and formation of gallstones are common in patients receiving long-term parenteral nutrition. Mild but transient abnormalities of serum transaminase, alkaline phosphatase, and bilirubin may occur in many parenterally nourished patients. Failure of the liver enzymes to plateau or return to normal over 7–14 days should suggest another etiology.

Intestinal Atrophy

Lack of intestinal stimulation is associated with intestinal mucosal atrophy, diminished villous height, bacterial overgrowth, reduced lymphoid tissue size, reduced IgA production, and impaired gut immunity. The full clinical implications of these changes are not well realized, although bacterial translocation has been demonstrated in animal models. The most efficacious method to prevent these changes is to provide nutrients enterally. In patients requiring total parenteral nutrition, it may be feasible to infuse small amounts of trophic feedings via the GI tract.

Special Formulations

Glutamine and Arginine

Glutamine is the most abundant amino acid in the human body, comprising nearly two-thirds of the free intracellular amino acid pool. Of this, 75 percent is found within the skeletal muscles. In healthy individuals, glutamine is considered a nonessential amino acid because it is synthesized within the skeletal muscles and the lungs. Glutamine is a necessary substrate for nucleotide synthesis in most dividing cells, and hence provides a major fuel source for enterocytes. It also serves as an important fuel source for immunocytes such as lymphocytes and macrophages, and a precursor for glutathione, a major intracellular antioxidant. During stress states such as sepsis, or in tumor-bearing hosts, peripheral glutamine stores are rapidly depleted and the amino acid is preferentially shunted as a fuel source toward the visceral organs and tumors, respectively. These situations create, at least experimentally, a

glutamine-depleted environment, with consequences including enterocyte and immunocyte starvation.

Arginine, also a nonessential amino acid in healthy subjects, first attracted attention for its immunoenhancing properties, wound-healing benefits, and improved survival in animal models of sepsis and injury. As with glutamine, the benefits of experimental arginine supplementation during stress states are diverse. Clinical studies in which arginine was administered enterally have demonstrated net nitrogen retention and protein synthesis compared to isonitrogenous diets in critically ill and injured patients and following surgery for certain malignancies. Some of these studies also are associated with in vitro evidence of enhanced immunocyte function. The clinical utility of arginine in improving overall patient outcome remains an area of investigation.

Omega-3 Fatty Acids

The provision of omega-3 polyunsaturated fatty acids (canola oil or fish oil) displaces omega-6 fatty acids in cell membranes, which theoretically reduce the proinflammatory response from prostaglandin production.

Nucleotides

RNA supplementation in solutions is purported, at least experimentally, to increase cell proliferation, provide building blocks for DNA synthesis, and improve T-helper cell function.

Fluid and Electrolyte Management of the Surgical Patient

Rosemary A. Kozar and Frederick A. Moore

Fluid and electrolyte management are paramount to the care of the surgical patient. Changes in both fluid volume and electrolyte composition occur preoperatively, intraoperatively, and postoperatively, and in response to trauma and sepsis.

BODY FLUIDS

Total Body Water

Water constitutes approximately 50–60 percent of total body weight. The relationship between total body weight and total body water (TBW) is primarily a reflection of body fat. As a result, young, lean males have a higher proportion of body weight as water than older adult or obese individuals. The highest percentage of TBW is found in newborns, with approximately 80 percent of their total body weight composed of water. This decreases to about 65 percent by 1 year of age and thereafter remains fairly constant.

Fluid Compartments

TBW is divided into two functional fluid compartments, the extracellular and intracellular. The extracellular fluid compartment comprises about one third of the TBW and the intracellular compartment the remaining two thirds. The extracellular water comprises 20 percent of the total body weight and is divided between plasma (5 percent of body weight) and interstitial fluid (15 percent of body weight).

Composition of Fluid Compartments

The extracellular fluid compartment is balanced between the principal cation—sodium and the principal anions—chloride and bicarbonate. The intracellular fluid compartment is composed primarily of the cations, potassium and magnesium, and of the anions, phosphate and proteins. Proteins add to the osmolality of the plasma and contribute to the balance of forces that determine fluid balance across the capillary endothelium. Water is distributed evenly throughout all fluid compartments of the body. Sodium, however, is confined to the extracellular fluid compartment, and because of its osmotic and electrical properties, it remains associated with water. Therefore, sodium-containing fluids are distributed throughout the extracellular fluid and add to the volume of both the intravascular and interstitial spaces.

Osmotic Pressure

The movement of water across a cell membrane depends primarily on osmosis. The principal determinants of osmolality are the concentrations of sodium,

glucose, and urea (blood urea nitrogen [BUN]): serum osmolality = 2 sodium + glucose/18 + BUN/2.8.

The osmolality of the intracellular and extracellular fluids is maintained between 290 and 310 mOsm in each compartment. Because cell membranes are permeable to water, any change in osmotic pressure in one compartment is accompanied by a redistribution of water until the effective osmotic pressure between compartments is equal.

CLASSIFICATION OF BODY FLUID CHANGES

Normal Exchange of Fluid and Electrolytes

Daily water losses for the average adult include about 1 L in urine, 250 mL in stool, and 600 mL as insensible losses. Insensible losses occur through both the skin (75 percent) and lungs (25 percent) and by definition is pure water. Insensible losses can be increased by fever, hypermetabolism, and hyperventilation. To clear the products of metabolism, the kidneys must excrete a minimum of 500–800 mL of urine per day, regardless of the amount of oral intake.

Disturbances in Fluid Balance

Extracellular volume deficit is the most common fluid disorder in surgical patients and can be either acute or chronic. Acute volume deficit is associated with cardiovascular and central nervous system (CNS) signs, although chronic deficits display tissue signs, such as a decrease in skin turgor and sunken eyes, in addition to cardiovascular and CNS signs (Table 2-1). Sodium concentration does not necessarily reflect volume status, and therefore may be high, normal, or low when a volume deficit is present. The most common etiology of volume deficit in surgical patients is a loss of gastrointestinal (GI) fluids from nasogastric suction, vomiting, diarrhea, or fistula. Additionally, sequestration secondary to soft-tissue injuries, burns, and intraabdominal processes such as peritonitis, obstruction, or prolonged surgery also can lead to volume deficits.

Extracellular volume excess may be iatrogenic or secondary to renal dysfunction, congestive heart failure, or cirrhosis. Both plasma and interstitial volumes are increased.

TABLE 2-1 Signs and Symptoms of Volume Disturbances

System	Volume deficit	Volume excess
Generalized	Weight loss Decreased skin turgor	Weight gain Peripheral edema
Cardiac	Tachycardia Orthostasis/hypotension Collapsed neck veins	Increased cardiac output Increased central venous pressure Distended neck veins Murmur
Renal	Oliguria Azotemia	
Gastrointestinal Pulmonary	Ileus	Bowel edema Pulmonary edema

Concentration Changes

Hyponatremia

A low serum sodium level occurs when there is an excess of extracellular water relative to sodium. Extracellular volume can be high, normal, or low. For most cases of hyponatremia, sodium concentration is decreased as a consequence of either sodium depletion or dilution. Dilutional hyponatremia frequently results from excess extracellular water and therefore is associated with a high extracellular volume status. Postoperative patients are particularly prone to increased secretion of antidiuretic hormone, which increases reabsorption of free water from the kidneys with subsequent volume expansion and hyponatremia. Physical signs of volume overload are usually absent and laboratory evaluation reveals hemodilution. Depletional causes of hyponatremia result from either a decreased intake or increased loss of sodium-containing fluids. Etiologies include decreased sodium intake, GI losses, or renal losses. Depletional hyponatremia often is accompanied by extracellular volume deficit.

Hyponatremia also can be seen with an excess of solute relative to free water, such as with untreated hyperglycemia or mannitol administration. When evaluating hyponatremia in the presence of hyperglycemia, the corrected sodium concentration should be calculated: for every 100-mg/dL increment in plasma glucose above normal the plasma sodium should decrease by 1.6 mEq/L. Lastly, extreme elevations in plasma lipids and proteins can cause pseudohyponatremia, because there is no true decrease in extracellular sodium relative to water.

Signs and symptoms of hyponatremia (Table 2-2) are dependent on the degree of hyponatremia and the rapidity with which it occurred. Clinical manifestations are primarily CNS in etiology and are related to cellular water intoxication and associated increases in intracranial pressure.

TABLE 2-2 Clinical Manifestations of Abnormalities in Serum Sodium

Body system	Hyponatremia
Central nervous system	Headache, confusion, hyper- or hypoactive deep tendon reflexes, seizures, coma, increased intracranial pressure
Musculoskeletal	Weakness, fatigue, muscle cramps/twitching
Gastrointestinal	Anorexia, nausea, vomiting, watery diarrhea
Cardiovascular	Hypertension and bradycardia if significant increases in intracranial pressure
Tissue	Lacrimation, salivation
Renal	Oliguria
Body system	Hypernatremia
Central nervous system	Restlessness, lethargy, ataxia, irritability, tonic spasms, delirium, seizures, coma
Musculoskeletal	Weakness
Cardiovascular	Tachycardia, hypotension, syncope
Tissue	Dry sticky mucous membranes, red swollen tongue, decreased saliva and tears
Renal	Oliguria
Metabolic	Fever

Hypernatremia

Hypernatremia results from either a loss of free water or a gain of sodium in excess of water. Like hyponatremia, it can be associated with an increased, normal, or decreased extracellular volume.

Hypervolemic hypernatremia usually is caused either by iatrogenic administration of sodium-containing fluids or mineralocorticoid excess as seen in hyperaldosteronism, Cushing's syndrome, and congenital adrenal hyperplasia. Urine sodium is typically greater than 20 mEq/L and urine osmolality is greater than 300 mOsm/L. Normovolemic hypernatremia can be associated with renal (diabetes insipidus, diuretics, renal disease) or nonrenal (GI or skin) causes of water loss.

Lastly, hypovolemic hypernatremia can be because of either renal or nonrenal water loss. Renal causes include diabetes insipidus, osmotic diuretics, adrenal failure, and renal tubular diseases. The urine sodium concentration is less than 20 mEq/L and urine osmolality is less than 300 to 400 mOsm/L. Nonrenal water loss can occur secondary to GI fluid losses or skin fluid losses such as fever or tracheotomies. Additionally, thyrotoxicosis can cause water loss as can the use of hypertonic glucose solutions for peritoneal dialysis. With nonrenal water loss, the urine sodium concentration is less than 15 mEq/L and the urine osmolality is greater than 400 mOsm/L.

Symptoms of hypernatremia are rare until the serum sodium concentration exceeds 160 mEq/L. As symptoms are related to hyperosmolality, CNS effects predominate (Table 2-2).

Composition Changes: Etiology and Diagnosis

Potassium Abnormalities

Although only 2 percent of the total body potassium is located within the extracellular compartment, this small amount is critical to cardiac and neuromuscular function.

Hyperkalemia. Hyperkalemia is caused by an excessive potassium intake, increased release of potassium from cells, or impaired excretion by the kidneys. Increased intake can be either from oral or intravenous supplementation, and from blood transfusions. Cell breakdown can release potassium in association with hemolysis, rhabdomyolysis, crush injuries, and GI hemorrhage. Acidosis can raise serum potassium levels by causing a shift of potassium ions to the extracellular compartment. Because aldosterone plays an important role in stimulating potassium secretion from the collecting ducts, any drug (like spironolactone and angiotensin-converting enzyme [ACE] inhibitors) that interferes with aldosterone activity inhibits potassium secretion. Impaired potassium excretion also occurs with renal insufficiency and renal failure.

Symptoms of hyperkalemia are primarily GI, neuromuscular, and cardiovascular. GI symptoms include nausea, vomiting, intestinal colic, and diarrhea; neuromuscular symptoms range from weakness to ascending paralysis to respiratory failure. Electrocardiogram (ECG) changes that may be seen with hyperkalemia include: peaked T waves, flattened P wave, prolonged PR interval (first-degree block), widened QRS complex, sine wave formation, and ventricular fibrillation.

Hypokalemia. Hypokalemia may be caused by inadequate intake, excessive renal excretion (hyperaldosteronism, medications such as diuretics that increase potassium excretion, or drugs such as penicillin that promote renal tubular loss of potassium), loss in GI secretions (direct loss of potassium in stool or renal potassium loss from vomiting or high nasogastric output), or intracellular shifts (as seen with metabolic alkalosis or insulin therapy). In cases in which potassium deficiency is because of magnesium depletion, potassium repletion is difficult unless hypomagnesemia is first corrected.

The symptoms of hypokalemia include ileus, constipation, weakness, fatigue, diminished tendon reflexes, paralysis, and cardiac arrest (pulseless electrical activity or asystole). ECG changes suggestive of hypokalemia include: U waves, T-wave flattening, ST-segment changes, and arrhythmias.

Magnesium Abnormalities

Hypermagnesemia. Hypermagnesemia is rare but can be seen with impaired renal function and excess intake in the form of total parenteral nutrition or magnesium-containing laxatives and antacids. Symptoms may be GI (nausea and vomiting), neuromuscular (weakness, lethargy, and decreased reflexes), or cardiovascular (hypotension and arrest). ECG changes are similar to those seen with hyperkalemia.

Hypomagnesemia. Hypomagnesemia results from poor intake (starvation, alcoholism, prolonged use of intravenous fluids, and total parenteral nutrition), increased renal excretion (alcohol, most diuretics, and amphotericin B), GI losses (diarrhea), malabsorption, acute pancreatitis, diabetic ketoacidosis, and primary aldosteronism.

Magnesium depletion is characterized by neuromuscular and CNS hyperactivity, and symptoms are similar to those of calcium deficiency, including hyperactive reflexes, muscle tremors, and tetany with a positive Chvostek's sign. Severe deficiencies can lead to delirium and seizures. ECG changes include: prolonged QT and PR intervals, ST-segment depression, flattening or inversion of P waves, Torsades de pointes, and arrhythmias. Hypomagnesemia can produce hypocalcemia and lead to persistent hypokalemia. When hypokalemia or hypocalcemia coexist with hypomagnesemia, magnesium should be aggressively replaced to assist in restoring potassium or calcium homeostasis.

Calcium Abnormalities

Although only approximately 50 percent of serum calcium is found in the ionized form, it is the ionized fraction that is responsible for neuromuscular stability. Total serum calcium is affected by albumin concentration, so that total serum calcium should be adjusted down by 0.8 mg/dL for every 1 g/dL decrease in albumin. Unlike changes in albumin, changes in pH will affect the ionized calcium concentration. Acidosis decreases protein binding, thereby increasing the ionized fraction of calcium.

Hypercalcemia. Primary hyperparathyroidism malignancy (associated bony metastasis or because of secretion of parathyroid hormone-related protein) accounts for most cases of symptomatic hypercalcemia. Symptoms of hypercalcemia include neurologic (depression, confusion, stupor, or coma), musculoskeletal (weakness and back and extremity pain), renal (polyuria and polydipsia as kidneys lose their ability to concentrate), and GI (anorexia, nausea, vomiting, constipation, abdominal pain, and weight loss). Cardiac symptoms

include hypertension, cardiac arrhythmias, and a worsening of digitalis toxicity. ECG changes of hypercalcemia include shortened QT interval, prolonged PR and QRS intervals, increased QRS voltage T-wave flattening and widening, and AV block.

Hypocalcemia. Etiologies of hypocalcemia include pancreatitis, massive soft tissue infections such as necrotizing fasciitis, renal failure, pancreatic and small-bowel fistulas, hypoparathyroidism, toxic shock syndrome, abnormalities in magnesium, and tumor lysis syndrome. Additionally, transient hypocalcemia commonly occurs following removal of a parathyroid adenoma as atrophy of the remaining glands and avid bone uptake of calcium occurs. Hungry bone syndrome can develop postoperatively in secondary or tertiary hyperparathyroidism as bone is being rapidly remineralized, requiring high-dose calcium supplementation. Additionally, malignancies associated with increased osteoclastic activity such as breast and prostate cancer can lead to hypocalcemia from increased bone formation. Calcium precipitation with organic anions is also a cause of hypocalcemia, such as that seen with hyperphosphatemia (tumor lysis syndrome or rhabdomyolysis), pancreatitis (chelation with free fatty acids), or massive blood transfusion (citrate).

Asymptomatic hypocalcemia may occur with hypoproteinemia (normal ionized calcium), but symptoms can develop with alkalosis (decreased ionized calcium). Symptoms are neuromuscular and cardiac in origin, including paresthesias, muscle cramps, carpopedal spasm, stridor, tetany, and seizures. Patients will demonstrate hyperreflexia and positive Chvostek's and Trousseau's sign. Decreased cardiac contractility and heart failure also can accompany hypocalcemia, as do the following ECG changes: prolonged QT interval, T-wave inversion, heart block, and ventricular fibrillation.

Phosphorus Abnormalities

Hyperphosphatemia. Hyperphosphatemia can be because of decreased urinary excretion or increased intake or production of phosphorus. Most cases of hyperphosphatemia are seen in patients with impaired renal function. Hypoparathyroidism or hyperthyroidism also can decrease urinary excretion of phosphorus and thus lead to hyperphosphatemia. Increased release of endogenous phosphorus can be seen in association with cell destruction, such as with rhabdomyolysis, tumor lysis syndrome, hemolysis, sepsis, severe hypothermia, or malignant hyperthermia. Excessive phosphate administration (phosphorus-containing laxatives) also may lead to elevated phosphate levels. Most cases of hyperphosphatemia are asymptomatic, but significant hyperphosphatemia can lead to metastatic soft tissue calcium-phosphorus complexes.

Hypophosphatemia. Decreased intake can lead to hypophosphatemia and occurs with malnutrition or decreased GI absorption. Most cases are because of an intracellular shift of phosphorus as occurs in association with respiratory alkalosis, insulin therapy, refeeding syndrome, and hungry bone syndrome. Symptoms are related to adverse effects on the oxygen availability of tissue and to a decrease in high-energy phosphates and can be manifested as cardiac dysfunction or muscle weakness.

Acid-Base Balance

Compensation for acid-base derangements is either respiratory or metabolic. Changes in ventilation in response to metabolic abnormalities are mediated by

TABLE 2-3 Predicted Changes in Acid-Base Disorders

Disorder	Predicted change
Metabolic	
Metabolic acidosis	$P_{\text{CO}_2} = 1.5 \times \text{HCO}_3^- + 8$
Metabolic alkalosis	$P_{\text{CO}_2} = 0.7 \times \text{HCO}_3^- + 21$
Respiratory	
Acute respiratory acidosis	$\Delta \text{pH} = (P_{\text{CO}_2} - 40) \times 0.008$
Chronic respiratory acidosis	$\Delta \text{pH} = (P_{\text{CO}_2} - 40) \times 0.003$
Acute respiratory alkalosis	$\Delta \text{pH} = (40 - P_{\text{CO}_2}) \times 0.008$
Chronic respiratory alkalosis	$\Delta \text{pH} = (40 - P_{\text{CO}_2}) \times 0.017$

hydrogen-sensitive chemoreceptors. Acidosis stimulates the chemoreceptors to increase ventilation whereas alkalosis decreases their activity and thus decreases ventilation. The kidneys provide compensation for respiratory abnormalities by either increasing or decreasing bicarbonate reabsorption for respiratory acidosis or alkalosis, respectively. Unlike the prompt change in ventilation that occurs with metabolic abnormalities, the compensatory response in the kidneys to respiratory abnormalities is delayed. Table 2-3 lists the predicted compensatory changes in response to metabolic or respiratory derangements. If the expected change in pH is exceeded, then a mixed acid-base abnormality may be present.

Metabolic Derangements

Metabolic acidosis. In evaluating a patient with metabolic acidosis, first measure the anion gap (AG), which is an index of unmeasured anions: $\text{AG} = [\text{Na}] - [\text{Cl} + \text{HCO}_3]$. The normal AG is less than 12 mmol/L.

Metabolic acidosis with an increased AG occurs from either exogenous acid ingestion (ethylene glycol, salicylate, or methanol) or endogenous acid production of β -hydroxybutyrate and acetoacetate in ketoacidosis, lactate in lactic acidosis, or organic acids in renal insufficiency. One of the most common causes of severe metabolic acidosis in surgical patients is lactic acidosis. With shock, lactate is produced as a by-product of inadequate tissue perfusion. The treatment is to restore perfusion with volume resuscitation rather than to attempt to correct the abnormality with exogenous bicarbonate. The administration of bicarbonate for the treatment of metabolic acidosis is controversial and the overzealous administration of bicarbonate can lead to metabolic alkalosis, which shifts the oxyhemoglobin dissociation curve to the left, interfering with oxygen unloading at the tissue level. An additional disadvantage is that sodium bicarbonate can actually exacerbate intracellular acidosis. There are commercially available buffers that do not increase CO_2 production and avoid intracellular acidosis, including Carbicarb and tromethamine. Carbicarb is an equimolar mixture of sodium bicarbonate and sodium carbonate that combines with hydrogen ions, producing bicarbonate rather than CO_2 . This buffer, however, is not yet available for use in humans. An alternative buffer is tris-hydroxymethyl aminomethane (THAM). THAM is excreted by the kidneys and therefore should be used with caution in patients with renal insufficiency. Side effects include hyperkalemia and hypoglycemia.

Metabolic acidosis with a normal anion gap results from either acid administration (HCl or NH_4^+) or a loss of bicarbonate from GI sources such as diarrhea, fistulas, ureterosigmoidostomy, or from renal loss. The bicarbonate loss is accompanied by a gain of chloride, thus the AG remains unchanged.

Metabolic alkalosis. Surgical patients with pyloric obstruction (seen in infants with pyloric stenosis or adults with duodenal ulcer disease) can develop hypochloremic, hypokalemic, or metabolic alkalosis. Unlike vomiting associated with an open pylorus, vomiting with an obstructed pylorus results only in the loss of gastric fluid, which is high in chloride and hydrogen, and thus a hypochloremic alkalosis. Initially the urinary bicarbonate level is high to compensate for the alkalosis. Hydrogen ion reabsorption also ensues with an accompanied potassium ion excretion. Additionally, in response to the volume deficit, aldosterone-mediated sodium reabsorption is accompanied by potassium excretion. The resulting hypokalemia leads to the excretion of hydrogen ions in the face of alkalosis, a paradoxical aciduria. Treatment includes replacement of the volume deficit with isotonic saline and potassium once adequate urine output is ensured.

Respiratory Derangements

Respiratory acidosis. This condition is associated with the retention of CO_2 secondary to decreased alveolar ventilation. As compensation is primarily renal, it is a delayed response. Treatment is directed at the underlying cause and at measures to ensure adequate ventilation.

Respiratory alkalosis. Most cases of respiratory alkalosis are acute in nature and secondary to alveolar hyperventilation. Etiologies include pain or anxiety, neurologic disorders (meningitis, trauma), drugs (such as salicylates), fever or gram-negative bacteremia, thyrotoxicosis, or hypoxemia. Acute hypocapnia can cause an uptake of potassium and phosphate into cells and increased binding of calcium to albumin, leading to symptomatic hypokalemia, hypophosphatemia, and hypocalcemia, with subsequent arrhythmias, paresthesias, muscle cramps, and seizures. Treatment should be directed at the underlying cause, but also may require direct treatment of the hyperventilation.

FLUID AND ELECTROLYTE THERAPY

Parenteral Solutions

The type of fluid administered depends on the patient's volume status and the type of concentration or compositional abnormality present. Both lactated Ringer's solution and normal saline are considered isotonic and are useful in replacing GI losses and extracellular volume deficits. Lactated Ringer's solution is slightly hypotonic in that it contains 130 mEq of sodium, which is balanced by 109 mEq of chloride and 28 mEq of lactate. Lactate is more stable than bicarbonate and is converted into bicarbonate in the liver following infusion. Sodium chloride is mildly hypertonic, containing 154 mEq of sodium that is balanced by 154 mEq of chloride, which may lead to a hyperchloremic metabolic acidosis. It is an ideal solution, however, for correcting volume deficits associated with hyponatremia, hypochloremia, and metabolic alkalosis.

The less concentrated sodium solutions, such as 0.45 percent sodium chloride, are useful to replace ongoing GI losses and for maintenance fluid therapy in the postoperative period. The addition of 5 percent dextrose (50 g of dextrose per liter) supplies 200 kcal/L, and it always is added to solutions containing less than 0.45 percent sodium chloride to maintain osmolality and thus prevent lysis of red blood cells (RBCs) that may occur with rapid infusion of hypotonic fluids.

Alternative Resuscitative Fluids

A number of alternative solutions for volume expansion and resuscitation are now available. Hypertonic saline solutions (3.5 percent and 5 percent) are used for correction of severe sodium deficits whereas a 7.5 percent solution has been used as a treatment modality in patients with closed-head injuries and as a potential resuscitative fluid. Renewed interest in this solution has occurred with recent evidence of its antiinflammatory and immunomodulatory properties.

Colloids have long been debated as effective volume expanders compared to isotonic crystalloids. Because of their molecular weight, they are confined to the intravascular space and their infusion results in more efficient plasma volume expansion. However, under conditions of severe hemorrhagic shock, capillary membrane permeability increases, permitting colloids to enter the interstitial space, which can worsen edema and impair tissue oxygenation. There are four major types of colloids available: albumin, dextrans, hetastarch, and gelatins, which are described by their molecular weight and size. Colloid solutions with smaller size particles and lower molecular weights exert a greater oncotic effect, but are retained within the circulation for a shorter period of time than larger and higher molecular weight colloids.

Albumin (molecular weight 70,000) is prepared from pooled human plasma and is available as either a 5 or 25 percent solution. Because it is a derivative of blood, it can be associated with allergic reactions. Albumin has been shown to induce renal failure and impair pulmonary function when used for resuscitation of hemorrhagic shock.

Dextrans are glucose polymers produced by bacteria grown on sucrose media and are available as either 40,000 (dextran 40) or 70,000 (dextran 70) molecular-weight solutions. They lead to initial volume expansion because of their osmotic effect, but are associated with alterations in blood viscosity. Thus dextrans are used primarily to lower blood viscosity rather than as volume expanders. Dextrans have, however, been used in association with hypertonic saline to help maintain intravascular volume.

Hydroxyethyl starch solutions are another group of alternative plasma expanders. Hetastarch is the only hydroxyethyl starch approved for use in the United States. It has a limited role in massive resuscitation because of its associated coagulopathy and hyperchloremic acidosis. Hextend is a modified, balanced, high-molecular-weight hydroxyethyl starch also available in the United States that is suspended in a lactate-buffered solution, rather than in saline. Unlike Hetastarch, no adverse effects on coagulation with Hextend other than the known effects of hemodilution have been demonstrated. Hextend has not been tested in massive resuscitation, and not all clinical studies show consistent results.

Gelatins are the fourth group of colloids and are produced from bovine collagen. The two major types are urea-linked gelatin and succinylated gelatin (modified fluid gelatin, Gelofusine). Gelofusine has been used abroad with mixed results and is currently not approved for use in the United States.

Correction of Life-Threatening Electrolyte Abnormalities

Sodium

Hyponatremia. Treatment of hyponatremia entails treatment of the associated water deficit. In hypovolemic patients, volume should be restored with normal saline. Once adequate volume status has been achieved, the water deficit

is replaced using a hypotonic fluid. To estimate the water deficit required to correct hyponatremia use the following formula:

$$\text{Water deficit (L)} = \frac{\text{serum sodium} - 140}{140} \times \text{TBW}$$

Estimate TBW as 50 percent of lean body mass in men and 40 percent in women.

The rate of fluid administered should be titrated to achieve a decrease in serum sodium of no more than 1 mEq/h and 12 mEq/L for treatment of acute hyponatremia. Even slower correction should be undertaken with chronic hyponatremia (0.7 mEq/L/h), as overly rapid correction can lead to cerebral edema and herniation. The type of fluid depends on the severity and ease of correction. Caution also should be exercised when using 5 percent dextrose in water to avoid overly rapid correction.

Hypонатremia. In patients with normal renal function, symptomatic hyponatremia does not occur until the serum sodium level is greater than or equal to 120 mEq/L. If neurologic symptoms are present, 3 percent normal saline should be used to increase the sodium by no more than 1 mEq/L/h until the serum sodium level reaches 130 mEq/L or neurologic symptoms are improved. Correction of asymptomatic hyponatremia should increase the sodium level by no more than 0.5 mEq/L to a maximum increase of 12 mEq/L per day, and even slower in chronic hyponatremia. The rapid correction of hyponatremia can lead to pontine myelinolysis, with seizures, weakness/paresis, akinetic movements, and unresponsiveness, and may result in permanent brain damage and death.

Potassium

Hyperkalemia. The goal is to reduce total body potassium, shift potassium from extracellular to intracellular, and to protect cells from the effects of increased potassium. All patients should have exogenous sources of potassium discontinued. Potassium can be removed from the body with a cation-exchange resin, such as Kayexalate, which binds potassium in exchange for sodium. Measures should also include shifting potassium intracellularly with glucose and bicarbonate. Glucose alone will cause a rise in insulin secretion, but in the acutely ill this response may be blunted and therefore both glucose and insulin are recommended. Circulatory overload and hyponatremia may result from the administration of Kayexalate and bicarbonate. When ECG changes are present, calcium chloride or calcium gluconate (5–10 mL of 10 percent solution) should also be administered to counteract the myocardial effects of hyperkalemia. It should be used cautiously in patients on digitalis as digitalis toxicity may occur. Dialysis should be considered when conservative measures fail.

Hypokalemia. Oral repletion is adequate for mild and asymptomatic hypokalemia. If intravenous repletion is required, usually no more than 10–20 mEq/L/h is advisable in an unmonitored setting. This can be increased to 40 mEq/L/h when accompanied by ECG monitoring, and even higher if cardiac arrest is imminent from a malignant arrhythmia. Caution should be exercised when oliguria or impaired renal function is coexistent.

Magnesium

Hyper magnesemia. Treatment consists of measures to withhold exogenous sources of magnesium, correct volume deficit and acidosis if present. To manage symptoms, calcium chloride (5–10 mL) will antagonize the cardiovascular effects. If elevated levels or symptoms persist, dialysis is indicated.

Hypomagnesemia. Correction can be oral or intravenous. For severe deficits (<1.0 mEq/L) or symptoms, administer 1–2 g of magnesium sulfate intravenously over 15 min or over 2 min if secondary to torsades de pointes (irregular ventricular arrhythmia). Simultaneous calcium gluconate will counteract the adverse side effects of a rapidly rising magnesium level and correct hypocalcemia, which is frequently associated with hypomagnesemia.

Calcium

Hypercalcemia. Treatment is required for symptomatic hypercalcemia which usually occurs when the serum level exceeds 12 mg/dL. The initial treatment is aimed at repleting the associated volume deficit and then inducing a brisk diuresis with normal saline.

Hypocalcemia. Symptomatic hypocalcemia should be treated with intravenous 10 percent calcium gluconate until serum levels are 7–9 mg/dL. Associated deficits in magnesium, potassium, and pH also must be corrected. Hypocalcemia will be refractory to treatment if hypomagnesemia is not first corrected.

Phosphorus

Hyperphosphatemia. Either phosphate binders (sucralfate or aluminum-containing antacids) or calcium acetate tablets (if hypocalcemia is present) can be used as treatment modalities. Dialysis is reserved for patients with renal failure.

Hypophosphatemia. Both oral and intravenous supplementation are available.

Preoperative Fluid Therapy

Maintenance fluids can be calculated using the following formula:

For the first 0 to 10 kg	Give 100 mL/kg per day
For the next 10 to 20 kg	Give an additional 50 mL/kg per day
For weight > 20 kg	Give 20 mL/kg per day

Preoperative volume deficits also should be considered in patients presenting with obvious GI loss and in patients with poor oral intake. Less obvious are third-space losses that occur with GI obstruction, peritoneal or bowel inflammation, ascites, crush injuries, burns, and severe soft-tissue infections.

Once a volume deficit is diagnosed, prompt fluid replacement should be instituted, usually with an isotonic crystalloid. If symptomatic electrolyte abnormalities accompany volume deficit, the abnormality should be corrected to the extent that the acute symptom is relieved prior to surgical intervention.

Intraoperative Fluid Therapy

With the induction of anesthesia, compensatory mechanisms are lost and hypotension will develop if volume deficits are not appropriately corrected prior

to surgery. In addition to measured blood loss, open abdominal surgeries are associated with continued third-space losses. Large soft tissue wounds, complex fractures, and burns also must be considered.

Postoperative Fluid Therapy

Therapy should be based on the patient's current estimated volume status and projected ongoing fluid losses. Both preexisting deficits and third space losses should be included along with the maintenance fluids. Initial fluids should be isotonic and then can be changed to 0.45 percent saline with added dextrose after the initial 24–48 hr. If normal renal function and adequate urine output are present, potassium may be added to the intravenous fluids.

Special Considerations in the Postoperative Patient

Volume excess is a common disorder in the postoperative period. The earliest sign of volume overload is weight gain. The average postoperative patient who is not receiving nutritional support should lose approximately one-quarter to one-half pound per day. Peripheral edema may not necessarily be associated with volume overload, as overexpansion of total extracellular fluid may exist in association with a deficit in the circulating plasma volume.

Volume deficits also can be encountered in surgical patients if preoperative losses were not completely corrected, intraoperative losses were underestimated, or postoperative losses were greater than appreciated. In most cases of volume deficit, replacement with an isotonic fluid will be sufficient.

ELECTROLYTE ABNORMALITIES IN SPECIFIC SURGICAL PATIENTS

Neurologic Patients

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) can occur following head injury or surgery to the CNS, but it also is seen with drugs (such as morphine, nonsteroidals, and oxytocin) and in a number of pulmonary (pneumonia, abscess, and tuberculosis) and endocrine disease states (hypothyroidism and glucocorticoid deficiency), and malignancies (most notably small-cell cancer of the lung, but also pancreatic carcinoma, thymoma, and Hodgkin's disease). It should be considered in patients who are euvoletic and hyponatremic with elevated urine sodium (> 20 mEq/L) and urine osmolality. Antidiuretic hormone (ADH) stimulation is considered inappropriate in that it is not caused by osmotic or volume-related conditions. Correction of the underlying problem should be attempted. In most cases, restriction of free water will correct the problem. The goal is to achieve net water balance, but to avoid volume depletion that compromises renal function. Furosemide also can be used to induce free water loss.

Diabetes Insipidus

Diabetes insipidus (DI) is a disorder of antidiuretic hormone stimulation and is manifested by dilute urine in the face of hypernatremia. Central DI results from a defect in antidiuretic hormone secretion, and nephrogenic DI from a defect in end-organ responsiveness to ADH. Central DI is frequently seen in association with pituitary surgery or injury (closed-head injury or anoxic encephalopathy).

Nephrogenic DI occurs in association with hypokalemia, radiocontrast dye, and drugs such as aminoglycosides and amphotericin. In patients tolerating oral intake, volume status is usually normal as thirst stimulates increased intake. Volume depletion can occur in patients incapable of oral intake. The diagnosis can be confirmed by documenting an increase in urine osmolality in response to a period of water deprivation. If mild, free water replacement is all that is needed. In more severe cases, vasopressin (5 units subcutaneously) can be added.

Cerebral Salt Wasting

Cerebral salt wasting is a diagnosis of exclusion that occurs in patients with a cerebral lesion and renal wasting of sodium and chloride with no other identifiable cause. Natriuresis in a patient with a contracted extracellular volume should prompt the diagnosis. Hyponatremia occurs as a secondary event, differentiating it from SIADH.

Malnourished Patients: Refeeding Syndrome

This is a potentially lethal condition that can occur with rapid and excessive feeding of patients with severe underlying malnutrition because of starvation, alcoholism, delayed enteral or parenteral support, anorexia nervosa, or massive weight loss in obese patients. With refeeding, a shift in metabolism from fat to carbohydrate stimulates insulin release, resulting in the cellular uptake of phosphate, magnesium, potassium, and calcium. Because of blunted basal insulin secretion, severe hyperglycemia may also arise. Symptoms include cardiac arrhythmias, confusion, respiratory failure, and even death. To prevent refeeding syndrome, caloric repletion should be instituted slowly.

Acute Renal Failure Patients

There are a number of fluid and electrolyte abnormalities specific to patients with acute renal failure. Oliguric renal failure requires close monitoring of serum potassium. Treatment should be instituted early and may need to include dialysis. Hyponatremia is common in established renal failure and derives from the breakdown of proteins, carbohydrates, and fats, and administered free water. Dialysis is required for severe hyponatremia. Hypocalcemia, hypermagnesemia, and hyperphosphatemia also are associated with acute renal failure. Metabolic acidosis is commonly seen with renal failure, as the kidneys lose their ability to clear acid by-products. Bicarbonate may be used but dialysis is frequently required.

Cancer Patients

Hypocalcemia can be seen following removal of a thyroid or parathyroid tumor or following a central neck dissection by damage to the parathyroid glands. Hungry bone syndrome produces hypocalcemia following parathyroid surgery for secondary or tertiary hyperparathyroidism when calcium is rapidly taken up by bones. Prostate and breast cancer can result in increased osteoblastic activity that increases bone formation thereby decreasing serum calcium. Hypomagnesemia is a side effect of ifosfamide and cisplatin therapy. Hypophosphatemia can be seen with hyperparathyroidism as phosphorus reabsorption is decreased, although oncogenic osteomalacia increases urinary excretion of phosphorus. Acute hypophosphatemia can occur as rapidly proliferating malignant cells

take up phosphorus in acute leukemia or from hungry bone syndrome following parathyroidectomy. Tumor lysis syndrome or bisphosphonates can also cause hyperphosphatemia.

Malignancy is the most common etiology of hypercalcemia. Bone destruction from bony metastasis is seen with breast or renal cell cancer, but also can occur with multiple myeloma. With Hodgkin and non-Hodgkin lymphoma, hypercalcemia results from increased calcitriol formation, which in turn increases absorption of calcium from both the GI tract and bone. Humoral hypercalcemia of malignancy is a common cause of hypercalcemia in cancer patients. As parathyroid-related protein is secreted, it binds to parathyroid receptors, stimulating calcium resorption from bone and decreasing renal excretion of calcium. The treatment of hypercalcemia of malignancy should begin with saline volume expansion and then a loop diuretic. A variety of drugs also are available. Bisphosphonates (etidronate and pamidronate) inhibit bone resorption and osteoclastic activity. They act slowly (within 48 hr) but last for up to 15 days. Calcitonin also is effective by inhibiting bone resorption and increasing renal excretion of calcium. It acts quickly (2–4 hr), but its use is limited by the development of tachyphylaxis. Corticosteroids may decrease tachyphylaxis and can be used alone to treat hypercalcemia. Gallium nitrates are potent inhibitors of bone resorption. They display a long duration of action but can cause nephrotoxicity. Mithramycin blocks osteoclastic activity but can be associated with liver, renal, and hematologic abnormalities, and therefore its use is limited to the treatment of Paget disease of the bone. For patients in whom hypercalcemia is severe and refractory, or who are unable to tolerate volume expansion (because of pulmonary edema or congestive heart failure), dialysis is an option.

BIOLOGY OF HEMOSTASIS

Hemostasis is a complex process that prevents or terminates blood loss from the intravascular space, provides a fibrin network for tissue repair, and ultimately, removes the fibrin when it is no longer needed. Four major physiologic events participate in this process.

Vascular Constriction

This is the initial response to injury, even at the capillary level. Vasoconstriction begins prior to platelet adherence as a reflex response to various stimuli. It is subsequently linked to platelet plug and fibrin formation. The vasoconstrictors thromboxane A_2 (TXA₂) and serotonin are released during platelet aggregation. Local physical factors, including the extent and orientation of injury to the blood vessel, also may influence the degree of bleeding.

Platelet Function

Platelets normally number 150,000–400,000/mm³, with an average life span of 10 days. They contribute to hemostasis by two processes. *Primary hemostasis* is a reversible process that is not affected by heparin administration. Platelets adhere to the subendothelial collagen of disrupted vascular tissue. This process requires von Willebrand factor (vWF), a protein congenitally absent in von Willebrand disease. The platelets expand and initiate a release reaction, recruiting additional platelets. The resulting aggregate forms a plug, sealing the disrupted vessel. ADP, TXA₂, and serotonin are the prominent mediators in this process. Opposing these mediators are prostacyclin, endothelium-derived relaxing factor (EDRF), and prostaglandin E₂ (PGE₂), which are vasodilators and inhibit aggregation. The second process by which platelets act, which is irreversible, involves *fibrinogen-dependent degranulation*. Platelet factor 3 is released, acting at several points in the coagulation cascade. Platelet-derived mediators also influence the subsequent fibrinolytic process.

Coagulation

Coagulation refers to a cascade of zymogen activation that ultimately results in the cleavage of fibrinogen to insoluble fibrin that stabilizes the platelet plug. The *intrinsic* pathway is initiated by exposure of coagulation factors to subendothelial collagen at the site of vascular damage. The *extrinsic* pathway is activated by tissue factors (glycoproteins). The two pathways converge at activated factor X (Xa), which, in turn, cleaves prothrombin to thrombin. All the coagulation factors except thromboplastin, factor VIII, and Ca²⁺ are synthesized in the liver. Factors II, VII, IX, and X are dependent on vitamin K.

Fibrinolysis

The patency of blood vessels is maintained by lysis of fibrin deposits and by antithrombin III (which neutralizes several of the proteases in the complement cascade). Fibrinolysis depends on plasmin, which is derived from the precursor plasma protein plasminogen. Plasmin lyses fibrin, the fragments of which interfere with platelet aggregation.

TESTS OF HEMOSTASIS AND BLOOD COAGULATION

The most valuable part of this assessment is a careful history and physical examination. Specific questions should be asked to determine if there was a prior history of transfusion, untoward bleeding during a major surgical procedure, any bleeding after a minor operation, any spontaneous bleeding, or any family history of bleeding difficulties.

The history should include a list of medications and underlying medical disorders (e.g., malignancy, liver or kidney disease) that may affect normal hemostasis. Laboratory studies also provide important clues of hemostatic ability.

Platelet count. Spontaneous bleeding rarely occurs with a platelet count of greater than $50,000/\text{mm}^3$. Platelet counts in this range are usually adequate to provide hemostasis following trauma or surgical procedures if other hemostatic factors are normal.

Bleeding time. This assesses the interaction between platelets and a damaged blood vessel and the formation of a platelet plug. Deficiencies in platelet number, platelet function, or some coagulation factors will yield a prolonged bleeding time.

Prothrombin time (PT). This test measures the extrinsic pathway of blood coagulation. Thromboplastin, a procoagulant, is added with calcium to an aliquot of citrated plasma, and the clotting time is determined. The test will detect deficiencies in factors II, V, VII, and X or fibrinogen.

Partial thromboplastin time (PTT). A screen of the intrinsic clotting pathway, the PPT will determine abnormalities in factors VIII, IX, XI, and XII. This test has a high sensitivity; only extremely mild deficiencies in factor VIII or IX will be missed. The PTT, used in conjunction with the PT, can help place a clotting defect in the first or second stage of the clotting process.

Thrombin time (TT). This screen detects abnormalities in fibrinogen and will detect circulating anticoagulants and inhibitors of anticoagulation.

Tests of fibrinolysis. Fibrin degradation products (FDPs) can be measured immunologically. Falsely positive results ($>10 \text{ mg/mL}$) may be seen in liver disease, kidney disease, thromboembolic disorders, and pregnancy.

EVALUATION OF THE SURGICAL PATIENT AS A HEMOSTATIC RISK

Preoperative Evaluation of Hemostasis

Rapaport has suggested four levels of concern (given the patient's history and the proposed operation) that should dictate the extent of preoperative testing.

Level I: The history is negative, and the procedure is relatively minor (e.g., breast biopsy or hernia repair). No screening tests are recommended.

Level II: The history is negative and a major operation is planned, but significant bleeding is not expected. A platelet count, blood smear, and PTT are recommended to detect thrombocytopenia, circulating anticoagulant, or intravascular coagulation.

Level III: The history is suggestive of defective hemostasis, and the patient is to undergo a procedure in which hemostasis may be impaired, such as operations using pump oxygenation or cell savers. This level also applies to situations where minimal postoperative bleeding could be detrimental, such as intracranial operations. A platelet count and bleeding time should be done to assess platelet function. A PT and PTT should be used to evaluate coagulation, and the fibrin clot should be checked to screen for abnormal fibrinolysis.

Level IV: These patients have a known hemostatic defect or a highly suggestive history. The same tests suggested for level III should be checked, and a hematologist should be consulted. In case of an emergency, assessment of platelet aggregation and a TT are indicated to detect dysfibrinogenemia or a circulating anticoagulant.

Patients with liver disease, obstructive jaundice, kidney failure, or malignancy should have the platelet count, PT, and PTT checked preoperatively.

CONGENITAL DEFECTS IN HEMOSTASIS

Classical Hemophilia (Factor VIII Deficiency)

Classical hemophilia (hemophilia A) is a sex-linked recessive disorder in which there is a failure to synthesize normal factor VIII. The incidence is approximately 1 in 10,000 to 1 in 15,000 persons. Spontaneous mutations account for almost 20 percent of cases. Clinical expression of the disease is highly variable.

The severity of the clinical manifestations is related to the degree of factor deficiency. Spontaneous bleeding and severe complications are the rule when virtually no factor VIII activity can be detected. Concentrations of approximately 5 percent of normal may produce no spontaneous bleeding, yet there may be severe bleeding with trauma or surgical therapy.

Significant bleeding is usually first noted when the subject is a toddler. At that time the child may be subject to bleeding into joints, epistaxis, and hematuria. Intracranial bleeding, associated with trauma in half the cases, accounts for 25 percent of deaths. Hemarthrosis is the most characteristic orthopedic problem. Retroperitoneal bleeding or intramural intestinal hematoma also may occur, causing nausea, vomiting, or crampy abdominal pain. Upper gastrointestinal examination may demonstrate uniform thickening of mucosal folds ("picket fence" or "stack of coins" appearance).

Treatment. The plasma concentration of factor VIII necessary to provide hemostatic integrity is normally quite small (as little as 2–3 percent). Once serious bleeding begins, however, much higher levels (30 percent) of activity are required to achieve hemostasis. The half-life of factor VIII is 8–12 h; after an initial transfusion, its half-life is approximately 4 h. One unit of factor VIII is considered to be the amount present in 1 mL normal plasma. Cryoprecipitate concentrates of factor VIII contain 9.6 units/mL. The amount of activity suggested to be repleted varies according to the severity of the lesion. To calculate

the amount of factor VIII needed: 1 unit/kg of body weight will yield approximately a 2 percent rise in activity. Half this amount is subsequently administered every 4–6 h to maintain a safe level.

Wet-frozen cryoprecipitate is preferred for replacement in patients with mild hemophilia, since it provides the lowest risk of viral hepatitis. Factor VIII concentrates are preferred in severe disease. In mild hemophilia A and mild von Willebrand disease, dDAVP, a synthetic derivative of vasopressin, has been used to produce a dose-dependent increase in all factor VIII activities and release plasminogen activator. Following major surgical treatment of a hemophiliac, transfusion replacement of factor VIII should be continued for at least 10 days. Even relatively minor procedures should be supplemented with factor VIII to achieve levels above 25–30 percent.

Christmas Disease (Factor IX Deficiency)

Factor IX deficiency is clinically indistinguishable from factor VIII deficiency. It is also inherited as an X-linked recessive disease with variable expression. The clinically severe form of the disease has a level of less than 1 percent of normal activity. Half the patients belong to this group.

Treatment. All patients require substitution therapy when major or minor surgery is performed. Current therapy involves the administration of factor IX concentrate. The initial half-life is shorter than that of factor VIII; its steady-state half-life is much longer (18–40 h). A number of factor IX concentrates are available. Konyne contains 10–60 units/mL of factor IX but has been associated with thromboembolic complications. Newer preparations have had additional clotting factors removed, and the incidence of thromboembolic events is lower. During severe hemorrhage, treatment should be directed to achieving levels of 20–50 percent of normal for the first 3–5 days and then maintaining a plasma level of 20 percent for approximately 10 days. Plasma activity should be monitored during the course of therapy. The development of antibodies occurs in about 10 percent of patients.

von Willebrand Disease

von Willebrand disease occurs in approximately 1 in 1000 individuals. The clinically severe form of the disease occurs much less frequently. This disorder is usually transmitted as an autosomal dominant trait, but recessive inheritance may occur. The disease is characterized by abnormal vWF and a decrease in the level of factor VIII:C (procoagulant) activity, which corrects the clotting abnormality in hemophilia A. Characteristically, patients with this disease have a prolonged bleeding time, but this is less consistent than the factor VIII:C reduction. A given patient may have an abnormal bleeding time on one occasion and a normal bleeding time on another. Ristocetin fails to cause platelet aggregation in about 70 percent of patients with this disease.

Clinical manifestations. Clinical manifestations are usually minimal until trauma or surgery makes them apparent. Spontaneous bleeding is often limited to the skin or mucous membranes. Epistaxis and menorrhagia are relatively common. Serious bleeding following minor surgery is not uncommon.

Treatment. Treatment is directed at correcting the bleeding time and factor VIII R:vWF (the von Willebrand factor). Only cryoprecipitate is effective (10–40 units/kg q12h). Replacement therapy should start 1 day before surgery,

and the duration of therapy should be the same as that described for classic hemophilia.

ACQUIRED HEMOSTATIC DEFECTS

Platelet Abnormalities

Thrombocytopenia, the most common abnormality of hemostasis in the surgical patient, may be due to massive blood loss, medications, or a variety of disease processes. Heparin-induced thrombocytopenia is notable for being reported in 0.6 percent of patients receiving heparin and is thought to be immune mediated. The lowest platelet counts occur after 4–15 days of initial therapy and after 2–9 days in patients receiving subsequent courses.

Abnormalities in platelet number also may be accompanied by abnormalities in function. Uremia affects bleeding time and platelet aggregation. Defects in platelet aggregation and secretion occur in patients with thrombocytopenia, polycythemia, or myelofibrosis.

Treatment. A count greater than $50,000/\text{mm}^3$ requires no specific therapy. Thrombocytopenia due to acute alcoholism, drug effect, or viral infection generally will correct within 1–3 weeks. Severe thrombocytopenia may be due to vitamin B₁₂ or folate deficiency. This condition is usually responsive to the appropriate nutrient therapy. In patients with idiopathic thrombocytopenia or lupus erythematosus, a platelet count of less than $50,000/\text{mm}^3$ may respond to steroid therapy or plasmapheresis. Splenectomy alone should not be performed to correct thrombocytopenia associated with splenomegaly due to portal hypertension.

Prophylactic platelet administration is not routinely required following massive blood transfusions. One unit of platelets contains approximately 5.5×10^5 platelets and would be expected to increase the circulating platelet count by $10,000/\text{mm}^3$ in a 70-kg man. In patients refractory to standard platelet transfusion, the use of human leukocyte antigen (HLA)-compatible platelets has proved effective.

Acquired Hypofibrinogenemia-Defibrination Syndrome (Fibrinogen Deficiency)

This is rarely an isolated defect because deficiencies in factors II, VI, and VIII and platelets usually accompany this state. Most patients with acquired hypofibrinogenemia suffer from disseminated intravascular coagulation (DIC). DIC is caused by the introduction of thromboplastic material into the circulation. This syndrome has been seen with a retained dead fetus, separation of the placenta, and amniotic fluid embolism. Defibrination has been observed in association with extracorporeal circulation, disseminated carcinoma, lymphoma, and a variety of infections (including both gram-negative and gram-positive sepsis).

It is difficult to distinguish DIC from secondary fibrinolysis because both show prolongation in the TT, PTT, and PT. The combination of a low platelet count, a positive plasma protamine test, reduced fibrinogen, and increased FDPs (taken in the context of the patient's underlying disease) is highly suggestive of the syndrome.

The prime consideration in treatment is relieving the underlying medical problem. The use of intravenous fluids is indicated to maintain volume. If there is active bleeding, hemostatic factors should be replaced with fresh frozen

plasma, cryoprecipitate, and platelet concentrates as needed. Most studies show that heparin is not indicated in acute forms of DIC but is indicated for purpura fulminans or venous thromboembolism. Fibrinolytic inhibitors may be used to block the accumulation of FDPs. They should not be used without prior effective antithrombotic treatment with heparin.

Fibrinolysis

The acquired hypofibrinogenemic state in the surgical patient also may be due to pathologic fibrinolysis. This can be seen in patients with metastatic prostatic carcinoma, shock, sepsis, hypoxia, neoplasia, cirrhosis, and portal hypertension. A reduction in fibrinogen and factors V and VIII is seen, since they all are substrates for the enzyme plasmin. Thrombocytopenia is not an accompaniment of the purely fibrinolytic state. Treatment of the underlying disorder (if identified) is warranted. ϵ -Aminocaproic acid (EACA), an inhibitor of fibrinolysis, also may be useful.

Myeloproliferative Diseases

Thrombocytopenia can be treated by standard therapy for the underlying disease. Ideally, the hematocrit should be kept below 48 percent and the platelet count less than $400,000/\text{mm}^3$. In a study with polycythemic patients undergoing major surgical procedures, 46 percent had complications perioperatively, including a 16 percent mortality (in 80 percent of whom the disease was not under control). Hemorrhage is the most common complication in this group, followed by thrombosis and infection. Preoperative use of antiplatelet agents (e.g., aspirin, dipyridamole) and anticoagulants has been suggested in these patients.

LIVER DISEASE

Advanced liver disease may result in decreased synthesis of the coagulation factors II, V, VII, X, and XIII. Also, there may be increased fibrinolysis due to the failure of the liver to clear plasminogen activators.

ANTICOAGULATION AND BLEEDING

Spontaneous bleeding may be a complication of anticoagulant therapy, with an incidence proportional to the degree of anticoagulation. Surgical therapy may be necessary in patients receiving anticoagulant therapy. The risk of thrombotic complications is increased when anticoagulant therapy is suddenly discontinued and may be due to a "rebound phenomenon." When the clotting time is less than 25 min in the heparinized patient or when the PT is less than 1.5 times control, reversal of anticoagulant therapy may not be necessary. If an emergent surgical procedure is necessary, anticoagulation can be reversed. Heparin can be reversed with protamine sulfate (1 mg protamine per 1000 units heparin). Bleeding is infrequently related to hypoprothrombinemia if the prothrombin concentration is greater than 15 percent. Warfarin can be discontinued several days before surgery. If emergency surgery is required, parenteral vitamin K₁ can be used. Reversal may take up to 6 h, so fresh frozen plasma may be needed.

LOCAL HEMOSTASIS

The goal of local hemostasis is to prevent the flow of blood from incised or transected blood vessels. The techniques may be classified as mechanical, thermal, or chemical.

Mechanical

The oldest mechanical device to effect closure of a bleeding point or to prevent blood from entering an area of disruption is digital pressure. The finger has the advantage of being the least traumatic means of hemostasis. Diffuse bleeding from multiple transected vessels may be controlled by mechanical techniques, including direct pressure over the bleeding area, pressure at a distance, or generalized pressure. Direct pressure is preferable and is not attended by the danger of tissue necrosis associated with a tourniquet. Gravitational suits have been used to create generalized pressure.

The hemostat represents a temporary mechanical device to stem bleeding. Ligature replaces a hemostat as a permanent method of hemostasis of a single vessel.

Thermal

Cautery effects hemostasis by denaturation of proteins, which results in coagulation of large areas of tissue. Cooling also has been applied to control bleeding and acts by increasing the local intravascular hematocrit and decreasing the blood flow by vasoconstriction. Cryogenic surgery uses temperatures between -20 (-4°F) and -180°C (-292°F).

Chemical

Some chemicals act as vasoconstrictors, others are procoagulants, and others have hygroscopic properties that aid in plugging disrupted blood vessels. Epinephrine is a vasoconstrictor, but because of its considerable absorption and systemic effects, it is generally used only on areas of mucosal oozing. Local hemostatic materials include gelatin foam, cellulose, and micronized collagen.

TRANSFUSION

Approximately 14 percent of all inpatient operations include blood transfusions. Blood provides transportation of oxygen to meet the body's metabolic demands and removes carbon dioxide.

Replacement Therapy

Banked whole blood is stored at 4°C (39.2°F) and has a storage life of up to 35 days. Up to 70 percent of transfused erythrocytes remain in the circulation 24 h after transfusion; 60 days after transfusion, approximately 50 percent of the cells will survive. Banked blood is rarely indicated.

Banked blood is a poor source of platelets. Factors II, VII, IX, and XI are stable in banked blood. Factor VIII rapidly deteriorates during storage. During the storage of whole blood, red cell metabolism and plasma protein degradation result in chemical changes in the plasma, including increases in lactate, potassium, and ammonia and a decrease in pH.

Typing and cross-matching. Serologic compatibility is routinely established for donor and recipient A, B, O, and Rh groups. As a rule, Rh-negative recipients should be transfused only with Rh-negative blood. In the patient receiving repeated transfusions, serum drawn less than 48 h before cross-matching should be used. Emergency transfusion can be performed with group O blood. If it is known that the prospective recipient is group AB, group A blood is preferable.

Fresh whole blood. This term refers to blood given within 24 h of its collection.

Packed red cells and frozen red cells. Packed cells have approximately 70 percent of the volume of whole blood. Use of frozen cells markedly reduces the risk of infusing antigens to which the patients have previously been sensitized. The red cell viability is improved, and the ATP and 2,3-diphosphoglycerate (2,3-DPG) concentrations are maintained.

Platelet concentrates. Platelet transfusions should be used for thrombocytopenia due to massive blood loss replaced with stored blood, thrombocytopenia due to inadequate production, and qualitative platelet disorders. Isoantibodies are demonstrated in about 5 percent of patients after 1–10 transfusions, 20 percent after 10–20 transfusions, and 80 percent after more than 100 transfusions. HLA-compatible platelets minimize this problem.

Fresh frozen plasma and volume expanders. Factors V and VIII require plasma to be fresh or freshly frozen to maintain activity. The risk of hepatitis is the same as that of whole blood or packed red cells. In emergency situations, lactated Ringer solution can be administered in amounts two to three times the estimated blood loss. Dextran or lactated Ringer solution with albumin can be used for rapid plasma expansion.

Concentrates. Antihemophilic concentrates are prepared from plasma with a potency of 20–30 times that of fresh frozen plasma. The simplest factor VIII concentrate is plasma cryoprecipitate. Albumin also may be used as a concentrate (25 g has the osmotic equivalent of 500 mL), with the advantage of being hepatitis-free.

INDICATIONS FOR REPLACEMENTS OF BLOOD OR ITS ELEMENTS

Volume replacement. The most common indication for blood transfusion in the surgical patient is the restoration of circulating blood volume. The hematocrit can be used to estimate blood loss, but up to 72 h is required to establish a new equilibrium after a significant blood loss.

In the normal person, reflex mechanisms allow the body to accommodate up to moderate-size blood losses. Significant hypotension develops only after about a 40 percent loss of blood volume.

Loss of blood during operation may be estimated by weighing the sponges (representing about 70 percent of the true loss). For patients who have normal preoperative blood values, Table 3-1 shows replacement recommendations.

Improvement in oxygen-carrying capacity. Transfusion should be performed only if treatment of the underlying anemia does not provide adequate blood counts for the patient's clinical condition. In general, raising hemoglobin levels above 7–8 g/dL provides little additional benefit. A whole blood substitute, Fluosol-DA, provides oxygen-carrying capacity in the absence of blood products.

TABLE 3-1 Blood Replacement Recommendations

Percentage of total blood volume loss	Replacement
20	Crystalloid solutions
20–50	Crystalloids and red cell concentrates (RBCs)
Above 50	Crystalloids, RBCs, and albumin or plasma
Continued bleeding above 50	Crystalloids, RBCs, fresh frozen plasma, and albumin or plasma

Replacement of clotting factors. Supplemental platelets or clotting factors may be required in the treatment of certain hemorrhagic conditions. Fresh frozen plasma is used in the treatment of a coagulopathy in patients with liver disease, but its efficacy is very low. The rigid use of PT and PTT to anticipate the effect of fresh frozen plasma is not justified. If fibrinogen is required, a plasma level greater than 100 mg/dL should be maintained.

Massive transfusion. This term refers to a single transfusion of greater than 2500 or 5000 mL over a 24-h period. A number of problems may accompany the use of massive transfusion, including thrombocytopenia, impaired platelet function, deficiency in factors V, VIII, and XI, and the increased acid load of stored blood products.

With large transfusions, a heater may be used to warm the blood, since hypothermia may result in decreased cardiac output and an acidosis.

Complications (Table 3-2)

Hemolytic reactions from blood group incompatibilities are usually manifest by a sensation of warmth and pain along the site of transfusion, flushing in the face, pain in the lumbar region, and constricting pain in the chest. The patient additionally may experience chills, fever, and respiratory distress. In anesthetized patients, two signs of reaction are abnormal bleeding and continued hypotension in the face of adequate replacement. The morbidity and mortality of hemolytic reactions are high and include oliguria, hemoglobinuria, hypotension, jaundice, nausea, and vomiting. The transfusion should be stopped immediately if a transfusion reaction is suspected. Samples of the recipient and donor blood should be sent for comparison with pretransfusion samples. Renal function should be monitored following a suspected transfusion reaction. Renal toxicity is affected by the rate of urinary excretion and the pH. Alkalinization of the urine prevents precipitation of hemoglobin.

TABLE 3-2 Complications of Transfusion

Complication	Risk per unit blood product
Infectious	
Hepatitis C	1:3300
Human immunodeficiency virus	1:40,000–1:225,000
Human T-lymphocyte virus (I and II)	1:50,000
Hepatitis B	1:200,000
Immunologic	
Fever, chills, urticaria	1:50–1:100
Hemolytic reaction	1:1000
Fatal hemolytic reaction	1:100,000

Febrile and allergic reactions. These occur in approximately 1 percent of transfusions. They appear as urticaria and fever occurring within 60–90 min of the start of the transfusion. Occasionally, the allergic reaction is severe enough to cause anaphylactic shock. Treatment consists of antihistamines, epinephrine, and steroids, depending on the severity of the reaction.

Transmission of disease. Posttransfusion viral hepatitis is the most common fatal complication of blood transfusion. Other viral illnesses may be transmitted (e.g., cytomegalovirus, human immunodeficiency virus, etc.), as well as several bacterial species.

Additional, less frequent complications include

Embolism: Intravenous volumes of less than 200 mL are generally well tolerated by normal adults.

Volume overload: The patient's risk is related to underlying cardiac reserve.

Bacterial sepsis: Gram-negative organisms and *Pseudomonas* predominate.

Thrombophlebitis: More commonly seen with prolonged infusions.

and Timothy R. Billiar*

Shock may be defined as inadequate delivery of oxygen and nutrients to maintain normal tissue and cellular function. The resultant cellular injury is initially reversible; if the hypoperfusion is severe enough and prolonged, the cellular injury becomes irreversible. The clinical manifestations of shock are the result of stimulation of the sympathetic and neuroendocrine stress responses, inadequate oxygen delivery, and end-organ dysfunction. Inadequate oxygen delivery is presumed to be the pathologic defect in shock. The management of the patient in shock is empiric; securing the airway and restoration of vascular volume and tissue perfusion often occur prior to definitive diagnosis.

The failure of physiologic systems to buffer the organism against external forces results in organ and cellular dysfunction, what is clinically recognized as shock.

Six types of shock have been described: hypovolemic, septic (vasodilatory), neurogenic, cardiogenic, obstructive, and traumatic shock. Hypovolemic shock, the most common type, results from loss of circulating blood volume. This may result from loss of whole blood (hemorrhagic shock), plasma, interstitial fluid (bowel obstruction), or a combination. Vasogenic shock results from decreased resistance within capacitance vessels, usually seen in sepsis. Neurogenic shock is a form of vasogenic shock in which spinal cord injury or spinal anesthesia causes vasodilatation because of acute loss of sympathetic vascular tone. Cardiogenic shock results from failure of the heart as a pump, as in arrhythmias or acute heart failure. Obstructive shock, caused by pulmonary embolism or tension pneumothorax, results in depressed cardiac output, which results from mechanical impediment to circulation rather than a primary cardiac failure. In traumatic shock, the soft-tissue injury and long-bone fractures that occur in association with blood loss yield an upregulation of proinflammatory mediators that is more complex than simple hemorrhagic shock. The clinical dilemma faced in a patient with shock is that the etiology may not be immediately apparent. Inadequate treatment results in ongoing hypoperfusion and activation of inflammatory mediators. Thus, treatment of the patient in shock is initially empiric, although the underlying etiology of the shock state is investigated.

Core principles in the early management of the critically ill or injured patient include: (1) definitive control of the airway, (2) prompt control of active hemorrhage (generally in the operating room, as delay in control of ongoing bleeding increases mortality), (3) volume resuscitation with red blood cells and crystalloid solution while operative control of bleeding is achieved (operating room resuscitation), (4) unrecognized or inadequately corrected hypoperfusion increases morbidity and mortality, and (5) care that excessive fluid resuscitation is monitored as it may exacerbate bleeding. Thus, both inadequate and uncontrolled volume resuscitation are harmful.

PATHOPHYSIOLOGY

Shock is defined as tissue hypoperfusion that is insufficient to maintain normal aerobic metabolism. The initial insult, whether hemorrhage, injury, or

infection, initiates both a neuroendocrine and inflammatory mediator response. The magnitude of the physiologic response is proportional to both the degree and the duration of the shock. Although the quantitative nature of the physiologic response in shock will vary with the etiology of shock, the qualitative nature of the response to shock is similar, with common pathways in all types of shock. Persistent hypoperfusion will result in hemodynamic derangements, end-organ dysfunction, cell death, and death of the patient if treated late or inadequately. Hemorrhagic shock most often is seen clinically; bleeding and resuscitation produce a “whole body” ischemia-reperfusion injury. The physiologic responses to hypovolemia are directed at preservation of perfusion to the heart and brain. To this end, vasoconstriction occurs, fluid excretion is curtailed, and fluid is shifted into the intravascular space. The major mechanisms achieving this response are: (1) prompt increase in cardiac contractility and peripheral vascular tone via the autonomic nervous system, (2) hormonal response to preserve salt and intravascular volume, and (3) changes in the local microcirculation to regulate regional blood flow. With substantial physiologic compensatory mechanisms for small volume blood loss, predominantly through the neuroendocrine response, hemodynamics may be maintained. This represents the compensated phase of shock. With continued hypoperfusion often not apparent clinically, cell death and tissue injury are ongoing and the decompensation phase of shock evolves. At this point in treatment, the cellular dysfunction can be reversed with appropriate volume resuscitation. If volume loss continues or volume resuscitation is insufficient, a vicious physiologic cycle will develop. With persistent hypoperfusion with low cardiac output, regional tissue hypoperfusion and progressive tissue and microcirculatory changes induce cardiovascular decompensation. This progression to the irreversible phase of shock often is insidious and recognized only in retrospect. Sufficient tissue injury and cell death have occurred to this point that continued volume resuscitation fails to reverse the process. Ultimately, even massive quantities of fluid resuscitation and vasopressors fail to maintain adequate blood pressure. As discussed later in this chapter, this vasodilatory response probably represents the common late phase of all forms of shock, regardless of etiology.

NEUROENDOCRINE RESPONSE

The goal of the neuroendocrine response to hemorrhage is to maintain perfusion to the heart and the brain, even at the expense of other organ systems. Peripheral vasoconstriction occurs and fluid excretion is inhibited. The mechanisms include autonomic control of peripheral vascular tone and cardiac contractility, hormonal response to stress and volume depletion, and local microcirculatory mechanisms that are organ specific and regulate regional blood flow. The initial stimulus is loss of circulating blood volume in hemorrhagic shock. The magnitude of the neuroendocrine response is based on both the volume of blood lost and the rate at which it is lost.

Afferent Signals

Afferent impulses transmitted from the periphery are processed within the central nervous system (CNS) and activate the reflexive effector responses or efferent impulses. These effector responses are designed to expand plasma

volume, maintain peripheral perfusion and tissue oxygen delivery, and restore homeostasis. Stimuli that can produce the neuroendocrine response include hypocolemia, pain, hypoxemia, hypercarbia, acidosis, infection, changes in temperature, emotional arousal, or hypoglycemia. The sensation of pain from injured tissue is transmitted via the spinothalamic tracts, resulting in activation of the hypothalamic-pituitary-adrenal axis, and activation of the autonomic nervous system (ANS) to induce direct sympathetic stimulation of the adrenal medulla to release catecholamines.

Baroreceptors in the atria of the heart become activated with low-volume hemorrhage or mild reductions in right atrial pressure. Receptors in the aortic arch and carotid bodies respond to alterations in pressure or stretch of the arterial wall, responding to larger reductions in intravascular volume or pressure. These receptors normally inhibit induction of the ANS. When activated, these baroreceptors diminish their output, thus disinhibiting the effect of the ANS. The autonomic nervous system then increases its output, principally via sympathetic activation at the vasomotor centers of the brain stem, producing centrally mediated constriction of peripheral vessels.

Chemoreceptors in the aorta and carotid bodies are sensitive to changes in oxygen tension, H^+ ion concentration, and CO_2 levels. Stimulation of the chemoreceptors results in vasodilatation of the coronary arteries, slowing of the heart rate, and vasoconstriction of the splanchnic and skeletal circulation.

Efferent Signals

Cardiovascular Response

Hemorrhage results in diminished venous return to the heart and decreased cardiac output. This is compensated by increased cardiac heart rate and contractility, and venous and arterial vasoconstriction. Stimulation of sympathetic fibers innervating the heart leads to activation of β_1 -adrenergic receptors that increase heart rate and contractility in this attempt to increase cardiac output. Increased myocardial oxygen consumption occurs as a result of the increased workload; thus, myocardial oxygen supply must be maintained or myocardial dysfunction will develop.

Direct sympathetic stimulation of the peripheral circulation via the activation of α_1 -adrenergic receptors on arterioles induces vasoconstriction and causes a compensatory increase in systemic vascular resistance and blood pressure. Selective perfusion to tissues occurs because of regional variations in arteriolar resistance, with blood shunted away from less essential organ beds such as the intestine, kidney, and skin. In contrast, the brain and heart have autoregulatory mechanisms that attempt to preserve their blood flow despite a global decrease in cardiac output. Direct sympathetic stimulation also induces constriction of venous vessels, decreasing the capacitance of the circulatory system and accelerating blood return to the central circulation.

Increased sympathetic output induces catecholamine release from the adrenal medulla. Catecholamine levels peak within 24–48 hours of injury, and then return to baseline. The majority of the circulating epinephrine is produced by the adrenal medulla, whereas norepinephrine is derived from synapses of the sympathetic nervous system. Catecholamine effects on peripheral tissues include stimulation of hepatic glycogenolysis and gluconeogenesis to increase circulating glucose availability to peripheral tissues, an increase in skeletal

muscle glycogenolysis, suppression of insulin release, and increased glucagon release.

Hormonal Response

The stress response includes activation of the autonomic nervous system as discussed above, and activation of the hypothalamic-pituitary-adrenal axis. Shock stimulates the hypothalamus to release corticotropin-releasing hormone, that results in the release of adrenocorticotrophic hormone (ACTH) by the pituitary. ACTH subsequently stimulates the adrenal cortex to release cortisol. Cortisol acts synergistically with epinephrine and glucagon to induce a catabolic state. Cortisol stimulates gluconeogenesis and insulin resistance, resulting in hyperglycemia and muscle cell protein breakdown and lipolysis to provide substrates for hepatic gluconeogenesis. Cortisol causes retention of sodium and water by the nephrons of the kidney. In the setting of severe hypovolemia, ACTH secretion occurs independently of cortisol negative feedback inhibition.

The renin-angiotensin system is activated in shock. Decreased renal artery perfusion, β -adrenergic stimulation, and increased renal tubular sodium concentration cause the release of renin from the juxtaglomerular cells. Renin catalyzes the conversion of angiotensinogen (produced by the liver) to angiotensin I, which is then converted to angiotensin II by angiotensin-converting enzyme (ACE) produced in the lung. Although angiotensin I has no significant functional activity, angiotensin II is a potent vasoconstrictor of both splanchnic and peripheral vascular beds, and also stimulates the secretion of aldosterone, ACTH, and antidiuretic hormone (ADH). Aldosterone, a mineralocorticoid, acts on the nephron to promote reabsorption of sodium, and as a consequence, water. Potassium and hydrogen ions are lost in the urine in exchange for sodium.

The pituitary also releases vasopressin or ADH in response to hypovolemia, changes in circulating blood volume sensed by baroreceptors and left atrial stretch receptors, and increased plasma osmolality detected by hypothalamic osmoreceptors. Epinephrine, angiotensin II, pain, and hyperglycemia increase production of ADH. ADH acts on the distal tubule and collecting duct of the nephron to increase water permeability, decrease water and sodium losses, and preserve intravascular volume. Also known as arginine vasopressin, ADH acts as a potent mesenteric vasoconstrictor, shunting circulating blood away from the splanchnic organs during hypovolemia. Vasopressin also increases hepatic gluconeogenesis and increases hepatic glycolysis.

Circulatory Homeostasis

Preload

At rest, the majority of the blood volume is within the venous system. Venous return to the heart generates ventricular end-diastolic wall tension, a major determinant of cardiac output. With decreased arteriolar inflow, there is active contraction of the venous smooth muscle and passive elastic recoil in the thin-walled systemic veins. This increases venous return to the heart, thus maintaining ventricular filling.

Ventricular Contraction

The Frank-Starling curve describes the force of ventricular contraction as a function of its preload. This relationship is based on force of contraction being determined by initial muscle length. Intrinsic cardiac disease will shift the

Frank-Starling curve and alter mechanical performance of the heart. Additionally, cardiac dysfunction has been demonstrated experimentally in burns and in hemorrhagic, traumatic, and septic shock.

Afterload

Afterload is the force that resists myocardial work during contraction. Arterial pressure is the major component of afterload influencing the ejection fraction. This vascular resistance is determined by precapillary smooth muscle sphincters. Blood viscosity will also increase vascular resistance. As afterload increases in the normal heart, stroke volume can be maintained by increases in preload. In shock, with decreased circulating volume and therefore diminished preload, this compensatory mechanism to sustain cardiac output is impeded.

Cellular Effects

As oxygen tension within cells decreases, there is a decrease in oxidative phosphorylation and the generation of adenosine triphosphate (ATP) slows or stops. When oxygen delivery is impaired so severely that mitochondrial respiration cannot be sustained, the state is called "dysoxia." As oxidative phosphorylation slows, the cells shift to anaerobic glycolysis that allows for the production of ATP from the breakdown of cellular glycogen. Under aerobic conditions, pyruvate, the end-product of glycolysis, is fed into the Krebs cycle for further oxidative metabolism. Under hypoxic conditions, the mitochondrial pathways of oxidative catabolism are impaired, and pyruvate is instead converted into lactate. The accumulation of lactic acid and inorganic phosphates is accompanied by a reduction in pH, resulting in intracellular metabolic acidosis.

Decreased intracellular pH (intracellular acidosis) can alter the activity of cellular enzymes, lead to changes in cellular gene expression, impair cellular metabolic pathways, and impede cell membrane ion exchange. Acidosis also leads to changes in cellular calcium (Ca^{2+}) metabolism and Ca^{2+} -mediated cellular signaling, which alone can interfere with the activity of specific enzymes and cell function. These changes in the normal cell function may progress to cellular injury or cell death.

As cellular ATP is depleted under hypoxic conditions, the activity of the membrane Na^+ , K^+ -ATPase slows, and thus the maintenance of cellular membrane potential and cell volume is impaired. Na^+ accumulates intracellularly, whereas K^+ leaks into the extracellular space. The net gain of intracellular sodium is accompanied by a gain in intracellular water and the development of cellular swelling. This influx is associated with a reduction in extracellular fluid volume. The changes in cellular membrane potential impair a number of cellular physiologic processes that are dependent on the membrane potential, such as myocyte contractility, cell signaling, and the regulation of intracellular Ca^{2+} concentrations. Once intracellular organelles such as lysosomes or cell membranes rupture, the cell will undergo death by necrosis.

Apoptosis has been detected in trauma patients with ischemia-reperfusion injury, in which both lymphocyte and intestinal epithelial cell apoptosis occur in the first 3 hours of injury. The intestinal mucosal cell apoptosis may compromise bowel integrity and lead to translocation of bacteria and endotoxins into the portal circulation during shock. Lymphocyte apoptosis also has been hypothesized to contribute to the immune suppression that is observed in trauma patients.

Tissue hypoperfusion and cellular hypoxia result not only in intracellular acidosis, but also in systemic metabolic acidosis as metabolic by-products of

anaerobic glycolysis exit the cells. The systemic changes in acid/base status may lag behind changes at the tissue level. In the setting of acidosis, the oxyhemoglobin dissociation curve is shifted toward the right. The decreased affinity of hemoglobin in erythrocytes for oxygen results in increased O_2 release and increased tissue extraction of oxygen. Additionally, hypoxia stimulates the production of erythrocyte 2, 3-diphosphoglycerate (2, 3-DPG), further contributing to the right shift of the oxyhemoglobin dissociation curve, promoting O_2 availability to the tissues during shock.

In addition to induction of changes in cellular metabolic pathways, shock also induces changes in cellular gene expression. The DNA binding activity of a number of nuclear transcription factors is altered by hypoxia and the production of oxygen radicals or nitrogen radicals that are produced at the cellular level by shock. Expression of other gene products such as heat-shock proteins, vascular endothelial growth factor (VEGF), inducible nitric oxide synthase (iNOS), and cytokines also is clearly increased by shock. Many of these shock-induced gene products, such as cytokines, have the ability themselves to subsequently alter gene expression in specific target cells and tissues. The involvement of multiple pathways emphasizes the complex, integrated, and overlapping nature of the response to shock.

Microcirculation

Shock induces profound changes in tissue microcirculation that are thought to contribute to organ function, organ dysfunction, and the systemic consequences of severe shock. These changes have been studied most extensively in models of sepsis and hemorrhage. After hemorrhage, larger arterioles vasoconstrict, most likely because of sympathetic stimulation, whereas smaller, distal arterioles dilate, presumably because of local mechanisms. Furthermore, flow at the capillary level is heterogeneous, with endothelial cell swelling and the aggregation of leukocytes producing diminished capillary perfusion in some vessels both during shock and following resuscitation. In sepsis, similar changes in microcirculatory function can also be demonstrated. Regional differences in blood flow can be demonstrated after proinflammatory stimuli, and the microcirculation in many organs is heterogeneous; blood flow is heterogeneous between and within organ systems. In hemorrhagic shock, correction of hemodynamic parameters and oxygen delivery and consumption generally restores tissue oxygenation. In contrast, regional tissue dysoxia often persists in sepsis, despite restoration of oxygen delivery and consumption variables. Whether this defect in oxygen extraction is the result of regional hypoxia or a defect in the pathways of mitochondrial respirations is not resolved. Shunting of oxygen from the microcirculation has been proposed as a possible etiology of the regional dysoxia seen in sepsis, despite adequate oxygen delivery.

The decreases in capillary perfusion and blood flow result in diminished capillary hydrostatic pressure. The changes in hydrostatic pressure promote an influx of fluid from the extravascular or extracellular space into the capillaries to increase circulating volume. However, these changes are associated with further loss of intracellular fluid volume because of increased cellular swelling. Resuscitation with volumes of fluid sufficient to restore the extracellular fluid deficit are associated with improved outcome after shock.

Capillary occlusion from endothelial cell swelling and neutrophil sludging and adherence may prevent restoration of capillary flow after adequate

resuscitation, and is termed no-reflow. The nonperfused capillary beds further compound the ischemic injury. Neutrophil sludging in the capillaries with adherence to endothelial cells results in release of proinflammatory mediators by these cells. Neutrophil depletion in animals subjected to hemorrhagic shock produces fewer capillaries with no-reflow and lower mortality.

IMMUNE AND INFLAMMATORY RESPONSE

Alterations in the activity of the innate host immune system can be responsible for both the development of shock (distributive or septic shock following severe infection), and the pathophysiologic sequelae of shock such as the proinflammatory changes seen following hemorrhage or multisystem trauma. When these predominantly paracrine mediators gain access to the systemic circulation, they can induce a variety of metabolic changes that are collectively referred to as the host inflammatory response. Understanding of the intricate, redundant, and interrelated pathways that comprise the inflammatory response to shock continues to expand. Despite limited understanding of how many therapeutic interventions impact the host response to illness, inappropriate or excessive inflammation appears to be an essential event in the development of acute respiratory distress syndrome (ARDS), multiple organ dysfunction syndrome (MODS), and posttraumatic immunosuppression that can prolong recovery.

The immune response to shock encompasses the elaboration of mediators with both proinflammatory and antiinflammatory properties. Furthermore, new mediators, new relationships between mediators, and new functions of known mediators are continually being identified. As new pathways are uncovered, understanding of the immune response to injury and the potential for therapeutic intervention by manipulating the immune response following shock will expand. What seems clear at present, however, is that the innate immune response can help restore homeostasis, or if it is excessive, promote cellular and organ dysfunction.

Multiple mediators have been implicated in the host immune response to shock. It is likely that some of the most important mediators have yet to be discovered, and the roles of many known mediators have not been defined. A comprehensive description of all of the mediators and their complex interactions is beyond the scope of this chapter (see Chapter 1 for a comprehensive review of the inflammatory mediators).

CELLULAR HYPOPERFUSION

Hypoperfused cells and tissues experience what has been termed oxygen debt. The oxygen debt is the deficit in tissue oxygenation over time that occurs during shock. When oxygen delivery is limited, oxygen consumption can be inadequate to match the metabolic needs of cellular respiration, creating a deficit in oxygen requirements at the cellular level. The measurement of oxygen deficit uses calculation of the difference between the estimated oxygen demand and the actual value obtained for oxygen consumption. Under normal circumstances, cells can “repay” the oxygen debt during reperfusion. The magnitude of the oxygen debt correlates with the severity and duration of hypoperfusion. Surrogate values for measuring oxygen debt include base deficit and lactate levels.

FORMS OF SHOCK

Hemorrhagic or Hypovolemic Shock

The most common cause of shock in the surgical or trauma patient is loss of circulating volume from hemorrhage. Acute blood loss results in reflexive decreased baroreceptor stimulation from stretch receptors in the large arteries, resulting in decreased inhibition of vasoconstrictor centers in the brain stem, increased chemoreceptor stimulation of vasomotor centers, and diminished output from atrial stretch receptors. These changes increase vasoconstriction and peripheral arterial resistance. Hypovolemia also induces sympathetic stimulation, leading to epinephrine and norepinephrine release, activation of the renin-angiotensin cascade, and increased vasopressin release. Peripheral vasoconstriction is prominent, although lack of sympathetic effects on cerebral and coronary vessels and local autoregulation promote maintenance of cardiac and CNS blood flow.

Diagnosis

Treatment of shock is initially empiric. The airway must be secured and volume infusion for restoration of blood pressure initiated while the search for the cause of the hypotension is pursued. Shock in a trauma patient and postoperative patient should be presumed to be because of hemorrhage until proven otherwise. The clinical signs of shock may be evident with an agitated patient, including cool clammy extremities, tachycardia, weak or absent peripheral pulses, and hypotension. Such apparent clinical shock results from at least 25–30 percent loss of the blood volume. However, substantial volumes of blood may be lost before the classic clinical manifestations of shock are evident. Thus when a patient is significantly tachycardiac or hypotensive, this represents both significant blood loss and physiologic decompensation. The clinical and physiologic response to hemorrhage has been classified according to the magnitude of volume loss. Loss of up to 15 percent of the circulating volume (700–750 mL for a 70-kg patient) may produce little in terms of obvious symptoms, although loss of up to 30 percent of the circulating volume (1.5 L) may result in mild tachycardia, tachypnea, and anxiety. Hypotension, marked tachycardia [pulse > 110–120 beats per minute (bpm)], and confusion may not be evident until more than 30 percent of the blood volume has been lost; loss of 40 percent of circulating volume (2 L) is immediately life-threatening, and generally requires operative control of bleeding. Young healthy patients with vigorous compensatory mechanisms may tolerate larger volumes of blood loss while manifesting fewer clinical signs despite the presence of significant peripheral hypoperfusion. These patients may maintain a near-normal blood pressure until a precipitous cardiovascular collapse occurs. Older adult patients may be taking medications that either promote bleeding (e.g., warfarin or aspirin), or mask the compensatory responses to bleeding (e.g., β blockers). Additionally, atherosclerotic vascular disease, diminishing cardiac compliance with age, inability to elevate heart rate or cardiac contractility in response to hemorrhage, and overall decline in physiologic reserve decrease the older adult patient's ability to tolerate hemorrhage.

In management of trauma patients, understanding the patterns of injury of the patient in shock will help direct the evaluation and management. Identifying the sources of blood loss in patients with penetrating wounds is relatively simple because potential bleeding sources will be located along the known

or suspected path of the wounding object. Patients with penetrating injuries who are in shock usually require operative intervention. Patients who suffer multisystem injuries from blunt trauma have multiple sources of potential hemorrhage. Blood loss sufficient to cause shock is generally of a large volume, and there are a limited number of sites that can harbor sufficient extravascular blood volume to induce hypotension (e.g., external, intrathoracic, intraabdominal, retroperitoneal, and long bone fractures). In the nontrauma patient, the gastrointestinal tract must always be considered as a site for blood loss. Substantial blood loss externally may be suspected from prehospital medical reports documenting a substantial blood loss at the scene of an accident, history of massive blood loss from wounds, visible brisk bleeding, or presence of a large hematoma adjacent to an open wound. Injuries to major arteries or veins with associated open wounds may cause massive blood loss rapidly. Direct pressure must be applied and sustained to minimize ongoing blood loss. Persistent bleeding from uncontrolled smaller vessels can, over time, precipitate shock if inadequately treated.

When major blood loss is not immediately visible, internal (intracavity) blood loss should be suspected. Each pleural cavity can hold 2–3 L of blood and can therefore be a site of significant blood loss. Diagnostic and therapeutic tube thoracostomy may be indicated in unstable patients based on clinical findings and clinical suspicion. In a more stable patient, a chest radiograph may be obtained to look for evidence of hemothorax. Major retroperitoneal hemorrhage typically occurs in association with pelvic fractures, which is confirmed by pelvic radiography in the resuscitation bay. Intraperitoneal hemorrhage is probably the most common source of blood loss inducing shock. The physical exam for detection of substantial blood loss or injury is insensitive and unreliable; large volumes of intraperitoneal blood may be present before physical exam findings are apparent. Findings with intraabdominal hemorrhage include abdominal distension, abdominal tenderness, or visible abdominal wounds. Hemodynamic abnormalities generally stimulate a search for blood loss prior to the appearance of obvious abdominal findings. Adjunctive tests are essential in the diagnosis of intraperitoneal bleeding; intraperitoneal blood may be rapidly identified by diagnostic ultrasound or diagnostic peritoneal lavage.

Treatment

Control of ongoing hemorrhage is an essential component of the resuscitation of the patient in shock. As mentioned above, treatment of hemorrhagic shock is instituted concurrently with diagnostic evaluation to identify a source. Patients who fail to respond to initial resuscitative efforts should be assumed to have ongoing active hemorrhage from large vessels and require prompt operative intervention. The appropriate priorities in these patients are to (1) secure the airway, (2) control the source of blood loss, and (3) intravenous volume resuscitation. Identifying the body cavity harboring active hemorrhage will help focus operative efforts; however, because time is of the essence, rapid treatment is essential and diagnostic laparotomy or thoracotomy may be indicated. The actively bleeding patient cannot be resuscitated until control of ongoing hemorrhage is achieved.

Patients who respond to initial resuscitative efforts, but then deteriorate hemodynamically, frequently have injuries that require operative intervention. The magnitude and duration of their response will dictate whether diagnostic

maneuvers can be performed to identify the site of bleeding. However, hemodynamic deterioration generally denotes ongoing bleeding for which some form of intervention (such as an operation or interventional radiology) is required. Patients who have lost significant intravascular volume, but hemorrhage is controlled or abated, will often respond to resuscitative efforts if the depth and duration of shock have been limited.

A subset of patients exists who fail to respond to resuscitative efforts despite adequate control of ongoing hemorrhage. These patients have ongoing fluid requirements despite adequate control of hemorrhage, have persistent hypotension despite restoration of intravascular volume necessitating vasopressor support, and may exhibit a futile cycle of uncorrectable hypothermia, hypoperfusion, acidosis, and coagulopathy that cannot be interrupted despite maximum therapy. These patients have deteriorated to decompensated or irreversible shock with peripheral vasodilation and resistance to vasopressor infusion. Mortality is inevitable once the patient manifests shock in its terminal stages.

Cardiogenic Shock

Cardiogenic shock is defined clinically as circulatory pump failure leading to diminished forward flow and subsequent tissue hypoxia, in the setting of adequate intravascular volume. Hemodynamic criteria include sustained hypotension (i.e., SBP <90 mmHg for at least 30 min), reduced cardiac index (<2.2 L/min per square meter), and elevated pulmonary artery wedge pressure (>15 mmHg). Mortality rates for cardiogenic shock are 50 to 80 percent. Acute, extensive myocardial infarction (MI) is the most common cause of cardiogenic shock; a smaller infarction in a patient with existing left ventricular dysfunction may also precipitate shock. Cardiogenic shock complicates 5–10 percent of acute MIs. Conversely, cardiogenic shock is the most common cause of death in patients hospitalized with acute MI. Although shock may develop early after myocardial infarction, it is typically not found on admission. Seventy-five percent of patients who have cardiogenic shock complicating acute MIs develop signs of cardiogenic shock within 24 h after onset of infarction (average 7 h). Recognition of the patient with occult hypoperfusion is critical to prevent progression to obvious cardiogenic shock with its high mortality rate; early initiation of therapy to maintain blood pressure and cardiac output is vital. Rapid assessment, adequate resuscitation, and reversal of the myocardial ischemia are essential in optimizing outcome in patients with acute MI. Prevention of infarct extension is a critical component. Large segments of nonfunctional but viable myocardium contribute to the development of cardiogenic shock after MI. In the setting of acute MI, expeditious restoration of coronary perfusion is mandatory to minimize mortality; the extent of myocardial salvage decreases exponentially with increased time to restoration of coronary blood flow. Inadequate cardiac function can be a direct result of cardiac injury, including profound myocardial contusion, blunt cardiac valvular injury, or direct myocardial damage (Table 4-1). The pathophysiology of cardiogenic shock involves a vicious cycle of myocardial ischemia which causes myocardial dysfunction, which results in more myocardial ischemia. When sufficient mass of the left ventricular wall is necrotic or ischemic and fails to pump, the stroke volume decreases. Decreased compliance results from myocardial ischemia, and compensatory increases in left ventricular filling pressures progressively occur.

Diagnosis

Rapid identification of the patient with pump failure and institution of corrective action are essential in preventing the ongoing spiral of decreased cardiac output from injury causing increased myocardial oxygen needs that cannot be met, leading to progressive and unremitting cardiac dysfunction. In evaluation of possible cardiogenic shock, other causes of hypotension must be excluded, including hemorrhage, sepsis, pulmonary embolism, and aortic dissection.

Confirmation of a cardiac source for the shock requires electrocardiogram and urgent echocardiography. Other useful diagnostic tests include chest radiograph, arterial blood gases, electrolytes, complete blood count, and cardiac enzymes. Invasive cardiac monitoring, which is generally not necessary, can be useful to exclude right ventricular infarction, hypovolemia, and possible mechanical complications.

Making the diagnosis of cardiogenic shock involves the identification of cardiac dysfunction or acute heart failure in a susceptible patient. Because patients with blunt cardiac injury typically have multisystem injury, hemorrhagic shock from intraabdominal bleeding, intrathoracic bleeding, and bleeding from fractures must be excluded. Relatively few patients with blunt cardiac injury will develop cardiac pump dysfunction. Those who do generally exhibit cardiogenic shock early in their evaluation. Therefore, establishing the diagnosis of blunt cardiac injury is secondary to excluding other etiologies for shock and establishing that cardiac dysfunction is present. Invasive hemodynamic

monitoring with a pulmonary artery catheter may uncover evidence of diminished cardiac output and elevated pulmonary artery pressure.

Treatment

After ensuring that an adequate airway is present and ventilation is sufficient, attention should be focused on support of the circulation. Intubation and mechanical ventilation are often required, if only to decrease work of breathing and facilitate sedation of the patient. Rapidly excluding hypovolemia and establishing the presence of cardiac dysfunction is essential. Treatment of cardiac dysfunction includes maintenance of adequate oxygenation to ensure adequate myocardial oxygen delivery and judicious fluid administration to avoid fluid overload and development of cardiogenic pulmonary edema. Electrolyte abnormalities, commonly hypokalemia and hypomagnesemia, should be corrected. Pain is treated with intravenous morphine sulfate or fentanyl. Significant dysrhythmias and heart block must be treated with antiarrhythmic drugs, pacing, or cardioversion if necessary.

When profound cardiac dysfunction exists, inotropic support may be indicated to improve cardiac contractility and cardiac output. Dobutamine primarily stimulates cardiac β_1 receptors to increase cardiac output, but may also vasodilate peripheral vascular beds, lower total peripheral resistance, and lower systemic blood pressure through effects on β_2 receptors. Ensuring adequate preload and intravascular volume is therefore essential prior to instituting therapy with dobutamine. Dopamine stimulates α receptors (vasoconstriction), β_1 receptors (cardiac stimulation), and β_2 receptors (vasodilation), with its effects on β receptors predominating at lower doses. Dopamine may be preferable to dobutamine in treatment of cardiac dysfunction in hypotensive patients. Tachycardia and increased peripheral resistance from dopamine infusion may worsen myocardial ischemia. Titration of both dopamine and dobutamine infusions may be required in some patients.

Epinephrine stimulates α and β receptors and may increase cardiac contractility and heart rate; however, it also may have intense peripheral vasoconstrictor effects that impair further cardiac performance. Catecholamine infusions must be carefully controlled to maximize coronary perfusion, although minimizing myocardial oxygen demand. Balancing the beneficial effects of impaired cardiac performance with the potential side effects of excessive reflex tachycardia and peripheral vasoconstriction requires serial assessment of tissue perfusion using indices such as capillary refill, character of peripheral pulses, adequacy of urine output, or improvement in laboratory parameters of resuscitation such as pH, base deficit, and lactate. Invasive monitoring is generally necessary in these unstable patients. The phosphodiesterase inhibitors amrinone and milrinone may be required on occasion in patients with resistant cardiogenic shock. These agents have long half-lives and induce thrombocytopenia and hypotension, and use is reserved for patients unresponsive to other treatment.

Patients whose cardiac dysfunction is refractory to cardiotonics may require mechanical circulatory support with an intraaortic balloon pump (IABP). Intraaortic balloon pumping increases cardiac output and improves coronary blood flow by reduction of systolic afterload and augmentation of diastolic perfusion pressure. Unlike vasopressor agents, these beneficial effects occur without an increase in myocardial oxygen demand. IABP can be inserted at the bedside in the ICU via the femoral artery through either a cutdown or using

the percutaneous approach. Aggressive circulatory support of patients with cardiac dysfunction from intrinsic cardiac disease has led to more widespread application of these devices and more familiarity with their operation by both physicians and critical care nurses.

Preservation of existing myocardium and preservation of cardiac function are priorities of therapy for patients who have suffered an acute myocardial infarction. Ensuring adequate oxygenation and oxygen delivery, maintaining adequate preload with judicious volume restoration, minimizing sympathetic discharge through adequate relief of pain, and correcting electrolyte imbalances are all straightforward nonspecific maneuvers that may improve existing cardiac function or prevent future cardiac complications. Anticoagulation and aspirin are given for acute myocardial infarction. Although thrombolytic therapy reduces mortality in patients with acute myocardial infarction, its role in cardiogenic shock is less clear. Patients in cardiac failure from an acute MI may benefit from pharmacologic or mechanical circulatory support in a manner similar to that of patients with cardiac failure related to blunt cardiac injury. Additional pharmacologic tools may include the use of β blockers to control heart rate and myocardial oxygen consumption, nitrates to promote coronary blood flow through vasodilatation, and ACE inhibitors to reduce ACE-mediated vasoconstrictive effects that increase myocardial workload and myocardial oxygen consumption.

Current guidelines of the American Heart Association (AHA) recommend percutaneous transluminal coronary angiography (PTCA) for patients with cardiogenic shock, ST elevation, left bundle-branch block, and age younger than 75 years. Early definition of coronary anatomy and revascularization is the pivotal step in treatment of patients with cardiogenic shock from acute MI. When feasible, PTCA (generally with stent placement) is the treatment of choice. Coronary artery bypass grafting (CABG) seems to be more appropriate for patients with multiple vessel disease or left main coronary artery disease.

Vasodilatory Shock (Septic Shock)

In vasodilatory shock, hypotension results from failure of the vascular smooth muscle to constrict appropriately. Vasodilatory shock is characterized by both peripheral vasodilatation with resultant hypotension, and resistance to treatment with vasopressors. Despite the hypotension, plasma catecholamine levels are elevated and the renin-angiotensin system is activated in vasodilatory shock. The most frequently encountered form of vasodilatory shock is septic shock. Other causes of vasodilatory shock include hypoxic lactic acidosis, carbon monoxide poisoning, decompensated and irreversible hemorrhagic shock, terminal cardiogenic shock, and postcardiotomy shock (Table 4-2). Thus, vasodilatory shock seems to represent the final common pathway for profound and prolonged shock of any etiology.

Septic shock is a by-product of the body's response to invasive or severe localized infection, typically from bacterial or fungal pathogens. In the attempt to eradicate the pathogens, the immune and other cell types (e.g., endothelial cells) elaborate soluble mediators that enhance macrophage and neutrophil killing effector mechanisms, increase procoagulant activity and fibroblast activity to localize the invaders, and increase microvascular blood flow to enhance delivery of killing forces to the area of invasion. When this response is overly exuberant or becomes systemic rather than localized, manifestations of sepsis may be evident. These findings include enhanced

cardiac output, peripheral vasodilation, fever, leukocytosis, hyperglycemia, and tachycardia. In septic shock, the vasodilatory effects are due in part to the upregulation of the inducible isoform of nitric oxide synthase (iNOS or NOS 2) in the vessel wall. iNOS produces large quantities of nitric oxide for sustained periods of time. This potent vasodilator suppresses vascular tone and renders the vasculature resistant to the effects of vasoconstricting agents.

Diagnosis

Attempts to standardize terminology have led to the establishment of criteria for the diagnosis of sepsis in the hospitalized adult. These criteria include manifestations of the host response to infection, in addition to identification of an offending organism. The terms sepsis, severe sepsis, and septic shock are used to quantify the magnitude of the systemic inflammatory reaction. Patients with sepsis have evidence of an infection, and systemic signs of inflammation (e.g., fever, leukocytosis, and tachycardia). Hypoperfusion with signs of organ dysfunction is termed severe sepsis. Septic shock requires the presence of the above, associated with more significant evidence of tissue hypoperfusion and systemic hypotension. Beyond the hypotension, maldistribution of blood flow and shunting in the microcirculation further compromise delivery of nutrients to the tissue beds.

Recognizing septic shock begins with defining the patient at risk. The clinical manifestations of septic shock will usually become evident and prompt the initiation of treatment before bacteriologic confirmation of an organism or the source of an organism is identified. In addition to fever, tachycardia, and tachypnea, signs of hypoperfusion such as confusion, malaise, oliguria, or hypotension may be present. These should prompt an aggressive search for infection including a thorough physical exam, inspection of all wounds, evaluation of intravascular catheters or other foreign bodies, obtaining appropriate cultures, and adjunctive imaging studies as needed.

Treatment

Evaluation of the patient in septic shock begins with an assessment of the adequacy of their airway and ventilation. Severely obtunded patients and patients whose work of breathing is excessive require intubation and ventilation to prevent respiratory collapse. Because vasodilation and decrease in total peripheral resistance may produce hypotension, fluid resuscitation and restoration of circulatory volume with balanced salt solutions is essential. Empiric antibiotics must be chosen carefully based on the most likely pathogens

(gram-negative rods, gram-positive cocci, and anaerobes), because the portal of entry of the offending organism and its identity may not be evident until culture data return or imaging studies are completed. Knowledge of the bacteriologic profile of infections in an individual unit can be obtained from most hospital infection control departments and will suggest potential responsible organisms. Antibiotics should be tailored to cover the responsible organisms once culture data are available, and if appropriate, the spectrum of coverage narrowed. Long-term empiric broad-spectrum antibiotic use should be minimized to reduce the development of resistant organisms, and to avoid the potential complications of fungal overgrowth and antibiotic-associated colitis from overgrowth of *Clostridium difficile*. Intravenous antibiotics will be insufficient to adequately treat the infectious episode in the settings of infected fluid collections, infected foreign bodies, and devitalized tissue. These situations may require multiple operations to ensure proper wound hygiene and healing.

The majority of septic patients have hyperdynamic physiology with supranormal cardiac output and low systemic vascular resistance. On occasion, septic patients may have low cardiac output despite volume resuscitation and even vasopressor support. Mortality in this group is high. Despite the increasing incidence of septic shock over the past several decades, the overall mortality rates have changed little. Recent evidences indicate the benefit of immediate goal-directed resuscitation in improving outcomes in sepsis.

After first-line therapy of the septic patient with antibiotics, intravenous fluids, and intubation if necessary, vasopressors may be necessary to treat patients with septic shock. Catecholamines are the vasopressors used most often. Occasionally, patients with septic shock will develop arterial resistance to catecholamines. Arginine vasopressin, a potent vasoconstrictor, is often efficacious in this setting. A recent study also reported significant positive impact of tight glucose management on outcome in critically ill patients. Mortality in patients receiving intensive insulin treatment is significantly lower and most notable in the patients requiring longer than 5 days in the intensive care unit (ICU).

Recent studies have reported benefit from intravenous infusion of recombinant human activated protein C for severe sepsis. Activated protein C is an endogenous protein that promotes fibrinolysis and inhibits thrombosis and inflammation. Treatment with activated protein C has been shown to reduce 28-day mortality rate from 31–25 percent; a reduction in relative risk of death of 19.4 percent.

The observation that severe sepsis is often associated with adrenal insufficiency or glucocorticoid receptor resistance has generated renewed interest in therapy for septic shock with corticosteroids. Seven-day treatment with low doses of hydrocortisone and fludrocortisone significantly and safely lowers the risk of death in patients with septic shock and relative adrenal insufficiency. Adrenal insufficiency is established in critically ill patients using a corticotropia stimulator test.

Neurogenic Shock

Neurogenic shock refers to diminished tissue perfusion as a result of loss of vasomotor tone to peripheral arterial beds. Loss of vasoconstrictor impulses results in increased vascular capacitance, decreased venous return, and decreased cardiac output. Neurogenic shock is usually secondary to spinal cord injuries

from vertebral body fractures of the cervical or high thoracic region that disrupt sympathetic regulation of peripheral vascular tone. Rarely, a spinal cord injury without bony fracture, such as an epidural hematoma impinging on the spinal cord, can produce neurogenic shock. Sympathetic input to the heart, which normally increases heart rate and cardiac contractility, and input to the adrenal medulla, which increases catecholamine release, may also be disrupted, preventing the typical reflex tachycardia that occurs with hypovolemia. Acute spinal cord injury results in activation of multiple secondary injury mechanisms: (1) vascular compromise to the spinal cord with loss of autoregulation, vasospasm, and thrombosis, (2) loss of cellular membrane integrity and impaired energy metabolism, and (3) neurotransmitter accumulation and release of free radicals. Importantly, hypotension contributes to the worsening of acute spinal cord injury as the result of further reduction in blood flow to the spinal cord. Management of acute spinal cord injury with attention to blood pressure control, oxygenation, and hemodynamics, essentially optimizing perfusion of an already ischemic spinal cord, seems to result in improved neurologic outcome. Patients with hypotension from spinal cord injury are best monitored in an intensive care unit, and carefully followed for evidence of cardiac or respiratory dysfunction.

Diagnosis

Acute spinal cord injury may result in bradycardia, hypotension, cardiac dysrhythmias, reduced cardiac output, and decreased peripheral vascular resistance. The severity of the spinal cord injury seems to correlate with the magnitude of cardiovascular dysfunction. Patients with complete motor injuries are over five times more likely to require vasopressors for neurogenic shock, as compared to those with incomplete lesions. The classic description of neurogenic shock consists of decreased blood pressure associated with bradycardia (absence of reflexive tachycardia because of disrupted sympathetic discharge), warm extremities (loss of peripheral vasoconstriction), motor and sensory deficits indicative of a spinal cord injury, and radiographic evidence of a vertebral column fracture. Patients with multisystem trauma that includes spinal cord injuries often have head injuries that may make identification of motor and sensory deficits difficult in the initial evaluation. Furthermore, associated injuries may occur that result in hypovolemia, further complicating the clinical presentation. In the multiply injured patient, other causes of hypotension including hemorrhage, tension pneumothorax, and cardiogenic shock must be sought and excluded.

Treatment

After the airway is secured and ventilation is adequate, fluid resuscitation and restoration of intravascular volume will often improve perfusion in neurogenic shock. Most patients with neurogenic shock will respond to restoration of intravascular volume alone, with satisfactory improvement in perfusion and resolution of hypotension. Administration of vasoconstrictors will improve peripheral vascular tone, decrease vascular capacitance, and increase venous return, but should only be considered once hypovolemia is excluded as the cause of the hypotension, and the diagnosis of neurogenic shock established. If the patient's blood pressure has not responded to what is felt to be adequate volume resuscitation, dopamine may be used first. A pure α agonist, such as phenylephrine may be used primarily or in patients unresponsive to dopamine.

Specific treatment for the hypotension is often of brief duration, as the need to administer vasoconstrictors typically lasts 24–48 hours. On the other hand, life-threatening cardiac dysrhythmias and hypotension may occur up to 14 days after spinal cord injury.

Obstructive Shock

Commonly, mechanical obstruction of venous return in trauma patients is because of the presence of tension pneumothorax. Cardiac tamponade occurs when sufficient fluid has accumulated in the pericardial sac to obstruct blood flow to the ventricles. The hemodynamic abnormalities in pericardial tamponade are because of elevation of intracardiac pressures with limitation of ventricular filling in diastole with resultant decrease in cardiac output. Acutely, the pericardium does not distend; thus small volumes of blood may produce cardiac tamponade. If the effusion accumulates slowly (e.g., in the setting of uremia, heart failure, or malignant effusion), the quantity of fluid producing cardiac tamponade may reach 2000 mL. The major determinant of the degree of hypotension is the pericardial pressure. With either cardiac tamponade or tension pneumothorax, reduced filling of the right side of the heart from either increased intrapleural pressure secondary to air accumulation (tension pneumothorax), or increased intrapericardial pressure precluding atrial filling secondary to blood accumulation (cardiac tamponade) results in decreased cardiac output associated with increased central venous pressure.

Diagnosis and Treatment

The diagnosis of tension pneumothorax should be made on clinical examination. The classic findings include respiratory distress (in an awake patient), hypotension, diminished breath sounds over one hemithorax, hyperresonance to percussion, jugular venous distention, and shift of mediastinal structures to the unaffected side with tracheal deviation. In most instances, empiric treatment with pleural decompression is indicated rather than delaying to wait for radiographic confirmation. When a chest tube cannot be immediately inserted, such as in the prehospital setting, the pleural space can be decompressed with a large caliber needle. Immediate return of air should be encountered with rapid resolution of hypotension. Unfortunately, not all of the clinical manifestations of tension pneumothorax may be evident on physical exam. Practically, three findings are sufficient to make the diagnosis of tension pneumothorax: respiratory distress or hypotension, decreased lung sounds, and hypertympany to percussion. Chest x-ray findings that may be visualized include deviation of mediastinal structures, depression of the hemidiaphragm, and hypopacification with absent lung markings. As discussed above, definitive treatment of a tension pneumothorax is immediate tube thoracostomy. The chest tube should be inserted rapidly, but carefully, and should be large enough to evacuate any blood that may be present in the pleural space. Our preference is via the fourth intercostal space (nipple level) at the anterior axillary line.

Cardiac tamponade results from the accumulation of blood within the pericardial sac, usually from penetrating trauma or chronic medical conditions such as heart failure or uremia. Although precordial wounds are most likely to injure the heart and produce tamponade, any projectile or wounding agent that passes in proximity to the mediastinum can potentially produce tamponade. Blunt cardiac rupture, a rare event in trauma victims who survive long enough to reach the hospital, can produce refractory shock and

tamponade in the multiply injured patient. The manifestations of cardiac tamponade may be catastrophic such as total circulatory collapse and cardiac arrest, or they may be more subtle. A high index of suspicion is warranted to make a rapid diagnosis. Patients who present with circulatory arrest from cardiac tamponade require emergency pericardial decompression, usually through a left thoracotomy (see Chapter 6 for indications for this maneuver). Cardiac tamponade may also be associated with dyspnea, orthopnea, cough, peripheral edema, chest pain, tachycardia, muffled heart tones, jugular venous distention, and elevated central venous pressure. The triad of Beck consists of hypotension, muffled heart tones, and neck vein distention. Unfortunately, absence of these clinical findings may not be sufficient to exclude cardiac injury and cardiac tamponade. Muffled heart tones may be difficult to appreciate in a busy trauma center and jugular venous distention and central venous pressure may be diminished by coexistent bleeding. Therefore, patients at risk for cardiac tamponade whose hemodynamic status permits additional diagnostic tests frequently require additional diagnostic maneuvers to confirm cardiac injury or tamponade.

Invasive hemodynamic monitoring may support the diagnosis of cardiac tamponade if elevated central venous pressure, pulsus paradoxus (i.e., decreased systemic arterial pressure with inspiration), or elevated right atrial and right ventricular pressure by pulmonary artery catheter are present. These hemodynamic profiles suffer from lack of specificity, the duration of time required to obtain them in critically injured patients, and their inability to exclude cardiac injury in the absence of tamponade. Chest radiographs may provide information on the possible trajectory of a projectile, but rarely are diagnostic because the acutely filled pericardium distends poorly. Echocardiography has become the preferred test for the diagnosis of cardiac tamponade. Good results in detecting pericardial fluid have been reported, but the yield in detecting pericardial fluid depends on the skill and experience of the ultrasonographer, body habitus of the patient, and absence of wounds that preclude visualization of the pericardium. Pericardiocentesis to diagnose pericardial blood and potentially relieve tamponade may be used. Performing pericardiocentesis under ultrasound guidance has made the procedure safer and more reliable. An indwelling catheter may be placed for several days in patients with chronic pericardial effusions. Needle pericardiocentesis may not evacuate clotted blood and has the potential to produce cardiac injury, making it a poor alternative in busy trauma centers.

Diagnostic pericardial window represents the most direct method to determine the presence of blood within the pericardium. The procedure is best performed in the operating room under general anesthesia. It can be performed through either the subxiphoid or transdiaphragmatic approach. Adequate equipment and personnel to rapidly decompress the pericardium, explore the injury, and repair the heart should be present. Once the pericardium is opened and tamponade relieved, hemodynamics usually improve dramatically and formal pericardial exploration can ensue. Exposure of the heart can be achieved by extending the incision to a median sternotomy, performing a left anterior thoracotomy, or performing bilateral anterior thoracotomies ("clamshell").

Traumatic Shock

The systemic response after trauma, combining the effects of soft-tissue injury, long-bone fractures, and blood loss, is clearly a different physiologic

insult than simple hemorrhagic shock. Multiple organ failure, including ARDS, develops relatively often in the blunt trauma patient, but rarely after pure hemorrhagic shock (such as a gastrointestinal bleed). The hypoperfusion deficit in traumatic shock is magnified by the proinflammatory activation that occurs following the induction of shock. In addition to ischemia or ischemia-reperfusion, accumulating evidence demonstrates that even simple hemorrhage induces proinflammatory activation that results in many of the cellular changes typically ascribed only to septic shock. Treatment of traumatic shock is focused on correction of the individual elements to diminish the cascade of proinflammatory activation, and includes prompt control of hemorrhage, adequate volume resuscitation to correct oxygen debt, débridement of nonviable tissue, stabilization of bony injuries, and appropriate treatment of soft tissue injuries.

ENDPOINTS IN RESUSCITATION

Shock is defined as inadequate perfusion to maintain normal organ function. With prolonged anaerobic metabolism, tissue acidosis and oxygen debt accumulate. Thus the goal in the treatment of shock is restoration of adequate organ perfusion and tissue oxygenation. Resuscitation is complete when oxygen debt is repaid, tissue acidosis is corrected, and aerobic metabolism restored. Clinical confirmation of this endpoint remains a challenge.

Resuscitation of the patient in shock requires simultaneous evaluation and treatment; the etiology of the shock often is not initially apparent. Hemorrhagic shock, septic shock, and traumatic shock are the most common types of shock encountered on surgical services. To optimize outcome in bleeding patients, early control of the hemorrhage and adequate volume resuscitation, including both red blood cells and crystalloid solutions, are necessary. Expedient operative resuscitation is mandatory to limit the magnitude of activation of multiple mediator systems and to abort the microcirculatory changes, which may evolve insidiously into the cascade that ends in irreversible hemorrhagic shock. Attempts to stabilize an actively bleeding patient anywhere but in the operating room are inappropriate. Any intervention that delays the patient's arrival in the operating room for control of hemorrhage increases mortality thus the important concept of operating room resuscitation of the critically injured patient.

Endpoints in resuscitation can be divided into systemic or global parameters, tissue-specific parameters, and cellular parameters. Global endpoints include vital signs, cardiac output, pulmonary artery wedge pressure, oxygen delivery and consumption, lactate, and base deficit (Table 4-3).

Assessment of Endpoints in Resuscitation

Oxygen Transport

Attaining supranormal oxygen transport variables has been proposed as a means to correct oxygen debt. However, evidence is insufficient to support the routine use of a strategy to maximize oxygen delivery in a group of unselected patients.

Inability to repay oxygen debt is a predictor of mortality and organ failure; the probability of death has been directly correlated to the calculated oxygen debt in hemorrhagic shock. Direct measurement of the oxygen debt in the resuscitation of patients is difficult. The easily obtainable parameters of

arterial blood pressure, heart rate, urine output, central venous pressure, and pulmonary artery occlusion pressure are poor indicators of the adequacy of tissue perfusion. Therefore, surrogate parameters have been sought to estimate the oxygen debt; serum lactate and base deficit have been shown to correlate with oxygen debt.

Lactate

Lactate is generated by conversion of pyruvate to lactate by lactate dehydrogenase in the setting of insufficient oxygen. Lactate is released into the circulation and is predominantly taken up and metabolized by the liver and kidneys. The liver accounts for approximately 50 percent and the kidney for about 30 percent of whole body lactate uptake. Elevated serum lactate is an indirect measure of the oxygen debt, and therefore an approximation of the magnitude and duration of the severity of shock. The admission lactate level, highest lactate level, and time interval to normalize the serum lactate are important prognostic indicators for survival. In contrast, individual variability of lactate may be too great to permit accurate prediction of outcome in any individual case. Base deficit and volume of blood transfusion required in the first 24 hours of resuscitation may be better predictors of mortality than the plasma lactate alone.

Base Deficit

Base deficit is the amount of base in millimoles that is required to titrate 1 L of whole blood to a pH of 7.40 with the sample fully saturated with O_2 at $37^\circ C$ ($80.6^\circ F$) and a $PaCO_2$ of 40 mmHg. It is usually measured by arterial blood gas analysis in clinical practice as it is readily and quickly available. The mortality of trauma patients can be stratified according to the magnitude of base deficit measured in the first 24 hours after admission. In a retrospective study of over 3000 trauma admissions, patients with a base deficit worse than 15 mmol/L had a mortality of 70 percent. Base deficit can be stratified into mild (3–5), moderate (6–14) and severe (≥ 15) categories, with a trend toward higher mortality with worsening base deficit in patients with trauma. Both the magnitude of the perfusion deficit as indicated by the base deficit and the time required to correct it are major factors determining outcome in shock.

Indeed, when elevated base deficit persists (or lactic acidosis) in the trauma patient, ongoing bleeding is often the etiology. Trauma patients admitted with a base deficit greater than 15 mmol/L required twice the volume of fluid infusion and 6 times more blood transfusion in the first 24 hours, as compared to patients with mild acidosis. Transfusion requirements increased as base deficit worsened and ICU and hospital lengths of stay increased. Mortality increased as base deficit worsened; the frequency of organ failure increased with greater base deficit. The probability of trauma patients developing ARDS has been reported to correlate with severity of admission base deficit and lowest base deficit within the first 24 hours postinjury. Persistently high base deficit is associated with abnormal oxygen utilization and higher mortality. Monitoring base deficit in the resuscitation of trauma patients assists in assessment of oxygen transport and efficacy of resuscitation.

Factors that may compromise the utility of the base deficit in estimating oxygen debt are the administration of bicarbonate, hypothermia, hypocapnia (overventilation), heparin, ethanol, and ketoacidosis. However, the base deficit remains one of the most widely used estimates of oxygen debt for its clinical relevance, accuracy, and availability.

Controversies about Fluids Used for Resuscitation

No differences in overall mortality, length of stay, or incidence of pulmonary edema have been noted in comparison of crystalloid to colloids in fluid resuscitation of critically ill patients. Subgroup analysis suggested a significant survival advantage in trauma patients in favor of crystalloid resuscitation. A systematic review of 30 randomized trials of human albumin administration in 1419 critically ill patients similarly noted an increased risk of mortality with the use of albumin infusion in treatment of hypovolemia, burns, and hypoalbuminemia. Additionally, albumin is several times more expensive than crystalloid solutions. The expense of the infusion of albumin-containing solution cannot be justified.

Several papers have suggested improved outcome with the use of hypertonic saline in the treatment of hemorrhagic shock. The clinical trials have shown marginal benefit with the infusion of hypertonic saline (7.5 percent sodium chloride). The benefit of hypertonic saline solutions may be immunomodulatory, in addition to shifting of fluids from intracellular compartments.

Use of Blood in Transfusion

Volume resuscitation in the trauma patient requires restoration of intravascular volume and repletion of sufficient oxygen-carrying capacity with red blood cell transfusion. Delay of transfusion of red blood cells in the actively bleeding trauma patients increases mortality.

Hypotensive Resuscitation

Reasonable conclusions controlled hypotension in the setting of uncontrolled hemorrhage include: any delay in surgery for control of hemorrhage increases mortality; with uncontrolled hemorrhage attempting to achieve normal blood pressure may increase mortality, particularly with penetrating injuries and short transport times; a goal of systolic blood pressure of 80–90 mmHg may be adequate in the patient with penetrating injury; and profound hemodilution

should be avoided by early transfusion of red blood cells. For the patient with blunt injury, in which the major cause of death is a closed head injury, the increase in mortality with hypotension in the setting of brain injury must be avoided. In this setting, a systolic blood pressure of 110 mmHg would seem to be more appropriate.

Although treatment of infection has been an integral part of the surgeon's practice since the dawn of time, the body of knowledge that led to the present field of surgical infectious disease was derived from the evolution of germ theory and antisepsis. Application of the latter to clinical practice, concurrent with the development of anesthesia, was pivotal in allowing surgeons to perform complex procedures that were previously associated with high rates of morbidity and mortality because of postoperative infections. Until recently the occurrence of infection related to the surgical wound was the rule rather than the exception. The development of modalities to effectively prevent and treat infection has occurred only within the last several decades.

The first intraabdominal operation to treat infection via "source control" (i.e., surgical intervention to eliminate the source of infection) was appendectomy. McBurney's classic report on early operative intervention for appendicitis was presented before the New York Surgical Society in 1889. Sir Alexander Fleming in 1928 noted a zone of inhibition around a mold colony (*Penicillium notatum*) that serendipitously grew on a plate of *Staphylococcus*, and he named the active substance penicillin. This first effective antibacterial agent subsequently led to the development of hundreds of potent antimicrobials, set the stage for their use as prophylaxis against postoperative infection, and became a critical component of the armamentarium to treat aggressive, lethal surgical infections.

Concurrent with the development of numerous antimicrobial agents were advances in the field of clinical microbiology. Many new microbes were identified, including numerous anaerobes; the autochthonous microflora of the skin, gastrointestinal tract, and other parts of the body that the surgeon encountered in the process of an operation were characterized in great detail. Subsequently, the initial clinical observations of surgeons such as Frank Meleney, William Altemeier, and others provided the observation that aerobes and anaerobes could synergize to cause serious soft tissue and severe intraabdominal infection.

The discovery of the first cytokines began to allow insight into the organism's response to infection, and led to an explosion in our understanding of the host inflammatory response. Expanding knowledge of the multiple pathways activated during the response to invasion by infectious organisms has permitted the design of new therapies targeted at modifying the inflammatory response to infection. Preventing and treating this process of multiple-organ failure during infection is one of the major challenges of modern critical care and surgical infectious disease.

PATHOGENESIS OF INFECTION

Host Defenses

The mammalian host possesses several layers of endogenous defense mechanisms that serve to prevent microbial invasion, limit proliferation of microbes within the host, and contain or eradicate invading microbes. They include site-specific defenses that function at the tissue level, and components that freely circulate throughout the body in both blood and lymph. Systemic host defenses

are recruited to a site of infection, a process that begins immediately on introduction of microbes into a sterile area of the body. Perturbation of one or more components of these defenses (e.g., via immunosuppressants, chronic illness, and burns) may have substantial negative impact on resistance to infection.

Entry of microbes into the mammalian host is precluded by the presence of a number of barriers that possess either an epithelial (integument) or mucosal (respiratory, gut, and urogenital) surface. However, barrier function is not solely limited to physical characteristics: host barrier cells may secrete substances that limit microbial proliferation or prevent invasion. Also, resident or commensal microbes (endogenous or autochthonous host microflora) adherent to the physical surface and to each other may preclude invasion, particularly of virulent organisms (colonization resistance).

The most extensive physical barrier is the integument or skin. In addition to the physical barrier posed by the epithelial surface, the skin harbors its own resident microflora that may block the attachment and invasion of noncommensal microbes. Microbes also are held in check by chemicals that sebaceous glands secrete and by the constant shedding of epithelial cells. Diseases of the skin (e.g., eczema and dermatitis) are associated with overgrowth of skin commensal organisms, and barrier breaches invariably lead to the introduction of these microbes.

The respiratory tract possesses several host defense mechanisms that facilitate the maintenance of sterility in the distal bronchi and alveoli under normal circumstances. In the upper respiratory tract, respiratory mucus traps larger particles including microbes. Smaller particles arriving in the lower respiratory tract are cleared via phagocytosis by pulmonary alveolar macrophages. Any process that diminishes these host defenses can lead to development of bronchitis or pneumonia.

The urogenital, biliary, pancreatic ductal, and distal respiratory tracts do not possess resident microflora in healthy individuals, although microbes may be present if these barriers are affected by disease or if microorganisms are introduced from an external source. In contrast, significant numbers of microbes are encountered in many portions of the gastrointestinal tract, with vast numbers being found within the oropharynx and distal colorectum, although the specific organisms differ. Organisms ingested into the stomach from the oropharynx are routinely killed in the highly acidic, low-motility environment of the stomach during the initial phases of digestion. Thus, small numbers of microbes populate the gastric mucosa (approximately 102–103 colony-forming units [CFU]/mL); this population expands in the presence of drugs or disease states that diminish gastric acidity. Microbes that are not destroyed within the stomach enter the small intestine, in which a certain amount of microbial proliferation takes place, such that approximately 105–108 CFU/mL are present in the terminal ileum.

The relatively low-oxygen, static environment of the colon is accompanied by the exponential growth of microbes that comprise the most extensive host endogenous microflora. Anaerobic microbes outnumber aerobic species approximately 100:1 in the distal colorectum, and approximately 1011–1012 CFU/g are present in feces. Large numbers of facultative and strict anaerobes (*Bacteroides fragilis* and other species) and several orders of magnitude fewer aerobic microbes (*Escherichia coli* and other Enterobacteriaceae species, *Enterococcus faecalis* and *E. faecium*, *Candida albicans* and other *Candida* species) are present.

Once microbes enter a sterile body compartment (e.g., pleural or peritoneal cavity) or tissue, host defenses act to limit and/or eliminate pathogens. Initially, several primitive and relatively nonspecific host defenses act to contain the nidus of infection. Within the peritoneal cavity, unique host defenses exist, including a diaphragmatic pumping mechanism whereby small particles within peritoneal fluid are expunged from the abdominal cavity via specialized structures on the undersurface of the diaphragm. Concurrently, containment by the omentum, the so-called “gatekeeper” of the abdomen and intestinal ileus, serves to wall off infection, albeit with the likely result of abscess formation.

Microbes also immediately encounter host defense mechanisms that reside within the tissues of the body. These include resident macrophages and complement (C) proteins and immunoglobulins (Ig, antibodies). Resident macrophages secrete a wide array of substances in response to the above-mentioned processes, which appear to regulate the cellular components of the host defense response. Macrophage cytokine synthesis is upregulated and includes secretion of tumor necrosis factor- α (TNF- α), interleukins (IL)-1, 6, and 8; and interferon- γ (INF- γ) within the tissue milieu, and, depending on the magnitude of the host defense response, the systemic circulation. Concurrently, a counterregulatory response is initiated consisting of binding proteins (TNF-BP), cytokine receptor antagonists (IL-1ra), and antiinflammatory cytokines (IL-4 and IL-10).

The interaction of microbes with these first-line host defenses leads to microbial opsonization (C1q, C3bi, and IgFc), phagocytosis, and extracellular (C5b6-9 membrane attack complex) and intracellular microbial destruction (phagocytic vacuoles). The classical and alternate complement pathways are activated both via direct contact with and via IgM and IgG binding to microbes (IgM > IgG), leading to the release of a number of different complement protein fragments (C3a, C4a, C5a) that are biologically active, acting to markedly enhance vascular permeability. Bacterial cell wall components and a variety of enzymes that are expelled from leukocyte phagocytic vacuoles during microbial phagocytosis and killing act in this capacity as well.

Simultaneously, the release of substances chemotactic to polymorphonuclear leukocytes (PMNs) in the bloodstream takes place. These consist of C5a, microbial cell wall peptides containing N-formyl-methionine, and macrophage cytokines such as IL-8. This process of host defense recruitment leads to further influx of inflammatory fluid and PMNs into the area of incipient infection, a process that begins within several minutes and may peak within hours or days. The magnitude of the response is related to several factors: (1) the initial number of microbes, (2) the rate of microbial proliferation in relation to containment and killing by host defenses, (3) microbial virulence, and (4) the potency of host defenses. In regard to the latter, drugs or disease states that diminish any or multiple components of host defenses are associated with higher rates and potentially more grave infections.

Definitions

Several possible outcomes can occur subsequent to microbial invasion and the interaction of microbes with resident and recruited host defenses: (1) eradication; (2) containment, often leading to the presence of purulence—the hallmark of chronic infection (e.g., a furuncle in the skin and soft tissue or abscess within the parenchyma of an organ or potential space); (3) locoregional infection (cellulitis, lymphangitis, and aggressive soft tissue infection) with or

without distant spread of infection (metastatic abscess); or (4) systemic infection (bacteremia or fungemia). The latter represents the failure of resident and recruited host defenses at the local level, and is associated with significant morbidity and mortality in the clinical setting. Additionally, it is not uncommon that disease progression occurs such that serious locoregional infection is associated with concurrent systemic infection. A chronic abscess also may intermittently drain and/or be associated with bacteremia.

Infection is defined by identification of microorganisms in host tissue or the blood stream, plus an inflammatory response to their presence. At the site of infection the classic findings of rubor, calor, and dolor in areas such as the skin or subcutaneous tissue are common. Most infections in normal individuals with intact host defenses are associated with these local manifestations, plus systemic manifestations such as elevated temperature, elevated white blood cell (WBC) count, tachycardia, or tachypnea. The systemic manifestations noted above comprise the systemic inflammatory response syndrome (SIRS). SIRS can be caused by a variety of disease processes, including pancreatitis, polytrauma, malignancy, and transfusion reaction, and infection. SIRS caused by infection is termed sepsis, and is mediated by the production of a cascade of proinflammatory mediators produced in response to exposure to microbial products. These products include lipopolysaccharide (endotoxin, LPS) derived from gram-negative organisms and many others. Patients have developed sepsis if they have met clinical criteria for SIRS and have evidence of a local or systemic source of infection. Severe sepsis is characterized as sepsis (defined above) combined with the presence of new-onset organ failure. Severe sepsis is the most common cause of death in noncoronary critical care units, with more than 200,000 deaths occurring annually in the United States. With respect to clinical criteria, a patient with sepsis and the need for ventilatory support, with oliguria unresponsive to aggressive fluid resuscitation, or with hypotension requiring vasopressors should be considered to have developed severe sepsis. Septic shock is a state of acute circulatory failure identified by the presence of persistent arterial hypotension (systolic blood pressure < 90 mmHg) despite adequate fluid resuscitation, without other identifiable causes. Septic shock is the most severe manifestation of infection, occurring in approximately 40 percent of patients with severe sepsis; it has an attendant mortality rate of 60–80 percent.

MICROBIOLOGY OF INFECTIOUS AGENTS

Bacteria

Table 5-1 lists common pathogens of surgical interest. Bacteria are responsible for the majority of surgical infections. Specific species are identified using Gram stain and growth characteristics on specific media. The Gram stain allows rapid classification of bacteria by color: gram-positive bacteria stain blue and gram-negative bacteria stain red. Bacteria are classified based on a number of additional characteristics including morphology [cocci and bacilli], the pattern of division (e.g., single organisms, groups of organisms in pairs [diplococci], clusters [staphylococci], and chains [streptococci]), and the presence and location of spores.

Gram-positive bacteria that frequently cause infections in surgical patients include aerobic skin and enteric organisms. Aerobic skin commensals are the most frequent cause of surgical site infections (SSIs); enterococci can cause nosocomial infections (urinary tract infections [UTIs] and bacteremia)

TABLE 5-1 Common Pathogens in Surgical Patients

Gram-positive aerobic cocci

Staphylococcus aureus
Staphylococcus epidermidis
Streptococcus pyogenes
Streptococcus pneumoniae
Enterococcus faecium, *E. faecalis*

Gram-negative aerobic bacilli

Escherichia coli
Haemophilus influenzae
Klebsiella pneumoniae
Proteus mirabilis
Enterobacter cloacae, *E. aerogenes*
Serratia marcescens
Acinetobacter calcoaceticus
Citrobacter freundii
Pseudomonas aeruginosa
Xanthomonas maltophilia

Anaerobes**Gram-positive**

Clostridium perfringens, *C. tetani*, *C. septicum*
Clostridium difficile
Peptostreptococcus spp.

Gram-negative

Bacteroides fragilis
Fusobacterium spp.

Other bacteria

Mycobacterium avium-intracellulare
Mycobacterium tuberculosis
Nocardia asteroides
Legionella pneumophila
Listeria monocytogenes

Fungi

Aspergillus fumigatus, *A. niger*, *A. terreus*, *A. flavus*
Blastomyces dermatitidis
Candida albicans
Candida glabrata, *C. parapsilosis*, *C. krusei*
Coccidioides immitis
Cryptococcus neoformans
Histoplasma capsulatum
Mucor/Rhizopus

Viruses

Cytomegalovirus
Epstein-Barr virus
Hepatitis B, C viruses
Herpes simplex virus
Human immunodeficiency virus
Varicella zoster virus

in immunocompromised or chronically ill patients, but are of relatively low virulence in healthy individuals.

There are many gram-negative bacterial species capable of causing infection in surgical patients. Most gram-negative organisms of interest to the surgeon belong to the family Enterobacteriaceae. Other gram-negative bacilli of note include *Pseudomonas* species, including *Pseudomonas aeruginosa* and *P. fluorescens* and *Xanthomonas* species.

Anaerobic organisms are unable to grow or divide poorly in air because of the absence of the enzyme catalase. Common anaerobes in the gastrointestinal (GI) tract include *Bacteroides fragilis*, which typically contribute to mixed infections.

Infection because of *Mycobacterium tuberculosis* was once one of the most common causes of death in Europe, causing one in four deaths in the seventeenth and eighteenth centuries. This organism and other related organisms (*M. avium-intracellulare* and *M. leprae*) are known as acid-fast bacilli and are typically slow-growing. Deoxyribonucleic acid (DNA)-based analysis is increasingly providing a means for preliminary, rapid detection.

Fungi

Fungi are typically identified by use of special stains (e.g., potassium hydroxide [KOH], India ink, methenamine silver, or Giemsa). Identification is assisted by observation of branching and septation in stained specimens or in culture. Fungi of relevance to surgeons include those that cause nosocomial infections in surgical patients as part of polymicrobial infections or fungemia (e.g., *Candida albicans* and related species), rare causes of aggressive soft tissue infections (e.g., *Mucor*, *Rhizopus*, and *Absidia* species), and so-called opportunistic pathogens that cause infection in the immunocompromised host (e.g., *Aspergillus* species, *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Cryptococcus neoformans*).

Viruses

Because of their small size and necessity for growth within cells, viruses are difficult to culture, requiring a longer time than is typically optimal for clinical decision making. Recent advances in technology have allowed for the identification of viral DNA or ribonucleic acid (RNA) using methods such as polymerase chain reaction. Most viral infections in surgical patients occur in the immunocompromised host, particularly those receiving immunosuppression to prevent rejection of a solid organ allograft. Relevant viruses include adenoviruses, cytomegalovirus, Epstein-Barr virus, herpes simplex virus, and varicella-zoster virus. Surgeons must be aware of the manifestations of hepatitis B and C virus, and human immunodeficiency virus infections, including their capacity to be transmitted to health care workers (described below).

PREVENTION AND TREATMENT OF SURGICAL INFECTIONS

General Principles

Maneuvers to diminish the presence of exogenous (surgeon and operating room environment) and endogenous (patient) microbes are termed prophylaxis, and consist of the use of mechanical, chemical, and antimicrobial modalities, or a combination of these methods.

The host resident microflora of the skin (patient and surgeon) and other barrier surfaces represent a potential source of microbes that can invade the body during trauma, thermal injury, or elective or emergent surgical intervention. A number of maneuvers are typically utilized to prevent spread of these organisms to the operative area, including preoperative scrub by operating room personnel, preoperative skin preparation (with clipping, not shaving), and intraoperative aseptic technique. Additional maneuvers are prudent when undertaking bowel surgery. Preparation of areas of the body such as the distal colorectum requires that body waste in the form of bacteria-laden feces be removed to the greatest extent possible. Current practice includes a clear liquid diet, a cathartic preparation (e.g., polyethylene glycol or buffered-saline laxative), and adequate oral hydration for 12–24 hours prior to colonic resection to flush the contents of the colon.

Although these modalities result in a significant reduction of microbial inoculum, they are not capable of sterilizing the hands of the surgeon or the skin or epithelial surfaces of the patient. This suggests the use of prophylactic antimicrobial agents, especially in patients undergoing procedures associated with the ingress of significant numbers of microbes (e.g., colonic resection) or in whom the consequences of infection carry increased risk (e.g., prosthetic vascular graft infection).

Source Control

The primary precept of surgical infectious disease therapy consists of drainage of all purulent material, debridement of all infected, devitalized tissue, and debris, and/or removal of foreign bodies at the site of infection, plus remediation of the underlying cause of infection. Other treatment modalities such as antimicrobial agents, although critical, are of secondary importance to effective surgery regarding treatment of surgical infections and overall outcome. Rarely, if ever, can an aggressive surgical infection be cured only by the administration of antibiotics, and never in the face of inadequate source control. Finally, it has been well-demonstrated that delay in operative intervention, whether because of misdiagnosis or the need for additional diagnostic studies, is associated with increased morbidity and mortality.

Appropriate Use of Antimicrobial Agents

Table 5-2 shows a classification of antimicrobial agents, mechanisms of action, and spectrum of activity. Prophylaxis consists of the administration of appropriate antimicrobial agent(s) prior to initiation of surgical procedures to reduce the number of microbes that enter the operative site. Timing of prophylaxis for surgery is critical: patients should receive a dose of agent within 30 minutes prior to creating the incision. Agents are selected according to their activity against microbes likely to be present at the surgical site. For the majority of infections not involving the GI tract or biliary/pancreatic tract a dose of first generation cephalosporin is appropriate (e.g., cephazolin). For cases involving the GI/biliary/pancreatic tracts, any one of a number of agents may be utilized (e.g., cefotetan, ampicillin-sulbactam, ertapenem, many others). Use of these prophylactic measures constitutes the current standard of care in North America. By definition, prophylaxis is limited to the time prior to and during the operative procedure; in the vast majority of cases only a single dose of antibiotic is required. However, patients who undergo prolonged procedures in which the duration of the operation exceeds the serum drug

1 = Reliable activity; +/- = variable activity; 0 = no activity.

The sensitivities presented are generalizations. The clinician should confirm sensitivity patterns at the locale where the patient is being treated since these patterns may vary widely depending on location.

half-life should receive an additional dose or doses of the antimicrobial agent. There is no evidence that administration of postoperative doses of an antimicrobial agent provides additional benefit.

Empiric therapy comprises the use of an antimicrobial agent or agents when the risk of a surgical infection is high, based on the underlying disease process (e.g., ruptured appendicitis), or when significant contamination during surgery has occurred (e.g., inadequate bowel preparation or considerable spillage of colon contents). Prophylaxis merges into empiric therapy in situations in which the risk of infection increases markedly because of intraoperative findings. Empiric therapy also often is employed in critically ill patients in whom a potential site of infection has been identified and severe sepsis or septic shock occurs. Invariably, empiric therapy should be limited to a short course of drug (3–5 days), and should be curtailed as soon as possible based on microbiologic data (i.e., absence of positive cultures) coupled with improvements in the clinical course of the patient.

Similarly, empiric therapy merges into therapy of established infection in some patients as well. However, among surgical patients, the manner in which therapy is employed, particularly in relation to the use of microbiologic data (culture and antibiotic sensitivity patterns), differs depending on whether the infection is monomicrobial or polymicrobial. Monomicrobial infections frequently are nosocomial infections occurring in postoperative patients, such as UTIs, pneumonia, or catheter-related infection. In polymicrobial infections, culture results are less helpful because it is invariably difficult to identify all microbes that comprise the initial polymicrobial inoculum. For this reason, the antibiotic regimen should not be modified solely on the basis of culture information, as it is less important than the clinical course of the patient. In clinical trials of antimicrobial therapy for appendicitis including antimicrobials with activity against appropriate gram-negative and anaerobic organisms, most failures could not be attributed to antibiotic selection, but rather were because of the inability to achieve effective source control.

Duration of antibiotic administration should be decided at the time the drug regimen is prescribed. As noted above, prophylaxis is limited to a single dose administered immediately prior to creating the incision. Empiric therapy should be limited to 3–5 days or less, and should be curtailed if the presence of a local site or systemic infection is not revealed.

In the later phases of postoperative antibiotic treatment of serious intraabdominal infection, the absence of an elevated WBC count, lack of band forms of PMNs on peripheral smear, and lack of fever ($<38.2^{\circ}\text{C}$ [100.5°F]) provide close to complete assurance that infection has been eradicated. Under these circumstances, antibiotics can be discontinued with impunity.

Allergy to antimicrobial agents must be considered prior to prescribing them. Penicillin allergy is quite common, the reported incidence ranging from 0.7–10 percent. Although avoiding the use of any beta-lactam drug is appropriate in patients who manifest significant allergic reactions to penicillins, the incidence of cross-reactivity appears highest for carbapenems, much lower for cephalosporins (approximately 5–7 percent), and extremely small or nonexistent for monobactams. Severe allergic manifestations to a specific class of agents, such as anaphylaxis, generally preclude the use of any agents in that class, except under circumstances in which use of a certain drug represents a lifesaving measure.

INFECTIONS OF SIGNIFICANCE IN SURGICAL PATIENTS

Surgical Site Infections

SSIs are infections of the tissues, organs, or spaces exposed by surgeons during performance of an invasive procedure. SSIs are associated with considerable morbidity and occasional lethality, and substantial health care costs and patient inconvenience and dissatisfaction. The development of SSIs is related to three factors: (1) the degree of microbial contamination of the wound during surgery, (2) the duration of the procedure, and (3) host factors such as diabetes, malnutrition, obesity, immune suppression, and a number of other underlying disease states (Table 5-3). By definition, an incisional SSI has occurred if a surgical wound drains purulent material or if the surgeon judges it to be infected and opens it.

Surgical wounds are classified based on the presumed magnitude of the bacterial load at the time of surgery (Table 5-4). Clean wounds (class I) include those in which no infection is present; only skin microflora potentially contaminate the wound, and no hollow viscus that contains microbes is entered. Class ID wounds are similar except that a prosthetic device (e.g., mesh or valve) is inserted. Clean/contaminated wounds (class II) include those in which a hollow viscus such as the respiratory, alimentary, or genitourinary tracts with indigenous bacterial flora is opened under controlled circumstances without significant spillage of contents. Contaminated wounds (class III) include open

TABLE 5-3. Risk Factors for Development of Surgical Site Infections

Patient factors
Older age
Immunosuppression
Obesity
Diabetes mellitus
Chronic inflammatory process
Malnutrition
Peripheral vascular disease
Anemia
Radiation
Chronic skin disease
Carrier state (e.g., chronic <i>Staphylococcus</i> carriage)
Recent operation
Local factors
Poor skin preparation
Contamination of instruments
Inadequate antibiotic prophylaxis
Prolonged procedure
Local tissue necrosis
Hypoxia, hypothermia
Microbial factors
Prolonged hospitalization (leading to nosocomial organisms)
Toxin secretion
Resistance to clearance (e.g., capsule formation)

TABLE 5-4. Wound Class, Representative Procedures, and Expected Infection Rates

Wound class	Examples of cases	Expected infection rates
Clean (class I)	Hernia repair, breast biopsy	1.0–5.4 percent
Clean/contaminated (class II)	Cholecystectomy, elective GI surgery	2.1–9.5 percent
Contaminated (class III)	Penetrating abdominal trauma, large tissue injury, enterotomy during bowel obstruction	3.4–13.2 percent
Dirty (class IV)	Perforated diverticulitis, necrotizing soft tissue infections	3.1–12.8 percent

accidental wounds encountered early after injury, those with extensive introduction of bacteria into a normally sterile area of the body because of major breaks in sterile technique (e.g., open cardiac massage), gross spillage of viscus contents such as from the intestine, or incision through inflamed, albeit nonpurulent, tissue. Dirty wounds (class IV) include traumatic wounds in which a significant delay in treatment has occurred and in which necrotic tissue is present, those created in the presence of overt infection as evidenced by the presence of purulent material, and those created to access a perforated viscus accompanied by a high degree of contamination.

The National Nosocomial Infection Surveillance (NNIS) risk index is commonly used to classify infection risk as well, and assesses three factors: (1) American Society of Anesthesiologists (ASA) Physical Status score greater than 2, (2) class III/IV wound, and (3) duration of operation greater than the 75th percentile for that particular procedure, to refine the risk of infection beyond that achieved by use of wound classification alone. Intriguingly, the risk of SSIs for class I wounds varies from approximately 1–2 percent for patients with low NNIS scores, to approximately 15 percent for patients with high NNIS scores (e.g., long operations and/or high ASA scores), and it seems clear that additional refinements are required.

Surgical management of the wound is also a critical determinant of the propensity to develop an SSI. In healthy individuals, class I and II wounds may be closed primarily, although skin closure of class III and IV wounds is associated with high rates of incisional SSIs (approximately 25–50 percent). The superficial aspects of these latter types of wounds should be packed open and allowed to heal by secondary intention, although selective use of delayed primary closure has been associated with a reduction in incisional SSI rates.

Effective therapy for incisional SSIs consists solely of incision and drainage without the addition of antibiotics. Antibiotic therapy is reserved for patients in whom evidence of severe cellulitis is present, or who manifest signs of concurrent sepsis. Although culture results are of epidemiologic interest, they rarely serve to direct therapy because antibiotics are not routinely withheld until results are known.

Intraabdominal Infections

Microbial contamination of the peritoneal cavity is termed peritonitis or intraabdominal infection, and is classified according to etiology. Primary microbial peritonitis occurs when microbes invade the normally sterile confines of the peritoneal cavity via hematogenous dissemination from a distant source of infection or direct inoculation. This process is more common among patients who retain large amounts of ascites, and in those being treated for renal failure via peritoneal dialysis. These infections invariably are monomicrobial and rarely require surgical intervention. Treatment consists of administration of an antibiotic to which the organism is sensitive. Removal of indwelling devices (e.g., peritoneal dialysis catheter or peritoneovenous shunt) may be required for effective therapy of recurrent infections.

Secondary microbial peritonitis occurs subsequent to contamination of the peritoneal cavity because of perforation or severe inflammation and infection of an intraabdominal organ. Examples include appendicitis, perforation of any portion of the GI tract, or diverticulitis. As noted previously, effective therapy requires source control to resect the diseased organ; débridement of necrotic, infected tissue and debris; and administration of antimicrobial agents directed against aerobes and anaerobes. A combination of agents or single agents with a broad spectrum of activity can be used for this purpose; conversion of a parenteral to an oral regimen when the patient's ileus resolves provides results similar to those achieved with intravenous antibiotics. Effective source control and antibiotic therapy is associated with low failure rates and a mortality rate of approximately 5–6 percent; inability to control the source of infection leads to mortality greater than 40 percent. The response rate to effective source control and use of appropriate antibiotics has remained approximately 70–90 percent over the past several decades.

Patients in whom standard therapy fails develop an intraabdominal abscess, leakage from a gastrointestinal anastomosis leading to postoperative peritonitis, or tertiary (persistent) peritonitis. The latter is a poorly understood entity that is more common in immunosuppressed patients in whom peritoneal host defenses do not effectively clear or sequester the initial secondary microbial peritoneal infection. Microbes such as *E. faecalis* and *E. faecium*, *S. epidermidis*, *C. albicans*, and *P. aeruginosa* can be identified, typically in combination, and may be selected based on their lack of responsiveness to the initial antibiotic regimen, coupled with diminished activity of host defenses. Unfortunately, even with effective antimicrobial agent therapy, this disease process is associated with mortality rates in excess of 50 percent.

Formerly, the presence of an intraabdominal abscess mandated surgical reexploration and drainage. Today, the vast majority of such abscesses can be effectively diagnosed via abdominal computed tomographic (CT) imaging techniques and drained percutaneously. Surgical intervention is reserved for those individuals who harbor multiple abscesses, those with abscesses in proximity to vital structures such that percutaneous drainage would be hazardous, and those in whom an ongoing source of contamination (e.g., enteric leak) is identified. The necessity of antimicrobial agent therapy and precise guidelines that dictate duration of catheter drainage have not been established. A short course (3–7 days) of antibiotics that possess aerobic and anaerobic activity seems reasonable, and most practitioners leave the drainage catheter in situ until it is clear that cavity collapse has occurred, output is less than 10–20 mL/day, no evidence of an ongoing

source of contamination is present, and the patient's clinical condition has improved.

Infections of the Skin and Soft Tissue

These infections can be classified according to whether or not surgical intervention is required. For example, superficial skin and skin structure infections such as cellulitis, erysipelas, and lymphangitis invariably are effectively treated with antibiotics alone, although a search for a local source of infection should be undertaken. Generally, drugs that possess activity against the gram-positive skin microflora that are causative are selected. Furuncles or boils may drain spontaneously or require surgical incision and drainage. Antibiotics are prescribed if significant cellulitis is present or if cellulitis does not rapidly resolve after surgical drainage. The astute clinician should be aware of the emerging incidence of community acquired methicillin-resistant *Staphylococcus aureus* in the setting of unresolving cellulitis after simple drainage, and consider culture of these wounds.

Aggressive soft tissue infections are rare, difficult to diagnose, and require immediate surgical intervention plus administration of antimicrobial agents. Failure to do so results in an extremely high mortality rate (approximately 80–100 percent), and even with rapid recognition and intervention, current mortality rates remain approximately 30–50 percent. These infections are classified based on the soft tissue layer(s) of involvement (e.g., skin and superficial soft tissue, deep soft tissue, and muscle) and the pathogen(s) that cause them.

Patients at risk for these types of infections include those who are older adult, immunosuppressed, or diabetic; those who suffer from peripheral vascular disease; or those with a combination of these factors. Additionally, over the last decade, aggressive necrotizing soft tissue infections among healthy individuals because of streptococci have been described. The diagnosis of necrotizing soft tissue infection is most commonly clinical. Not surprisingly, patients often develop sepsis syndrome or septic shock without an obvious cause. Affected areas include the extremities, perineum, trunk, and torso. Careful examination should be undertaken for an entry site from which grayish, turbid semipurulent material ("dishwater pus") can be expressed, and for the presence of skin changes (bronze hue or brawny induration), blebs, or crepitus. The patient often develops pain at the site of infection that appears to be out of proportion to any of the physical manifestations. Any of these findings mandates immediate surgical intervention, which should consist of exposure and direct visualization of potentially infected tissue (including deep soft tissue, fascia, and underlying muscle) and radical resection of affected areas. Radiologic studies should be undertaken only in patients in whom the diagnosis is not seriously considered, as they delay surgical intervention and frequently provide confusing information. Antimicrobial agents directed against gram-positive and gram-negative aerobes and anaerobes (e.g., vancomycin plus a carbapenem), and high-dose aqueous penicillin G (16,000 to 20,000 units/day) should be administered. Approximately 60–70 percent of such infections are polymicrobial, the remainder being caused by a single organism such as *P. aeruginosa*, *Clostridium perfringens*, or *Streptococcus pyogenes*. Most patients should be returned to the operating room on a scheduled basis for evaluation and further debridement, if necessary. Antibiotic therapy can be refined based on culture and sensitivity results, particularly in the case of monomicrobial soft tissue infections.

Postoperative Nosocomial Infections

Surgical patients are prone to develop a wide variety of nosocomial infections during the postoperative period, which include SSIs, UTIs, pneumonia, and bacteremic episodes. SSIs are discussed above, and the latter types of nosocomial infections are related to prolonged use of indwelling tubes and catheters for the purpose of urinary drainage, ventilation, and venous and arterial access, respectively.

The presence of a postoperative UTI should be considered based on urinalysis demonstrating WBCs or bacteria, a positive test for leukocyte esterase, or a combination of these elements. The diagnosis is established after greater than 104 CFU/mL of microbes are identified by culture techniques in symptomatic patients, or greater than 105 CFU/mL in asymptomatic individuals. Treatment with a single antibiotic that achieves high levels in the urine is appropriate. Postoperative surgical patients should have indwelling urinary catheters removed as quickly as possible, typically within 1–2 days, as long as they are mobile.

Prolonged mechanical ventilation is associated with an increased incidence of pneumonia, and is frequently because of pathogens common in the nosocomial environment. Frequently these organisms are highly resistant to many different agents. The diagnosis is established based on clinical criteria of purulent sputum, fever, elevated WBC, and roentgenographic evidence of one or more areas of pulmonary consolidation. Consideration should be given to performing bronchoalveolar lavage to obtain samples to assess by Gram stain and to performing a culture to assess for the presence of microbes. Surgical patients should be weaned from mechanical ventilation as soon as feasible to reduce the incidence of this complication.

Infection associated with indwelling intravascular catheters has become a common problem among hospitalized patients. Because of the complexity of many surgical procedures, these devices are increasingly used for physiologic monitoring, vascular access, drug delivery, and parenteral nutrition. Among the several million catheters inserted each year in the United States, approximately 25 percent will become colonized, and approximately 5 percent will be associated with bacteremia. Many patients who develop intravascular catheter infections are asymptomatic, often exhibiting an elevation in the WBC count. Blood cultures obtained from a peripheral site and drawn through the catheter that reveal the presence of the same organism increase the index of suspicion for the presence of a catheter infection. Obvious purulence at the exit site of the skin tunnel, severe sepsis syndrome because of any type of organism when other potential causes have been excluded, or bacteremia because of gram-negative aerobes or fungi should lead to catheter removal.

Sepsis

A number of studies have demonstrated the importance of empiric antimicrobial agent therapy in patients who develop severe sepsis concurrent with fluid resuscitation, metabolic support, and control of any site-specific source of infection. Use of institutional and unit-specific sensitivity patterns and knowledge of likely pathogens are critical in selecting an appropriate agent. Retrospective reviews demonstrate that appropriate initial therapy is associated with a two- to threefold reduction in mortality.

A number of new therapies for treatment of patients with severe sepsis have recently been demonstrated to be of significant benefit in patients with severe

sepsis or septic shock. Drotrecogin alpha (activated), also known as Xigris, is a recombinant form of human-activated protein C. The use of this agent in a series of patients with sepsis syndrome has been associated with a 6 percent overall reduction in mortality (31–25 percent, $p = 0.005$). Evaluation of the surgical cohorts of several grouped trials suggests that the benefits of this agent are confined to those patients with at least two organ failures (e.g., elevated lactate plus respiratory failure). The use of this agent should be considered in patients with severe infection who have completed their source control procedure, and who develop severe sepsis with at least two organs failing. Current recommendations are a dose of 24 $\mu\text{g/kg}$ per h given for 96 h. The infusion should be interrupted for procedures or surgery, or for significant life-threatening bleeding.

A number of investigators have revisited the issue of corticosteroids for the treatment of septic shock. A number of randomized, controlled trials have demonstrated the benefit of replacement doses of corticosteroids in patients with severe shock states. In patients who develop septic shock, these authors currently initiate low-dose hydrocortisone (100 mg/8 h) after performing a corticotropin stimulation test (baseline cortisol level, corticotropin 250 mcg intravenously, cortisol level 1 h later). Adrenal insufficiency is identified if the baseline cortisol level is less than 34 mcg/dL, or if an increase of less than 9 mcg/dL occurs after corticotropin stimulation. Low-dose steroid therapy should be discontinued in patients with normal adrenal function.

Blood-Borne Pathogens

Although alarming to contemplate, the risk of human immunodeficiency virus (HIV) transmission from patient to surgeon is low. By December 31, 2001, there had been six cases of surgeons with HIV seroconversion from a possible occupational exposure, from a total of 470,000 HIV cases to that date reported to the Centers for Disease Control and Prevention (CDC). The risks for acquiring HIV infection are related to the prevalence of HIV infection in the population being cared for, the probability of transmission from a percutaneous injury suffered while caring for an infected patient, the number of such injuries sustained, and the use of postexposure prophylaxis. Annual calculated risks for acquiring HIV infection in Glasgow, Scotland, ranged from one in 200,000 for general surgeons not utilizing postexposure prophylaxis to as low as one in 10,000,000 with use of routine postexposure prophylaxis after significant exposures. Postexposure prophylaxis begun early for HIV significantly decreases the risk of seroconversion for health care workers with occupational exposure to HIV.

Transmission of HIV (and other infections spread by blood and body fluid) from patient to health care worker can be minimized by observation of universal precautions, which include the following: (1) routine use of barriers (such as gloves and/or goggles) when anticipating contact with blood or body fluids, (2) washing of hands and other skin surfaces immediately after contact with blood or body fluids, and (3) careful handling and disposal of sharp instruments during and after use.

Hepatitis B virus (HBV) is a DNA virus that only affects humans. Primary infection with HBV generally is self-limited (approximately 6 percent of those infected are older than 5 years of age), but can progress to a chronic carrier state. Death from chronic liver disease or hepatocellular cancer occurs in roughly 30 percent of chronically infected persons. Surgeons and other

health care workers are at high risk for this blood-borne infection and should receive the HBV vaccine. In the postexposure setting, hepatitis B immune globulin (HBIG) confers approximately 75 percent protection from HBV infection.

Hepatitis C virus (HCV), previously known as non-A, non-B hepatitis, is a RNA flavivirus first identified specifically in the late 1980s. This virus is confined to humans and chimpanzees. A chronic carrier state develops in 75–80 percent of patients with the infection, with chronic liver disease occurring in three fourths of patients developing chronic infection. The number of new infections per year has declined since the 1980s because of the incorporation of testing of the blood supply for this virus. Fortunately, HCV virus is not transmitted efficiently through occupational exposures to blood, with the seroconversion rate after accidental needlestick reported to be approximately 2 percent.

INITIAL EVALUATION AND RESUSCITATION OF THE INJURED PATIENT

Airway Management

Insuring an adequate airway is the first priority because efforts to restore cardiovascular integrity will be futile unless the oxygen content of the blood is adequate. Simultaneously, all blunt trauma patients require cervical spine immobilization until injury is ruled out. This can be accomplished with a hard (Philadelphia) collar or sand bags on both sides of the head taped to the back board.

Patients who are conscious and have a normal voice, in general, do not require further evaluation or early attention to their airway. Patients who have an abnormal voice or altered mental status require further airway evaluation. Direct laryngoscopic inspection will often reveal blood, vomit, or soft tissue swelling as sources of airway obstruction. Suctioning may afford immediate relief in many patients. Altered mental status is the most common indication for intubation because of the patient's inability to protect their airway. Options for airway access include nasotracheal, orotracheal, or surgical. Nasotracheal intubation can only be accomplished in patients who are breathing spontaneously and is contraindicated in the apneic patient. Nasotracheal intubation is primarily employed by paramedics in the field.

Orotracheal intubation can be performed in patients with potential cervical spine injuries provided that manual in-line cervical immobilization is maintained. The advantages of orotracheal intubation are the direct visualization of the vocal cords, the ability to use larger diameter endotracheal tubes, and applicability to apneic patients. The disadvantage is that conscious patients usually require neuromuscular blockade or deep sedation. Those who attempt rapid sequence induction must be thoroughly familiar with the details and contraindications of the procedure (see Chapter 45). Patients in whom attempts at intubation have failed or are precluded because of extensive facial injuries require a surgical airway. Cricothyroidotomy is preferred over tracheostomy in most emergent situations.

Breathing

All injured patients should receive supplemental oxygen therapy and be monitored by pulse oximetry. The following conditions may constitute an immediate threat to life because of inadequate ventilation: (1) tension pneumothorax, (2) open pneumothorax, or (3) flail chest/pulmonary contusion. The diagnosis of tension pneumothorax is implied by the finding of respiratory distress in combination with any of the following physical signs: tracheal deviation away from the affected side, decreased breath sounds on the affected side, distended neck veins or systemic hypotension, or subcutaneous emphysema on the affected side. Immediate tube thoracostomy is indicated without awaiting chest radiograph confirmation.

An open pneumothorax or sucking chest wound occurs with full-thickness loss of the chest wall permitting a free communication between the pleural space and the atmosphere. Definitive treatment requires wound closure and tube thoracostomy.

Flail chest occurs when four or more ribs are fractured in at least two locations. Paradoxical movement of this free floating segment of chest wall may occasionally be sufficient to compromise ventilation. However, it is of greater physiologic importance that patients with flail chest frequently have an underlying pulmonary contusion. Respiratory failure in these patients may not be immediate and frequent reevaluation is warranted. The initial chest radiograph usually underestimates the degree of pulmonary contusion.

Circulation

A first approximation of the patient's cardiovascular status is obtained by palpating peripheral pulses. In general, a systolic blood pressure of 60 mm Hg is required for the carotid pulse to be palpable, 70 mm Hg for the femoral pulse and 80 mm Hg for the radial pulse.

External control of hemorrhage should be obtained before restoring circulating volume. Manual compression and splints will frequently control extremity hemorrhage. Blind clamping should be avoided because of the risk to adjacent structures, particularly nerves. Digital control of hemorrhage for penetrating injuries of the head, neck, thoracic outlet, groin, and extremities is key. A gloved finger should be placed through the wound directly on the bleeding vessel applying only enough pressure to control active bleeding. The surgeon performing this maneuver must then walk with the patient to the operating room for definitive treatment. Scalp lacerations through the galea aponeurotica tend to bleed profusely; and can be controlled with Rainey clips or a large nylon continuous stitch.

Intravenous access for fluid resuscitation is begun with two peripheral catheters, 16 gauge or larger in an adult. Blood should be drawn simultaneously and sent for typing and hematocrit. Venous lines for volume resuscitation should be short with a large diameter. Saphenous vein cut downs at the ankle or percutaneous femoral vein catheter introducers are preferred. Secondary central venous introducers should be placed in the OR in the event vena caval crossclamping is performed. If two attempts at percutaneous peripheral access are unsuccessful, in hypovolemic children younger than 6 years of age, interosseous cannulation should be performed in the proximal tibia or distal femur if the tibia is fractured.

Initial Fluid Resuscitation

Initial fluid resuscitation is a 1 L intravenous bolus of normal saline, Ringer lactate, or other isotonic crystalloid in an adult or 20 mL/kg Ringer lactate in a child. This is repeated one time in an adult and twice in a child prior to administering red blood cells. Classic signs and symptoms of shock are tachycardia, hypotension, tachypnea, mental status changes, diaphoresis and pallor. None of these signs or symptoms taken alone can predict the patient's organ perfusion status. When viewed as a constellation, they can help to evaluate the patient's response to treatment.

There are several caveats that must be kept in mind. Individuals in good physical condition, particularly trained athletes with a low resting pulse rate, may manifest only a relative tachycardia. Patients on β -blocking medications

TABLE 6-1 Signs and Symptoms for Different Classes of Shock

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	>2000
Blood loss (%BV)	Up to 15%	15–30%	30–40%	>40%
Pulse rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	>35
Urine output (mL/h)	>30	20–30	5–15	Negligible
CNS/mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic

BV = blood volume; CNS = central nervous system.

may not be able to increase their heart rate in response to stress. In children relative bradycardia can occur with severe blood loss and is an ominous sign. On the other hand, hypoxia, pain, apprehension, and stimulant drugs (cocaine, amphetamines) will produce a tachycardia. In healthy patients blood volume must decrease by 30–40 percent before hypotension occurs (Table 6-1). Younger patients with good sympathetic tone can maintain systemic blood pressure with severe intravascular deficits.

Acute changes in mental status can be caused by hypoxia, hypercarbia, hypovolemia or may be an early sign of increasing intracranial pressure (ICP). A deterioration in mental status may be subtle and may not progress in a predictable fashion. Previously cooperative patients may become anxious and combative as they become hypoxic; whereas, a patient agitated from drugs or alcohol may become somnolent if hypovolemic shock develops. Urine output is a sensitive indicator of organ perfusion. Adequate urine output is .5 mL/kg/h in an adult, 1 mL/kg/h in a child, and 2 mL/kg/h in an infant younger than 1 year of age.

Based on the initial response to fluid resuscitation, hypovolemic injured patients will separate themselves into three broad categories: responders, transient responders, and nonresponders.

Persistent Hypotension (Nonresponders)

The spectrum of disease in this category ranges from nonsurvivable multisystem injury to problems as simple as a tension pneumothorax. An evaluation of the patient's neck veins and central venous pressure (CVP) is an important early maneuver. CVP determines right ventricular preload; and in otherwise healthy trauma patients, its measurement yields objective information regarding the patient's overall volume status. A hypotensive patient with a CVP less than 5 cm H₂O is hypovolemic and is likely to have ongoing hemorrhage. A hypotensive patient with a CVP greater than 15 cm H₂O is likely to be in cardiogenic shock.

In trauma patients the differential diagnosis of cardiogenic shock is a short list: 1) tension pneumothorax, 2) pericardial tamponade, 3) myocardial contusion or infarction, and 4) air embolism. Tension pneumothorax is the most frequent cause of cardiac failure. Traumatic pericardial tamponade most

often is associated with penetrating injury to the heart. As blood leaks out of the injured heart, it accumulates in the pericardial sac. When the pressure exceeds that of the right atrium, right ventricular preload is reduced. With acute tamponade as little as 100 mL of blood within the pericardial sac can produce life-threatening hemodynamic compromise. The usual presentation is a patient with a penetrating injury in proximity to the heart who is hypotensive and has distended neck veins or an elevated CVP. Ultrasonography (US) in the emergency department using a subxiphoid or parasternal view is extremely helpful. Once the diagnosis of cardiac tamponade is established, pericardiocentesis should be performed. Evacuation of as little as 15–25 mL of blood may dramatically improve the patient's hemodynamic profile. While pericardiocentesis is being performed, preparation should be made for emergent transport to the OR. If pericardiocentesis is unsuccessful and the patient remains severely hypotensive (SBP <70 mm Hg) emergency department thoracotomy should be performed. This is best accomplished using a left anterolateral thoracotomy, longitudinal pericardiotomy anterior to the phrenic nerve, followed by evacuation of the pericardial sac and temporary control of the cardiac injury. The patient is then transported to the OR for definitive repair.

Myocardial contusion from direct myocardial impact occurs in approximately one third of patients sustaining significant blunt chest trauma. The diagnostic criteria for myocardial contusion include specific electrocardiograph abnormalities, but serial cardiac enzyme determinations lack sensitivity, and are not predictive of complications. Life-threatening complications of ventricular arrhythmias and cardiac pump failure occur in less than 5 percent and less than 1 percent of patients, respectively.

Air embolism is a frequently overlooked lethal complication of pulmonary injury. It occurs when air from an injured bronchus enters an adjacent injured pulmonary vein and returns to the left heart. Air accumulation in the left ventricle impedes diastolic filling; and during systole, it is pumped into the coronary arteries disrupting coronary perfusion. The typical scenario is a patient with a penetrating chest injury who appears hemodynamically stable but suddenly arrests after being intubated and placed on positive pressure ventilation. The patient should be placed in the Trendelenburg position to trap the air in the apex of the left ventricle. Emergency thoracotomy is followed by cross clamping the pulmonary hilum on the side of the injury to prevent further introduction of air. Air is aspirated from the apex of the left ventricle with an 18-gauge needle and 50-mL syringe. Vigorous open cardiac massage is used to force the air bubbles through the coronary arteries. The highest point of the aortic root is also aspirated to prevent air from entering the coronaries or embolizing to the brain. The patient should be kept in Trendelenburg and the hilum clamped until the pulmonary venous injury is controlled.

Persistent hypotension with flat neck veins because of uncontrolled hemorrhage is associated with a high mortality. A rapid search for the source or sources of hemorrhage including abdominal ultrasound, anteroposterior chest and pelvic radiographs, which usually will indicate the regions of the body responsible for the blood loss. Type O red blood cells (O negative for women of childbearing age) or type-specific red blood cells should be administered and the patient taken directly to the OR for exploration. For patients with a sustained systolic blood pressure of less than 70 mm Hg despite blood administration, emergency department thoracotomy should be considered. The clearest indication for this procedure is penetrating chest trauma. The goal of emergency department thoracotomy for thoracic injuries is control of

hemorrhage; for abdominal injuries the goal is to sustain central circulation and limit abdominal blood loss by clamping the descending thoracic aorta.

Transient Responders

Hypotensive patients who transiently respond to fluid administration usually have some degree of active hemorrhage. Those with penetrating injuries should be taken to the OR for exploration. Those with multiple blunt injuries constitute a diagnostic dilemma. It is during these diagnostic evaluations where the greatest hazard exists because monitoring is compromised, and the environment is suboptimal to deal with acute problems.

SECONDARY SURVEY

Once the conditions which constitute an immediate threat to life have been addressed or excluded, the patient is examined in a systematic fashion, literally head to toe, to identify all occult injuries. Special attention should be given to the patient's back, axillae, and perineum because injuries in these areas are easily overlooked. All patients should undergo digital rectal examination and a Foley catheter should be inserted to decompress the bladder, obtain a urine specimen, and monitor urine output. Stable patients at risk for urethral injury should undergo urethrography before catheterization. A nasogastric tube should be inserted to decrease the risk of gastric aspiration and to allow inspection of the contents for blood suggestive of occult gastroduodenal injury.

For patients with severe blunt trauma, anterior/posterior chest and pelvic radiographs should be obtained as soon as possible. For patients with truncal gunshot wounds, posterior/anterior and lateral radiographs of the chest and abdomen are warranted. It also is helpful to mark the entrance and exit sites with metallic clips.

Mechanisms and Patterns of Injury

Evaluation and decision making are far more difficult in blunt than in penetrating trauma. In general, more energy is transferred over a wider area during blunt trauma than from a gunshot wound (GSW) or stab wound (SW). Injuries involving high energy transfer include auto-pedestrian accidents, motor vehicle accidents in which the car's change of speed exceeds 20 mph or in which the patient has been ejected, motorcycle accidents, and falls from heights greater than 20 feet. The greatest risk factors from the field associated with life-threatening injuries are death of another occupant in the vehicle and an extrication time greater than 20 min.

Patients who have sustained high energy transfer trauma have certain patterns of injury related to the mechanism. When unrestrained drivers suffer frontal impacts, their heads strike the windshield, their chests and upper abdomens hit the steering column, and their legs or knees contact the dashboard. The resultant injuries frequently include facial fractures, cervical spine fractures, laceration of the thoracic aorta, myocardial contusion, injury to the spleen and liver, and fractures of the pelvis and lower extremities.

Penetrating injuries are classified according to the wounding agent (i.e., SWs, GSWs, or shotgun wounds [SGW]). Experience in urban trauma centers indicate that high velocity GSWs (bullet speed greater than 2000 ft/s) are infrequent in the civilian setting. Close-range (<7 meters) SGWs are tantamount to high velocity wounds because the entire energy of the load is delivered to a

small area. Long-range SGWs result in a diffuse pellet pattern in which pellets are dispersed and of comparatively low energy.

Regional Assessment and Special Diagnostic Tests

Head

The Glasgow Coma Scale (GSC) should be determined for all injured patients (Table 6-2). It is calculated by adding the scores of the best motor response, best verbal response, and eye opening. Scores range from 3 (the lowest) to 15 (normal). Scores of 13–15 indicate mild head injury; 9–12, moderate injury; and less than 9, a severe injury. The GSC is useful for both triage and prognosis.

Examination of the head should focus on potentially treatable neurologic injuries. Of great importance are the presence of lateralizing findings, e.g., a unilateral dilated pupil unreactive to light, asymmetric movement of the extremities either spontaneously or in response to noxious stimuli, or a unilateral Babinski sign suggests a treatable intracranial mass lesion or major structural damage.

Epidural hematomas occur when blood accumulates between the skull and dura and are caused by disruption of the middle meningeal artery or other small arteries in that potential space from a skull fracture. Subdural hematomas occur between the dura and cortex and are caused by venous disruption or laceration of the parenchyma of the brain.

Because of the underlying brain injury, prognosis is much worse with subdural hematomas. Intraparenchymal hematomas and contusions can occur anywhere within the brain. Diffuse hemorrhage into the subarachnoid space may cause vasospasm and reduce cerebral blood flow. Diffuse axonal injury (DAI) results from high speed deceleration injury and represents direct axonal damage. On computed tomography (CT) a blurring of the gray/white matter interface may be seen along with multiple small punctate hemorrhages. Early evidence of DAI on CT scan is associated with a poor outcome. Magnetic

TABLE 6-2 Glasgow Coma Scale^a

	Adults	Infants/children
Eye opening	4 Spontaneous	Spontaneous
	3 To voice	To voice
	2 To pain	To pain
	1 None	None
Verbal	5 Oriented	Alert, normal vocalization
	4 Confused	Cries but consolable
	3 Inappropriate words	Persistently irritable
	2 Incomprehensible words	Restless, agitated, moaning
	1 None	None
Motor response	6 Obeys commands	Spontaneous, purposeful
	5 Localizes pain	Localizes pain
	4 Withdraws	Withdraws
	3 Abnormal flexion	Abnormal flexion
	2 Abnormal extension	Abnormal extension
	1 None	None

^aScore is calculated by adding the scores of the best motor response, best verbal response, and eye opening. Scores range from 3 (the lowest) to 15 (normal).

resonance imaging (MRI) often can identify DAI with greater precision than CT.

Significant penetrating injuries usually are produced by bullets from hand guns. While the diagnosis usually is obvious, in some instances, wounds in the auditory canal, mouth and nose can be elusive.

Neck

In evaluating the neck of blunt trauma victims, all patients should be assumed to have cervical spine injuries until proven otherwise. The presence of posterior midline pain or tenderness should provoke a thorough radiologic evaluation. The three view cervical spine series: lateral with visualization of C7-T1, anterior/posterior, and transoral odontoid views will detect most significant fractures. CT will identify almost all fractures but miss some subluxations. MRI is presently considered the most definitive test.

Spinal cord injuries can be complete or partial. Complete injuries have loss of motor function and sensation two or more levels below the bony injury. Patients with high spinal cord disruption are at risk for spinal shock because of physiologic disruption of sympathetic fibers. Central cord syndrome usually occurs in older persons who suffer hyperextension injuries. Motor function and pain and temperature sensation are preserved in the lower extremities but diminished in the upper extremities. Anterior cord syndrome is characterized by diminished motor function and pain and temperature sensation below the level of the injury. Position, vibratory sensation, and crude touch are maintained. Brown-Sequard syndrome is usually the result of a penetrating injury in which the right or left half of the spinal cord is transected. This rare lesion is characterized by the ipsilateral loss of motor function, proprioception, and vibratory sensation, whereas pain and temperature sensation are lost on the contralateral side.

Selective management of penetrating neck wounds are based on the neck divided into three zones. Zone one is between the clavicles and cricoid cartilage, zone two is between the cricoid cartilage and the angle of the mandible, and zone three is above the angle of mandible. Hemodynamically stable patients with zone one injuries should undergo angiography of the great vessels, soluble contrast esophagram followed by barium esophagram, esophagoscopy, and bronchoscopy. An alternate is CT scanning to determine which of these studies is needed.

Unstable patients with zone two injuries or those with evidence of airway compromise, an expanding hematoma, or significant external hemorrhage should be explored promptly. Stable patients without the above findings are observed for 12 h. Patients with right-to-left transcervical GSWs, however, may warrant diagnostic evaluation depending on the trajectory.

Patients with zone three penetrating injuries require carotid and vertebral angiography if there is evidence of arterial bleeding because 1) exposure of the distal internal carotid and vertebral arteries is difficult, 2) the internal carotid artery may have to be ligated, a maneuver associated with a high risk of stroke and 3) active hemorrhage from the external carotid and vertebral arteries can be controlled by selective embolization.

Chest

Most chest injuries are evaluated by physical examination and chest radiographs. Patients with large air leaks following tube thoracostomy and those

who are difficult to ventilate should undergo fiberoptic bronchoscopy to search for bronchial tears or foreign bodies.

Perhaps the most feared occult injury in trauma is a tear of the descending thoracic aorta. Widening of the mediastinum on AP chest radiograph suggests this injury. The widening is caused by the formation of a hematoma around the injured aorta, which is temporarily contained by the mediastinal pleura. However, it is well established that this injury can occur with an entirely normal chest radiograph, although the incidence is approximately 5 percent. Because of this and the dire consequences of missing the diagnosis, dynamic CT scanning is frequently performed based on mechanism of injury. Aortic tears usually occur just distal to the left subclavian artery where the aorta is tethered by the ligamentum arteriosum. In 2–5 percent of cases the tear occurs in the ascending aorta, transverse arch or at the diaphragm.

Penetrating thoracic trauma is evaluated by physical examination, plain posteroanterior (PA) and lateral chest radiographs with metallic markings of entrance and exit wounds and CVP measurement. Based on the estimated trajectory of the missile or blade, bronchoscopy may be indicated to evaluate the trachea. Patients at risk for esophageal injury should undergo esophagoscopy and then a soluble contrast esophagram looking for extravasation of contrast. If no extravasation is seen, a barium esophagram should be performed for greater detail. Failure to identify esophageal injuries leads to fulminant mediastinitis, which often is fatal.

Abdomen

The abdomen is a diagnostic black box. Physical examination of the abdomen is unreliable, however, the presence of abdominal rigidity or gross abdominal distention in a patient with truncal trauma is an indication for prompt surgical exploration. Drugs, alcohol, head, and spinal cord injuries frequently complicate physical examination. It may also be impractical in patients who require general anesthesia for the treatment of other injuries.

The diagnostic approach to penetrating and blunt abdominal trauma differ substantially. Anterior truncal GSWs between the fourth intercostal space and the pubic symphysis whose trajectory by radiograph or entrance/exit wound suggests peritoneal penetration should undergo laparotomy. GSWs to the back or flank are more difficult to evaluate because of the greater thickness of tissue between the skin and the abdominal organs, SWs that penetrate the peritoneal cavity are less likely to injure intraabdominal organs. Anterior and lateral stab wounds to the trunk should be explored under local anesthesia in the emergency department to determine whether the peritoneum has been violated. Injuries that do not penetrate the peritoneal cavity do not require further evaluation. For SWs to the abdomen, diagnostic peritoneal lavage (DPL) sensitivity for detecting intraabdominal injury exceeds 95 percent. The results of DPL are considered to be grossly positive if more than 10 mL of free blood can be aspirated. If less than 10 mL is withdrawn, a liter of normal saline is instilled and the effluent is sent to the laboratory for red blood cell count, amylase alkaline phosphatase, and bilirubin levels. A red blood cell count greater than 100,000/ μ L is considered positive. The detection of bile or of vegetable or fecal material, or the observation of effluent draining through a chest tube, a nasogastric tube, or a Foley catheter also constitutes a positive result.

SWs to the lower chest present a unique diagnostic opportunity. After the administration of adequate local anesthesia and extension of the wound as necessary, a finger is placed into the thoracic cavity to palpate the diaphragm.

Confirmation of diaphragm penetration is an indication for laparotomy. For similar cases when a hole is not palpable but risk of a diaphragmatic injury exists, a DPL should be performed. A red cell count in the effluent of greater than 10,000 is considered positive when evaluating for a diaphragmatic injury. For red cell counts between 1,000 and 10,000, thoracoscopy should be considered.

Blunt abdominal trauma is currently evaluated by US in most major trauma centers with CT in selected cases to refine the diagnosis. Although this method is exquisitely sensitive for detecting intraperitoneal fluid collections larger than 250 mL, it is relatively poor for staging solid organ injuries. DPL is still appropriate for patients whose condition cannot be explained by US.

CT remains an important diagnostic tool because of its specificity for hepatic, splenic, and renal injuries. CT is indicated primarily for hemodynamically stable patients who are candidates for nonoperative therapy. The role of laparoscopy remains to be clarified, but it may expand with the availability of a smaller laparoscope that can be inserted under local anesthesia.

Pelvis

Blunt injury to the pelvis can produce complex fractures. Plain radiographs may reveal gross abnormalities, but CT scans are often necessary to assess the pelvis for stability. Sharp spicules of bone can lacerate the rectum or vagina and bladder. Gross blood on urinalysis may not always occur, and a cystogram should be performed if more than a few red cells are seen. Urethral injuries are suspected by the findings of blood at the meatus, scrotal, or perineal hematomas, and a high reading prostate on rectal exam.

Urethrograms should be done in stable patients prior to placing the Foley catheter to avoid false passage stricture. Major vascular injuries are uncommon in blunt pelvic trauma; however, disruption of the iliofemoral system may occur. Angiography is indicated if thrombosis of the arterial system is suspected. Surgeons should be aware that life threatening hemorrhage can be associated with pelvic fractures. The source may be the lower lumbar arteries and veins or branches of the internal iliac arteries and veins. These injuries are frequently not amenable to surgical repair and usually occur with disruption of the posterior elements of the pelvis. Evaluation of penetrating injuries of the pelvis is similar to blunt injuries in stable patients.

Extremities

Injury of the extremities from any cause requires plain radiographs to evaluate fractures. Ligamentous injuries, particularly those of the knee and shoulder when related to sports activities, can be imaged with MRI. In general, vascular diagnosis is limited to the arterial system unless there is uncontrolled external venous hemorrhage or venous injuries are uncovered during operative exploration. Physical diagnosis will localize arterial injuries in many instances. In general, hard signs constitute indications for operative exploration.

Controversy in vascular trauma is the management of patients with soft signs of injury, particularly in those with injuries in proximity to major vessels. One approach has been to measure systolic pressures using the Doppler and compare the injured side with the uninjured side. If the pressures are within 10 percent of each other a significant injury is excluded and no further evaluation is performed. If the difference is greater than 10 percent, an arteriogram is indicated. Others argue that there are occult injuries, such as pseudoaneurysms or injuries of the profunda femoris or peroneal arteries, which may not be sampled

with this technique. If hemorrhage occurs from these injuries, compartment syndrome and limb loss may occur.

TREATMENT

General Considerations

There has been a remarkable change in operative approach over the past 20 years. In general, faster techniques are employed, and shorter more frequent operations have become common. For example, at the authors' institution, virtually all suture lines are created with a continuous single layer. There is no evidence that this method is less secure than interrupted multilayer techniques, and it is clearly faster. Drains, once considered mandatory for many parenchymal injuries and some anastomoses, have virtually disappeared. Fluid collections which accumulate in a delayed fashion are now effectively managed by interventional radiologists. Injuries once thought to mandate resection, such as splenic injuries, are now managed with suture repair or even nonoperatively. The treatment of most colonic injuries is primary repair.

The management of patients with multiple injuries requires the early establishment of therapeutic priorities. While the concept of life over limb and limb over cosmesis seems obvious, decision making can be subtle.

Closed head injuries are common with both abdominal and thoracic trauma. A patient hits a tree while skiing. Evaluation reveals an epidural hematoma with an 8-mm midline shift and hypotension with free intraperitoneal fluid. Fortunately, a craniotomy and laparotomy can and should be done simultaneously. In fact, craniotomy for trauma can be performed concurrent with almost any procedure.

Another dilemma is a serious fracture, e.g., an open comminuted femoral fracture, in a patient who has just undergone a major thoracoabdominal procedure. Patients in this condition do not tolerate additional blood or thermal energy loss well and are at risk for sudden death. Consequently, the open femoral fracture will have to be deferred until the patient's metabolic situation improves despite increasing the risk of osteomyelitis and even limb loss.

Transfusion Practices and the Blood Bank

Fresh whole blood, arguably the optimal replacement material for shed blood, is no longer available. Therefore, whole blood must be recreated from its component parts: packed red blood cells (pRBCs), fresh frozen plasma (FFP), and platelet packs. Most trauma patients receive between one and five units of pRBCs and no other components. However, major trauma centers and their associated blood banks have the capability of transfusing tremendous quantities of blood components. It is not unusual to see 100 component units transfused during one procedure and have the patient survive. Red cell transfusion rates (a seldom used figure) of 20–40 units of packed red cells per hour are not uncommon in severely injured patients.

The causal relationship of core hypothermia, metabolic acidosis and postinjury coagulopathy has been observed in a number of studies. The pathophysiology is multifactorial and includes inhibition of temperature dependent enzyme activated coagulation cascades, platelet dysfunction, endothelial abnormalities, and a poorly understood fibrinolytic activity.

Primary hemostasis relies on platelet adherence and aggregation to injured endothelium resulting in the formation of the platelet plug. A platelet count

of $50,000/\text{mm}^3$ is considered adequate for tissue hemostasis if they are normal. However, platelet dysfunction is a well documented complication of massive transfusion which is clearly aggravated by associated hypothermia. Consequently, the recommended target is greater than $100,000$ cells per mm^3 for platelet transfusion.

Blood typing, and to a lesser extent, crossmatching is essential to avoid life-threatening intravascular hemolytic transfusion reactions. A complete type and crossmatch requires from 20–45 min. Therefore, trauma patients requiring emergency transfusions are given type O, type-specific, or biologically compatible red blood cells. As a crosscheck for ABO compatibility, one of the many steps of the crossmatch (e.g., a saline crossmatch) often is performed. The administrative and laboratory time required is approximately 5 min, and the risk of intravascular hemolysis is about 0.05 percent. The risk increases to 1.0 percent with a history of previous transfusions or pregnancy and up to 3.0 percent with both.

Prophylactic Measures

Injured patients undergoing an operation should receive presumptive antibiotics. Presently, the authors use second generation cephalosporins for laparotomies and first generation cephalosporins for all other operations. Additional doses should be administered during the procedure based on blood loss and the half-life of the antibiotic. The role of postoperative antibiotics in trauma patients remains to be defined, but the trend has been to reduce the duration. Tetanus prophylaxis is administered to all patients according to published guidelines.

Deep venous thrombosis and other venous complications occur more often in injured patients than generally believed. This is particularly true for patients with major fractures of the pelvis and lower extremities, those with coma or spinal cord injury and probably in those with injury of the large veins in the abdomen and lower extremities. The authors employ pulsatile compression stockings in all injured patients and selectively place inferior vena caval filters in addition for those at very high risk. The role of inferior vena caval filters has expanded in removable devices. Low-molecular-weight heparins (LMWHs) have been shown effective in patients with orthopedic injuries, but its utility in patients with other injuries remains to be elucidated.

Principles and Techniques of Vascular Repair

A knowledge of vascular surgical techniques is essential for surgeons caring for injured patients. Life- or limb-threatening injuries occur everywhere in the body; bullets, knives, fractures, and shearing forces do not discriminate between visceral and vascular structures. General surgery requires precision in the scale of millimeters; vascular surgery requires precision on the scale of tenths of millimeters. Visual magnification is necessary for many repairs. A complete set of instruments specifically designed for vascular surgery should always be available. These sets must contain the clamps, tissue forceps, scissors, and needle holders necessary to control and repair vessels ranging from the thoracic aorta to the tibial arteries using sutures ranging from 3-0 to 7-0.

The initial control of vascular injuries should be accomplished digitally by applying just enough pressure directly on the bleeding site to stop the hemorrhage. Some bleeding vessels may need to be gently pinched between

the thumb and index finger. These maneuvers, along with suction, usually create a dry enough field to safely permit the dissection necessary to define the injury. In general sharp dissection with fine scissors is preferable to blunt dissection because the latter may aggravate the injury. Once a sufficient length of vessel is available a vascular thumb forceps is used to grasp the vessel. If the vessel is not transected, forceps can be placed directly across the injury. This will minimize or eliminate bleeding while the dissection necessary for clamping is completed. If the vessel is transected (or nearly so) digital control is maintained on one side while the other is occluded with a thumb forceps. The vessel is then sharply mobilized to allow an appropriate vascular clamp to be applied. When definitive control of all injuries is achieved, heparinized saline (50 units/mL) is injected into the proximal and distal ends of the injured vessel to prevent thrombosis. The exposed intima and media at the site of the injury is highly thrombogenic and small clots often form. These clots should be carefully removed to prevent thrombosis or embolism when the clamps are removed. Because of the frequency with which embolism occurs, routine balloon catheter exploration of the distal vessel has been recommended. Ragged edges of the injury site should be judiciously débrided using sharp dissection.

Injuries of the large veins such as the vena cavae, innominate, and iliac veins pose a special problem for hemostasis. Numerous large tributaries make adequate hemostasis difficult to achieve, and their thin walls render them susceptible to further or additional iatrogenic injury. When such an injury is encountered, tamponade with a folded laparotomy pad held directly over the bleeding site usually will establish hemostasis sufficient to prevent exsanguination. If hemostasis is not adequate to expose the vessel proximal and distal to the injury, sponge sticks can be strategically placed on either side of the injury and carefully adjusted to improve hemostasis. This maneuver requires both skill and discipline to maintain a dry field. On occasion the operative field will be sufficient to delineate and repair the injury. However, it is often difficult or impossible for the assistant or assistants to maintain complete control of hemorrhage with sponge sticks. In this situation, the vessel can be exposed on either side of the sponge stick and a vascular clamp applied. The clamp can then be sequentially advanced toward the injury until hemostasis is complete.

Some arteries and most veins can be ligated without significant sequelae. Arteries for which repair should always be attempted include the carotid, innominate, brachial, superior mesenteric, proper hepatic, renal, iliac, femoral, popliteal, and the aorta. In the forearm and lower leg at least one of the two palpable vessels should be salvaged. The list of veins for which repair should be attempted is short: the superior vena cava, the inferior vena cava proximal to the renal veins and the portal vein. There are notable vessels not listed for which repair is not necessary (e.g., the subclavian artery and the superior mesenteric vein). The surgeon must keep in mind that there are few absolutes when discussing the treatment of vascular injuries. The portal vein can be ligated successfully provided adequate fluid is administered to compensate for the dramatic but transient edema which occurs in the bowel. If the alternative to ligation in exsanguination, the correct decision is obvious. On the other hand, ligation of some vessels such as the popliteal vein and left or right branch of the portal vein may result in morbidity for the patient which is not life threatening. Therefore, the authors' attempt to repair all arteries larger than 3 mm and all veins larger than 10-mm diameter depending on the patient's physiologic condition.

Within the last decade, some arterial injuries have been treated by observation without subsequent complications. These include small pseudoaneurysms, intimal dissections, small intimal flaps, and A-V fistulas in the extremities, and occlusions of small (<2 mm) arteries. Follow-up angiography is obtained within 2–4 weeks to ensure that healing has occurred.

Lateral suture is appropriate for small arterial injuries with little or no loss of tissue. End to end anastomosis is used if the vessel is transected or nearly so. The severed ends of the vessel are mobilized and small branches are ligated and divided as necessary to obtain the desired length. Arterial defects of 1–2 cm usually can be bridged. The surgeon should not be reluctant to divide small branches to obtain additional length because most injured patients have normal vasculature and the preservation of potential collateral flow is not as important as in atherosclerotic surgery. To avoid postoperative stenosis, particularly in smaller arteries, some techniques such as beveling or spatulation should be used so that the completed anastomosis is slightly larger in diameter than the native artery.

Interposition grafts are employed when end to end anastomosis cannot be accomplished without tension and despite mobilization. For vessels less than 6 mm in diameter, autogenous saphenous vein from the groin should be used because polytetrafluoroethylene (PTFE) grafts less than 6 mm in diameter have a prohibitive rate of thrombosis. In practice, injuries of the brachial, popliteal and internal carotid arteries require the saphenous vein for interposition grafting. When the saphenous vein is harvested for treating an arterial injury in the lower extremity, it should be taken from the contralateral extremity. Because the status of the ipsilateral venous system is unknown, the saphenous on that side may become an important tributary. Larger arteries must be bridged by artificial grafts. Some authorities have advocated the use of free internal iliac arterial grafts because of the greater thickness and strength of its wall compared to the saphenous vein. The authors believe that this vessel is unnecessarily tedious to remove and has no advantage over the saphenous vein.

Transposition procedures can be used when an artery has a bifurcation of which one vessel can safely be ligated. Injuries of the proximal internal carotid can be treated by mobilizing the adjacent external carotid, dividing it distal to the internal injury and performing an end to end anastomosis between it and the distal internal carotid. The proximal stump of the internal carotid is oversewn in such a way as to avoid a blind pocket where a clot may form. Injuries of the ipsilateral external and contralateral common iliac arteries can be handled in a similar fashion provided flow is maintained in at least one internal iliac artery. Arterial injuries often are grossly contaminated from enteric or external sources. Many surgeons are naturally reluctant to place artificial grafts in situ in this circumstance. The situation arises most often with aortic or iliac arterial injuries when the colon is also injured. For the aorta there are few options. Ligation of the aorta with unilateral or bilateral axillofemoral bypass can be performed. However, these are lengthy procedures, which are prone to thrombosis and infection. Furthermore, most patients who require an aortic graft will not tolerate the time required to perform an axillofemoral bypass. Therefore, even in the presence of fecal contamination, it has been common practice to use PTFE or Dacron in situ for aortic injuries. Every effort is made to remove and control contamination following the control of hemorrhage, but before the graft is brought into the operative field. This includes copious irrigation of the abdominal cavity and changing of drapes, gowns, gloves and instruments. Following placement of the graft, it is

covered with peritoneum or omentum prior to definitive treatment of the enteric injuries.

Suture selection for arterial injuries is based on the diameter of the vessel being repaired. The use of progressively finer suture for smaller diameter vessels encourages the inclusion of less tissue with more closely placed sutures which is necessary for success. When performing anastomoses where the vessels are tethered (e.g., the thoracic and abdominal aorta), these authors employ the parachute technique to ensure precision placement of the posterior suture line. If this technique is used, traction on both ends of the suture must be maintained, or leakage from the posterior aspect of the suture line is probable. A single temporary suture 180 degrees from the posterior row often is used to maintain alignment.

Venous injuries are inherently more difficult to repair successfully because of their propensity to thrombose. Small injuries without loss of tissue can be treated with lateral suture. More complex repairs often fail. It should be noted that thrombosis does not occur acutely but rather gradually over 1–2 weeks. Advantage can be taken of this fact because adequate collateral circulation, sufficient to avoid acute venous hypertensive complications, usually develops within several days. Therefore, it is reasonable to use PTFE for venous interposition grafting and accept a gradual but eventual thrombosis while buying time for collateral circulation to develop. On the other hand, chronic venous hypertensive complications in the lower extremities often can be avoided with any level of ligation by: 1) elastic bandages carefully applied in the OR at the end of the procedure and 2) continuous elevation of the lower extremities to 30 degrees. These measures should be maintained for 1 week. The patient is then ambulated. If no edema occurs with the bandages removed, elevation is no longer necessary. It is a reasonable precaution to have the patient wear compressive stockings up to the knee for a few months afterward.

There are several circumstances where a more aggressive approach should be considered. Ligation of the superior vena cava has been associated with sudden blindness because of compression of the optic nerve from venous hypertension. Ligation of suprarenal vena cava is believed to be associated with acute renal failure from venous hypertension. Chronic venous insufficiency of the lower extremities may be caused by ligation of the infrarenal vena cava or any in-line vein below that level, particularly the popliteal vein. Interposition grafting can be considered in these situations but the choice of material is problematic. One option is to use artificial material because it is rapidly available in hemodynamically correct sizes. The drawback is that thrombosis is inevitable when placed below the renal veins. Artificial grafts have performed satisfactorily in cases of suprarenal vena caval and superior vena caval replacement. The jugular vein can be used to replace similar sized vessels (e.g., the portal or femoral). The saphenous vein is too small to replace any important vein. Panel grafts and spiral grafts constructed around a mandrel (chest tube) using saphenous vein occasionally have been performed. These procedures are extremely tedious and have no apparent advantage over ligation in most instances.

The technology employed by interventional radiologists is advancing at an incredible pace. They have the ability to cannulate virtually any artery in the body and either dilate it, place an intraluminal filter, stent or graft in it or occlude it. At present their services are most valuable for treating arterial or venous injuries which are surgically inaccessible such as stent placement in the internal carotid artery near or in the base of the skull, controlling hemorrhage in hepatic injuries or pelvic fractures.

Staged Operations, Abdominal Compartment Syndrome and Nonoperative Management

The most common causes of death for trauma patients are head injury, exsanguination from cardiovascular injuries, and sepsis with multiple-organ failure. Another cause of death has become apparent as the capability of delivering massive quantities of red blood cells and other components developed. Surgeons are now able to continue to operate on the most severely injured patients until a constellation of metabolic derangements develop. These are characterized by the triad of an obvious coagulopathy, profound hypothermia, and metabolic acidosis. Hypothermia from evaporative and conductive heat loss and diminished heat production occurs despite warming blankets and blood warmers. The metabolic acidosis of shock is exacerbated by aortic clamping, vasopressors, massive transfusions, and impaired myocardial performance. Coagulopathy is caused by dilution, hypothermia and acidosis. Each of these factors reinforces the others resulting in a critically ill patient who is at high risk for a fatal arrhythmia. This downward spiral has been referred to as the bloody vicious cycle.

Heat loss appears to be the central event because neither of the other components can be corrected until core temperature returns toward normal. Laboratory and mathematical heat exchange models have demonstrated that evaporative heat loss from an open abdomen is by far the greatest source. A concomitant open thoracic cavity greatly accelerates the rate of the patient's deterioration and can cause the syndrome by itself. This is the rationale for the immediate abdominal closure and the reason it has been successful.

Staged operations are indicated when a coagulopathy develops and core temperature drops below 34°C (93.2°F). A refractory acidosis almost always exists. Several unorthodox techniques can be used to expedite wound closure. Bleeding raw surfaces, often of the liver, are packed with laparotomy pads. Small enteric injuries are closed with staples, and large ones are stapled on both sides with stapling devices and the damaged segment removed. Clamps may be left on unrepaired vascular injuries, or the vessels are ligated. Injuries of the pancreas and kidneys are not treated if they are not bleeding. No drains are placed, and the abdomen is closed with sharp towel clips placed 2 cm apart which include only the skin. Towel clips are used because they do not cause bleeding as needles do and they can be applied very rapidly, usually in 60–90 s. The closure of just the skin allows for the abdominal or thoracic cavities to accommodate a greater volume without increased pressure. The clips are covered with a towel, and a plastic adhesive sheet is placed over the towel to prevent excessive fluid from draining onto the patient's bedding. Cold wet drapes are removed, and the patient is covered from head to toe with layers of warm blankets. It should be noted that many of these unorthodox treatments, including the creation of closed loop bowel obstructions and unrepaired renal injuries are not compatible with survival. However, reoperation is planned within 2–24 h, and the treatments are tolerated well within that time frame. Furthermore, the goal is to complete the procedure as soon as possible or the patient will certainly die. If the surgeon believes that the patient's metabolic problems can be corrected in a short time (2 h or less), the patient may remain in the OR while additional blood products are administered and rewarming measures are instituted. Patients who are in very poor condition and will require several h for metabolic corrections should be transferred to the surgical intensive care unit (SICU). If the patient's condition

improves as evidenced by normalization of coagulation studies, the correction of acid/base balance, and a core temperature of at least 36°C (96.8°F) he should be returned to the OR for removal of packs and definitive treatment of his injuries.

There are several complications associated with this treatment. Failure to identify noncoagulopathic hemorrhage can lead to exsanguination. Most patients with coagulopathic hemorrhage will have a gradual decrease in the need for pRBCs, FFP, and platelets and an improvement in coagulation studies count as temperature rises. Patients with vascular hemorrhage will not, and they must be returned to the OR for reexploration.

A second complication is referred to as the abdominal or thoracic compartment syndrome. These entities are caused by an acute increase in intracavitary pressure. In the abdomen the compliance of the abdominal wall and the diaphragm permit the accumulation of many liters of fluid before intraabdominal pressure (IAP) increases. There are primarily two sources for this fluid, blood and edema. Blood accumulates because of the coagulopathy or missed vascular injury described above. The cause of edema is multifactorial. Ischemia and reperfusion cause capillary leakage; loss of oncotic pressure occurs; and in the case of the small bowel which is often eviscerated, prolongation and narrowing of veins and lymphatics caused by traction impairs venous and lymphatic drainage. The resulting edema may be dramatic. Similar phenomena occur in the chest. As fluid continues to accumulate, the compliant limit of the abdominal cavity is eventually exceeded; and IAP increases. When IAP exceeds 15 mmHg, serious physiologic changes begin to occur. The lungs are compressed by the upward displacement of the diaphragm. This causes a decrease in functional residual capacity, increased airway pressure and, ultimately, hypoxia. Cardiac output decreases because of diminished venous return to the heart and increased afterload. Blood flow to every intraabdominal organ is reduced because of increased venous resistance. As IAP exceeds 25–30 mmHg, life-threatening hypoxia and anuric renal failure occur. Cardiac output is further reduced but can be returned toward normal with volume expansion and inotropic support. However, the only method for treating hypoxia and renal failure is to decompress the abdominal cavity by opening the incision. This results in an immediate diuresis and a resolution of hypoxia. Failure to decompress the abdominal cavity will eventually cause lethal hypoxia and/or organ failure. There have been a few reports of sudden hypotension when the abdomen is opened. However, volume loading to enhance cardiac output has largely eliminated this problem. IAP is measured using the Foley catheter. Because the bladder is a passive reservoir at low volumes (50–100 mL), it imparts no intrinsic pressure but can transmit IAP. Fifty mL of saline are injected into the aspiration port of the urinary drainage tube with an occlusive clamp placed across the tube just distal to the port. The saline is used to create a standing column of fluid between the bladder and port, which can transmit IAP to a recording device. The needle in the port is connected to a CVP manometer using a three way stopcock. The manometer is filled with saline and opened to the drainage tube. IAP is read at the meniscus with manometer zeroed at the pubic symphysis. Bladder pressures measured in this fashion are both reliable and consistent. Pressures less than 15 mmHg do not require decompression.

In the chest similar phenomena occur. Edema of the heart and lungs develops and the heart may also dilate. Blood accumulation is rarely a problem

because of the use of chest tubes. However, the diagnosis usually is apparent in the OR because the heart tolerates compression poorly. Attempts to close the chest in this setting are associated with profound hypotension, and it becomes obvious that an alternative method of closure is necessary. At present the most popular material used to accommodate the addition of volume in the chest or abdomen is a 3-L plastic urologic irrigation bag, which has been cut open and sterilized. The bag is sewn to the skin or fascia using no. 2 nylon suture with a simple running technique. As many as four bags may need to be sewn together to cover a large defect. Closed suction drains are placed beneath the plastic to remove blood and serous fluid which inevitably accumulate. The entire closure is covered with a iodinated plastic adhesive sheet to simplify nursing care. Patients whose renal function has not been impaired will have a diuresis. Exogenous fluids are held to a minimum to facilitate the resolution of edema. Definitive wound closure can usually be performed in 48–72 h.

Patients who develop sepsis and multiple-organ failure (MOF) are problematic and do not resolve their edema until sepsis and MOF resolve. This may require several weeks. The bags have been left in place up to 3 weeks with the patient surviving. However, the authors make every effort to at least close the skin over the viscera to decrease protein and heat loss and to inhibit infection. If these attempts are unsuccessful and the abdomen remains open with granulating tissue exposed, lateral traction forces of the abdominal wall will eventually cause an enteric fistula. The risk of developing a fistula increases rapidly after 2 weeks with an open abdomen. These problems are extremely difficult to treat. Several approaches have been used to avoid this catastrophic complication including polyglycolic acid or polypropylene mesh sewn to the fascia, split thickness skin grafts placed directly on the bowel, musculocutaneous flaps, and traction devices. Of these options skin grafts appear to have the greatest success although the abdominal wall hernia will eventually require reconstruction.

Nonoperative treatment for blunt injuries of the liver, spleen, and kidneys is now the rule rather than the exception. Up to 90 percent of children and 50 percent of adults are treated in this manner. As interventional radiology continues to advance, these numbers will certainly increase. The primary requirement for this therapy is hemodynamic stability. The extent of the patient's injuries should be delineated by CT. Recurrent hemorrhage from the liver and kidneys has been infrequent, but delayed hemorrhage or rupture of the spleen is an important consideration in the decision to pursue nonoperative management. The patient should be monitored in the intensive care unit for at least the first 24 h. Because CT will miss some enteric injuries, frequent abdominal examination should be performed. Usually the fall in hematocrit will stabilize within 24 h. If the hematocrit continues to fall, angiography with embolization of bleeding sites should be considered particularly for hepatic and renal injuries. CT usually is repeated at least once during the hospitalization to assess major hepatic or splenic lesions requiring transfusion. Gradually increasing activity is permitted following discharge. Patients involved in contact or high impact sports such as football should have complete healing of the injury documented radiographically before resuming participation. This can take several months.

Complications of nonoperative treatment include continuing hemorrhage, delayed hemorrhage, necrosis of liver, spleen or kidney from embolization, abscess, biloma, and urinoma. Hemorrhage may be treated by interventional

radiology although open operative control is often necessary. Most infectious complications can be treated by percutaneous drainage. Bilomas are usually resorbed.

HEAD

Injuries of the Brain

General principles of the management of cerebral injuries have changed in recent years. Attention is now focused on maintaining or enhancing cerebral perfusion rather than merely lowering ICP. For example, it has been found that hyperventilation to a PaCO_2 less than 30 mmHg to induce cerebral vasoconstriction actually exacerbates cerebral ischemia despite decreasing ICP. These secondary iatrogenic cerebral injuries cause more harm than previously appreciated. Other treatments or conditions which must be avoided include decreased cardiac output because of the excessive use of osmotic diuretics, sedatives or barbiturates, and hypoxia. Nevertheless, the measurement of ICP is still important and is efficiently accomplished with a ventriculostomy tube. The tube also permits the withdrawal of cerebrospinal fluid which is the safest method for lowering ICP. Although an ICP of 10 mmHg is believed to be the upper limit of normal, therapy is not usually initiated until the ICP reaches 20 mmHg. Cerebral perfusion pressure (CPP) is an important measurement which is used to monitor therapy. CPP is equal to the mean arterial pressure (MAP) minus the ICP, and 60 mmHg is the lowest acceptable pressure. This figure can be adjusted by either lowering ICP or raising MAP. In practice, both are manipulated. Paralysis, sedation, osmotic diuresis, and barbiturate coma are all still used with coma being the last resort. The goal of fluid therapy is to achieve a euvolemic state, and arbitrary fluid restriction is avoided. Whether boosting MAP with pressors or inotropes in patients with an elevated ICP resistant to treatment improves outcome is unclear, although recent data suggests it does. Moderate hypothermia may also be helpful by decreasing metabolic requirement.

Indications for operative intervention for space occupying hematomas are based on the amount of midline shift, the location of the clot, and the patient's ICP. Greater than 5 mm of shift is usually considered an indication for evacuation. However this is not an absolute rule. Smaller hematomas causing less shift in treacherous locations, such as the posterior fossa, may require drainage because of the threat of brainstem compression or herniation. Removal of small hematomas may also improve ICP and CPP in patients with an elevated ICP, which is refractory to medical therapy. The treatment of DAI includes the control of cerebral edema and general supportive care. These authors frequently employ percutaneous tracheostomy for airway control and percutaneous endoscopic gastrostomy for enteral access in head injured patients whose recovery is unlikely or prolonged. Prognosis is related to GSC. Serious head injuries, GSC 3–8, have a poor prognosis, and an institutional existence is almost a certainty. Mild brain injury, GSC 13–15, have a good prognosis; independent living is probable. However, neuropsychiatric testing often reveals significant abnormalities.

General surgeons in small or rural communities without emergency neurosurgical coverage may be required to perform a burr hole in one life-saving circumstance. This occurs in a patient with an epidural hematoma. As blood from a torn vessel, usually the middle meningeal artery, accumulates, the temporal lobe is forced medially, which compresses the third cranial nerve and

eventually the brainstem. This sequence of events results in the typical clinical course: 1) initial loss of consciousness, 2) awakening and a lucid interval, 3) recurrent loss of consciousness with a unilaterally fixed, dilated pupil, and 4) cardiac arrest. Because these patients do not usually have a serious underlying cortical injury, chance for a complete recovery often is possible. The burr hole should be made on the same side as the dilated pupil. The goal of the procedure is not to control the hemorrhage but to decompress the intracranial space. Because a craniotomy is required for the control of hemorrhage, the patient's head should be loosely wrapped with a thick layer of gauze to absorb the bleeding, and he should be transferred to a facility with emergency neurosurgical capability for a craniotomy.

NECK

Blunt Injury

Cervical Spine

Blunt trauma may involve the cervical spine, spinal cord, larynx, carotid, and vertebral arteries, and the jugular veins. Treatment of injuries to the cervical spine is based on the level of injury, the stability of the spine, the presence of subluxation, the extent of angulation, and the extent of neurologic deficit. In general, cautious axial traction in line with the mastoid process is used to reduce subluxations. A halo-vest combination can accomplish this and also provide rigid external fixation for definitive treatment when left in place for 3–6 months. Today this device is the treatment of choice for many cervical spine injuries. Surgical fusion usually is reserved for those with neurologic deficit, those who demonstrate angulation greater than 11 degrees on flexion and extension radiographs, or those who remain unstable after external fixation.

Spinal Cord

Injuries of spinal cord, particularly complete injuries, remain essentially untreatable. Approximately 3 percent of patients who present with flaccid quadriplegia actually have concussive injuries, and these patients represent the very few who seem to have miraculous recoveries. A recent prospective randomized study comparing methylprednisolone with placebo demonstrated a significant improvement in outcome (usually one or two spinal levels) for those who received the corticosteroid within 8 h of injury. The standard dosage is 30 mg/kg given as an intravenous bolus followed by a 5.4 mg/kg infusion administered over the next 23 h. Patients with spinal cord injuries are also at high risk for deep venous thrombosis and pulmonary embolus. Prophylactic anticoagulation is essential.

Larynx

The larynx may be fractured by a direct blow which can result in airway compromise. A hoarse voice is highly suggestive. A cricothyroidotomy, or tracheostomy if time permits, should be done to protect the airway in cases of severe fracture. The larynx is anatomically repaired with fine wires and sutures. If direct repair of internal laryngeal structures is necessary, the thyroid cartilage is split longitudinally in the midline and opened like a book. This is referred to as a laryngeal fissure.

Carotid and Vertebral Arteries

Blunt injury to the carotid or vertebral arteries may cause dissection, thrombosis, or pseudoaneurysm. More than half the patients have a delayed diagnosis. Facial contact resulting in hypertension and rotation appears to be the mechanism. To reduce delayed recognition, the authors employ angiography in patients at risk to identify these injuries before neurologic symptoms develop. The injuries frequently occur at or extend into the base of the skull and are usually not surgically accessible. Currently accepted treatment for thrombosis and dissection is anticoagulation with heparin followed by Coumadin for 3 months. Pseudoaneurysms also occur near the base of the skull. If they are small, they can be followed with repeat angiography. If enlargement occurs consideration should be given to the placement of a stent across the aneurysm by an interventional radiologist. Another possibility is to approach the intracranial portion of the carotid by removing the overlying bone and performing a direct repair. This method has only recently been described and has been performed in a limited number of patients.

Thrombosis of the internal jugular veins caused by blunt trauma can occur unilaterally or bilaterally. These injuries are usually discovered incidentally and are generally asymptomatic. Bilateral thrombosis can aggravate cerebral edema in patients with serious head injuries. Stent placement should be considered in such patients if their ICP remains elevated. Laryngeal edema resulting in airway compromise can also occur.

Penetrating Injuries

Penetrating injuries in zones two or three that require operative intervention are explored using an incision along the anterior border of the sternocleidomastoid muscle. If bilateral exploration is necessary, the inferior end of the incision can be extended to the opposite side. Midline wounds or significant bilateral injuries can be exposed via a large collar incision at the appropriate level. Alternatively, bilateral anterior sternocleidomastoid incisions can be employed.

Carotid and Vertebral Arteries

Exposure of the distal carotid artery in zone three is difficult. The first step is to divide the ansa cervicalis and mobilize the hypoglossal nerve. Next, the portion of the posterior belly of the digastric muscle which overlies the internal carotid is resected. The glossopharyngeal and vagus nerves are mobilized and retracted as necessary. If accessible, the styloid process and attached muscles are removed. At this point anterior displacement of the mandible may be helpful, and various methods for accomplishing this have been devised. Some authorities have advocated division and elevation of the vertical ramus. However, two remaining structures still prevent exposure of the internal carotid to the base of the skull: the parotid gland and facial nerve. Excessive anterior traction on the mandible or parotid may damage the facial nerve, particularly the mandibular branch. Unless the surgeon is willing to resect the parotid and divide the facial nerve, division of the ramus is seldom helpful.

All penetrating carotid injuries should be repaired if possible. Inaccessible carotid injuries near the base of the skull can be treated by interventional radiologists with a stent if the anatomy of the injury is favorable. Otherwise the artery will need to be thrombosed or ligated. If ligation is necessary the patient

should be anticoagulated with heparin followed by Coumadin for 3 months. This treatment may prevent a stroke by inhibiting the generation of thrombi from the surface of the clot at the circle of Willis while the endothelium heals. Without anticoagulation the risk of stroke with ligation has been approximately 20–30 percent, and most strokes occur a few days after ligation. Tangential wounds of the internal jugular vein should be repaired by lateral venorrhaphy, but extensive wounds are efficiently addressed by ligation.

Vertebral artery injuries usually result from penetrating trauma although thrombosis and pseudoaneurysms can occur from blunt injury. The diagnosis is made by angiography or when significant hemorrhage is noted posterior to the carotid sheath during neck exploration. Exposure of the vertebral artery above C6 where it enters its bony canal is complicated by the overlying anterior elements of the canal and the tough fascia covering the artery between the elements. The artery is approached through an anterior neck incision by retracting the contents of carotid sheath laterally. The muscular attachments to the elements are removed. Care must be taken to avoid injury to the cervical spinal nerves which are located directly behind and lateral to the bony canal. Some authorities have recommended using a high speed burr to remove the anterior element of the canal thereby avoiding the venous plexus between the elements. The authors have not found this to be a problem and have often carefully excised the fascia between the elements and lifted the artery out of its canal with a tissue forceps. The treatment for vertebral artery injuries is ligation both proximal and distal to the injury. There is rarely, if ever, an indication for repair. Neurologic complications are uncommon. Exposure of the vertebral artery above C2 is extremely difficult. Rather than using a direct operative approach these authors expose the vessel below C5, outside the bony canal, clamp the artery proximally, and insert a no. 3 balloon tipped catheter. The catheter is advanced to the level of the injury or distal to it, and the balloon is inflated with saline until back bleeding stops. The tube to the catheter is crimped over on itself and secured in this position with several heavy silk sutures. The catheter is trimmed so that it can be left in the wound under the skin. The proximal end of the artery is ligated. One week later the catheter is removed under local anesthesia. Rebleeding has not occurred in these authors' experience. The same approach can be used for the distal internal carotid. An alternative approach is to have the interventional radiologist place coils to induce thrombosis proximal and distal to the injury if the lesion is diagnosed by angiography. Injuries of the proximal vertebral can be exposed by a median sternotomy with a neck extension.

Trachea and Esophagus

Injuries of the trachea are repaired with a running 3-0 absorbable monofilament suture. Tracheostomy is not required in most patients. Esophageal injuries are repaired in a similar fashion. If an esophageal wound is large, or if tissue is missing, a sternocleidomastoid muscle pedicle flap is warranted, and a closed suction drain is a reasonable precaution. The drain should be near but not in contact with the esophageal or any other suture line. It can be removed in 7–10 days if the suture line remains secure. Care must be taken when exploring the trachea and esophagus to avoid iatrogenic injury to the recurrent laryngeal nerve.

Penetrating injuries of the neck often create wounds in adjacent hollow structures, e.g., the trachea and esophagus or carotid artery and esophagus. If, following repair, these adjacent suture lines are in contact, the stage is set

for devastating postoperative fistulous complications. To avoid these complications, viable tissue should routinely be interposed between adjacent suture lines. Viable strips of the sternocleidomastoid muscle or strap muscles are useful for this purpose.

Thoracic Outlet

Great Vessels

While most injuries of the great vessels of the thoracic outlet (zone one) are caused by penetrating trauma, the innominate and subclavian arteries are occasionally injured from blunt trauma. As mentioned previously angiography is desirable for planning the incision. If this is not possible because of hemodynamic instability, a reasonable approach can be inferred from the chest radiograph and the location of the wounds. If the patient has a left hemothorax, a left third or fourth interspace anterolateral thoracotomy should be performed because the proximal left subclavian artery may be injured. Hemorrhage can be controlled digitally until the vascular injury is delineated. Additional incisions or extensions are often required. A third or fourth interspace right anterolateral thoracotomy may be used for thoracic outlet injury presenting with hemodynamic instability and a right hemothorax. A median sternotomy with a right clavicular extension can also be used. Unstable patients with injuries near the sternal notch may have a large mediastinal hematoma or have lost blood directly to the outside. These patients should be explored via a median sternotomy.

If angiography has identified an arterial injury, a more direct approach can be employed. A median sternotomy is used for exposure of the innominate, proximal right carotid and subclavian, and the proximal left carotid arteries. The proximal left subclavian artery presents a unique challenge. Because it arises from the aortic arch far posteriorly, it is not readily approached via median sternotomy. A posterolateral thoracotomy provides excellent exposure but severely limits access to other structures and is not recommended. The best option is to create a full thickness flap of the upper chest wall. This is accomplished with a third or fourth interspace anterolateral thoracotomy for proximal control, a supraclavicular incision with a resection of the medial third of the clavicle, and a median sternotomy which links the two horizontal incisions. The ribs can be cut laterally for additional exposure, which allows the flap to be folded laterally with little effort. This incision has been referred to as a book or trap door thoracotomy for obvious reasons. The mid-portion of the subclavian artery is accessible by removing the proximal third of either clavicle, with the skin incision made directly over the clavicle. Muscular attachments are stripped away, and the clavicle is divided with a Gigli saw. The medial remnant of the clavicle is forcefully elevated. The periosteum is dissected from the posterior aspect of the bone until the sternoclavicular joint is reached. The capsular attachments are cut with a heavy scissors or knife and the bone is discarded. The periosteum and underlying fascia is very tough and must be sharply incised along the direction of the vessel. The subclavian vein is mobilized and the artery is directly underneath. The anterior scalene is divided for injuries just proximal to the thyrocervical trunk; the relatively small phrenic nerve should be identified on its anterior aspect and spared. Iatrogenic injury to cords of the brachial plexus can occur.

The great vessels are rather fragile and are easily torn during dissection or crushed with a clamp. For this reason some advocate oversewing proximal

injuries of the artery on the side of the aortic arch and sewing a graft onto a new location on the arch. The graft is then sewn to the artery without tension. Technical details of the repair are similar to those described in the Principles and Techniques of Vascular Repair section.

Trachea and Esophagus

The trachea and esophagus are difficult to approach at the thoracic outlet. The combination of a neck incision and a high anterolateral thoracotomy may be used. Alternatively, these structures can be approached via a median sternotomy provided the left innominate vein and artery are divided. Temporary division of the innominate artery is tolerated well in otherwise healthy people, but the vessel should be repaired following treatment of the tracheal or esophageal injury. The vein does not need to be repaired. As in the neck, adjacent suture lines should be separated by viable tissue. A portion of the sternocleidomastoid can be rotated down for this purpose.

Chest

The most common life-threatening complications from both blunt and penetrating thoracic injury are hemothorax, pneumothorax, or a combination of both. Approximately 85 percent of these patients can be treated definitively with a chest tube. Because of the viscosity of blood at various stages of coagulation, a 36F or larger chest tube should be used. If one tube fails to completely evacuate the hemothorax (a “caked hemothorax”), a second tube should be placed. If the second chest tube does not remove the blood, a thoracotomy should be performed because of the risk of life-threatening hemorrhage. Common sources of blood loss include intercostal vessels, internal thoracic artery, pulmonary parenchyma, and the heart. Less common sources are the great vessels, aortic arch, azygous vein, superior vena cava, and inferior vena cava. Blood may also enter the chest from an abdominal injury through a perforation or tear in the diaphragm. Table 6-3 lists indications for operative treatment of penetrating thoracic injuries.

The indications for thoracotomy in blunt trauma are based on specific preoperative diagnoses. These include pericardial tamponade, tear of the descending thoracic aorta, rupture of a mainstem bronchus, and rupture of the esophagus. Thoracotomy for hemothorax in the absence of the above diagnoses is rarely indicated. A shattered chest wall that produces a hemothorax is better treated by the interventional radiologist with embolization.

TABLE 6-3 Indications for Operative Treatment of Penetrating Thoracic Injuries

Caked hemothorax
Large air leak with inadequate ventilation or persistent collapse of the lung
Drainage of more than 1500 mL of blood when chest tube is first inserted
Continuous hemorrhage of more than 200 mL/h for ≥ 3 consecutive h
Esophageal perforation
Pericardial tamponade

Thoracic Incisions

The selection of incisions is important and depends on the organs being treated. For exploratory thoracotomy for hemorrhage, the patient is supine and an anterolateral thoracotomy is performed. Depending on findings, the incision can be extended across the sternum or even further for a bilateral anterolateral thoracotomy. The fifth interspace usually is preferred unless the surgeon has a precise knowledge of which organs are injured and that exposure would be enhanced by selecting a different interspace. The heart, lungs, aortic arch, great vessels, and esophagus are accessible with these incisions.

The heart can also be approached via a median sternotomy. Because little else can be done in the chest through this incision, it is usually reserved for stab wounds of the anterior chest in patients who present with pericardial tamponade. Posterolateral thoracotomies are rarely used because ventilation is impaired in the dependent lung, and the incision cannot be extended. There are two specific exceptions. Injuries of the posterior aspect of the trachea or mainstem bronchi near the carina are inaccessible from the left or from the front. The only possible approach is through the right chest using a posterolateral thoracotomy. A tear of the descending thoracic aorta can only be repaired through a left posterolateral thoracotomy. Because the authors use left heart bypass for these procedures, the patient's hips and legs are rotated toward the supine position to gain access to the left groin for femoral artery cannulation. It is also helpful for optimal exposure to resect the fourth rib and enter the chest through its bed.

Heart

Most cardiac injuries are the result of penetrating trauma, and any part of the heart is susceptible. Control of hemorrhage while the heart is being repaired is crucial and several techniques can be used. The atria can be clamped with a Satinsky vascular clamp. Digital control and suturing beneath the finger is possible anywhere in the heart although the technique requires skill and a long, curved cardiovascular needle. The reality of blood borne viral infections raises the question if this method should ever be used today. If the hole is small, a peanut sponge clamped in the tip of a hemostat can be placed into the wound or the blood loss may be accepted while sutures are being placed. For larger holes a 16F Foley catheter with a 30-mL balloon can be inflated with 10 mL of saline. Gentle traction on the catheter will control hemorrhage from any cardiac wound because wounds too large for balloon tamponade are incompatible with survival. Suture placement with the balloon inflated is problematic. Usually the ends of the wound are closed progressively toward the middle until the amount of blood loss is acceptable with the balloon removed. The use of skin staples for the temporary control of hemorrhage has become popular particularly when emergency department thoracotomy has been performed. It has the advantages of reducing the risk of needle stick injury to the surgeon or assistant and does not mandate the attention required by a balloon catheter. In most instances, however, hemostasis is neither perfect nor definitive. Inflow occlusion of the heart, by clamping the superior and inferior vena cavae can be performed for short periods, and this may be essential for the treatment of extensive or multiple wounds and for those that are difficult to expose.

Trauma surgeons accept the fact that interior structures of the heart may be damaged, which impair cardiac output. However, immediate repair of valvular damage or acute septal defects is rarely necessary and requires total

cardiopulmonary bypass, which has a high mortality in this situation. Most patients who survive to make it to the hospital do well with only external repair. Following recovery, the heart can be thoroughly evaluated; and if necessary secondary repair can be performed under more controlled conditions. Coronary artery injuries also pose difficult problems. Ligation leads to acute infarction distal to the tie; but again, reconstruction requires bypass. The right coronary artery can probably be ligated anywhere but the resultant arrhythmias may be extremely resistant to treatment. The left anterior descending and circumflex cannot be ligated proximally without causing a large infarct. Such injuries are extremely rare and usually produce death in the field.

Blunt cardiac injury can present in several ways. A sharp blow to the pericardium can provoke ventricular fibrillation. This is referred to as a commotio cordis and is inevitably fatal unless it is recognized immediately and resuscitation implemented. The heart can also be contused. Most of these patients present with new arrhythmias, e.g., a bundle branch block or premature ventricular contractions. Cardiac enzymes have not been helpful in making the diagnosis. Finally, the heart can rupture. The right atrium and right ventricle are most susceptible but survival is possible provided the diagnosis is suspected.

Lungs, Trachea and Bronchi

Pulmonary injuries requiring operative intervention usually result from penetrating injury. Formerly the entrance and exit wounds were oversewn to control hemorrhage. This set the stage for air embolism, which occasionally caused sudden death in the OR, or in the immediate postoperative period. A recent development, pulmonary tractotomy, has been employed to reduce this problem and the need for pulmonary resection. Linear stapling devices are inserted directly into the injury tract and are positioned to cause the least degree of devascularization. Two staple lines are created and the lung is divided between. This allows direct access to the bleeding vessels and leaking bronchi. No effort is made to close the defect. Lobectomy or pneumonectomy is rarely necessary. Lobectomy is only indicated for a completely devascularized or destroyed lobe. Parenchymal injuries severe enough to require pneumonectomy are rarely survivable, and major pulmonary hilar injuries necessitating pneumonectomy are usually lethal in the field.

Injuries of the trachea are managed in the same fashion described above. Because exposure can be difficult, provisions should be made to deflate the lung on the operative side by using a double lumen endotracheal tube (a double-lumen tube is seldom needed for cardiac or pulmonary injury). Repair of mainstem bronchial injuries and tracheal injuries near the carina may result in a complete loss of ventilation when the overlying pleura is opened even if a double lumen tube is used. Gases from the ventilator will preferentially escape from the injury and neither lung will be ventilated. Digital occlusion of the injury can control air loss if the injury is small. Larger injuries are an imminent threat to life. To avoid this catastrophe, a 6–7-mm cuffed endotracheal tube should be on the operative field and a second ventilator available. If ventilation is inadequate, the surgeon can insert and inflate the endotracheal tube into the main bronchus on the opposite side through the injury to permit ventilation of one lung while the injury is repaired. Eventually the tube will have to be removed to close the defect but the remaining hole can be controlled digitally. Alternatively, it may be possible for the anesthesiologist to cannulate the opposite bronchus although little time is available.

Esophagus

The majority of esophageal injuries are caused by penetrating trauma through blunt disruption. Because of their proximity, combined tracheoesophageal injuries do occur. Many authors recommend the interposition of viable muscle between the repairs to prevent tracheoesophageal fistula.

Descending Thoracic Aorta

Conceptually, two techniques have been advocated. The simpler technique, often referred to as "clamp and sew," is accomplished with the application of vascular clamps proximal and distal to the injury and repairing or replacing the damaged portion of the aorta. This method results in transient hypoperfusion of the spinal cord distal to the clamps and all abdominal organs. Large doses of vasodilators are also required to reduce afterload and avoid acute left heart failure. If the clamping time is short, less than 30 min, paraplegia has been uncommon. Longer clamping times have been associated with paraplegia in approximately 10 percent of patients. Unfortunately, clamping times of less than 30 min have been difficult to achieve for many tears requiring complex repair. The second method has been to employ left heart bypass. With this method a volume of oxygenated blood is siphoned from the left heart and pumped into the distal aorta. Flow rates of 2–3 L appear to provide adequate protection by maintaining a distal perfusion pressure greater than 65 mmHg. These authors prefer this method. The left superior pulmonary vein is cannulated to remove blood from the heart rather than the left atrium because the vein is tougher and less prone to tear. The left femoral artery is cannulated to return the blood to the distal aorta. A centrifugal pump is employed because it is not as thrombogenic as a roller pump and, strictly speaking, heparinization is not required. This can be a significant benefit in a patient with multiple injuries, particularly in those with intracranial hemorrhage. However, occasional small cerebral infarcts have occurred, and 5,000–10,000 units of heparin is usually administered unless contraindicated by associated injuries.

Once bypass is initiated, the proximal vascular clamp is applied between the left common carotid and left subclavian; and the distal clamp is placed distal to the injury. The left subclavian is clamped separately. The hematoma is entered, and the injury evaluated. In most patients a short gelatin sealed Dacron graft is placed, usually 18–22 mm in diameter. Primary repair without a graft is possible in some patients. A 3-0 polypropylene suture is used for the anastomoses or suture lines. Air and clot are flushed from the aorta between two clamps and the subclavian artery prior to tying the final suture. Following completion of the repair, the clamps are removed; and the patient is weaned from the pump. The cannulae are removed, and the vessels are repaired. A recent meta-analysis comparing clamp-and-sew with left heart bypass revealed a significantly lower incidence of paraplegia when the pump is used.

Injuries of the transverse arch do occur from blunt trauma. The proximal clamp can usually be placed between the innominate and left carotid arteries without cerebral infarction. The proximal clamp, however, cannot be placed proximal to the innominate artery. A possible approach to injuries in which the clamps completely exclude the cerebral circulation is with profound hypothermia and circulatory arrest (see Chapter 21).

Small intimal flaps of the thoracic aorta without hematomas can be treated nonoperatively. Intraluminal mediastinal stents may also provide a solution but their role remains to be defined. Penetrating injuries of the thoracic aorta are rare and do not afford enough time to set up the pump. Therefore, there is no choice but to use the clamp-and-sew technique. Partially occluding clamps should be used if possible.

Abdomen

Emergent Abdominal Exploration

All abdominal explorations in adults are performed using a long midline incision because of its versatility. For children younger than 6 years, a transverse incision may be advantageous. If the patient has been in shock or is currently unstable, no attempt should be made to control bleeding from the abdominal wall until major sources of hemorrhage have been identified and controlled. The incision should be made with a scalpel rather than with an electrosurgical unit because it is faster. Liquid and clotted blood are rapidly evacuated with multiple laparotomy pads and suction. Additional pads are then placed in each quadrant to localize hemorrhage and the aorta is palpated to estimate blood pressure.

If exsanguinating hemorrhage is encountered on opening the abdomen, it is usually caused by injury to the liver, aorta, inferior vena cava or iliac vessels. If the liver is the source, the hepatic pedicle should be immediately clamped (a Pringle maneuver) and the liver compressed posteriorly by tightly packing several laparotomy pads between the hepatic injury and the underside of the right anterior chest wall. This combination of maneuvers will temporarily control the hemorrhage from virtually all survivable hepatic injuries.

If exsanguinating hemorrhage is originating near the midline in the retroperitoneum, direct manual pressure is applied with a laparotomy pad, and the aorta is exposed at the diaphragmatic hiatus and clamped. The same approach is used in the pelvis except that the infrarenal aorta can be clamped, which is both easier and safer because splanchnic and renal ischemia are avoided. Injuries of the iliac vessels pose a unique problem for emergency vascular control. Because there are so many large vessels in proximity, multiple vascular injuries are common. Furthermore, venous injuries are not controlled with aortic clamping. A helpful maneuver in these instances is pelvic vascular isolation. For stable patients with large midline hematomas, clamping the aorta proximal to the hematoma is also a wise precaution. Many surgeons take a few moments, once overt hemorrhage has been controlled, to identify obvious sources of enteric contamination and minimize further spillage. This can be accomplished with a running suture or with Babcock clamps.

Any organ can be injured by either blunt or penetrating trauma, however, certain organs are injured more often depending on the mechanism. In blunt trauma, organs which cannot yield to impact by elastic deformation are most likely to be injured. The solid organs, liver, spleen, and kidneys, are representative of this group. For penetrating trauma organs with the largest surface area when viewed from the front are most prone to injury (i.e., the small bowel, liver, and colon). Because bullets and knives usually follow straight lines, adjacent structures are commonly injured (e.g., the pancreas and duodenum).

All abdominal organs are systematically examined by visualization, palpation, or both. Missed injuries are a serious problem with often fatal results. In

penetrating trauma missed injuries can occur if wound tracks are not followed their entire distance. A second common reason is failure to explore retroperitoneal structures such as the ascending and descending colons, the second and third portion of the duodenum and ureters. Furthermore, injuries of the aorta or vena cava may be temporarily tamponaded by overlying structures. If the retroperitoneum is opened and the injury overlooked, delayed massive hemorrhage may occur following abdominal closure. Blunt abdominal injuries are usually obvious; but injuries of the pancreas, duodenum, bladder, and even the aorta can be overlooked.

Vascular Injuries

Injury to the major arteries and veins in the abdomen are a technical challenge to the surgeon and are often fatal. All vessels are susceptible to injury with penetrating trauma. While vascular injuries in blunt trauma are far less common all vessels also can be injured. Several vessels are notoriously difficult to expose. These include the retrohepatic vena cava, suprarenal aorta, the celiac axis, the proximal superior mesenteric artery, the junction of the superior mesenteric, splenic and portal veins, and the bifurcation of the vena cava. The suprarenal aorta, celiac axis, proximal superior mesenteric and left renal arteries can all be exposed by left medial visceral rotation. Division of the left crus of the diaphragm will permit access to the aorta above the celiac axis. The maneuver is much more difficult and time consuming than it first appears. In contrast mobilization of the right colon and a Kocher maneuver will expose the entire vena cava except the retrohepatic portion, and it is technically simple. This is referred to as a right medial visceral rotation.

The junction of the superior mesenteric, splenic, and portal veins can be exposed by dividing the neck of the pancreas. This provides excellent exposure of this difficult area. Management of the transected pancreas will be discussed below.

The bifurcation of the vena cava is obscured by the right common iliac artery. This vessel should be divided to expose extensive vena caval injuries of this area. The artery must be repaired after the venous injury is treated.

Liver

The lower costal margins impair visualization and a direct approach to the liver. The right lobe can be mobilized by dividing the right triangular and coronary ligaments. The right lobe can then be rotated medially into the surgical field. Mobilization of the left lobe is accomplished in the same fashion. On occasion it may be necessary to extend the midline abdominal incision into the chest. This is best accomplished with a median sternotomy.

The Pringle maneuver is one of the most useful techniques for evaluating the extent of hepatic injuries. The Pringle maneuver will differentiate between hemorrhage from the hepatic artery and portal vein, which ceases when the clamp is applied, and that from the hepatic veins and retrohepatic vena cava, which will not.

Techniques for the temporary control of hemorrhage from the liver are necessary when dealing with an extensive injury to provide the anesthesiologist with sufficient time to restore circulating blood volume before proceeding.

The temporary hemostatic techniques, which have proven most useful are manual hepatic compression, the Pringle maneuver and perihepatic packing. Manual compression of a bleeding hepatic injury may be a lifesaving maneuver. The addition of laparotomy pads on the surface of the liver distributes digital forces and lessens the chance of aggravating the injury. Manual compression is best suited for immediate attempts to prevent exsanguination and for periodic control during a complex procedure.

Perihepatic packing also is capable of controlling hemorrhage from most hepatic injuries, and it has the advantage of freeing the surgeon's hands. The right costal margin is elevated, and the pads are strategically placed over and around the bleeding site. Additional pads should be placed between the liver, diaphragm, and anterior chest wall until the bleeding has been controlled. Fortunately, hemorrhage from the left lobe can usually be controlled by mobilizing the lobe and compressing it between the surgeon's hands.

The Pringle maneuver often is used as an adjunct to packing for the temporary control of the arterial hemorrhage. Properly applied, a Pringle maneuver will eliminate all hepatopetal flow. The length of time that a Pringle maneuver can remain in place without causing irreversible ischemic damage to the liver is unknown. Several authors have documented a Pringle maneuver applied for over 1 h without appreciable hepatic damage.

Special techniques have been developed for controlling hemorrhage from juxtahepatic venous injuries. These formidable procedures include hepatic vascular isolation with clamps, the atriocaval shunt, and the Moore-Pilcher balloon. Hepatic vascular isolation with clamps is accomplished by the application of a Pringle maneuver, clamping the aorta at the diaphragm and clamping of the suprarenal and suprahepatic vena cavae.

The atriocaval shunt was designed to achieve hepatic vascular isolation while permitting venous blood to enter the heart from below the diaphragm. After a few early successes, enthusiasm for the shunt declined as mortality rates with its use ranged from 50–80 percent. A variation of the original atriocaval shunt has been the substitution of 9-mm endotracheal tube for the usual large chest tube. While this change may seem trivial, surrounding the suprarenal vena cava for a snare tourniquet is extremely difficult because exsanguinating hemorrhage must be controlled by posterior compression of the liver which severely restricts access to that segment of the vena cava.

An alternative to the atriocaval shunt is the Moore-Pilcher balloon. This device is inserted through the femoral vein and advanced into the retrohepatic vena cava. The catheter itself is hollow, and placed holes below the balloon permit blood to flow into the right atrium from the inferior vena cava.

Numerous methods for the definitive control of hepatic hemorrhage have been developed. Minor lacerations may be controlled with manual compression applied directly to the injury site. For similar injuries which do not respond to compression, topical hemostatic techniques have been successful. Small bleeding vessels may be controlled with electrocautery. Microcrystalline collagen can be used. The powder is placed on a clean 4x4 sponge and applied directly to the oozing surface. Topical thrombin can also be applied to minor bleeding injuries by saturating either a gelatin foam sponge or a microcrystalline collagen pad and applying it to the bleeding site.

Fibrin glue appears to be an effective topical agent. Fibrin glue is made by mixing concentrated human fibrinogen (cryoprecipitate) with bovine thrombin and calcium. Commercially available products are also available with a variety of delivery systems.

Suturing of the hepatic parenchyma remains an effective hemostatic technique. Although this treatment has been maligned as a cause of hepatic necrosis, hepatic sutures often are used for persistently bleeding lacerations less than 3 cm in depth. It is also an appropriate alternative for deeper lacerations if the patient will not tolerate further hemorrhage. The preferred suture is 2-0 or 0 chromic attached to a large, curved, blunt needle. Venous hemorrhage because of penetrating wounds which traverse the central portion of the liver can be managed by suturing the entrance and exit wounds with horizontal mattress sutures.

Hepatotomy with selective ligation of bleeding vessels is an important technique usually reserved for transhepatic penetrating wounds. Hepatotomy is performed using the finger fracture technique. The dissection continues until the bleeding vessels are identified and controlled. An alternative to suturing the entrance and exit wounds of a transhepatic injury or extensive hepatorrhaphy is the use of an intrahepatic balloon. These authors' method is to tie a large Penrose drain to a hollow catheter and ligate the opposite end of the drain. The balloon is then inserted into the bleeding wound and inflated with soluble contrast media. If the control of the hemorrhage is successful, a stopcock or clamp is used to occlude the catheter and maintain the inflation. The catheter is left in the abdomen and removed at a subsequent operation 24–48 h later.

Hepatic arterial ligation may be appropriate for patients with recalcitrant arterial hemorrhage from deep within the liver. Its primary role is in transhepatic injuries when application of the Pringle maneuver results in the cessation of arterial hemorrhage. While ligation of the right or left hepatic artery is well-tolerated in humans, ligation of the proper hepatic artery (distal to the origin of the gastroduodenal artery) is not necessarily associated with survival. An uncommon but perplexing hepatic injury is the subcapsular hematoma. This lesion occurs when the parenchyma of the liver is disrupted by blunt trauma, but the Glisson capsule remains intact. Subcapsular hematomas discovered during an exploratory laparotomy which involve less than 50 percent of the surface of the liver and are not expanding or ruptured, should be left alone. Hematomas that are expanding during an operation may require exploration. These lesions often are caused by uncontrolled arterial hemorrhage, and packing alone may not be successful. An alternative strategy would be to pack the liver to control venous hemorrhage, close the abdomen, and transport the patient to the angiographic suite for hepatic arteriography and embolization of the bleeding vessel. Ruptured hematomas require exploration and selective ligation, with or without packing.

Resectional débridement is indicated for the removal of peripheral portions of nonviable hepatic parenchyma. The mass of tissue removed should rarely exceed 25 percent of the liver. It should be reserved for patients who are in good metabolic condition and who will tolerate additional blood loss. An alternative for patients with extensive unilobar injuries is anatomic hepatic resection. However, the mortality rate for trauma patients exceeds 50 percent in most series. A reasonable indication for anatomic lobectomy occurs in patients whose hemorrhage has been controlled by perihepatic packing and/or arterial ligation but whose left or right lobe is nonviable. Because the mass of the remaining necrotic liver is large and the risk of subsequent infection is high, it should be removed as soon as the patient's condition permits.

Omentum has been used to fill large defects in the liver. Rationale for the use of the omentum to fill defects is that it provides an excellent source for macrophages, and that it fills a potential dead space with viable

tissue. The omentum can also provide a little additional support for parenchymal sutures and often is strong enough to prevent them from cutting through the Glisson capsule. Closed suction drains should be used if bile is seen oozing from the liver and in most patients with deep central injuries.

Complications following significant hepatic trauma include hemorrhage, infection, and various fistulas. Postoperative hemorrhage can be expected in a considerable percentage of patients treated with perihepatic packing. In most instances where postoperative hemorrhage is suspected, the patient is best served by returning him to the OR. Arteriography with embolization may be considered in selected patients.

Infections within and around the liver occur in about 3 percent of patients. Perihepatic infections develop more often in victims of penetrating trauma than blunt trauma. Persistent elevation of temperature and white blood cell count after the third or fourth postoperative day should prompt a search for intraabdominal infection. Many perihepatic infections can be treated with CT-guided drainage. Infected hematomas and infected necrotic liver require open operative intervention.

Bilomas are loculated collections of bile which may or may not be infected. If infected, the biloma is essentially an abscess and should be treated as such. If sterile, it will eventually be reabsorbed. Biliary ascites is caused by disruption of a major bile duct. Reoperation with the establishment of appropriate drainage is the prudent course.

Biliary fistulas occur in approximately 3 percent of patients with hepatic injuries. They are usually of little consequence and most will close without specific treatment.

Because hemorrhage from hepatic injuries often is treated without identifying and controlling each individual bleeding vessel, arterial pseudoaneurysms may develop. They may rupture into a bile duct resulting in hemobilia, which is characterized by intermittent episodes of right upper quadrant pain, upper gastrointestinal hemorrhage, and jaundice. If the aneurysm ruptures into a portal vein, portal venous hypertension with bleeding esophageal varices may occur. Each of these complications is best managed with hepatic arteriography and embolization.

Gall Bladder and Extrahepatic Bile Ducts

Injuries of the gallbladder are treated by lateral suture or cholecystectomy, whichever is easier. If lateral suture is performed, absorbable suture should be used. Injuries of the extrahepatic bile ducts are a challenge. If ducts are of normal size and texture (i.e., small in diameter and thin walled). These factors usually preclude primary repairs except for the smallest lacerations. Some injuries can be treated by the insertion of a T-tube through the wound or by lateral suture using 4-0 to 6-0 monofilament absorbable suture. Virtually all transections and any injury associated with significant tissue loss will require a Roux-en-y choledochojejunostomy. Injuries of the hepatic ducts are almost impossible to satisfactorily repair under emergency circumstances. One approach is to intubate the duct for external drainage and attempt a repair when the patient recovers. Alternatively, the duct can be ligated if the opposite lobe is normal and uninjured. For patients who are critically ill, the common duct also can be treated by intubation with external drainage.

Spleen

Splenic injuries are treated nonoperatively, by splenic repair, partial splenectomy, or resection depending on the extent of the injury and the condition of the patient. Enthusiasm for splenic salvage has been driven by the evolving trend toward nonoperative management of solid organ injuries and the rare but often fatal complication of overwhelming postsplenectomy infection (OPSI). These infections are caused by encapsulated bacteria and are very resistant to treatment. OPSI occurs most often in young children and immunocompromised adults.

To safely remove or repair the spleen it should be mobilized to the extent that it can be brought to the surface of the abdominal wall. This requires division of the attachments between the spleen and splenic flexure of the colon. Next, an incision is made in the peritoneum and endoabdominal fascia beginning at the inferior pole, a centimeter or two away from the spleen, and continuing posteriorly and superiorly until the esophagus is encountered. It often is helpful to rotate the operating table 20 degrees to the patient's right so that the weight of abdominal viscera aids in their own retraction. A plane can then be established between the spleen and pancreas and Gerota fascia, which can be extended to the aorta.

Hilar injuries or a pulverized splenic parenchyma usually are treated by splenectomy. Splenectomy also is indicated for lesser splenic injuries in patients with multiple abdominal injuries who have developed a coagulopathy; and it usually is necessary in patients with failed splenic salvage attempts. Partial splenectomy can be used in patients in whom only a portion of the spleen has been destroyed, usually the superior or inferior half. When placing horizontal mattress sutures across a raw edge, gentle compression of the parenchyma by an assistant will facilitate hemostasis. Drains are never used after completion of the repair or resection. If splenectomy is performed, pneumococcal vaccine is routinely given.

Diaphragm

In blunt trauma the diaphragm is injured on the left in 75 percent of cases, presumably because the liver diffuses some of the energy on the right side. For both blunt and penetrating trauma the diagnosis is suggested by an abnormality of the diaphragmatic shadow on chest radiograph. The typical injury from blunt trauma is a large tear in the central tendon. Regardless of etiology, acute injuries are repaired through an abdominal incision. The laceration is closed with a 0- monofilament permanent suture using a simple running technique.

Duodenum

Duodenal hematomas are caused by a direct blow to the abdomen, and they occur more often in children than adults. The diagnosis is suspected by the onset of vomiting following blunt abdominal trauma; barium examination of the duodenum reveals either the coiled spring sign or obstruction. Most duodenal hematomas in children can be managed nonoperatively. Resolution of the obstruction occurs in the majority of patients in 7–14 days. If surgical intervention becomes necessary, evacuation of the hematoma is associated with equal success but fewer complications than bypass procedures. A new approach is laparoscopic evacuation if the obstruction persists more than 7 days.

Duodenal perforations can be caused by both blunt and penetrating trauma. Blunt injuries are difficult to diagnose because the contents of the duodenum

have a neutral pH, few bacteria and often are contained by the retroperitoneum. Mortality may exceed 30 percent if the lesion is not identified and treated within 24 h. The perforations are not reliably identified by initial oral contrast CT examinations; and, therefore, these authors often obtain contrast radiographs with soluble contrast followed with barium if necessary. Most perforations of the duodenum can be treated by primary repair. Occasionally, penetrating injuries will damage only the pancreatic aspect of the second or third portion. Because the duodenum cannot be adequately mobilized to repair the injury directly, the wound should be extended laterally or the duodenum divided so that the pancreatic aspect can be sutured from the inside.

Challenges arise when there is a substantial loss of duodenal tissue. Extensive injuries of the first portion of the duodenum can be repaired by débridement and anastomosis. In contrast, the second portion is tethered to the head of the pancreas by its blood supply and the ducts of Wirsung and Santorini so that the length of duodenum that can be mobilized from the pancreas is limited to approximately a centimeter and will do little to alleviate tension on a suture line. As a result, suture repair of the second portion when tissue is lost often results in an unacceptably narrow lumen, and end-to-end anastomosis is virtually impossible; therefore, more sophisticated repairs are required. For extensive injuries proximal to the accessory papilla, débridement, and end-to-end anastomosis is appropriate. For lesions between the accessory papilla and the papilla of Vater, a vascularized jejunal graft, either a patch or tubular interposition graft, may be required. A Roux-en-y duodenojejunostomy is also appropriate. Duodenal injuries with tissue loss distal to the papilla of Vater and proximal to the superior mesenteric vessels are best treated by Roux-ex-Y duodenojejunostomy. Duodenum and proximal jejunum are drained into the jejunum.

Injuries to the third and fourth portions of the duodenum with tissue loss pose other problems. Owing to the notoriously short mesentery of the third and fourth portions of the duodenum, mobilization is limited because of the risk of ischemia. It is the preference of these authors to resect the third and fourth portions and perform a duodenojejunostomy on the right side of the superior mesenteric vessels.

An important adjunct for complex duodenal repairs is the pyloric exclusion technique. By occluding the pylorus and performing a gastrojejunostomy, the gastrointestinal steam can be diverted away from the duodenal repair. If a fistula does develop, it is functionally an end fistula, which is easier to manage and more likely to close than a lateral fistula. To perform a pyloric exclusion, a gastrostomy is first made on the greater curvature as close to the pylorus as possible. The pylorus is then grasped with a Babcock clamp via the gastrostomy and oversewn with a 0 polypropylene suture. A gastrojejunostomy restores gastrointestinal continuity. Experience has shown that the absorbable sutures do not last long enough to be effective, and even heavy polypropylene will give way in 3–4 weeks in most patients. A linear staple line across the outside the pylorus provides the most permanent pyloric closure.

Pancreas

Blunt pancreatic transection at the neck of the pancreas can occur with a direct blow to the abdomen. As an isolated injury it is more difficult to detect than blunt duodenal rupture; however, a missed pancreatic injury is more benign. Because the main pancreatic duct is transected, the patient will develop a pseudocyst or pancreatic ascites, but there is little inflammation because the

pancreatic enzymes remain inactivated. The diagnosis can occasionally be made with CT using fine cuts through the pancreas.

Optimal management of pancreatic trauma is determined by the location of the injury and whether or not the main pancreatic duct is injured. Pancreatic injuries in which the pancreatic duct is not injured may be treated by drainage or left alone. In contrast, pancreatic injuries associated with a ductal injury always require treatment. Direct exploration of perforations or lacerations will confirm the diagnosis of a ductal injury in most instances. This leaves a small but significant percentage of patients whom the diagnosis is in doubt, and more invasive investigations may be required. One recommendation has been to perform operative pancreatography. This procedure requires direct access to the duct either by way of a duodenotomy or following resection of the tail of the pancreas.

An expeditious alternative to pancreatography is to pass a 1.5–2.0-mm coronary artery dilator into the main duct via the papilla and observe the pancreatic wound. If the dilator is seen in the wound, a ductal injury is confirmed.

A third method for identifying pancreatic ductal injuries is the use of endoscopic retrograde pancreatography (ERP). This technique may be difficult to perform in an anesthetized patient in the OR, but the surgeon can assist by manipulating the duodenum or occluding the distal portion to facilitate air insufflation. ERP is very helpful in the delayed diagnosis of a ductal injury or in those patients who are too sick to explore adequately during the initial operation.

Rather than accepting the risks of pancreatography or aggressive local exploration, a final option for identifying ductal injuries in the head of the pancreas is to do nothing other than drain the pancreas. If pancreatic fistula or pseudocyst develops, the diagnosis is confirmed. Fortunately, the majority of pancreatic fistulas will close spontaneously with only supportive care.

There are two options for treating injuries of the neck, body, and tail when the main duct is transected. Distal pancreatectomy with or without splenectomy is the preferred approach. The spleen can be preserved by dissecting the pancreas from the splenic vein.

For injuries to the head of the pancreas that involve the main pancreatic duct but not the intrapancreatic bile duct, distal pancreatectomy alone rarely is indicated because the risk of pancreatic insufficiency is significant if more than 85–90 percent of the gland is resected. A more limited resection from the site of the injury to the neck of the pancreas, with preservation of the pancreaticoduodenal vessels and common duct, will allow for closure of the injured proximal pancreatic duct. Pancreatic function can then be preserved by a Roux-en-y pancreatojejunostomy with the distal pancreas.

In contrast to injuries of the pancreatic duct, the diagnosis of injuries to the intrapancreatic common bile duct is simple. The first method is to squeeze the gallbladder and observe the pancreatic wound. If bile is seen leaking from the pancreatic wound, the presence of an injury is established. Operative cholangiography is diagnostic in questionable cases. If a patient with an intrapancreatic bile duct injury is critically ill, external drainage can be used until the patient is fit for definitive treatment. For most injuries division of the common bile duct superior to the first portion of the duodenum, ligation of the distal common duct, and reconstruction with a Roux-en-y choledochojejunostomy is recommended.

While many authorities advocate routine drainage of all pancreatic injuries, these authors do not drain contusions, lacerations in which the probability

of a major ductal injury is small or pancreatic anastomoses. We do drain pancreatic injuries when there is a possible major ductal injury although we cannot identify it. If a drain is desirable, closed suction devices are associated with fewer infectious complications than sump or Penrose drains. Nutritional support is important and electrolyte replacement may be necessary.

Pancreaticoduodenal Injuries

Because the pancreas and duodenum are in physical contact, combined pancreaticoduodenal injuries are not uncommon. These lesions are dangerous because of the risk of duodenal suture line dehiscence and the development of a lateral duodenal fistula. The simplest treatment is to repair the duodenal injury and drain the pancreatic injury. This method is appropriate for combined injuries without major duodenal tissue loss and without pancreatic or biliary ductal injuries. With more extensive injuries, consideration should be given to providing additional protection by adding a pyloric exclusion.

While most pancreatic and duodenal injuries can be treated with relatively simple procedures, a few will require a pancreatoduodenectomy. Examples of such injuries include transection of both the intrapancreatic bile duct and the main pancreatic duct in the head of the pancreas, avulsion of the papilla of Vater from the duodenum, and destruction of the entire second portion of the duodenum.

Colon

There are two conceptually different methods for treating colonic injuries: primary repair and colostomy. Primary repairs include lateral suture of perforations and resection of the damaged colon with reconstruction by ileocolostomy or colocolostomy. The advantage of primary repairs is that definitive treatment is carried out at the initial operation. The disadvantage is that leakage may occur. Several different styles of colostomies have been used to manage colonic injuries. In some instances the injured colon can be exteriorized like a loop colostomy. The injured area can be resected and an end colostomy or ileostomy performed, and the distal colon can be brought to the abdominal wall as a mucous fistula or oversewn and left in the abdominal cavity. The advantage of colostomy is avoiding a suture line in the abdomen. The disadvantage is that a second operation is required to close the colostomy. Often overlooked disadvantages are the complications associated with the creation of a colostomy, some of which may be fatal.

Numerous large retrospective and several prospective studies have now clearly demonstrated that primary repair is safe and effective in the majority of patients with penetrating injuries. Colostomy is still appropriate in a few patients but the current dilemma is how to select them. The authors' approach is to repair all injuries regardless of the extent and location and reserve colostomy for patients with protracted shock who are also candidates for damage control. The theory used to support this approach is that systemic factors are more important than local factors in determining whether a suture line will heal. When a colostomy is required, performing a loop colostomy proximal to a distal repair should be avoided because a proximal colostomy does not protect a distal suture line. All suture lines and anastomoses are performed with the running single layer technique.

Complications related to the colonic injury and its treatment may include intraabdominal abscess, fecal fistula, wound infection, and stomal complications. Intraabdominal abscess occurs in approximately 10 percent of patients

and most are managed with percutaneous drainage. Fistulas occur in 1–3 percent of patients and usually present as an abscess or wound infection, which after drainage, is followed by continuous fecal output. Most colonic fistulas will heal spontaneously. Wound infection can be effectively avoided by leaving the skin and subcutaneous tissue open and relying on healing by secondary intention or delayed primary closure.

Stomal complications include necrosis, stenosis, obstruction and prolapse. Taken together they occur in approximately 5 percent of patients, and most require reoperation. Necrosis is a particularly serious complication which must be recognized and treated promptly. Failure to do so can result in life-threatening septic complications including necrotizing fasciitis.

Rectum

Rectal injuries differ from colonic injuries in two important ways, mechanisms of injury and accessibility. The rectum is often injured by GSW, rarely by SW, and frequently by acts of auto-eroticism and high pressure injuries caused by air guns or water under high pressure as used in golf course irrigation systems. The second difference is limited access to the rectum because of the surrounding bony pelvis.

The diagnosis is suggested by the course of projectiles, the presence of blood on digital examination of the rectum and history. Patients in whom a rectal injury is suspected should undergo proctoscopy. Hematomas, contusions, lacerations and gross blood may be seen. If the diagnosis is still in question, radiograph examinations with soluble contrast enemas are indicated. At times, it may be difficult to determine whether an injury is present. These authors believe that these patients should be treated as if they do have an injury.

The portion of the rectum proximal to the peritoneal reflection is referred to as the intraperitoneal segment and that distal to the reflection as the extraperitoneal segment. Injuries of the intraperitoneal portion (including its posterior aspect) are treated as previously outlined in the section on colonic injuries. Access to extraperitoneal injuries is so restricted, that indirect treatment usually is required. While colostomies proximal to a suture line are avoided in patients with colonic injuries, there is often no option in patients with extraperitoneal injuries; and sigmoid colostomies are appropriate for most patients. Properly constructed loop colostomies are preferred because they are quick and easy to fashion, and they provide total fecal diversion. Essential elements include: 1) adequate mobilization of the sigmoid colon so the loop will rest on the abdominal wall without tension, 2) maintenance of the spur of the colostomy above the level of the skin, 3) longitudinal incision in the tenia coli, and 4) immediate maturation in the OR using 3-0 braided absorbable suture.

If a perforation is inadvertently uncovered during dissection, it should be repaired as described above. Otherwise, it is not necessary to explore the extraperitoneal rectum to repair a perforation. If the injury is extensive the rectum should be divided at the level of injury, the distal rectum oversewn, and an end colostomy created. In rare instances where the anal sphincters have been destroyed, and abdominoperineal resection may be necessary.

Extraperitoneal injuries of the rectum should be drained via a retroanal incision. The drains, either Penrose or closed-suction, should be placed close to the perforation and should be left in until they fall out spontaneously or drainage diminishes. Irrigation of the distal rectum is advocated by some authorities. It may be of benefit in a patient whose rectum is loaded with feces. If it is done, the irrigation solution should be isotonic and the anus should be

mechanically dilated to avoid forcing feces out of a perforation. If the patient has a concomitant bladder injury and adjacent suture lines are created, a flap of viable omentum should be placed between.

Complications are similar in frequency and nature to colonic injuries. Pelvic osteomyelitis may also occur. Bone biopsy should be performed to secure the diagnosis and bacteriology. Culture specific intravenous antibiotics should be administered for 2–3 months. Débridement may be necessary.

Stomach and Small Intestine

Gastric injuries can occasionally be missed if a wound is located within the mesentery of the lesser curvature or high in the posterior fundus. The stomach should be clamped at the pylorus and inflated with air or methylene blue colored saline if there is any question. Patients with injuries which damage both nerves of Latarjet or both vagi should have a drainage procedure (see Chapter 25). If the distal antrum or pylorus are severely damaged it can be reconstructed with a Billroth I or II procedure. Although the authors emphasize the single layer running suture line, a running two-layer suture line is preferred for the stomach because of its rich blood supply.

With the almost universal use of CT for the diagnosis of blunt abdominal injury, injury to the small intestine can be missed. Wounds of the mesenteric border also can be missed if the exploration is not comprehensive. Most injuries are treated with a lateral single layer running suture. Multiple penetrating injuries often occur close together. Judicious resections with end to end anastomosis may be appropriate.

Kidneys

There are two unique aspects to the diagnosis and treatment of renal injuries. First, virtually all injuries can be diagnosed by CT. Second, the fact that there are two identical organs makes the sacrifice of one a viable therapeutic option. Nearly 95 percent of all blunt renal injuries are treated nonoperatively. The diagnosis is suspected by the finding of microscopic or gross hematuria, and confirmed by CT. Most cases of urinary extravasation and hematuria will resolve in a few days with bed rest. Persistent gross hematuria can be treated by embolization. Persistent urinomas can be drained percutaneously. Operative treatment occasionally is necessary for similar lesions that do not respond to these less-invasive measures.

If a perinephric hematoma is encountered during laparotomy from blunt trauma, exploration is indicated if it is expanding or pulsatile. Very large hematomas should be explored because of the risk of a major vascular injury. If emergent vascular control is necessary, a large curved vascular clamp can easily be placed across the hilum from below with the clamp parallel to the vena cava and aorta.

Hemostatic and reconstructive techniques used to treat blunt renal injuries are similar to those used to treat the liver and spleen, although two additional concepts are employed: 1) the collecting system should be closed separately, and 2) the renal capsule preserved to close over the repair of the collecting system. Permanent sutures should be avoided because of the risk of calculus formation. If nephrectomy is being considered and the status of the opposite kidney is unknown, it should be palpated. The presence of a palpably normal opposite kidney is assurance that the patient will not be rendered anephric by a unilateral nephrectomy. Unilateral renal agenesis occurs in one in 1000 patients.

The renal arteries and veins are uniquely susceptible to traction injury caused by blunt trauma. This causes thrombus formation resulting in high-grade stenosis or thrombosis. These injuries can be detected by CT. If the patient does not have more urgent injuries and treatment and repair can be accomplished within 1–3 h of admission, it should be attempted. If repair is not possible within this time frame, leaving the kidney in situ does not necessarily lead to hypertension or abscess formation. Isolated renal vein injuries can occur from blunt trauma. The vein may either be torn or avulsed from the vena cava. In either case a large hematoma develops that often leads to an operation and nephrectomy.

All penetrating wounds to kidneys are explored. Bleeding perforations and lacerations are treated using the same hemostatic techniques as described above. Renal vascular injuries are common following penetrating trauma. Injuries involving the collecting system should be closed separately if they are large. Small perforations which penetrate the collecting system can be controlled by suture of the capsule and parenchyma. Perforations of the renal pelvis should be meticulously repaired with fine sutures, and drains should be employed selectively.

Ureters

Injuries of the ureters from external trauma are rare. They occur in a few patients with pelvic fractures and are uncommon in penetrating trauma. The diagnosis in blunt trauma may be made by CT or retrograde uterography. More often the injury is not identified until a complication (e.g., a urinoma) becomes apparent. In penetrating trauma ureteral injuries are discovered during the exploration of the retroperitoneum. If an injury is suspected but not identified, methylene blue or indigo carminate are administered intravenously. Staining of the tissue by the dye may facilitate identification of the injury. Most injuries can be repaired primarily using the same technique described above for small arteries. The suture these authors use is 5-0 absorbable monofilament. When the ureter is mobilized, the dissection should be at least a centimeter away from the ureter to avoid injury to its delicate vascular plexus. The kidney can also be mobilized to gain length. Injuries of the distal ureter can be treated by reimplantation. The psoas hitch and Boari flap may be helpful in selected distal ureteral injuries. If the patient is critically ill and being considered for a staged laparotomy, or if the surgeon is uncomfortable with ureteral repair, the ureter can be ligated on both sides of the injury and a nephrostomy performed.

Bladder

Bladder injuries are diagnosed by cystography, CT, or during laparotomy. A postvoid view enhance the accuracy of cystography. Blunt ruptures of the intraperitoneal portion are closed with a running single layer closure using 3-0 absorbable monofilament suture. Blunt extraperitoneal rupture is treated with a Foley catheter; direct operative repair is not necessary. The Foley can be removed in 10–14 days. Penetrating bladder injuries are treated in the same fashion although injuries near the trigone should be repaired through an incision in the dome to avoid injury to the intravesicular ureter.

Urethra

Blunt disruption of the posterior urethra is managed by bridging the defect with a Foley catheter. This requires passing catheters through the urethral meatus

and through an incision in the bladder. Strictures are not uncommon but can be managed electively. Penetrating injuries are treated by direct repair.

Pelvis

Pelvic fractures can cause exsanguinating retroperitoneal hemorrhage without associated major vascular injury; branches of the internal iliac vessels and the lower lumbar arteries often are responsible. Hemorrhage also comes from small veins and from the cancellous portion of the fractured bones. Most pelvic fractures which cause life-threatening hemorrhage involve disruption of the posterior elements (i.e., the sacroiliac joints and associated ligaments) and often are biomechanically unstable.

A hemodynamically unstable patient may be bleeding from sources other than the pelvis, for example, the spleen. However, large retroperitoneal hematomas also can cause a hemoperitoneum particularly if overlying peritoneum ruptures. Determining the source of hemorrhage is a dilemma. These authors have employed US to aid in this decision. If US is unequivocally positive, the blood is assumed to be coming from an injury unrelated to the pelvic fracture; and a laparotomy is performed. If the US is negative, attention is directed toward treating the pelvic fracture. Clearly, the decision to operate or not may be wrong; and the plan may need to be altered accordingly.

Several methods have been employed to control hemorrhage associated with pelvic fractures. These include immediate external fixation, angiography with embolization, pelvic volume reduction and pelvic packing. No single technique is effective for treating all fractures and there is little agreement among specialists regarding which should be used. Anterior external fixation will decrease pelvic volume, tamponade bleeding and prevent secondary hemorrhage. Many orthopedic surgeons remain unconvinced of the efficacy of external fixation for grossly unstable posterior fractures. Tightly wrapping the pelvis with a sheet and taping the knees together reduces pelvic volume and is employed in the trauma center of these authors. Angiography with embolization is very effective for controlling arterial hemorrhage, but arterial hemorrhage occurs in only 10–20 percent of patients. Pelvic packing may control venous hemorrhage.

Because of the options available and differences of opinion regarding treatment, these authors have found it desirable to reach agreements with the other specialists involved including orthopedic surgeons, interventional radiologists, the blood bank, and anesthesiologists. These agreements avoid the time lost to unnecessary debate.

Another clinical challenge is the open pelvic fracture. In many instances the wounds are located in the perineum and the risk of pelvic sepsis and osteomyelitis is high. To reduce the risk of infection, a sigmoid colostomy is recommended. The pelvic wound is manually débrided and the wound is then left to heal by secondary intention.

Extremities

Most injuries of the extremities are within the domain of the orthopedic and plastic surgeons except for isolated vascular injuries that have been discussed above. There are two extremity injuries, however, which need to be emphasized: 1) vascular injuries associated with fractures and 2) compartment syndromes.

Vascular Injuries with Fractures

Vascular injuries associated with fractures are rare but serious, and amputation rates of more than 50 percent have been noted. These injuries can be caused by both blunt and penetrating trauma. Particular fractures and dislocations are more likely to be associated with vascular injury than others. In the upper extremity, a fractured clavicle or first rib may lacerate the distal subclavian artery. The axillary artery may be injured in patients with dislocations of the shoulder or proximal humeral fractures. Supracondylar fractures of the distal humerus and dislocations of the elbow are associated with brachial arterial injuries. In all the above fractures and dislocations, vascular injuries are uncommon.

In the lower extremity, the orthopedic injury most commonly associated with vascular injury is dislocation of the knee, where the popliteal artery and/or vein may be injured in as many as 30 percent of patients. The popliteal vessels may also be injured in patients with supracondylar fractures of the femur or tibial plateau fractures.

Three different mechanisms can produce paralysis and numbness in an injured extremity: ischemia, nerve injury and compartment syndrome. As a result, failure to accurately perform and document the neuromuscular function of the injured extremity can and will lead to missed injuries and improper treatment.

A rational approach would be to consider all the above options based on the condition of the patient's extremity. If the extremity is clearly viable and there is no hemorrhage from the vascular injury, the fracture should be treated first. If the limb is at risk from ischemia, prompt revascularization is required. When little or no fracture manipulation is anticipated, definitive vascular repair is performed first. If extensive manipulation is required in a ischemic extremity, temporary shunts can be placed followed by vascular repair after the fracture has been treated.

Combined orthopedic and vascular injuries frequently occur in open fractures, and the use of external fixation devices for these injuries has become common. Unfortunately, these devices may significantly hinder vascular repair because of their location and bulk. Preoperative planning should avoid this technical problem.

Because of the severity of combined orthopedic and vascular injuries, the need for immediate amputation may arise. When the primary nerve is transected in addition to a fracture and arterial injury, such as the popliteal nerve, popliteal artery and distal femur, primary amputation should be strongly considered. This difficult clinical decision is best reached through a collaborative effort.

Compartment Syndrome

Compartment syndromes can occur anywhere in the extremities. As in the abdomen, the pathophysiology is an acute increase in pressure in a closed space, which impairs blood flow to the structures within. The etiologies of extremity compartment syndromes include arterial hemorrhage into a compartment, venous ligation or thrombosis, crush injuries, infections, crotalid envenomation, and ischemia/reperfusion. In conscious patients, pain is the prominent symptom. Active or passive motion of involved muscles increases the pain. Progression to paralysis can occur. The most prone site is in the anterior compartment of the leg; a well described early sign is paresthesia or numbness

between the first and second toes caused by pressure on the deep peroneal nerve.

In comatose or obtunded patients, the diagnosis is more difficult to secure. A compatible history, firmness of the compartment to palpation and diminished mobility of the joint are suggestive. The absence of a pulse distal to the affected compartment, a frozen joint, and myoglobinuria are late signs and suggest a poor prognosis. As in the abdomen, compartment pressure can be measured. The small handheld Stryker device is a convenient tool for this purpose. Pressures greater than 45 mm Hg usually require operative intervention. Patients with pressures between 30 and 45 mm Hg should be watched closely.

Treatment for compartment syndrome is fasciotomy. Note that the soleus must be detached from the tibia to decompress the deep flexor compartment.

Prognosis is related to the severity, duration, and etiology of the compartment syndrome. Those who develop compartment syndrome from crush injuries, crotalid envenomation, and particularly ischemia/reperfusion have a poor prognosis. Fasciotomy should still be attempted although infection and amputation are a frequent outcome.

Thermal burns and related injuries are a major cause of death and disability in the United States and worldwide. The interactive multidisciplinary team has proven to be the least expensive and most efficient method of treating major burn injury, of which the initial acute care is only a small part of the total treatment. Burn patients often require years of supervised rehabilitation, reconstruction, and psychosocial support.

EPIDEMIOLOGY

In the United States, approximately 1.1 million individuals annually are burned seriously enough to seek health care; approximately 45,000 of these require hospitalization, and approximately 4500 die. More than 90 percent of burns are preventable, with nearly one-half being smoking-related or because of substance abuse.

The annual number of burn deaths in the United States has decreased from approximately 15,000 in 1970 to around 4500 at present. Over the same period, the burn size associated with a 50 percent mortality rate has increased from 30 percent of the total body surface area (TBSA) to greater than 80 percent TBSA in otherwise healthy young adults. The duration of hospital stay has been cut in half. Almost 95 percent of the patients admitted to burn centers in the United States now survive, and over one-half of them return to preburn levels of physical and social functioning within 12–24 months following injury. The quality of burn care is no longer measured only by survival, but also by long-term function and appearance.

As with other forms of trauma, burns frequently affect children and young adults. In children less than 8 years of age, the most common burns are scalds, usually from the spilling of hot liquids. In older children and adults, the most common burns are flame-related, usually the result of house fires, the ill-advised use of flammable liquids as accelerants, or are smoking- or alcohol-related. Chemicals or hot liquids, followed by electricity, and then molten or hot metals most often cause work-related burns. The hospital expenses and the societal costs related to time away from work or school are staggering.

Etiology

Cutaneous burns are caused by the application of heat, cold, or caustic chemicals to the skin. When heat is applied to the skin, the depth of injury is proportional to the temperature applied, duration of contact, and thickness of the skin.

Scald Burns

Scalds, usually from hot water, are the most common cause of burns in civilian practice. Water at 60°C (140°F) creates a deep partial-thickness or full-thickness burn in 3 seconds. At 69°C (156°F), the same burn occurs in 1 second. As a reference point, freshly brewed coffee generally is about 82°C

(180°F). Exposed areas of skin tend to be burned less deeply than clothed areas, as the clothing retains the heat and keeps the hot liquid in contact with the skin for a longer period of time. Immersion scalds are always deep, severe burns. Deliberate scalds, many times immersion injuries, are responsible for about 5 percent of the pediatric admissions to burn centers. The physician should note any discrepancy between the history provided by the caregiver and the distribution or probable cause of a burn. Any suspicious burn requires in-patient admission and must be reported promptly to the appropriate authorities. Scald burns from grease or hot oil are usually deep partial-thickness or full-thickness burns, as the oil or grease may be in the range of 200°C (400°F). Tar and asphalt burns are a special kind of scald. The tar should be removed by application of a petroleum-based ointment or a nontoxic solvent (e.g., Medisol or sunflower oil) under a dressing. The dressing should be removed and the ointment or solvent reapplied frequently until the tar has dissolved. Only then can the extent of the injury and the depth of the burn be estimated accurately.

Flame Burns

Flame burns are the second most common mechanism of thermal injury. Although the incidence of injuries caused by house fires has decreased with the use of smoke detectors, smoking-related fires, improper use of flammable liquids, motor vehicle collisions, and ignition of clothing by stoves or space heaters are responsible for most flame burns. Patients whose bedding or clothes have been on fire rarely escape without some full-thickness burns.

Flash Burns

Flash burns are next in frequency. Explosions of natural gas, propane, butane, petroleum distillates, alcohols, and other combustible liquids, and electrical arcs cause intense heat for a brief time period. Clothing, unless it ignites, is protective. Flash burns generally have a distribution over all exposed skin, with the deepest areas facing the source of ignition. Flash burns are typically superficial or partial-thickness, their depth depending on the amount and kind of fuel that explodes. However, electrical arc burns and those from gasoline are often full-thickness and require grafting.

Contact Burns

Contact burns result from contact with hot metals, plastic, glass, or hot coals. They are usually limited in extent, but are invariably deep. The exhaust pipes of motorcycles cause a classic burn of the medial lower leg that although small, usually requires excision and grafting. Contact burns are often fourth-degree burns, especially those in unconscious or postictal patients, and those caused by molten materials.

Burn Prevention

More than 90 percent of all burns are preventable, and ongoing prevention and education efforts seem to be the most effective means to impact burn incidence. Individual burn centers, the American Burn Association (ABA), and the International Society for Burn Injury (ISBI) have produced numerous public service announcements regarding hot water, carburetor flashes, grilling-related burns, scalds, and other kinds of burn injury.

HOSPITAL ADMISSION AND BURN CENTER REFERRAL

The severity of symptoms from smoke inhalation and the magnitude of associated burns dictate the need for hospital admission and specialized care. Any patient who has a symptomatic inhalation injury or more than trivial burns should be admitted to a hospital. As a rule of thumb, if the burns cover more than 5 to 10 percent total body surface area (TBSA), the patient should be referred to a designated burn center. In the absence of burns, admission depends on the severity of respiratory symptoms, presence of premorbid medical problems, and the social circumstances of the patient.

Burn Center Referral Criteria

The ABA has identified the following injuries as those requiring referral to a burn center after initial assessment and stabilization at an emergency department:

1. Partial-thickness and full-thickness burns totaling greater than 10 percent TBSA in patients younger than 10 or older than 50 years of age.
2. Partial-thickness and full-thickness burns totaling greater than 20 percent TBSA in other age groups.
3. Partial-thickness and full-thickness burns involving the face, hands, feet, genitalia, perineum, or major joints.
4. Full-thickness burns greater than 5 percent TBSA in any age group.
5. Electrical burns, including lightning injury.
6. Chemical burns.
7. Inhalation injury.
8. Burn injury in patients with preexisting medical disorders that could complicate management, prolong the recovery period, or affect mortality.
9. Any burn with concomitant trauma (e.g., fractures) in which the burn injury poses the greatest risk of morbidity or mortality. If the trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable, before being transferred to a burn center. The physician's decisions should be made with the regional medical control plan and triage protocols in mind.
10. Burn injury in children admitted to a hospital without qualified personnel or equipment for pediatric care.
11. Burn injury in patients requiring special social, emotional, and/or long-term rehabilitative support, including cases involving suspected child abuse.

EMERGENCY CARE

Care at the Scene

Airway

Once flames are extinguished, initial attention must be directed to the airway. Any patient rescued from a burning building or exposed to a smoky fire should be placed on 100 percent oxygen via a nonrebreather mask if there is any suspicion of smoke inhalation. If the patient is unconscious or in respiratory distress, endotracheal intubation should be performed by appropriately trained personnel.

Other Injuries and Transport

Once an airway is secured, the patient is assessed for other injuries. Emergency medical personnel should place an intravenous line and begin fluid administration with lactated Ringer (LR) solution at a rate of approximately 1 L/h in the case of an adult with a severe burn; otherwise, a maintenance rate is appropriate assuming no concomitant, nonthermal trauma. For transport, the patient should be kept warm and wrapped in a clean sheet or blanket. Sterility is not required. Before or during transport, constricting clothing and jewelry should be removed from burned parts, because local swelling begins almost immediately.

Cold Application

Small burns, particularly scalds, may be treated with immediate application of cool water. It has been mathematically demonstrated that cooling cannot reduce skin temperature enough to prevent further tissue damage, but there is evidence in animals that cooling delays edema formation. Iced water should never be used, even on the smallest of burns.

Emergency Room Care

The primary rule for the emergency physician is to ignore the burn. As with any form of trauma, the airway, breathing, and circulation protocol (ABC) must be strictly followed. Although a burn is a dramatic injury, a careful search for other life-threatening injuries is the first priority. Only after making an overall assessment of the patient's condition should attention be directed to the burn.

Emergency Assessment of Inhalation Injury

The patient's history is an integral part of assessing the extent of their injuries. Inhalation injury should be suspected in anyone with a flame burn, and assumed until proven otherwise in anyone burned in an enclosed space. Careful inspection of the mouth and pharynx should be done early, and endotracheal intubation performed as needed. Hoarseness and expiratory wheezes are signs of potentially serious airway edema or inhalation injury. Copious mucus production and carbonaceous sputum (i.e., expectorated sputum and not just black flecks in the saliva) are also positive signs, but their absence does not rule out inhalation injury. Carboxyhemoglobin levels should be obtained, and elevated levels or any symptoms of carbon monoxide (CO) poisoning are presumptive evidence of associated inhalation injury. A decreased P-to-F ratio, the ratio of arterial oxygen pressure (P_{aO_2}) to the percentage of inspired oxygen (F_{iO_2}), is one of the earliest indicators of smoke inhalation. A ratio of less than 250 is an indication for endotracheal intubation rather than for increasing the F_{iO_2} .

Fluid Resuscitation in the Emergency Room

As burns approach 20 percent TBSA, local proinflammatory cytokines enter the circulation and result in a systemic inflammatory response. The microvascular leak, permitting loss of fluid and protein from the intravascular compartment into the extravascular compartment, becomes generalized. Resuscitation begins by starting intravenous LR solution at a rate tailored to the extent of the burn using the Parkland/Baxter formula (Table 7-1), as both over- and under-resuscitation are deleterious. Burn patients requiring intravenous resuscitation

TABLE 7-1 Formulas for Estimating Adult Burn Patient Resuscitation Fluid Needs

	Electrolyte	Colloid	D ₅ W
Colloid formulas			
Evans	Normal saline 1.0 mL/kg/% burn	1.0 mL/kg/% burn	2000 mL
Brooke	Lactated Ringer solution 1.5 mL/kg/% burn	0.5 mL/kg	2000 mL
Slater	Lactated Ringer solution 2 L/24 h	Fresh frozen plasma 75 mL/kg/24 h	
Crystalloid formulas			
Parkland	Lactated Ringer solution	4 mL/kg/% burn	
Modified Brooke	Lactated Ringer solution	2 mL/kg/% burn	

Hypertonic saline formulas

Hypertonic saline solution (Monafo)—Volume to maintain urine output at 30 mL/h; fluid contains 25 mEq Na/L

Modified hypertonic (Warden)—Lactated Ringer solution + 50 mEq NaHCO₃ (180 mEq Na/L) for 8 h to maintain urine output at 30–50 mL/h; lactated

Ringer solution to maintain urine output at 30–50 mL/h beginning 8 h postburn

Dextran formula (Demling)—Dextran 40 in saline: 2 mL/kg/h for 8 h; lactated Ringer solution: volume to maintain output at 30 mL/h; fresh frozen plasma: 0.5 mL/kg/h for 18 h beginning 8 h postburn

Source: Reproduced with permission from Warden GD: Burn shock resuscitation. *World J Surg* 16:16, 1992.

should have a Foley catheter placed and urine output monitored hourly, the goal being 30 mL/h in adults and 1.0 mL/kg per h in young children.

Patients with burns covering less than 50 percent TBSA usually can begin resuscitation via two large-bore peripheral intravenous lines. Upper extremities are preferable, even if the intravenous line must pass through burned skin or eschar. Patients with burns greater than 50 percent TBSA, or those who have associated medical problems, are at the extremes of age, or have concomitant inhalation injuries should have additional central venous access established with invasive hemodynamic monitoring.

Tetanus Prophylaxis

Burns are tetanus-prone wounds. The need for tetanus prophylaxis is determined by the patient's current immunization status.

Gastric Decompression

Many burn centers begin enteral feeding on admission. If patient transport is via air ambulance or is going to take more than a few hours, the safest course is usually to decompress the stomach with a nasogastric tube.

Pain Control

During the initial phase of burn care, medications should be given intravenously, as subcutaneous and intramuscular injections are variably absorbed. Pain control is best managed with intravenous doses of an opiate until analgesia is adequate without inducing hypotension.

Psychosocial Care

Psychosocial care should begin immediately. The patient and family must be comforted and given a realistic assessment regarding the prognosis of the burns. If the patient is a child, and if the circumstances of the burn are suspicious, physicians in all states are required by law to report any suspected case of child abuse to local authorities.

Care of the Burn Wound

After all other assessments have been completed, attention should be directed to the burn itself. If the patient is to be transferred within 24 h of injury, the wounds can be minimally dressed in gauze. However, the size of the burn should always be calculated to establish the proper level of fluid resuscitation, and pulses distal to circumferential deep burns should be monitored.

Escharotomy

Thoracic escharotomy. The adequacy of oxygenation and ventilation must be monitored continuously throughout the resuscitation period. Ventilation may be compromised by chest wall inelasticity related to a deep circumferential burn of the thorax. Pressures required for ventilation increase and arterial PCO₂ rises. When required, escharotomies are performed bilaterally in the anterior axillary lines. If there is significant extension of the burn onto the adjacent abdominal wall, the escharotomy incisions should be extended to this area by a transverse incision along the costal margins.

Escharotomy of the extremities. Edema formation in the tissues under the tight, unyielding eschar of a circumferential burn on an extremity may produce significant vascular compromise that, if left unrecognized and untreated, will lead to permanent, serious neuromuscular and vascular deficits. All jewelry must be removed from the extremities to avoid distal ischemia. Skin color, sensation, capillary refill, and peripheral pulses must be assessed hourly in any extremity with a circumferential burn. The occurrence of any of the following signs or symptoms may indicate poor perfusion of a distal extremity warranting escharotomy: cyanosis, deep tissue pain, progressive paresthesia, progressive decrease or absence of pulses, or the sensation of cold extremities. An ultrasonic flowmeter (Doppler) is a reliable means for assessing arterial blood flow, the need for an escharotomy, and also can be used to assess adequacy of circulation after an escharotomy.

When necessary, escharotomies may be done as bedside procedures with a sterile field and scalpel or electrocautery. Local anesthesia is unnecessary as full-thickness eschar is insensate; however, intravenous opiates or anxiolytics should be used. The incision, which must avoid major neurovascular and musculotendinous structures, should be placed along the mid-medial or mid-lateral aspect of the extremity. To permit adequate separation of the cut edges for decompression, the incision should be carried down through the eschar, which includes devitalized dermis, to the subcutaneous fat. The incision should extend the length of the constricting full-thickness burn and across involved joints. When a single escharotomy incision does not result in restoring adequate distal perfusion, a second escharotomy incision on the contralateral aspect of the extremity should be performed. Digital escharotomy is controversial in its efficacy and rarely required.

BURN SEVERITY

The severity of any burn injury is related to the size and depth of the burn, and to the part of the body that has been burned. Burns are the only truly quantifiable form of trauma. The single most important factor in predicting burn-related mortality, need for specialized care, and the type and likelihood of complications is the overall size of the burn as a proportion of the patient's TBSA. Treatment plans, including initial resuscitation and subsequent nutritional requirements, are directly related to the size of burn.

Burn Size

A general idea of the burn size can be made by using the rule of nines. Each upper extremity accounts for 9 percent of the TBSA, each lower extremity accounts for 18 percent, the anterior and posterior trunk each account for 18 percent, the head and neck account for 9 percent, and the perineum accounts for 1 percent. Although the rule of nines is reasonably accurate for adults, a number of more precise charts have been developed that are particularly helpful in assessing pediatric burns. For smaller burns, an accurate assessment of size can be made by using the patient's palmar hand surface, including the digits, which amounts to approximately 1 percent of TBSA.

Burn Depth

Along with burn size and patient age, the depth of the burn is a primary determinant of mortality. Burn depth is also the primary determinant of the patient's long-term appearance and functional outcome.

Burns not extending all the way through the dermis leave behind epithelium-lined skin appendages, including sweat glands and hair follicles with attached sebaceous glands. When dead dermal tissue is removed, epithelial cells swarm from the surface of each appendage to meet swarming cells from neighboring appendages, forming a new, fragile epidermis on top of a thinned and scarred dermal bed. Skin appendages vary in depth, and the deeper the burn, the fewer the appendages that contribute to healing, and the longer the burn takes to heal. The longer the burn takes to heal, the less dermis remains, the greater the inflammatory response, and the more severe the scarring.

With aggressive surgical treatment, an accurate estimation of burn depth is crucial. Burns that heal within 3 weeks usually do so without hypertrophic scarring or functional impairment, although long-term pigmentary changes are common. Burns that take longer than 3 weeks to heal often produce unsightly hypertrophic scars, frequently lead to functional impairment, and provide only a thin, fragile epithelial covering for many weeks or months. State-of-the-art burn care involves early excision and grafting of all burns that will not heal within 3 weeks. The challenge is to determine which burns will heal within 3 weeks, and are thus better treated by nonoperative wound care.

Burn depth is dependent on the temperature of the burn source, the thickness of the skin, the duration of contact, and the heat-dissipating capability of the skin. Burns are classified according to increasing depth as epidermal (first-degree), superficial and deep partial-thickness (second-degree), full-thickness (third-degree), and fourth-degree. Many burns have a mixture of clinical characteristics, making precise classification difficult.

Shallow Burns

Epidermal burns (first-degree). As implied, these burns involve only the epidermis. They do not blister, but become erythematous because of dermal vasodilation, and are quite painful. Over 2–3 days the erythema and pain subside. By about the fourth day, the injured epithelium desquamates in the phenomenon of peeling, which is well known after sunburn.

Superficial partial-thickness (second-degree). Superficial partial-thickness burns include the upper layers of dermis, and characteristically form blisters with fluid collection at the interface of the epidermis and dermis. When blisters are removed, the wound is pink and wet. The wound is hypersensitive, and the burns blanch with pressure. If infection is prevented, superficial partial-thickness burns heal spontaneously in less than 3 weeks, and do so without functional impairment. They rarely cause hypertrophic scarring, but in pigmented individuals the healed burn may never completely match the color of the surrounding normal skin.

Deep Burns

Deep partial-thickness (second-degree). Deep partial-thickness burns extend into the reticular layers of the dermis. They also blister, but the wound surface is usually a mottled pink-and-white color immediately after the injury because of the varying blood supply to the dermis (white areas have little to no blood flow and pink areas have some blood flow). The patient complains of discomfort rather than pain. When pressure is applied to the burn, capillary refill occurs slowly or may be absent. The wound often is less sensitive to pinprick than the surrounding normal skin. If not excised and grafted, and if infection is prevented, these burns will heal in 3–9 weeks, but invariably do so with considerable scar formation. Unless active physical therapy is continued throughout the healing process, joint function can be impaired, and hypertrophic scarring is common.

Full-thickness (third-degree). Full-thickness burns involve all layers of the dermis and can heal only by wound contracture, epithelialization from the wound margin, or skin grafting. They appear white, cherry red, or black, and may or may not have deep blisters. Full-thickness burns are described as being leathery, firm, and depressed when compared with adjoining normal skin, and they are insensate. The difference in depth between a deep partial-thickness burn and a full-thickness burn may be less than 1 mm. The clinical appearance of full-thickness burns can resemble that of deep partial-thickness burns. They may be mottled in appearance, rarely blanch on pressure, and may have a dry, white appearance. In some cases, the burn is translucent, with clotted vessels visible in the depths. Some full-thickness burns, particularly immersion scalds, have a red appearance and initially may be confused with superficial partial-thickness burns. However, they can be distinguished because they do not blanch with pressure. Full-thickness burns develop a classic burn eschar, a structurally intact but dead and denatured dermis that if left in situ over days and weeks, separates from the underlying viable tissue.

Fourth-degree. Fourth-degree burns involve not only all layers of the skin, but also subcutaneous fat and deeper structures. These burns almost always have a charred appearance, and frequently only the cause of the burn gives a clue to the amount of underlying tissue destruction. Electrical burns, contact burns,

some immersion burns, and burns sustained by patients who are unconscious at the time of burning may all be fourth-degree.

Assessment of Burn Depth

The standard technique for determining burn depth has been clinical observation of the wound. A burn is a dynamic process for the first few days; a burn appearing shallow on day 1 may appear considerably deeper by day 3. Furthermore, the kind of topical wound care used can dramatically change the appearance of the burn. Evaluation by an experienced surgeon regarding whether a partial-thickness burn will heal in 3 weeks is about 70 percent accurate. Other techniques to quantify burn depth involve (1) the ability to detect dead cells or denatured collagen (e.g., biopsy, ultrasound, and vital dyes), (2) assessment of changes in blood flow (e.g., fluorometry, laser Doppler, and thermography), (3) analysis of the color of the wound (e.g., light reflectance methods), and (4) evaluation of physical changes, such as edema (e.g., nuclear magnetic resonance imaging). Nonetheless, the most common modality of burn depth estimation used in state-of-the-art burn care today is still clinical observation.

THE PHYSIOLOGIC RESPONSE TO BURN INJURY

Burn patients with or without inhalation injury commonly manifest an inflammatory process involving the entire organism; the term systemic inflammatory response syndrome (SIRS) summarizes that condition. SIRS with infection (i.e., sepsis syndrome) is a major factor determining morbidity and mortality in thermally injured patients. Pathologic alterations of the metabolic, cardiovascular, gastrointestinal, and coagulation systems occur, with resulting hypermetabolism; increased cellular, endothelial, and epithelial permeability; classic hemodynamic alterations; and often extensive microthrombosis. The cardiovascular manifestations of SIRS largely disappear within 24–72 hours, but the patient remains in a hypermetabolic state until wound coverage is achieved.

Burn Shock

Burn shock is a complex process of circulatory and microcirculatory dysfunction that is not easily or fully repaired by fluid resuscitation. Tissue trauma and hypovolemic shock result in the formation and release of local and systemic mediators, which produce an increase in vascular permeability and microvascular hydrostatic pressure. Most mediators act to increase permeability by altering venular endothelial integrity. The early phase of burn edema, lasting from minutes to an hour, is attributed to mediators such as histamine, products of platelet activation, eicosanoids, and proteolytic products of the coagulation, fibrinolytic, and kinin cascades. Vasoactive amines may also act by increasing microvascular blood flow or vascular pressures, accentuating the burn edema.

In addition to the loss of microvascular integrity, thermal injury also causes changes at the cellular level. The reduction in cardiac output after burn injury is a result of cellular shock, hypovolemic shock, and increased systemic vascular resistance (SVR) because of sympathetic stimulation from the release of multiple mediators. The cardiac myocyte shock state is a result of impaired calcium homeostasis and subsequent intracellular signaling dysregulation.

Metabolic Response to Burn Injury

Hypermetabolism

Resting energy expenditure (REE) after burn injury can be as much as 100 percent above predictions based on standard calculations for size, age, sex, and weight. Some debate persists regarding the genesis of this phenomenon, but increased heat loss from the burn wound and increased beta-adrenergic stimulation are probably primary factors. On average, the REE is approximately 1.3 times the predicted basal metabolic rate (BMR) obtained using the Harris-Benedict equation.

Glucose metabolism is elevated in almost all critically ill patients, including those with burn injuries. Gluconeogenesis and glycogenolysis are increased in burn patients, as are plasma insulin levels. The basal rate of glucose production is elevated despite this hyperinsulinemic state. Hyperglycemia complicates the acute management of many significant burns and may be related to increased mortality and decreased graft take. Further, hyperglycemia may exacerbate muscle catabolism in burn patients although not influencing REE. Exogenous insulin administration to achieve euglycemia has been shown to decrease donor site healing time and decrease length of stay, although ameliorating skeletal muscle catabolism.

Lipolysis occurs at a rate in excess of the requirements for fatty acids as an energy source because of alterations in substrate cycling. In burn patients, the majority of released fatty acids are not oxidized, but rather re-esterified into triglycerides, resulting in fat accumulation in the liver. The acute and long-term consequences of this hepatic steatosis are unclear. β blockade using propranolol appears promising as a means to manipulate peripheral lipolysis and potentially prevent hepatic steatosis.

Proteolysis is increased in burn patients. Following utilization, protein is excreted primarily in the urine as urea. This results in an increased efflux of amino acids from the skeletal muscle pool, including the gluconeogenic amino acids alanine and glutamine (Gln). Protein intake greater than 1 g/kg per day has been recommended for all thermally injured patients, and for burn patients with normal renal function, the recommended protein intake is 2 g/kg per day. Beneficial effects of Gln supplementation, or its metabolic precursors, have been demonstrated in burn patients. The precise mechanisms by which direct and indirect Gln supplementation improves outcome remain unclear. The anabolic steroid oxandrolone also has been shown to improve donor-site healing time, diminish weight loss, and blunt protein catabolism during the acute phase of burn wound healing.

Neuroendocrine Response

Catecholamines are massively elevated following burn injury, and appear to be the major endocrine mediators of the hypermetabolic response in thermally injured patients. Pharmacologic beta-blockade using propranolol diminishes the intensity of postburn hypermetabolism. Conversely, growth hormone (GH) levels are attenuated following thermal injury. Although early studies of exogenous GH as an anticatabolic agent were promising in the pediatric population, ultimately its use has been supplanted by less expensive, safer, and equally effective pharmacotherapies such as propranolol and oxandrolone.

Immunologic Response to Burn Injury

The immune status of the burn patient has a profound impact on outcome in terms of survival and major morbidity. Many mediators are released from both injured and uninjured tissues at the wound site where they exert local and systemic effects. The timetable of induction/suppression and physiologic sequelae are similar in patients suffering thermal and nonthermal trauma.

FLUID MANAGEMENT

Proper fluid management is critical to survival following major thermal injury. An aggressive approach to fluid therapy has led to reduced mortality rates in the first 48 hours postburn; nonetheless, approximately 50 percent of the deaths still occur within the first 10 days after burn injury, owing to multiple-organ failure syndrome (MOFS) and overwhelming sepsis. One of the principal causes, particularly of MOFS, is inadequate fluid resuscitation and maintenance. Fluid management following successful resuscitation from burn shock is equally as important.

Burn Resuscitation

The primary goal of fluid resuscitation is to ensure end-organ perfusion by replacing fluid that is sequestered as a result of the thermal injury. Support of the burned patient in this manner is principally aimed at the first 24–48 hours after injury, when the rate of development of hypovolemia is maximal. A critical concept to understand is that massive fluid shifts occur even although total body water initially remains unchanged. What actually changes is the volume of each fluid compartment, with intracellular and interstitial volumes increasing at the expense of intravascular volume.

Multiple resuscitation formulas, employing various solutions at different volumes and rates, have evolved over time (see Table 7-1). However, neither consensus statements nor evidence-based guidelines have emerged demonstrating the superiority of one formula over another. Nonetheless, accepted recommendations continue to be that resuscitation should proceed in a manner sufficient to maintain end-organ perfusion and abrogate electrolyte disturbances, although being flexible and amenable to individual patient differences, regardless of the composition, volume, or infusion rate of the solution employed.

Special Considerations in Burn Shock Resuscitation

Pediatric fluid resuscitation. The burned child represents a special challenge, as resuscitation must be much more precise than that for an adult with a similar burn. Children weighing less than 20 kg have limited glucose reserves; as such, they require the addition of dextrose-based maintenance fluids to their calculated resuscitation volumes, or profound hypoglycemia will ensue. Further, children require relatively more fluid for burn shock resuscitation than adults, with fluid requirements for children averaging approximately 6 mL/kg/ % TBSA. This is most likely reflective of the near twofold increase in urine output (1.0–1.5 mL/kg body weight per h) required to ensure adequate end-organ perfusion in children. Finally, children commonly require formal resuscitation for relatively small burns of 10–20 percent TBSA.

Inhalation injury. Inhalation injury undoubtedly increases the fluid requirements for successful resuscitation following thermal injury, with volumes of

approximately 1.5 times compared to patients without inhalation injury. Inhalation injury accompanying thermal trauma increases the magnitude of the total body injury via disproportionate increases in systemic inflammation.

Invasive hemodynamic monitoring. The use of pulmonary artery catheters (PACs), with or without goal-directed therapy, has not typically been part of burn shock resuscitation. Nonetheless, certain patients may benefit from invasive hemodynamic monitoring to try and precisely direct their resuscitation. It is generally accepted that patients with known significant premorbid cardiac or pulmonary disease, associated inhalation injury, or concomitant nonthermal trauma, and older adults might require PAC monitoring during burn resuscitation. Goal-directed, hemodynamic resuscitation in burn patients has met with mixed results. It is likely that attainment of hemodynamic goals merely represents sufficient physiologic reserve to survive the injury, and not specific salutary effects of the therapy. In fact, hemodynamic resuscitation of burn shock is universally associated with substantially increased fluid volumes and predisposes to complications of overresuscitation.

Overresuscitation. Failure to institute appropriate early fluid resuscitation following thermal injury is associated with substantially worse outcomes. With modern burn care, this has become the rare exception, and in fact, many burn patients may actually be overresuscitated. Specific complications have emerged that appear to only be attributable to excessive resuscitation, namely abdominal compartment syndrome (ACS). ACS is preventable and iatrogenic in the vast majority of patients, owing to injudicious resuscitation. Early and appropriate resuscitation following major thermal injury is of paramount importance to ensure a good outcome; however, overresuscitation may produce complications that nullify the gains.

Choice of Fluids and Rate of Administration

Most patients can be resuscitated with crystalloid, specifically LR solution. Normal saline should be avoided, as the volumes required for resuscitation invariably lead to a complicating hyperchloremic metabolic acidosis. In patients with massive burns, young children, and burns complicated by severe inhalation injury, a combination of crystalloid and colloid can be used to achieve the desired goal of end-organ perfusion while minimizing edema.

Resuscitation formulas (see Table 7-1) should only be considered general guidelines for burn shock resuscitation. Ultimately, the volume and rate of infused fluid should maintain a urine output of 30 mL/h in adults (approximately 0.5 mL/kg per h), with lower limits acceptable in the face of known renal insufficiency, and 1.0 to 1.5 mL/kg per h in children. Resuscitation is considered successful when there is no further accumulation of edema, usually between 18 and 24 h postburn, and the volume of infused fluid required to maintain adequate urine output approximates the patient's maintenance fluid volume, which is normal maintenance volume plus evaporative water loss.

Fluid Replacement Following Burn Shock Resuscitation

Colloid replacement should be used sparingly, in the form of albumin, and only after 24 hours postburn. The total daily maintenance fluid requirement in

the adult patient is calculated by the following formula, where m^2 is square meters of TBSA:

$$\begin{aligned} \text{Total maintenance fluid} = & (1500 \text{ mL}/m^2) + \text{evaporative water loss} \\ & \times [(25 + \%TBSA \text{ burn} \times m^2 \times 24)] \end{aligned}$$

A general guideline is that a patient will require approximately 1.5 times their normal maintenance fluids.

After initial resuscitation, urine output alone is an unreliable guide to sufficient hydration. Adult patients with major thermal injuries require a urine output of approximately 1000 to 1500 mL/24 h; children require approximately 3 to 4 mL/kg per h averaged over 24 h.

INHALATION INJURY

Of some 45,000 fire victims admitted to hospitals each year, approximately 30 percent sustain an inhalation injury. CO poisoning, thermal injury, and smoke inhalation are three distinct aspects of clinical inhalation injury. Although the symptoms and treatment of each vary, the distinct injuries may coexist and require concomitant treatment.

Carbon Monoxide Poisoning

The majority of house fire deaths can be attributed to CO poisoning. CO is a colorless, odorless, and tasteless gas with an affinity for hemoglobin (Hb) approximately 200 times that of oxygen. CO reversibly binds to Hb to form carboxyhemoglobin (COHb), which interferes with oxygen delivery to the tissues. The half-life ($T_{1/2}$) of COHb when breathing room air is approximately 4 h. On 100 percent oxygen, the $T_{1/2}$ is reduced to 45–60 minutes. In a hyperbaric oxygen chamber at 2 atm, it is approximately 30 minutes, and at 3 atm it is about 15–20 minutes.

Levels of COHb are easily measured, but the degree of impairment may not directly correlate with blood levels. A COHb less than 10 percent typically does not cause symptoms. At approximately 20 percent, healthy persons complain of headache, nausea, vomiting, and loss of manual dexterity. At approximately 30 percent, patients become weak, confused, and lethargic. At 40–60 percent, the patient lapses into a coma, and levels greater than 60 percent are usually fatal.

Diagnosis and Treatment

Patients burned in an enclosed space or having any signs or symptoms of neurologic impairment should be placed on 100 percent oxygen via a nonre-breather face mask while waiting for measurement of COHb levels. The use of pulse oximetry (SpO_2) to assess arterial oxygenation in the CO-poisoned patient is contraindicated, as the COHb results in erroneously elevated SpO_2 measurements. If intubation is required, then hyperventilation with 100 percent oxygen should be instituted. The use of hyperbaric oxygen (HBO) therapy remains controversial. HBO therapy in burn patients with CO poisoning is of unknown therapeutic value or efficacy, and should only be used when: (1) the COHb is greater than 25 percent, (2) a neurologic deficit exists, (3) no

formal burn resuscitation is required (typically TBSA <10–15 percent), (4) pulmonary function is stable with an intact airway, and (5) interfacility transfer does not compromise burn care.

Thermal Airway Injury

The term “pulmonary burn” is a misnomer. True thermal damage to the lower respiratory tract and pulmonary parenchyma is extremely rare, unless live steam or exploding gases are inhaled.

Thermal injury to the respiratory tract is usually immediate and manifests as mucosal and submucosal erythema, edema, hemorrhage, and ulceration. It is usually limited to the upper airway (above the vocal cords) and proximal trachea for two reasons: (1) the oropharynx and nasopharynx provide an effective mechanism for heat exchange; and (2) sudden exposure to hot air typically triggers reflex closure of the vocal cords.

Patients with the greatest risk of upper airway obstruction from thermal airway injury are those injured in an explosion, with burns of the face and upper thorax, or those who have been unconscious in a fire. The presence of significant intraoral and pharyngeal injury is a clear indication for immediate endotracheal intubation.

Smoke Inhalation

Hundreds of toxic products are released during combustion (flaming) or pyrolysis (smoldering), depending on the type of fuel burned, the oxygen content of the environment, and the actual temperature of burning. Some 280 toxic substances have been identified in wood smoke alone. Petrochemical science has produced a wealth of plastic materials used in homes and automobiles, that when burned, produce nearly all of these substances, and many other products not yet characterized. Prominent by-products of incomplete combustion are oxides and hydrogenated moieties of sulfur and nitrogen, and numerous aldehydes.

After inhalation, highly soluble acidic and basic compounds rapidly dissolve in the water lining the mucosa of the respiratory tract, causing direct epithelial injury, manifested as epithelial edema, submucosal hemorrhage, and necrosis. Epithelial injury can occur at all levels of the respiratory tract, from oropharynx to alveolus. Although the chemical mechanisms of injury may be different among toxic products, the overall end-organ response is relatively homogeneous. There is an immediate loss of bronchial epithelial cilia and decreased alveolar surfactant levels. Atelectasis results, compounded by small-airway edema, and is only slowly reversed by normal ventilation. This regional hypoventilation results in worsening atelectasis, intrapulmonary shunt, and subsequent hypoxemia. Wheezing and air hunger are common early manifestations of inhalation injury.

Much of the pulmonary response appears to be related more to the severity of an associated cutaneous burn than to the degree of smoke inhalation. Without associated cutaneous thermal injury, the mortality from isolated inhalation injury is quite low. Symptomatic treatment usually leads to complete resolution of symptoms in a few days. However, in the presence of burns, inhalation injury approximately doubles the mortality rate from burns of any size.

Diagnosis

Anyone with a flame burn sustained in an enclosed space should be assumed to have an inhalation injury until proven otherwise. In obtaining a history, emphasis should be placed on findings specific to the smoke exposure and to the type of therapy instituted prior to hospitalization. The duration of exposure correlates with the severity of lung injury.

A thorough examination should be performed and include evaluation of the face and oropharyngeal airway for hoarseness, stridor, edema, or soot impaction suggesting injury; chest auscultation for wheezing or rhonchi suggesting injury to distal airways; level of consciousness associated with decreased hypoxemia, CO poisoning, or cyanide poisoning; and testing for the presence of neurologic deficits associated with CO. Copious mucus production and carbonaceous expectorated sputum are hard signs of inhalation injury, but their absence does not rule out injury. An elevated COHb or any symptoms of CO poisoning are presumptive evidence of associated smoke inhalation. Anyone suspected of smoke inhalation should have an arterial blood gas drawn. One of the earliest indicators of injury is a decreased P-to-F ratio.

The early need for bronchoscopic evaluation and diagnosis remains controversial. Aside from documenting the presence of edema, tracheal erythema, and/or carbon deposits, fiberoptic bronchoscopy (FOB) does not materially influence the treatment of smoke inhalation. It is operator-dependent, not risk-free, and yield with FOB appears to be strongly dependent on clinical suspicion of inhalation injury. Given these limitations, it is recommended that a history, physical examination, and laboratory studies be used to make the diagnosis of inhalation injury, and the use of FOB be reserved for exceptional cases requiring therapeutic FOB (e.g., expansion of lobar collapse or removal of obstructing intrabronchial secretions or casts).

Treatment

Upper airway. No standard treatment has evolved to ensure survival after smoke inhalation. In the presence of increasing oropharyngeal and laryngeal edema, rapid endotracheal intubation is indicated. A tracheostomy is never an emergency procedure and should not be used as the initial step in airway management. The incidence of postextubation stridor in burn victims is as high as 47 percent. The treatment of postextubation stridor includes the administration of nebulized racemic epinephrine and helium-oxygen (heliox) mixtures. Steroids are never indicated.

Lower airway and alveoli. Tracheobronchitis, commonly seen with inhalation injury, produces wheezing, coughing, and retained secretions. The ventilation-perfusion mismatch present in these patients can result in mild to moderate hypoxemia, varying with the degree of premorbid lung disease; therefore supplemental oxygen should be administered routinely. Although a trial of bronchodilators is indicated in patients with premorbid bronchospastic disease, the overall efficacy is questionable.

The usual presenting sign of distal airway injury is hypoxemia. Upper airway patency absolutely must be assured, and airway resistance minimized. Overall treatment for smoke inhalation is supportive, with the goal being maintenance of adequate oxygenation and ventilation until the lungs heal. The need for mechanical ventilation is determined by refractory hypoxemia. The precise mode of initial mechanical ventilation appears less important than ensuring a lung protective strategy.

Elective tracheostomy in burn patients remains controversial. Nonetheless, if the upper airway is in danger of imminent obstruction and endotracheal intubation attempts are unsuccessful, emergent cricothyroidotomy is indicated, with conversion to a formal tracheostomy soon thereafter. For patients requiring prolonged endotracheal intubation, tracheostomy should be performed at the discretion of the managing burn surgeon. There is no outcome benefit to early tracheostomy in burn patients.

Prophylactic antibiotics are not indicated with inhalation injury, which is a chemical pneumonitis. Subsequent burn wound management and treatment of eventual bacterial pneumonia may be made more difficult with the early use of antibiotics, as it rapidly leads to the selection of resistant organisms. Likewise, steroids are contraindicated with inhalation injury.

WOUND MANAGEMENT

Early Excision and Grafting

For deeper burns (i.e., deep partial-thickness and full-thickness burns), rather than waiting for spontaneous separation, the eschar is surgically removed and the wound closed via grafting techniques and/or immediate flap procedures tailored to the individual patient. This aggressive surgical approach to burn wound management is known as early excision and grafting (E&G). The optimal timing of early E&G has yet to be definitively determined; however, E&G within 3–7 days, and certainly by 10 days, following injury appears prudent. Early E&G has reduced burn mortality more than any other intervention. Early wound closure also reduces hospital stay, duration of illness, septic complications, and the need for major reconstruction, although decreasing hospital costs.

Current Status of Wound Care

Solid clinical and experimental evidence support the following conclusions:

1. Small (i.e., <20 percent) full-thickness burns and burns of indeterminate depth, if treated by an experienced surgeon, can be safely excised and grafted with a decrease in hospital stay, costs, and time away from work or school.
2. Early E&G dramatically decreases the number of painful débridements required.
3. Patients with burns of 20–40 percent TBSA will have fewer infectious wound complications if treated with early E&G.
4. In animal models, the immunosuppression and hypermetabolism associated with burns can be ameliorated by early burn wound removal.

Clinical impressions, without hard data supporting them, include the following:

1. Scarring is less severe in wounds closed early, leading to better appearance and fewer reconstructive procedures. There is no good measure of “acceptable” cosmetic appearance, and comparative studies await a consistent scale to measure results.
2. Mortality from wound infection is lower in patients with major burns after early excision. Because wounds exceeding donor skin availability cannot be closed completely until donor sites can be reharvested, definitive proof will come only when a durable permanent covering (i.e., skin substitute) can be applied in a timely fashion.

3. Mortality from other complications of major burns may be lower with early E&G. Ameliorating the stress, hypermetabolism, and overall bacterial load of the patients enables them to resist other complications. The only data to support this conclusion come from animal studies.

Technical Considerations

Excision of greater than 10 percent of TBSA should be done in a highly structured environment, preferably a dedicated burn center. Blood loss can be massive, and graft loss can be catastrophic. Smaller burns in important areas (e.g., hands, face, and feet) also require considerable experience. Excisional procedures should be performed as early as possible after the patient is stabilized, usually within a week of injury. Any burn projected to take longer than 3 weeks to heal is a candidate for E&G within the first postburn week.

Excision can be performed to include the burn and subcutaneous fat to the level of the investing fascia (fascial excision), or by tangentially removing thin slices of burned tissue until a viable bed remains (tangential excision). Fascial excision assures a viable bed for grafting, but takes longer, sacrifices potentially viable tissue, and leaves a permanent cosmetic defect. Tangential excision can create massive blood loss and risks grafting on a bed of uncertain viability, but sacrifices minimal living tissue, and leads to a superior cosmetic result. Fascial excisions are typically reserved for deeper burns; however, they can be useful in other selected patients.

If careful attention is given to sound principles of plastic surgery, the risk that there will be a need for subsequent reconstruction can be decreased. Split-thickness skin graft (STSG) junctures should be avoided over joints, and grafts should be placed transversely when possible. Adjacent pieces of STSG should be approximated carefully with a small amount of overlap. Thick STSGs (e.g., >0.015 inch) typically yield a better appearance than do thin grafts (e.g., >0.010 inch). With larger burns (>20 percent TBSA), STSGs are meshed to allow greater wound coverage per graft. However, if at all possible, cosmetically important areas should be grafted with a single sheet of STSG.

Donor Sites

As aggressive programs of early E&G developed, care and healing of donor sites became a priority. Donor sites are quite painful as they are a superficial partial-thickness injury, and appropriate dressings diminish donor site pain. Reports indicate that there is no optimal donor site dressing; however, moist wound healing is superior to dry wound healing.

Healed donor sites are still not free of complications. In addition to hypertrophic scarring and pigmentation changes, blistering for several weeks may trouble patients. Blisters are self-limiting and treated with bandages or ointments until they re-epithelialize. Donor site infections occur in approximately 5 percent of patients and can be devastating, with conversion of a partial-thickness to a full-thickness wound requiring a STSG for closure. Infection is treated aggressively with systemic and topical antibiotics.

Skin Substitutes

The ideal skin substitute must be permanent, affordable, resist hypertrophic scarring, provide normal pigmentation, and grow with developing children; however, it has yet to be developed.

Dermal Substitutes

The development of dermal substitutes has added greatly to the capabilities of the burn surgeon, especially when faced with a large burn and limited donor sites. They readily facilitate complete excision of the entire burn with wound closure. Depending on the product, grafting with STSG may be immediate or delayed until the dermal substitute has engrafted. Currently three dermal substitutes are available in the United States: INTEGRA, AlloDerm, and Dermagraft. These products are fundamentally similar in that they allow for the creation of a “neo-dermis” populated by the patient’s own mesenchymal cells on which a thin STSG is placed. The use of thinner STSG allows for earlier re-cropping of donor sites, quicker closure of the complete burn, and less donor site scarring. Successful use of any one of the available dermal substitutes is technique-dependent and associated with a learning curve.

Cultured Skin

Apligraf is a Food and Drug Administration (FDA)-approved biologic dressing composed of cultured neonatal keratinocytes and fibroblasts. This allograft bioengineered product has been approved for use in chronic nonhealing ulcers, but has not yet been widely marketed for the burn patient.

Epicel is currently the only FDA-approved cultured epithelial autograft (CEA) product available. These grafts are created from a full-thickness biopsy of the patient’s own skin and require 3 weeks to grow. They are quite expensive at approximately \$14,500 for 750 cm².

NUTRITIONAL SUPPORT

The nutritional effects of the hypermetabolic response to thermal injury are manifested as exaggerated energy expenditure and massive nitrogen loss. Nutritional support is aimed at provision of calories to match energy expenditure, although providing enough nitrogen to replace or support body protein stores.

Caloric Requirements

The magnitude of increase in the metabolic rate following thermal injury is directly proportional to the TBSA of the burn. The total energy expenditure may be elevated anywhere from 15–100 percent above basal needs. Mathematical formulas exist for the calculation of daily caloric requirements in burn patients. The formula most widely used is Long’s modification of the Harris-Benedict equation (Table 7-2). Periodic determination of resting energy expenditure (REE) via indirect calorimetry may be used to allow more accurate adjustments of caloric provision. Total urine nitrogen (TUN) excretion is easy to measure, and accurately reflects the degree of catabolism. The TUN should be monitored regularly, with the goal being a persistently positive nitrogen balance. Various visceral proteins are commonly measured, typically as part of a “nutrition panel,” to assess ongoing nutritional status.

TABLE 7-2 Long Modification of the Harris-Benedict Equation

Men

$BMR = (66.47 \pm 13.75 \text{ weight} \pm 5.0 \text{ height} = 6.76 \text{ age})$
 $\times (\text{activity factor}) \times (\text{injury factor})$

Women

$BMR = (655.10 \pm 9.56 \text{ weight} + 1.85 \text{ height} = 4.68 \text{ age})$
 $\times (\text{activity factor}) \times (\text{injury factor})$

Activity factor

Confined to bed: 1.2
 Out of bed: 1.3

Injury factor

Minor operation: 1.20
 Skeletal trauma: 1.35
 Major sepsis: 1.60
 Severe thermal burn: 1.5

BMR = basal metabolic rate.

Carbohydrates

Carbohydrates, in the form of glucose, appear to be the best source of non-protein calories in the thermally injured patient. Provision of glucose to obligate tissues occurs at the expense of lean body mass (i.e., skeletal muscle) if adequate nutrition is not provided. The wound uses glucose by anaerobic glycolytic pathways, producing large amounts of lactate as an end product. In the liver, lactate is extracted and used for gluconeogenesis via the Cori cycle. Concomitantly, alanine, Gln, and other amino acids contribute to the increased gluconeogenesis. Increased ureagenesis, with urea derived from body protein stores, parallels the rise in hepatic glucose production. The hyperglycemia observed in burn patients is a consequence of accelerated glucose flux, not decreased peripheral utilization.

Because glucose that is obtained via gluconeogenic pathways ultimately derives from protein stores, depletion of body protein during burn hypermetabolism leads to energy deficits, malfunctioning of glucose-dependent energetic processes, and skeletal muscle wasting. High-carbohydrate enteral nutrition formulations appear to blunt this catabolism, resulting in skeletal muscle sparing. Optimal glucose oxidation during burn hypermetabolism occurs at intakes of approximately 5 mg/kg per min.

Protein

Combining glucose and protein-containing nutrients improves nitrogen balance and allows more calories to be used for the restoration of nitrogen balance than would be possible if either nutrient were used alone. Protein administration promotes synthesis of visceral and muscle protein, without appreciably affecting the rate of catabolism. Exogenous glucose retards catabolism, but exerts little effect on protein synthesis. Both mechanisms improve nitrogen balance, and sufficient glucose (approximately 7 g/kg per day) and protein (approximately 2 g/kg per day) should be components of the nutritional regimen for the severely burned catabolic patient.

The importance of Gln as a metabolic fuel source has been recognized, and it is considered a conditionally essential amino acid. During critical illness, circulating concentrations of Gln fall. Gln supplementation has been associated with improved outcomes following thermal injury.

Fat

The role of fat as a source of nonprotein calories is dependent on the extent of injury and associated hypermetabolism. Following significant thermal injury, there are alterations in substrate cycling and fatty acid oxidation that favor re-esterification and hepatic deposition of triglycerides. Fat appears to be a poor caloric source overall, and especially for the maintenance of nitrogen equilibrium and lean body mass, in burn-induced hypermetabolism. Patients with only moderate elevations in metabolic rate can use lipid calories efficiently, but these patients rarely require nutritional support.

Even more important than their energy inefficiency, fats appear to affect outcome following thermal injury. Patients fed low-fat enteral diets had fewer infectious complications, improved wound healing, shorter lengths of stay, and apparently reduced mortality compared to controls fed standard, relatively high-fat, enteral diets.

Vitamins and Minerals

Vitamin requirements in critically ill, hypermetabolic burn patients remain poorly defined. The fat-soluble vitamins (A, D, E, and K) are extensively stored in fat depots and are only slowly depleted during prolonged feeding of vitamin-free solutions. The water-soluble vitamins (B complex and C) are not stored in appreciable amounts, and are rapidly depleted. All vitamins should be supplemented. The dosage guidelines of the National Advisory Group/American Medical Association (NAG/AMA) are reasonable for burn patients unless symptoms of deficiency occur, with the exception of vitamin C. Vitamin C has an essential role in wound repair, and it is prudent to supplement the NAG/AMA recommended dose with approximately 1000 mg of vitamin C daily. Of note, all commercially available enteral feeding formulations meet NAG/AMA recommendations for vitamins and minerals.

Minerals and trace elements are essential because of their role in metabolic processes. Frequent determinations of serum levels are the best guides to electrolyte replacement. Less is known about trace element requirements after thermal injury. Zinc deficiency has been documented in burn patients; thus, empiric zinc supplementation is warranted following major burns.

Route of Administration

The route of nutritional support is important because it directly influences outcome. Total enteral nutrition (TEN) is the overwhelmingly favored mode of alimentation in the severely burned. Total parenteral nutrition (TPN) is used only when complete enteral failure is encountered, as TPN is associated with increased mortality.

In severely burned patients, gastroparesis may limit intragastric nutritional support, particularly in the early postburn period. However, immediate intragastric feeding appears to limit gastroparesis and is unquestionably safe. Even in the face of intragastric feeding intolerance, TEN should not be abandoned. Postpyloric feeding tends to work well in the burn patient with gastroparesis. Prokinetics should be used as needed.

Composition of Enteral Nutrition

In burn patients, a high-protein, high-carbohydrate, low-fat diet with fiber is optimal. As noted earlier, appropriate supplements to include Gln, vitamins,

minerals, and trace elements are indicated, and add to the benefits of TEN. Immune-enhancing diets (e.g., IMPACT) offer no clear advantage over standard high-protein formulas in the burn population. Monitoring of TEN to assess tolerance and effectiveness is as important as the selection of the formula or timing of initiation. Careful nutrition and metabolic assessment can help ensure optimal support with minimal complications. Although superior to TPN, TEN still has associated complications, and any evidence of feeding intolerance should be actively investigated.

INFECTION

Infectious mortality following thermal injury has significantly declined over the past 2 decades, with the greatest reduction attributed to early E&G. However, following successful resuscitation, most acute morbidity and virtually all mortality in severely burned patients are still related to infection. Nonetheless, prophylactic systemic antibiotics are not part of modern burn care, as they do not reduce septic complications and only lead to increased bacterial resistance.

Risk Factors for Infection

The extent of burn injury as determined by TBSA is one of the major determinants of overall outcome, and the incidence of infection correlates with burn severity. Children appear to be more susceptible to systemic infection than adults for any given size burn. However, burns involving less than 20 percent TBSA in otherwise healthy individuals are rarely associated with life-threatening infection. The presence of an inhalation injury strongly correlates with infection, particularly pneumonia. Premorbid diabetes significantly increases infection rates following thermal injury, especially when coupled with poor glycemic control. Age is not an independent risk factor for infection following thermal injury.

Clinical Manifestations and Diagnosis

Hyperthermia, tachycardia, increased ventilation, and high cardiac output are part of the normal response to major burns in otherwise healthy patients.

The most important observations are related to the temporal association of physiologic events. Abrupt onset of hyperglycemia, fall in blood pressure, and decrease in urinary output should suggest the possibility that the patient is becoming unstable. If these findings are associated with development of hypothermia, feeding intolerance, and/or a falling platelet count, the patient is probably developing sepsis. Even with firm clinical evidence of sepsis, a definitive microbiologic diagnosis of infection can sometimes be difficult to obtain.

Specific Infections

Wound Infection

All burn wounds become colonized by 72 hours after injury with the patient's own flora or with endemic organisms from the treatment facility. Bacteria colonize the surface of the wound and may penetrate the avascular eschar. This colonization is invariable and without clinical significance; hence, routine early wound cultures are not efficacious and only increase costs. Bacterial proliferation may occur beneath the eschar at the viable-nonviable tissue interface,

leading to eschar separation if early E&G is not practiced. In a few patients, microorganisms may breach this barrier and invade the deeper underlying viable tissue, producing wound sepsis.

The essential pathologic feature of burn wound sepsis is invasion of organisms into viable tissue, which is diagnosed via biopsy and quantitative tissue culture demonstrating greater than 105 organisms per g of tissue. Any organisms capable of invading tissue can produce burn wound sepsis. The likelihood of sepsis increases in proportion to the size of the wound. Superficial wound swab cultures should never be used to evaluate potential invasive burn wound infection. Once the diagnosis of burn wound sepsis is confirmed, appropriate parenteral antibiotics should be administered and the wound promptly excised.

Before the introduction of effective topical antimicrobial agents, up to 60 percent of the deaths in burn centers were caused by burn wound sepsis. The three agents with proven broad-spectrum antimicrobial activity when applied to the burn wound are silver sulfadiazine (SSD), mafenide acetate, and silver nitrate (Table 7-3). SSD is the most common agent used in burn centers and has antifungal properties in addition to good bacterial coverage. However, SSD does not penetrate eschar. Only mafenide acetate is able to penetrate eschar, and it is the only agent capable of suppressing dense subeschar bacterial proliferation. The main disadvantage of mafenide acetate is its carbonic anhydrase inhibition, which may produce a hyperchloremic metabolic acidosis. However, this is typically of little clinical consequence. Silver nitrate must be used before bacteria have penetrated the wound. Its disadvantages are the associated electrolyte imbalances and methemoglobinemia. Since the introduction of effective topical therapy, fungal burn wound infections, primarily involving highly invasive *Phycomycetes* and *Aspergillus* organisms, have increased.

A newly emerging variant of burn wound infection, the "melting graft-wound syndrome," was recently reported and involves progressive epithelial loss (melting) from a previously well-taken graft, healed burn wound, or healed donor site. These infections have potentially devastating consequences. As such, appropriate systemic antibiotics, topical antibiotics, and aggressive wound care are mandatory for effective treatment. Reexcision and grafting rarely are required for salvage.

Pneumonia

One result of the prolonged and improved survival of severely burned patients is that the respiratory tract has become the most common source of infection. It is generally agreed that inhalation injury increases the risk of developing pneumonia.

The diagnosis of pneumonia is confirmed by the presence of characteristic infiltrates on chest radiographs and positive cultures. The most efficacious and sensitive method of obtaining tracheobronchial specimens for microbiologic analysis remains controversial. Regardless of specimen collection methodology, colonization of the upper airway in patients requiring mechanical ventilation should not be confused with a respiratory tract infection.

Single-agent therapy is generally appropriate and efficacious regardless of the pathogen, including *Pseudomonas aeruginosa*. Pneumonia still carries a significant mortality rate of approximately 25 percent in mechanically ventilated burn patients. Prophylactic antibiotics should not be used, as they only select for resistant organisms and do not reduce the incidence of pneumonia. Likewise, early tracheostomy does not lower pneumonia rates in either children or adults suffering major thermal injury. Consistent infection control

TABLE 7-3 Topical Antimicrobial Agents for Burn Wound Care

Silver nitrate	Mafenide acetate	Silver sulfadiazine
Active component		
0.5 percent in aqueous solution	11.1 percent in water-miscible base	1.0 percent in water-miscible base
Spectrum of antimicrobial activity		
Gram-negative—good	Gram-negative—good	Gram-negative—variable
Gram-positive—good	Gram-positive—good	Gram-positive—good
Yeast—good	Yeast—poor	Yeast—good
Method of wound care		
Occlusive dressings	Exposure	Exposure or single-layer dressings
Advantages		
Painless	Penetrates eschar	Painless
No hypersensitivity reaction	Wound appearance readily monitored	Wound appearance readily monitored when exposure method used
No gram-negative resistance	Joint motion unrestricted	
Dressings reduce evaporative heat loss	No gram-negative resistance	Easily applied
Greater effectiveness against yeasts		Joint motion unrestricted when exposure method used
		Greater effectiveness against yeast
Disadvantages		
Deficits of sodium, potassium, calcium, and chloride	Painful on partial-thickness burns	Neutropenia and thrombocytopenia
No eschar penetration	Susceptibility to acidosis as a result of carbonic anhydrase inhibition	Hypersensitivity—infrequent
Limitation of joint motion by dressings	Hypersensitivity reactions in 7% of patients	Limited eschar penetration
Methemoglobinemia—rare		
Argyria—rare		
Staining of environment and equipment		

practices and timely extubation seem to be the only effective means to lower the incidence of pneumonia.

Vascular Catheter-Related Infections

The incidence of peripheral suppurative thrombophlebitis following thermal injury is miniscule in the modern era, as saphenous venous cutdowns have been abandoned and standard line care is routine. The true incidence of central line sepsis in burn patients is unknown. Nonetheless, routine central venous catheter changes without evidence of infection are probably unwarranted and only increase complication rates; there are no conclusive data in the burn literature to support routine catheter changes. Contrary to popular belief, the specific central line site does not appear to influence infection rates in the burn

patient. However, the distance from the burn wound does appear to correlate inversely with infection, and every effort should be made to place intravenous lines as far from the burn as possible.

ELECTRICAL INJURY AND BURNS

Electrical injuries are particularly dangerous, as they can be instantaneously fatal and also put rescuers in significant danger. Injury severity depends on the amperage of the current, the pathway of current through the victim's body, and the duration of contact with the source. Electrical current sources are typically classified as either low- or high-voltage, with 1000 volts (V) being the dividing line, and distinct injuries are associated with each type. Over 95 percent of all electrical injuries and electrical burns are caused by low-voltage commercial alternating current in the range of 0–220 V. An electrical burn potentially has three different components: (1) the true electrical injury from current flow, (2) an arc or flash flame injury produced by current arcing at a temperature of approximately 4000°C (7232°F) from its source to ground, and (3) a flame injury from the ignition of clothing or surroundings.

Acute Management and Multisystem Involvement

Electrical burns are thermal injuries from very intense heat and from electrical disruption of cell membranes. As electrical current meets tissue, it is converted to heat in direct proportion to the amperage of the current and the resistance of the tissues through which it passes. The smaller the size of the body part through which the electricity passes, the more intense the heat and the less the heat is dissipated into surrounding tissue. Fingers, hands, forearms, feet, and lower legs are frequently totally destroyed by high-voltage injuries. Areas of larger volume, like the trunk, usually dissipate enough current to prevent extensive damage to viscera unless the contact point(s) are on the abdomen or chest. Although cutaneous manifestations of electrical burns may appear limited, burned skin should not be considered the only injury, as massive underlying tissue destruction may be present. Resuscitation needs are usually far in excess of what would be expected on the basis of the cutaneous burn size, and associated flame and/or flash burns often compound the problem.

Myoglobinuria frequently accompanies electrical burns, but the clinical significance appears to be minimal, as modern burn resuscitation protocols alone appear to be sufficient treatment for myoglobinuria. Cardiac damage may be present, most commonly with conduction system derangements. Even with high-voltage injuries, a normal cardiac rhythm on admission generally means that subsequent dysrhythmia is unlikely.

The nervous system is exquisitely sensitive to electricity. The most devastating injury with frequent brain damage occurs when current passes through the head, but spinal cord damage is possible whenever current has passed from one side of the body to the other. Delayed transverse myelitis can occur days or weeks after injury. Anterior spinal artery syndrome from vascular dysregulation can also precipitate spinal cord dysfunction. Damage to peripheral nerves is common and may cause permanent functional impairment. Persistent neurologic symptoms may lead to chronic pain syndromes, and posttraumatic stress disorders are apparently more common after electrical burns than thermal burns.

Cataracts are a well-recognized sequela of high-voltage electrical burns. They occur in 5–7 percent of patients, frequently are bilateral, occur even in the absence of contact points on the head, and typically manifest within 1–2 years of injury.

Wound Management

There are two unique situations in which immediate surgical treatment is indicated for patients with electrical burns. Rarely, massive deep tissue necrosis will lead to acidosis or myoglobinuria that will not resolve with standard resuscitation techniques; major débridement and/or amputation may be necessary as an emergency procedure. More commonly, injured deep tissues undergo significant swelling, increasing the risk of compartment syndrome, and potentially leading to further tissue loss. Escharotomies and fasciotomies should be performed at compartment pressures of 30 mmHg or more, or with clinical indications of compartment syndrome. Any progression of median or ulnar nerve deficit in a hand that has been electrically burned is an indication for immediate median and ulnar nerve release at the wrist. If immediate decompression or débridement is not required, definitive surgical procedures can be done in the usual time frame, between days 3 and 5.

CHEMICAL BURNS

Strong acids or alkalis cause most chemical burns. They typically are associated with industrial accidents, assaults, or the improper use of harsh household solvents and cleaners. In contrast to thermal injury, chemical burns cause progressive damage and injury until the chemicals are inactivated by reaction with tissues or diluted by therapeutic irrigation. Acid burns typically are more self-limiting than alkali burns. Acids tend to “tan” the skin, creating an impermeable barrier of coagulation necrosis debris along the leading edge of the chemical burn that limits further penetration. Alkalis combine with cutaneous lipids to create a soap, and are thus able to continue dissolving the skin until they are neutralized.

Initial Care

All involved clothing should be removed, and unlike thermal injury, the burns should be irrigated with copious amounts of tepid water. Irrigating for at least 15 minutes under a running stream of tepid water may limit the overall severity of the burn; however, care should be taken to avoid hypothermia. Neutralizing agents or antidotes are contraindicated, except with hydrofluoric acid burns. Delay deepens the chemical burn, and neutralizing agents may even produce thermal burns, as they frequently generate substantial heat on neutralization of the offending agent. Powdered chemicals should be brushed off skin and clothing.

Wound Management

A full-thickness chemical burn may appear deceptively superficial. Chemical burns should be considered deep partial-thickness or full-thickness until proven otherwise. As such, they are best treated by early E&G after full demarcation of injury.

Some chemicals, such as phenol, cause severe systemic effects, although hydrofluoric acid may cause death from hypocalcemia even after moderate

exposure. Hydrofluoric acid burns are unique chemical burns in that they should be acutely treated with an antidote, calcium. Calcium gluconate should be administered intraarterially and topically, and all electrolyte abnormalities aggressively corrected.

PAIN CONTROL

All burn injuries are painful, whether the injury is simply sunburn or an extensive partial-thickness or full-thickness burn covering a large portion of the body. Attempts to manage pain in the thermally injured are frequently frustrating because of the unpredictable physiologic and psychologic reactions to the burn.

Total elimination of pain in burn patients is not possible, short of general anesthesia. The burn patient may experience acute pain from dressing changes, operative procedures, and rehabilitation therapy exercises. Patients may also have chronic background pain associated with the wound maturation process. There is a wide degree of intra- and interindividual variation with respect to the experience of burn-related pain. Pain management involves both pharmacologic and nonpharmacologic modalities.

CHRONIC PROBLEMS

Hypertrophic Scar Formation

The etiology and pathophysiology of hypertrophic scars are still incompletely understood. Burn scar hypertrophy classically develops in deeper partial-thickness and full-thickness injuries that are allowed to heal by primary intention. Hypertrophy of excised and grafted burn wounds occurs less frequently, and is partly dependent on the time from injury to excision, the site of the wound, and the patient's race or ethnicity. Delayed excision is more likely to result in hypertrophic scarring, and pigmented individuals are at an increased risk. Donor sites also can become hypertrophic, and this propensity appears to be related to graft thickness, donor site infection, and patient characteristics.

Hypertrophic scarring should be distinguished from a keloid. Both exhibit excessive collagen formation; however, a keloid grows beyond the original dimensions of the injury, although a hypertrophic scar is confined to its original anatomic boundaries. Hypertrophic scars frequently flatten with time and pressure, whereas keloids do not.

Numerous treatments have been postulated for hypertrophic scarring; however, few have proven to be efficacious. Pressure applied directly to a hypertrophic scar via various vehicles has been the most widely used treatment modality. Elasticized, custom-fitted, compression garments and silicone dressings are the most widely used and accepted pressure therapies. The most successful approach to residual hypertrophic burn scars is initial pressure therapy until the wound matures, followed by subsequent excision and grafting if necessary. Intralesional injection of corticosteroids may reduce the bulk of the hypertrophic scar mass, and may be used in combination with other treatment modalities.

Marjolin's Ulcer

Chronic ulceration of old burn scars was noted by Marjolin to predispose to malignant degeneration. Squamous cell carcinoma is most common, although

basal cell carcinomas occasionally occur, and rare tumors such as malignant fibrous histiocytoma, sarcoma, and melanoma have been reported. These lesions typically appear decades after the original injury in wounds that healed primarily, but acute cases arising within a year of injury have been reported. They also can arise in grafted areas and appear to have an even longer time to occurrence when they do. The precise incidence of burn scar carcinoma is unknown.

Heterotopic Ossification

Heterotopic ossification (HO) is a rare complication of thermal injury, but is associated with significant morbidity. It most commonly occurs in patients with major full-thickness burns and typically is found adjacent to an involved joint 1–3 months after injury. The upper extremity is most commonly affected. Limitation of physical activity usually precedes radiographic evidence of calcification, which is located in the muscle and surrounding soft tissue of the joint. The precise etiology of HO is not known; however, restricted activity promotes mobilization of body calcium stores and may lead to deposition of calcium in the soft tissues.

PHASES OF WOUND HEALING

The wound healing process follows a predictable pattern that can be divided into overlapping phases defined by the cellular populations and biochemical activities: (1) hemostasis and inflammation, (2) proliferation, and (3) maturation and remodeling. This sequence of events is fluid and overlapping. All wounds need to progress through this series of cellular and biochemical events that characterizes the phases of healing to successfully re-establish tissue integrity.

Hemostasis and Inflammation

Hemostasis precedes and initiates inflammation with the ensuing release of chemotactic factors from the wound site. Wounding disrupts tissue integrity, leading to division of blood vessels and direct exposure of extracellular matrix to platelets. Exposure of subendothelial collagen to platelets results in platelet aggregation, degranulation, and activation of the coagulation cascade resulting in a fibrin clot. Platelet α granules release a number of wound-active substances such as platelet-derived growth factor (PDGF), transforming growth factor- β (TGF- β), platelet-activating factor (PAF), fibronectin, and serotonin. In addition to achieving hemostasis, the fibrin clot serves as scaffolding for the migration into the wound of inflammatory cells such as polymorphonuclear leukocytes (PMNs, neutrophils) and monocytes.

Cellular infiltration after injury follows a characteristic, predetermined sequence. PMNs are the first infiltrating cells to enter the wound site, peaking at 24–48 h. Increased vascular permeability, local prostaglandin release, and the presence of chemotactic substances such as complement factors, interleukin-1 (IL-1), tumor necrosis factor- α (TNF- α), TNF- β , platelet factor 4, or bacterial products all stimulate neutrophil migration.

The second population of inflammatory cells that invades the wound consists of macrophages. Derived from circulating monocytes, macrophages achieve significant numbers in the wound by 48–96 h postinjury and remain present until wound healing is complete.

Macrophages, like neutrophils, participate in wound débridement via phagocytosis and contribute to microbial stasis via oxygen radical and nitric oxide synthesis. The macrophage's most pivotal function is activation and recruitment of other cells via mediators such as cytokines and growth factors. By releasing such mediators as TGF- β , vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF), epithelial growth factor (EGF), and lactate, macrophages regulate cell proliferation, matrix synthesis, and angiogenesis. Macrophages also play a significant role in regulating angiogenesis and matrix deposition and remodeling.

T lymphocytes comprise another population of inflammatory/immune cells that routinely invades the wound. Less numerous than macrophages, T-lymphocyte numbers peak at about 1 week postinjury and bridge the transition from the inflammatory to the proliferative phase of healing. The lymphocytes' role in wound healing is not yet fully defined.

Proliferation

The proliferative phase roughly spans days 4 through 12. During this phase, tissue continuity is re-established. Fibroblasts and endothelial cells are the last cell populations to infiltrate the healing wound, and the strongest chemotactic factor for fibroblasts is PDGF. On entering the wound environment, recruited fibroblasts first need to proliferate, and then become activated, to carry out their primary function of matrix synthesis and remodeling. This activation is mediated mainly by the cytokines and growth factors released from wound macrophages.

Endothelial cells also proliferate extensively during this phase of healing. These cells participate in the formation of new capillaries (angiogenesis). Endothelial cells migrate from intact venules close to the wound. Their migration, replication, and new capillary tubule formation are under the influence of such cytokines and growth factors as TNF- α , TGF- β , and VEGF.

Matrix Synthesis

Biochemistry of Collagen

Collagen is the most abundant protein in the body. Type I collagen is the major component of extracellular matrix in skin. Type III, which also normally is present in skin, becomes more prominent and important during the repair process.

Biochemically, each chain of collagen is composed of a glycine residue in every third position. The second position in the triplet is made up of proline or lysine during the translation process. The polypeptide chain that is translated from mRNA is called procollagen. Release of procollagen into the endoplasmic reticulum results in the hydroxylation of proline to hydroxyproline and of lysine to hydroxylysine by specific hydroxylases. Prolyl hydroxylase requires oxygen and iron as cofactors, α -ketoglutarate as co-substrate, and ascorbic acid (vitamin C) as an electron donor. In the endoplasmic reticulum, the procollagen chain assumes an α -helical configuration after it is glycosylated by the linking of galactose and glucose at specific hydroxylysine residues. Three α -helical chains entwine to form a right-handed superhelical structure called procollagen. Although initially joined by weak, ionic bonds, the procollagen molecule becomes much stronger by the covalent cross-linking of lysine residues.

Extracellularly, the procollagen strands undergo further polymerization and cross-linking. The resulting collagen monomer is further polymerized and cross-linked by the formation of intra and intermolecular covalent bonds.

Proteoglycan Synthesis

Glycosaminoglycans comprise a large portion of the "ground substance" that makes up granulation tissue. Rarely found free, they couple with proteins to form proteoglycans. The polysaccharide chain is made up of repeating disaccharide units composed of glucuronic or iduronic acid and a hexosamine, which is usually sulfated. The disaccharide composition of proteoglycans varies from about 10 units in the case of heparan sulfate to as much as 2000 units in the case of hyaluronic acid.

The major glycosaminoglycans present in wounds are dermatan and chondroitin sulfate. Fibroblasts synthesize these compounds, increasing their concentration greatly during the first 3 weeks of healing. The interaction between

collagen and proteoglycans is being actively studied. As scar collagen is deposited, the proteoglycans are incorporated into the collagen scaffolding. However, with scar maturation and collagen remodeling, the content of proteoglycans gradually diminishes.

Maturation and Remodeling

The maturation and remodeling of the scar begins during the fibroplastic phase, and is characterized by a reorganization of previously synthesized collagen. Collagen is broken down by matrix metalloproteinases (MMPs). The net wound collagen content is the result of a balance between collagenolysis and collagen synthesis. There is a net shift toward collagen synthesis and eventually the re-establishment of extracellular matrix composed of a relatively acellular collagen-rich scar.

Wound strength and mechanical integrity in the fresh wound are determined by both the quantity and quality of the newly deposited collagen. The deposition of matrix at the wound site follows a characteristic pattern: fibronectin and collagen type III constitute the early matrix scaffolding; glycosaminoglycans and proteoglycans represent the next significant matrix components; and collagen type I is the final matrix. By several weeks postinjury the amount of collagen in the wound reaches a plateau, but the tensile strength continues to increase for several more months. Fibril formation and fibril cross-linking result in decreased collagen solubility, increased strength, and increased resistance to enzymatic degradation of the collagen matrix. Scar remodeling continues for many (6–12) months postinjury, gradually resulting in a mature, avascular, and acellular scar. The mechanical strength of the scar never achieves that of the uninjured tissue.

Epithelialization

Although tissue integrity and strength are being re-established, the external barrier must also be restored. This process, beginning within 1 day of the injury, is characterized primarily by proliferation and migration of epithelial cells adjacent to the wound. Marginal basal cells at the edge of the wound lose their firm attachment to the underlying dermis, enlarge, and begin to migrate across the surface of the provisional matrix. Fixed basal cells in a zone near the cut edge undergo a series of rapid mitotic divisions, and these cells appear to migrate by moving over one another in a leapfrog fashion until the defect is covered. Once the defect is bridged, the migrating epithelial cells lose their flattened appearance, become more columnar in shape, and increase their mitotic activity. Layering of the epithelium is re-established, and the surface layer eventually keratinizes.

Re-epithelialization is complete in less than 48 h in the case of approximated incised wounds, but may take substantially longer in the case of larger wounds, in which there is a significant epidermal/dermal defect. If only the epithelium and superficial dermis are damaged, such as occurs in split-thickness skin graft (STSG) donor sites or in superficial second-degree burns, then repair consists primarily of re-epithelialization with minimal or no fibroplasia and granulation tissue formation. The stimuli for re-epithelialization remain incompletely defined; however, it appears that the process is mediated by a combination of a loss of contact inhibition; exposure to constituents of the extracellular matrix, particularly fibronectin; and cytokines produced by immune mononuclear cells. In particular EGF, TGF- β , basic fibroblast growth factor (bFGF), PDGF, and IGF-1 have been shown to promote epithelialization.

Wound Contraction

All wounds undergo some degree of contraction. For wounds that do not have surgically approximated edges, the area of the wound will be decreased by this action (healing by secondary intention). The myofibroblast has been postulated as being the major cell responsible for contraction, and it differs from the normal fibroblast in that it possesses a cytoskeletal structure. Typically this cell contains α -smooth muscle actin in thick bundles called stress fibers, giving myofibroblasts contractile capability. The α -smooth muscle actin is undetectable until day 6, and then is increasingly expressed for the next 15 days of wound healing. After 4 weeks this expression fades and the cells are believed to undergo apoptosis. Of note, undifferentiated fibroblasts may also contribute to wound contraction.

CLASSIFICATION OF WOUNDS

Wounds are classified as either acute or chronic. Acute wounds heal in a predictable manner and time frame. The process occurs with few, if any, complications, and the end result is a well-healed wound. Surgical wounds can heal in several ways. An incised wound that is clean and sutured closed is said to heal by primary intention. Often, because of bacterial contamination or tissue loss, a wound will be left open to heal by granulation tissue formation and contraction; this constitutes healing by secondary intention. Delayed primary closure, or healing by tertiary intention, represents a combination of the first two, consisting of the placement of sutures, allowing the wound to stay open for a few days, and the subsequent closure of the sutures.

Normal healing is affected by both systemic and local factors (Table 8-1). The clinician must be familiar with these factors and should attempt to counteract their deleterious effects. Complications occurring in wounds with higher risk can lead to failure of healing or the development of chronic, nonhealing wounds.

Factors Affecting Wound Healing

Advanced Age

Most surgeons believe that aging produces intrinsic physiologic changes that result in delayed or impaired wound healing. Clinical experience demonstrating a decrease in wound closure rates and tensile strength with increasing age tends to support this belief.

Hypoxia, Anemia, and Hypoperfusion

Low oxygen tension has a deleterious effect on all aspects of wound healing. Fibroplasia, although stimulated initially by the hypoxic wound environment, is significantly impaired by local hypoxia. Optimal collagen synthesis requires oxygen as a cofactor, particularly for the hydroxylation steps. Increasing subcutaneous oxygen tension levels and oxygen delivery by avoiding hypovolemia or increasing the fraction of inspired oxygen (F_{iO_2}) of inspired air for brief periods during and immediately following surgery results in enhanced collagen deposition and in decreased rates of wound infection after elective surgery.

Mild to moderate normovolemic anemia does not appear to adversely affect wound oxygen tension and collagen synthesis, unless the hematocrit falls below 15 percent.

Steroids and Chemotherapeutic Drugs

Large doses or chronic usage of glucocorticoids reduce collagen synthesis and wound strength. The major effect of steroids is to inhibit the inflammatory phase of wound healing and the release of lysosomal enzymes. The stronger the antiinflammatory effect of the steroid compound used, the greater the inhibitory effect on wound healing. Steroids used after the first 3–4 days postinjury do not affect wound healing as severely as when they are used in the immediate postoperative period. Therefore, if possible, their use should be delayed or, alternatively, forms with lesser antiinflammatory effects should be administered.

In addition to their effect on collagen synthesis, steroids also inhibit epithelialization and contraction and contribute to increased rates of wound infection, regardless of the time of administration. Steroid-delayed healing of cutaneous wounds can be stimulated to epithelialize by topical application of vitamin A. Collagen synthesis of steroid-treated wounds also can be stimulated by vitamin A.

All chemotherapeutic antimetabolite drugs adversely affect wound healing by inhibiting early cell proliferation and wound deoxyribonucleic acid (DNA) and protein synthesis.

Metabolic Disorders

Diabetes mellitus is the best known of the metabolic disorders contributing to increased rates of wound infection and impaired healing. Uncontrolled diabetes results in reduced inflammation, angiogenesis, and collagen synthesis. Additionally, the large and small vessel disease that is the hallmark of advanced diabetes contributes to local hypoxemia. Defects in granulocyte function, capillary ingrowth, and fibroblast proliferation all have been described in diabetes. In wound studies on experimental diabetic animals, insulin restores collagen synthesis and granulation tissue formation to normal levels if given during the early phases of healing. In clean, noninfected, and well-perfused experimental

wounds in human diabetic volunteers, type I diabetes mellitus was noted to decrease wound collagen accumulation in the wound, independent of the degree of glycemic control. Type II diabetic patients showed no effect on collagen accretion when compared to healthy, age-matched controls. It remains unclear whether decreased collagen synthesis or an increased breakdown because of an abnormally high proteolytic wound environment is responsible.

Careful preoperative correction of blood sugar levels improves the outcome of wounds in diabetic patients. Increasing the inspired oxygen tension, judicious use of antibiotics, and correction of other coexisting metabolic abnormalities all can result in improved wound healing.

Uremia also has been associated with disordered wound healing. Experimentally, uremic animals demonstrate decreased wound collagen synthesis and breaking strength. The contribution of uremia alone to this impairment, rather than that of associated malnutrition, is difficult to assess. The clinical use of dialysis to correct the metabolic abnormalities and nutritional restoration should impact greatly on the wound outcome of such patients.

Nutrition

The clinician must pay close attention to the nutritional status of patients with wounds, because wound failure or wound infections may be no more than a reflection of poor nutrition. Although the full interaction of nutrition and wound healing is still not fully understood, efforts are being made to develop wound-specific nutritional interventions and the pharmacologic use of individual nutrients as modulators of wound outcomes.

Clinically, it is extremely rare to encounter pure energy or protein malnutrition, and the vast majority of patients exhibit combined protein-energy malnutrition. Such patients have diminished hydroxyproline accumulation (an index of collagen deposition) into subcutaneously implanted polytetrafluoroethylene tubes when compared to normally nourished patients. Furthermore, malnutrition correlates clinically with enhanced rates of wound complications and increased wound failure following diverse surgical procedures. This reflects impaired healing response and reduced cell-mediated immunity, phagocytosis, and intracellular killing of bacteria by macrophages and neutrophils during protein-calorie malnutrition.

The possible role of single amino acids in enhanced wound healing has been studied for the last several decades. Arginine appears most active in terms of enhancing wound fibroplasia. Indeed, arginine supplementation in both rats and humans has been shown to increase wound collagen deposition. Conversely, arginine deficiency in rats results in decreased wound-breaking strength and wound-collagen accumulation.

The vitamins most closely involved with wound healing are vitamin C and vitamin A. Vitamin C deficiency leads to a defect in wound healing, particularly via a failure in collagen synthesis and cross-linking. Biochemically, vitamin C is required for the conversion of proline and lysine to hydroxyproline and hydroxylysine. Vitamin C deficiency also has been associated with an increased incidence of wound infection, and if wound infection does occur, it tends to be more severe. These effects are believed to be because of an associated impairment in neutrophil function, decreased complement activity, and decreased walling-off of bacteria secondary to insufficient collagen deposition. The recommended dietary allowance is 60 mg daily. In severely injured or extensively burned patients this requirement may increase to as high as 2 g

daily. There is no evidence that excess vitamin C is toxic; however, there is no evidence that supertherapeutic doses of vitamin C are of any benefit.

Vitamin A deficiency impairs wound healing, although supplemental vitamin A benefits wound healing in nondeficient humans and animals. Vitamin A increases the inflammatory response in wound healing, probably by increasing the lability of lysosomal membranes. There is an increased influx of macrophages, with an increase in their activation and increased collagen synthesis. Vitamin A directly increases collagen production and epidermal growth factor receptors when it is added in vitro to cultured fibroblasts. As mentioned before, supplemental vitamin A can reverse the inhibitory effects of corticosteroids on wound healing. Vitamin A also can restore wound healing that has been impaired by diabetes, tumor formation, cyclophosphamide, and radiation. Serious injury or stress leads to increased vitamin A requirements. In the severely injured patient, supplemental doses of vitamin A have been recommended. Doses ranging from 25,000 to 100,000 international units per day have been advocated. Vitamin A can reach toxic doses if taken in excess.

The connections between specific minerals and trace elements and deficits in wound healing are complex. Frequently, deficiencies are multiple and include macronutrient deficiencies.

Zinc is the most well-known element in wound healing and has been used empirically in dermatologic conditions for centuries. It is essential for wound healing in animals and humans. There are over 150 known enzymes for which zinc is either an integral part or an essential cofactor, and many of these enzymes are critical to wound healing. With zinc deficiency there is decreased fibroblast proliferation, decreased collagen synthesis, impaired overall wound strength, and delayed epithelialization. These defects are reversed by zinc supplementation. To date, no study has shown improved wound healing with zinc supplementation in patients who are not zinc deficient.

Infections

Wound infections continue to represent a major medical problem, both in terms of how they affect the outcome of surgical procedures, and for their impact on the length of hospital stay and medical costs. Exhaustive studies have been undertaken to examine the appropriate prophylactic treatment of operative wounds. Bacterial contaminants normally present on skin are prevented from entry into deep tissues by intact epithelium. Surgery breaches the intact epithelium, allowing bacteria access to these tissues and the blood stream. Antibiotic prophylaxis is most effective when adequate concentrations of antibiotic are present in the tissues at the time of incision. Addition of antibiotics after operative contamination has occurred is clearly ineffective in preventing postoperative wound infections.

Studies that compare operations performed with and without antibiotic prophylaxis demonstrate that class II, III, and IV procedures (see below) treated with appropriate prophylactic antibiotics have only one-third the wound infection rate of previously reported untreated series. More recently, repeat dosing of antibiotics has been shown to be essential in decreasing postoperative wound infections in operations with durations exceeding the biochemical half-life ($T_{1/2}$) of the antibiotic, or in which there is large-volume blood loss and fluid replacement. In lengthy cases, those in which prosthetic implants are used, or when unexpected contamination is encountered, additional doses of antibiotic may be administered for 24 h postoperatively.

Selection of antibiotics for use in prophylaxis should be tailored to the type of surgery to be performed, operative contaminants that might be encountered during the procedure, and the profile of resistant organisms present at the institution where the surgery is performed.

The incidence of wound infection is about 5–10 percent nationwide and has not changed during the last few decades. Quantitatively, it has been shown that if the wound is contaminated with >105 microorganisms, the risk of wound infection is markedly increased, but this threshold may be much lower in the presence of foreign materials. The source of pathogens for the infection is usually the endogenous flora of the patient's skin, mucous membranes, or from hollow organs. The most common organisms responsible for wound infections in order of frequency are *Staphylococcus* species, coagulase-negative *Streptococcus*, enterococci, and *Escherichia coli*. The incidence of wound infection bears a direct relationship to the degree of contamination that occurs during the operation from the disease process itself (clean—class I, clean contaminated—class II, contaminated—class III, and dirty—class IV). Many factors contribute to the development of postoperative wound infections. Most surgical wound infections become apparent within 7–10 days postoperatively.

The mere presence of bacteria in an open wound, either acute or chronic, does not constitute an infection, because large numbers of bacteria can be present in the normal situation. Secondly, the bacteria grown may not be representative of the bacteria causing the actual wound infection. Contamination is the presence of bacteria without multiplication, colonization is multiplication without host response, and infection is the presence of host response in reaction to deposition and multiplication of bacteria. The presence of a host response helps to differentiate between infection and colonization as seen in chronic wounds. The host response that helps in diagnosing wound infection comprises cellulitis, abnormal discharge, delayed healing, change in pain, abnormal granulation tissue, bridging, and abnormal color and odor.

Chronic Wounds

Chronic wounds are defined as wounds that have failed to proceed through the orderly process that produces satisfactory anatomic and functional integrity or that have proceeded through the repair process without producing an adequate anatomic and functional result. The majority of wounds that have not healed in 3 months are considered chronic. Skin ulcers, which usually occur in traumatized or vascularly compromised soft tissue, also are considered chronic in nature, and proportionately are the major component of chronic wounds. In addition to the factors discussed above that can delay wound healing, factors such as repeated trauma, poor perfusion or oxygenation, and/or excessive inflammation may also play a role in the etiology of chronic wounds.

Unresponsiveness to normal regulatory signals also has been implicated as a predictive factor of chronic wounds. This may come about as a failure of normal growth factor synthesis, and thus an increased breakdown of growth factors within a wound environment that is markedly proteolytic because of overexpression of protease activity or a failure of the normal antiprotease inhibitor mechanisms. Fibroblasts from chronic wounds also have been found to have decreased proliferative potential, perhaps because of senescence or decreased expression of growth factor receptors. Chronic wounds occur because of various etiologic factors, and several of the most common are discussed below.

Malignant transformation of chronic ulcers can occur in any long-standing wound (Marjolin ulcer). Any wound that does not heal for a prolonged period of time is prone to malignant transformation. In patients with suspected malignant transformations, biopsy of the wound edges must be performed to rule out malignancy. Cancers arising *de novo* in chronic wounds include both squamous and basal cell carcinomas.

Ischemic Arterial Ulcers

These wounds occur because of a lack of blood supply and are painful at presentation. They are usually located on the most distal portions of the extremities and are associated with other symptoms of peripheral vascular disease, such as intermittent claudication, rest pain, night pain, and color changes. On examination, there may be diminished or absent pulses with decreased ankle-brachial index and poor formation of granulation tissue. Other signs of peripheral ischemia, such as dryness of skin, hair loss, scaling, and pallor can be present. The wound itself is usually shallow with smooth margins and a pale base. The management of these wounds includes revascularization and wound care. After establishing adequate blood supply, most wounds progress to heal satisfactorily.

Venous Stasis Ulcers

Although there is unanimous agreement that venous ulcers are because of venous stasis and back pressure, there is less consensus regarding what are the exact pathophysiologic pathways that lead to ulceration and impaired healing. On the microvascular level, there is alteration and distention of the dermal capillaries with leakage of fibrinogen into the tissues; polymerization of fibrinogen into fibrin cuffs leads to perivascular cuffing that can impede oxygen exchange, thus contributing to ulceration. These same fibrin cuffs and the leakage of macromolecules such as fibrinogen and α_2 -macroglobulin trap growth factors and impede wound healing. Another hypothesis suggests that neutrophils adhere to the capillary endothelium and cause plugging with diminished dermal blood flow. Venous hypertension and capillary damage lead to extravasation of hemoglobin. The products of this breakdown are irritating and cause pruritus and skin damage. The resulting brownish pigmentation of skin combined with the loss of subcutaneous fat produces characteristic changes called lipodermatosclerosis. Regardless of the pathophysiologic mechanisms, the clinically characteristic picture is that of an ulcer that fails to re-epithelialize despite the presence of adequate granulation tissue.

Venous stasis occurs because of the incompetence of either the superficial or deep venous systems. Chronic venous ulcers are usually because of the incompetence of the deep venous system and are commonly painless. Stasis ulcers tend to occur at the sites of incompetent perforators, the most common being above the medial malleolus, over the Cockett perforator. On examination, the typical location combined with a history of venous incompetence and other skin changes is diagnostic. The wound is usually shallow with irregular margins and pigmented surrounding skin.

The cornerstone of treatment of venous ulcers is compression therapy. The most commonly used method is the rigid, zinc oxide-impregnated, nonelastic bandage. Most venous ulcers can be healed with perseverance and by addressing the venous hypertension. Unfortunately, recurrences are frequent.

Diabetic Wounds

Ten to 15 percent of diabetic patients run the risk of developing ulcers. There are approximately 50,000–60,000 amputations performed in diabetic patients each year in the United States. The major contributors to the formation of diabetic ulcers include neuropathy, foot deformity, and ischemia. The neuropathy is both sensory and motor. The loss of sensory function allows unrecognized injury to occur from ill-fitting shoes, foreign bodies, or other trauma. The motor neuropathy (Charcot foot) leads to collapse or dislocation of the interphalangeal or metatarsophalangeal joints, causing pressure on areas with little protection. There is also severe micro- and macrovascular circulatory impairment.

Once ulceration occurs, the chances of healing are poor. The management of diabetic wounds involves local and systemic measures. Achievement of adequate blood sugar levels is very important. Most diabetic wounds are infected, and eradication of the infectious source is paramount to the success of healing. Treatment should address the possible presence of osteomyelitis, and should employ antibiotics that achieve adequate levels both in soft tissue and bone. Wide débridement of all necrotic or infected tissue is another cornerstone of treatment. Off-loading of the ulcerated area by using specialized orthotic shoes or casts allows for ambulation while protecting the fragile wound environment. Topical application of PDGF and granulocyte-macrophage colony-stimulating factor has met with limited but significant success in achieving closure. The application of engineered skin allograft substitutes, although expensive, has also shown some success.

Decubitus or Pressure Ulcers

The incidence of pressure ulcers ranges from 2.7–9 percent in the acute care setting, in comparison to 2.4–23 percent in long-term care facilities. The expense of pressure sore management in the United States is approximately \$1.3 billion annually, with an average cost of \$50,000–\$60,000 per ulcer. A pressure ulcer is a localized area of tissue necrosis that develops when a soft tissue is compressed between a bony prominence and an external surface. Excessive pressure causes capillary collapse and impedes the delivery of nutrients to body tissues. Pressure ulcer formation is accelerated in the presence of friction, shear forces, and moisture. Other contributory factors in the pathogenesis of pressure ulcers include immobility, altered activity levels, altered mental status, chronic conditions, and altered nutritional status. The four stages of pressure ulcer formation are as follows: stage I, nonblanchable erythema of intact skin; stage II, partial-thickness skin loss involving epidermis or dermis or both; stage III, full-thickness skin loss, but not through the fascia; and stage IV, full-thickness skin loss with extensive involvement of muscle and bone.

The treatment of established pressure ulcers is most successful when carried out in a multidisciplinary manner by involving wound care teams consisting of physicians, nurses, dietitians, physical therapists, and nutritionists. Care of the ulcer itself comprises débridement of all necrotic tissue, maintenance of a favorable moist wound environment that will facilitate healing, relief of pressure, and addressing host issues such as nutritional, metabolic, and circulatory status. Débridement is most efficiently carried out surgically, but enzymatic proteolytic preparations and hydrotherapy also are used. The wound bed should be kept moist by employing dressings that absorb secretions but do not desiccate the wound. Operative repair, usually involving flap rotation, has

been found to be useful in obtaining long-term closure only in highly motivated patients.

EXCESS HEALING

Excess Dermal Scarring

Hypertrophic scars (HTSs) and keloids represent an overabundance of fibroplasia in the dermal healing process. HTSs rise above the skin level but stay within the confines of the original wound and often regress over time. Keloids rise above the skin level as well, but extend beyond the border of the original wound and rarely regress spontaneously. Both HTSs and keloids occur after trauma to the skin and may be tender, pruritic, and cause a burning sensation. Keloids are fifteen times more common in darker-pigmented ethnicities, with individuals of African, Spanish, and Asian ethnicities being especially susceptible. Men and women are equally affected. Genetically, the predilection to keloid formation appears to be autosomal dominant with incomplete penetration and variable expression.

A HTS usually develops within 4 weeks after trauma. The risk of a HTS increases if epithelialization takes longer than 21 days, independent of site, age, and race. Rarely elevated more than 4 mm above the skin level, HTSs stay within the boundaries of the wound. They usually occur across areas of tension and flexor surfaces, which tend to be at right angles to joints or skin creases. The lesions are initially erythematous and raised, and over time may evolve into pale, flatter scars.

Keloids can result from surgery, burns, skin inflammation, acne, chickenpox, zoster, folliculitis, lacerations, abrasions, tattoos, vaccinations, injections, insect bites, ear piercing, or may arise spontaneously. Keloids tend to occur 3 months to years after the initial insult, and even minor injuries can result in large lesions. They vary in size from a few millimeters to large, pedunculated lesions with a soft to rubbery or hard consistency. Although they project above surrounding skin, they rarely extend into underlying subcutaneous tissues. Certain body sites have a higher incidence of keloid formation, including the skin of the earlobe and the deltoid, presternal, and upper back regions. They rarely occur on eyelids, genitalia, palms, soles, or across joints. Keloids rarely involute spontaneously, although surgical intervention can lead to recurrence, often with a worse result.

Histologically, both HTSs and keloids demonstrate increased thickness of the epidermis with an absence of rete ridges. There is an abundance of collagen and glycoprotein deposition. Normal skin has distinct collagen bundles, mostly parallel to the epithelial surface, with random connections between bundles by fine fibrillar strands of collagen. In HTSs, the collagen bundles are flatter, more random, and the fibers are in a wavy pattern. In keloids, the collagen bundles are virtually nonexistent, and the fibers are connected haphazardly in loose sheets with a random orientation to the epithelium. The collagen fibers are larger and thicker and myofibroblasts are generally absent.

Keloidal fibroblasts have normal proliferation parameters, but synthesize collagen at a rate 20 times greater than that observed in normal dermal fibroblasts, and 3 times higher than fibroblasts derived from HTSs. Abnormal amounts of extracellular matrix such as fibronectin, elastin, and proteoglycans also are produced. The synthesis of fibronectin, which promotes clot generation, granulation tissue formation, and re-epithelialization, decreases during the normal healing process; however, production continues at high levels for

months to years in HTSs and keloids. This perturbed synthetic activity is mediated by altered growth factor expression. TGF- β expression is higher in HTSs, and both HTS- and keloid-derived fibroblasts respond to lower concentrations of TGF- β than do normal dermal fibroblasts. HTSs also express increased levels of insulin-like growth factor-1, which reduces collagenase messenger ribonucleoprotein acid (mRNA) activity and increases mRNA for types I and II procollagen.

Unfortunately, the underlying mechanisms that cause HTSs and keloids are not known.

Treatment goals include restoration of function to the area, relief of symptoms, and prevention of recurrence. Many patients seek intervention because of cosmetic concerns. Because the underlying mechanisms causing keloids and HTSs remain unknown, many different modalities of treatment have been used without consistent success.

Excision alone of keloids is subject to a high recurrence rate, ranging from 45–100 percent. There are fewer recurrences when surgical excision is combined with other modalities such as intralesional corticosteroid injection, topical application of silicone sheets, or the use of radiation or pressure. Surgery is recommended for debulking large lesions or as second-line therapy when other modalities have failed. Silicone application is relatively painless and should be maintained for 24 h a day for about 3 months to prevent rebound hypertrophy. It may be secured with tape or worn beneath a pressure garment. The mechanism of action is not understood, but increased hydration of the skin, which decreases capillary activity, inflammation, hyperemia, and collagen deposition, may be involved. Silicone is more effective than other occlusive dressings and is an especially good treatment for children and others who cannot tolerate the pain involved in other modalities.

Intralesional corticosteroid injections decrease fibroblast proliferation, collagen and glycosaminoglycan synthesis, the inflammatory process, and TGF- β levels. When used alone, however, there is a variable rate of response and recurrence, therefore steroids are recommended as first-line treatment for keloids and second-line treatment for HTSs if topical therapies have failed. Intralesional injections are more effective on younger scars. They may soften, flatten, and give symptomatic relief to keloids, but they cannot make the lesions disappear nor can they narrow wide HTSs. Success is enhanced when used in combination with surgical excision. Serial injections every 2–3 weeks are required. Complications include skin atrophy, hypopigmentation, telangiectasias, necrosis, and ulceration.

Although radiation destroys fibroblasts, it has variable, unreliable results and produces poor results with 10–100 percent recurrence when used alone. It is more effective when combined with surgical excision. The timing, duration, and dosage for radiation therapy remain controversial, but doses ranging from 1500–2000 rads appear effective. Given the risks of hyperpigmentation, pruritus, erythema, paresthesias, pain, and possible secondary malignancies, radiation should be reserved for adults with scars resistant to other modalities.

Pressure aids collagen maturation, flattens scars, and improves thinning and pliability. It reduces the number of cells in a given area, possibly by creating ischemia, which decreases tissue metabolism and increases collagenase activity. External compression is used to treat HTSs, especially after burns. Therapy must begin early, and a pressure between 24 and 30 mmHg must be achieved to exceed capillary pressure, yet preserve peripheral blood circulation. Garments

should be worn for 23–24 h a day for up to 1 or more years to avoid rebound hypertrophy. Scars older than 6–12 months respond poorly.

Topical retinoids also have been used as treatment for both HTSs and keloids, with reported responses of 50–100 percent. Intralesional injections of INF- γ , a cytokine released by T lymphocytes, reduce collagen types I, II, and III by decreasing mRNA and possibly by reducing levels of TGF- β . This treatment is experimental, and complications are frequent and dose-dependent. Intralesional injections of chemotherapeutic agents such as 5-fluorouracil have been used both alone and in combination with steroids. The use of bleomycin has been reported to achieve some success in older scars resistant to steroids.

Peritoneal Scarring

Peritoneal adhesions are fibrous bands of tissues formed between organs that are normally separated and/or between organs and the internal body wall. Most intraabdominal adhesions are a result of peritoneal injury, either by a prior surgical procedure or because of intraabdominal infection. Postmortem examinations demonstrate adhesions in 67 percent of patients with prior surgical procedures and in 28 percent with a history of intraabdominal infection. Intraabdominal adhesions are the most common cause (65–75 percent) of small bowel obstruction, especially in the ileum. Operations in the lower abdomen have a higher chance of producing small bowel obstruction. Following rectal surgery, left colectomy, or total colectomy, there is an 11 percent chance of developing small bowel obstruction within 1 year, and this rate increases to 30 percent by 10 years. Adhesions also are a leading cause of secondary infertility in women and can cause substantial abdominal and pelvic pain. Adhesions account for 2 percent of all surgical admissions and 3 percent of all laparotomies in general surgery.

Adhesions form when the peritoneal surface is damaged because of surgery, thermal or ischemic injury, inflammation, or foreign body reaction. The injury disrupts the protective mesothelial cell layer lining the peritoneal cavity and the underlying connective tissue. The injury elicits an inflammatory response consisting of hyperemia, fluid exudation, release and activation of white blood cells and platelets in the peritoneal cavity, activation of inflammatory cytokines, and the onset of the coagulation and complement cascades. Fibrin deposition occurs between the damaged but opposed serosal surfaces. These filmy adhesions are often transient and degraded by proteases of the fibrinolytic system, with restoration of the normal peritoneal surface. If insufficient fibrinolytic activity is present, permanent fibrous adhesions will form by collagen deposition within 1 week of the injury.

There are two major strategies for adhesion prevention or reduction. Surgical trauma is minimized within the peritoneum by careful tissue handling, avoiding desiccation and ischemia, and spare use of cautery, laser, and retractors. Fewer adhesions form with laparoscopic surgical techniques because of reduced tissue trauma. The second major advance in adhesion prevention has been the introduction of barrier membranes and gels, which separate and create barriers between damaged surfaces, allowing for adhesion-free healing. Modified oxidized regenerated cellulose and hyaluronic acid membranes or solutions have been shown to reduce adhesions in gynecologic patients, and are being investigated for their ability to prevent adhesion formation in general surgical patients.

TREATMENT OF WOUNDS

Local Care

Management of acute wounds begins with obtaining a careful history of the events surrounding the injury. The history is followed by a meticulous examination of the wound. Examination should assess the depth and configuration of the wound, the extent of nonviable tissue, and the presence of foreign bodies and other contaminants. Examination of the wound may require irrigation and débridement of the edges of the wound, and is facilitated by use of local anesthesia. Antibiotic administration and tetanus prophylaxis may be needed, and planning the type and timing of wound repair should take place.

After completion of the history, examination, and administration of tetanus prophylaxis, the wound should be meticulously anesthetized. Lidocaine (0.5–1 percent) or bupivacaine (0.25–0.5 percent) combined with a 1:100,000 to 1:200,000 dilution of epinephrine provides satisfactory anesthesia and hemostasis. Epinephrine should not be used in wounds of the fingers, toes, ears, nose, or penis, because of the risk of tissue necrosis secondary to terminal arteriole vasospasm in these structures.

Irrigation to visualize all areas of the wound and remove foreign material is best accomplished with normal saline (without additives). High-pressure wound irrigation is more effective in achieving complete débridement of foreign material and nonviable tissue. Iodine, povidone-iodine, hydrogen peroxide, and organically based antibacterial preparations have all been shown to impair wound healing because of injury to wound neutrophils and macrophages, and thus should not be used directly on the wound bed. All hematomas present within wounds should be carefully evacuated and any remaining bleeding sources controlled with ligature or cautery. If the injury has resulted in the formation of a marginally viable flap of skin or tissue, these should be resected or revascularized prior to further wound repair and closure.

Having ensured hemostasis and adequate débridement of nonviable tissues and removal of any remaining foreign bodies, irregular, macerated, or beveled wound edges should be débrided to provide a fresh edge for reapproximation. Great care must be taken to realign wound edges properly—this is particularly important for wounds that cross the vermilion border, eyebrow, or hairline.

In general, the smallest suture required to hold the various layers of the wound in approximation should be selected to minimize suture-related inflammation. Nonabsorbable or slowly absorbing monofilament sutures are most suitable for approximating deep fascial layers, particularly in the abdominal wall. Subcutaneous tissues should be closed with braided absorbable sutures, with care to avoid placement of sutures in fat.

In areas of significant tissue loss, rotation of adjacent musculocutaneous flaps may be required to provide sufficient tissue mass for closure. These flaps may be based on intrinsic blood supply, or may be moved from distant sites as free flaps and anastomosed into the local vascular bed. In areas with significant superficial tissue loss, STSG may be required and will speed formation of an intact epithelial barrier to fluid loss and infection. It is essential to ensure hemostasis of the underlying tissue bed prior to placement of STSGs, as the presence of a hematoma below the graft will prevent the graft from taking. In acute, contaminated wounds with skin loss, use of porcine xenografts or cadaveric allografts is prudent until the danger of infection passes.

After closing deep tissues and replacing significant tissue deficits, skin edges should be reapproximated for cosmesis and to aid in rapid wound healing. Skin

edges may be quickly reapproximated with surgical staples or nonabsorbable monofilament sutures. Care must be taken to remove these from the wound prior to epithelialization of the skin tracts in which sutures or staples penetrate the dermal layer. Failure to remove the sutures or staples prior to 7–10 days (or 3–5 days for the face) after repair will result in a cosmetically inferior wound. Where wound cosmesis is important, the above problems may be avoided by placement of buried dermal sutures using absorbable braided sutures. This method of wound closure allows for a precise reapproximation of wound edges, and may be enhanced by application of wound closure tapes to the surface of the wound. Intradermal absorbable sutures do not require removal. Use of skin tapes alone is only recommended for closure of the smallest superficial wounds.

Recently, octyl-cyanoacrylate tissue glues have shown promise for the management of simple, linear wounds with viable skin edges. These new glues are less prone to brittleness and have superior burst-strength characteristics. Studies have shown them to be suitable for use in contaminated situations without significant risk of infection. When used in the above types of wounds, these glues appear to provide superb cosmetic results and result in significantly less trauma than sutured repair, particularly when used in pediatric patients.

Antibiotics

Antibiotic treatment of acute wounds must be based on organisms suspected to be found within the infected wound and the patient's overall immune status. When a single specific organism is suspected, treatment may be commenced using a single antibiotic. Conversely, when multiple organisms are suspected, as with enteric contamination or when a patient's immune function is impaired by diabetes, chronic disease, or medication, treatment should commence with a broad-spectrum antibiotic or several agents in combination. Lastly, the location of the wound and the quality of tissue perfusion to that region will significantly impact wound performance after injury. Antibiotics also can be delivered topically as part of irrigations or dressings, although the efficacy of this practice is questionable.

Dressings

The main purpose of wound dressings is to provide the ideal environment for wound healing. Covering a wound with a dressing mimics the barrier role of epithelium and prevents further damage. Additionally, application of compression provides hemostasis and limits edema. Occlusion of a wound with dressing material can control the level of hydration and oxygen tension within the wound thus limiting tissue desiccation. It also may allow the transfer of gases and water vapor from the wound surface to the atmosphere. Because it may enhance bacterial growth, occlusion is contraindicated in infected and highly exudative wounds.

Absorbent Dressings

Accumulation of wound fluid can lead to maceration and bacterial overgrowth. Ideally, the dressing should absorb without getting soaked through. The dressing must be designed to match the exudative properties of the wound and may include cotton, wool, and sponge.

Nonadherent Dressings

Nonadherent dressings are impregnated with paraffin, petroleum jelly, or water-soluble jelly for use as nonadherent coverage. A secondary dressing must be placed on top to seal the edges and prevent desiccation and infection.

Occlusive and Semiocclusive Dressings

Occlusive and semiocclusive dressings should only be used for clean, minimally exudative wounds. These film dressings are waterproof and impervious to microbes, but permeable to water vapor and oxygen.

Hydrocolloid and Hydrogel Dressings

Hydrocolloids and hydrogels form complex structures with water which aids in atraumatic removal of the dressing. Absorption of exudates by the hydrocolloid dressing leaves a yellowish-brown gelatinous mass after dressing removal that can be washed off. Hydrogel has high water content. Hydrogels allow a high rate of evaporation without compromising wound hydration.

Alginates

Alginates are derived from brown algae and contain long chains of polysaccharides containing mannuronic and glucuronic acid. Processed as the calcium form, alginates turn into soluble sodium alginate through ion exchange in the presence of wound exudates. The polymers gel, swell, and absorb a great deal of fluid. Alginates are used in open surgical wounds with medium exudation, and on full-thickness chronic wounds.

Medicated Dressings

Medicated dressings have long been used as a drug-delivery system. Agents delivered in the dressings include benzoyl peroxide, zinc oxide, neomycin, and bacitracin-zinc. These agents have been shown to increase epithelialization by 28 percent.

The type of dressing to be used depends on the amount of wound drainage. A nondraining wound can be covered with semiocclusive dressing. Drainage of less than 1–2 mL/day may require a semiocclusive or absorbent nonadherent dressing. Moderately draining wounds (3–5 mL/day) can be dressed with a nonadherent primary layer plus an absorbent secondary layer plus an occlusive dressing to protect normal tissue. Heavily draining wounds (>5 mL/day) require a similar dressing as moderately draining wounds, but with the addition of a highly absorbent secondary layer.

Mechanical Devices

The VAC (vacuum-assisted closure) system assists in wound closure by applying localized negative pressure to the surface and margins of the wound. This negative pressure therapy is applied to a special foam dressing cut to the dimensions of the wound and positioned in the wound cavity or over a flap or graft. The continuous negative pressure is very effective in removing exudates from the wound. This form of therapy has been found to be effective for chronic open wounds (diabetic ulcers and stages 3 and 4 pressure ulcers), acute and traumatic wounds, flaps and grafts, and subacute wounds (i.e., dehiscent incisions).

Skin Replacements

All wounds require coverage to prevent evaporative losses and infection and to provide an environment that promotes healing. Both acute and chronic wounds may demand use of skin replacement, and several options are available.

Conventional Skin Grafts

Split- or partial-thickness grafts consist of the epidermis plus part of the dermis, although full-thickness grafts retain the entire dermis. Autologous grafts are transplants from one site on the body to another; allogeneic grafts (allografts, homografts) are transplants from a living nonidentical donor or cadaver to the host; and xenogeneic grafts (heterografts) are taken from another species (e.g., porcine). Split-thickness grafts require less blood supply to restore skin function. The dermal component of full-thickness grafts lends mechanical strength and resists wound contraction better, resulting in improved cosmesis. Allogeneic and xenogeneic grafts are subject to rejection, and may contain pathogens.

The use of skin grafts or bioengineered skin substitutes and other innovative treatments cannot be effective unless the wound bed is adequately prepared.

Skin Substitutes

Skin substitutes promote healing, either by stimulating host cytokine generation or by providing cells that may also produce growth factors locally. Their disadvantages include limited survival, high cost, and the need for multiple applications.

Composite substitutes provide both the dermal and epidermal components essential for permanent skin replacement. The acellular (e.g., native collagen or synthetic material) component acts as a scaffold, promotes cell migration and growth, and activates tissue regeneration and remodeling. The cellular elements re-establish lost tissue and associated function, synthesize extracellular matrix components, produce essential mediators such as cytokines and growth factors, and promote proliferation and migration.

Cultured epithelial autografts (CEAs) represent expanded autologous or homologous keratinocytes. CEAs are expanded from a biopsy of the patient's own skin, will not be rejected, and can stimulate re-epithelialization and the growth of underlying connective tissue. Keratinocytes harvested from a biopsy roughly the size of a postage stamp are cultured with fibroblasts and growth factors and grown into sheets that can cover large areas and give the appearance of normal skin. Until the epithelial sheets are sufficiently expanded, the wound must be covered with an occlusive dressing or a temporary allograft or xenograft.

Viable fibroblasts can be grown on bioabsorbable or nonbioabsorbable meshes to yield living dermal tissue that can act as a scaffold for epidermal growth. Fibroblasts stimulated by growth factors can produce type I collagen and glycosaminoglycans which adhere to the wound surface to permit epithelial cell migration, and adhesive ligands (e.g., the matrix protein fibronectin), which promote cell adhesion. This approach has the virtue of being less time-consuming and expensive than culturing keratinocyte sheets.

Growth Factor Therapy

It is believed that nonhealing wounds result from insufficient or inadequate growth factors in the wound environment. Although there is a large body of work demonstrating the effects of growth factors in animals, translation of these data into clinical practice has met with limited success.

At present, only platelet-derived growth factor BB (PDGF-BB) is currently approved by the Food and Drug Administration (FDA) for treatment of diabetic foot ulcers. Application of recombinant human PDGF-BB in a gel suspension to these wounds increases the incidence of total healing and decreases healing time.

As the population ages, oncology is becoming a larger portion of surgical practice. Modern cancer therapy is multidisciplinary, involving the coordinated care of surgeons, medical oncologists, radiation oncologists, reconstructive surgeons, pathologists, radiologists, and primary care physicians. Primary (or definitive) therapy refers to en bloc resection of tumor with adequate margins of normal tissues and in some cases regional lymph nodes. Adjuvant therapy refers to radiation therapy and systemic therapies, including chemotherapy, immunotherapy, hormonal therapy, and increasingly, biologic therapy. The primary goal of surgical and radiation therapy is local and regional control. On the other hand, the primary goal of systemic therapies is systemic control by treating distant foci of subclinical disease to prevent recurrence. Surgeons must be familiar with adjuvant therapies to coordinate multidisciplinary care. Knowledge of cancer epidemiology, etiology, staging and natural history is also required to determine the optimal surgical therapy.

EPIDEMIOLOGY

Basic Principles of Cancer Epidemiology

The term incidence refers to the number of new cases occurring; incidence usually is expressed as the number of new cases per 100,000 persons per year. Mortality refers to the number of deaths occurring and is expressed as the number of deaths per 100,000 persons per year. Incidence and mortality data are usually available through cancer registries.

The incidence of cancer is variable by geography. This is due in part to genetic differences and in part to differences in environmental and dietary exposures. Epidemiologic studies that monitor trends in cancer incidence and mortality have tremendously enhanced our understanding of the etiology of cancer.

The two types of epidemiologic studies that are conducted most often to investigate the etiology of cancer and the effect of prevention modalities are cohort studies and case-control studies. Cohort studies follow a group of people who initially do not have a disease over time and measure the rate of development of a disease. In cohort studies, a group that is exposed to a certain environmental factor or intervention usually is compared to a group that has not been exposed (e.g., smokers vs. nonsmokers). Case-control studies compare a group of patients affected with a disease to a group of individuals without the disease for a given exposure. The results are expressed in terms of an odds ratio, or relative risk. A relative risk less than 1 indicates a protective effect, although a relative risk greater than 1 indicates an increased risk of developing the disease with exposure.

Cancer Incidence and Mortality in the United States

In the year 2003, an estimated 1,334,100 new cases of invasive cancer will be diagnosed in the United States. Furthermore, an estimated 556,500 people will die from cancer in the United States in the same year. The most common

causes of cancer death in men are cancers of the lung and bronchus, prostate, and colon and rectum; in women, the most common cancers are of the lung and bronchus, breast, and colon and rectum.

Trends in Cancer Incidence and Mortality

Cancer deaths accounted for 23 percent of all deaths in the United States in 2000, second only to deaths from heart disease, which accounted for 29.6 percent of total deaths. As the life expectancy of the human population increases because of reductions in other causes of death such as infections and cardiovascular disease, cancer is becoming the leading cause of death. Cancer is already the leading cause of death among women aged 40–79 and among men aged 60–79.

Cancer incidence increased by 0.3 percent per year in females during the period from 1987 to 1999, but it stabilized in males between 1995 and 1999. Interestingly, prostate cancer rates increased dramatically between 1988 and 1992, and declined between 1992 and 1995. These trends are thought to reflect the extensive use of prostate-specific antigen (PSA) screening, leading to the earlier diagnosis of prostate cancers.

From 1992 to 1999, for all cancer types combined, cancer death rates decreased by 1.5 percent per year in males and by 0.6 percent per year in females. In fact, the 5-year survival rates from 1974 to 1998 reveal improvement in relative survival rates for cancers in almost all sites. How much of this improvement reflects actual improvement of cancer therapy and how much simply reflects earlier diagnosis of tumors with stage-for-stage outcome remaining unchanged, is not yet known.

Global Statistics on Cancer Incidence and Mortality

It has been estimated that there were a total of 10.1 million new cancer cases around the world in 2000, a number 22 percent higher than estimates for 1990. The most common cancers in terms of new cases were lung cancer (1.2 million), breast cancer (1.05 million), colon-rectum (945,000), stomach (876,000), and liver (564,000) in 2000. The most common causes of death because of cancer in 2000 were cancers of the lung (1.1 million), stomach (647,000), and liver cancer (549,000).

Stomach Cancer

The incidence of stomach cancer varies significantly among different regions of the world. The age-adjusted incidence is highest in Japan. The difference in risk by country is presumed to be because of differences in dietary factors and in the incidence of infection with *Helicobacter pylori*, which is known to play a major role in gastric cancer development. Fortunately, a steady decline is being observed in the incidence and mortality rates of gastric cancer. This may be related to improvements in preservation and storage of foods.

Breast Cancer

The incidence of breast cancer is high in all of the most highly developed regions except Japan, including the United States and Canada, Australia, and Northern and Western Europe. The highest breast cancer incidence is in the United States and the lowest is in China. Although breast cancer has been linked to cancer susceptibility genes, mutations in these genes account for only 5–10 percent of breast tumors, suggesting that the wide geographic variations

in breast cancer incidence are not because of geographic variations in the prevalence of these genes. Most of the differences, therefore, are attributed to differences in reproductive factors, diet, and other environmental differences. Indeed, breast cancer risk increases significantly in females who have migrated from Asia to America. Overall, the incidence of breast cancer is rising in most countries.

Colon and rectal cancer. The incidence of colon and rectal cancer is higher in developed countries than developing countries. The incidence rates are highest in Australia/New Zealand, North America, and Northern and Western Europe. These geographic differences are thought to reflect environmental exposures and are presumed to be mainly dietary differences.

Liver cancer. Eighty percent of liver cancers occur in developing countries. The incidence of liver cancer is especially high in China and other countries in Eastern Asia. Worldwide, the major risk factors for liver cancer are infection with hepatitis viruses and consumption of foods contaminated with aflatoxin. Hepatitis B immunization in children has recently been shown to reduce the incidence of hepatitis infection in China, Korea, and West Africa. Whether this will translate into a reduction in the incidence in liver cancer in these regions will soon be determined.

Prostate cancer. The incidence of prostate cancer is dramatically higher in North America than in China, Japan, and the rest of Asia, and even in Northern and Western Europe. A considerable part of the international differences in prostate cancer incidence is thought to reflect differences in diagnostic practices. As previously mentioned, the introduction of PSA screening has led to a significant increase in the diagnosis of prostate cancer in the United States.

Esophageal cancer. Geographic variations in the incidence of esophageal cancer are also striking. The highest incidence of this cancer is in Southern Africa and China. These geographic differences are attributed to nutritional deficiencies and exposures to exogenous carcinogens. Esophageal cancer in North America and Europe is attributed to tobacco and alcohol use.

The mortality rates of different cancers also vary significantly among countries. This is attributable not only to variations in incidence but also to variations in survival after a cancer diagnosis. Survival rates are influenced not only by treatment patterns but also by variations in cancer screening practices, which affect the stage of cancer at diagnosis. For example, the 5-year survival rate of stomach cancer is much higher in Japan, where the cancer incidence is high enough to warrant mass screening and is presumed to lead to earlier diagnosis. In the case of prostate cancer, the mortality rates diverge much less than the incidence rates among countries. Survival rates for prostate cancer are much higher in North America than in developing countries (88 vs. 41 percent). It is possible that the extensive screening practices in the United States allow discovery of cancers at an earlier, more curable stage; however, it is also possible that this screening leads to discovery of more latent, less biologically aggressive cancers, which may not have caused death even if they had not been identified.

CANCER BIOLOGY

Cell Proliferation and Transformation

In normal cells, cell growth and proliferation are under strict control. In cancer cells, cells become unresponsive to normal growth controls, leading to uncontrolled growth and proliferation. Abnormally proliferating, transformed cells outgrow normal cells in the culture dish (i.e., in vitro) and commonly display several abnormal characteristics. These include loss of contact inhibition (i.e., cells continue to proliferate after a confluent monolayer is formed); an altered appearance and poor adherence to other cells or the substratum; loss of anchorage-dependence for growth; immortalization; and gain of tumorigenicity (i.e., the ability to give rise to tumors when injected into an appropriate host).

Cancer Initiation

Tumorigenesis is proposed to have three steps: initiation, promotion, and progression. Initiating events may lead a single cell to acquire a distinct growth advantage, such as gain of function of genes known as oncogenes, or loss of function of genes known as tumor suppressor genes. Subsequent events can lead to accumulations of additional deleterious mutations in the clone.

Cancer is a disease of clonal progression as tumors arise from a single cell and accumulate mutations that confer on the tumor an increasingly aggressive behavior. Most tumors are thought to go through a progression from benign lesions to in situ tumors to invasive cancers (e.g., atypical ductal hyperplasia to ductal carcinoma in situ to invasive ductal carcinoma of the breast). Fearon and Vogelstein proposed the model for colorectal tumorigenesis. Colorectal tumors arise from the mutational activation of oncogenes coupled with mutational inactivation of tumor suppressor genes, the latter being the predominant change. Mutations in at least four or five genes are required for formation of a malignant tumor, although fewer changes suffice for a benign tumor. Although genetic mutations often occur in a preferred sequence, a tumor's biologic properties are determined by the total accumulation of its genetic changes.

Gene expression is a multistep process that starts from transcription of a gene into messenger ribonucleic acid (mRNA) and then translation of this sequence into the functional protein. There are several controls at each level. In addition to alterations at the genome level, alterations at the transcription level (e.g., methylation of the DNA leading to transcriptional silencing), or at the mRNA processing, mRNA stability, mRNA translation, or protein stability levels, can alter critical proteins and thus contribute to tumorigenesis.

Cell-Cycle Dysregulation in Cancer

The proliferative advantage of tumor cells is a direct result of their ability to bypass quiescence. Mutations or alterations in the expression of cell-cycle proteins, growth factors, growth factor receptors, intracellular signal transduction proteins, and nuclear transcription factors all can lead to disturbance of the basic regulatory mechanisms that control the cell cycle, allowing unregulated cell growth and proliferation.

The cell cycle is divided into four phases. During the synthetic or S phase, the cell generates a single copy of its genetic material, although in the mitotic or M phase, the cellular components are partitioned between the two identical daughter cells. The G1 and G2 phases represent gap phases during which the cells prepare themselves for completion of the S and M phases, respectively.

When cells cease proliferation, they exit the cell cycle and enter the quiescent state referred to as G0.

Cell-cycle progression is regulated by a series of checkpoints that prevent cells from entering a new phase without completing the previous phase. The central regulators are serine-threonine kinases referred to as the cyclin-dependent kinases (CDKs). CDK4 and CDK6 are thought to be involved in the early G1 phase, whereas CDK2 is required to complete G1 and initiate S phase. CDK4 and CDK6 form active complexes with the D-type cyclins, cyclins D1, D2, and D3. CDK2 is activated by the cyclins E1 and E2, during the G1/S transition and by cyclins A1 and A2, during the S phase.

The principal downstream target of the activated complex of cyclin D and CDK4 or CDK6 is the retinoblastoma protein (Rb). In its hypophosphorylated form, Rb suppresses cellular growth by binding the E2F family of transcription factors. Furthermore, Rb binding to the promoter as a complex with E2F can actively repress transcription through chromatin remodeling, by recruiting proteins such as histone deacetylases and SWI/SNF complexes. Following cyclin/CDK-mediated phosphorylation, Rb releases E2F transcription factors that then activate downstream transcriptional targets involved in S phase, such as DNA polymerase alpha, cyclin A, cyclin E, and CDK1.

Regulators of CDKs can affect cell-cycle progression. CDKs are phosphorylated and activated by CDK-activating kinase. CDK inhibitors (CKIs) comprise two classes, the INK4 family and the WAF/Kip family. The INK4 family has four members: INK4A (p16), INK4B (p15), INK4C (p18), and INK4D (p19). The INK4 proteins bind CDK4 and CDK6 and prevent their association with D-type cyclins and cyclin D activation. The WAF/Kip family members include WAF1 (p21), KIP1 (p27), and KIP2 (p57). These CKIs bind and inactivate cyclin/CDK2 complexes.

Molecular alterations of human tumors have demonstrated that cell-cycle regulators are frequently mutated. Other alterations include overexpression of cyclins D1 and E, and CDK4 and CDK6, and loss of CKIs INK4A, INK4B, and KIP1.

Oncogenes

Normal cellular genes that contribute to cancer when abnormal are called oncogenes. The normal counterpart of such a gene is referred to as a protooncogene. Oncogenes are usually designated by three-letter abbreviations, such as *myc* or *ras*. Oncogenes are further designated by the prefix of “v-” for virus or “c-” for cell or chromosome, corresponding to the origin of the oncogene when it was first detected. Protooncogenes can be activated (have increased activity) or overexpressed (expressed at increased protein levels) by translocation (e.g., *abl*), promoter insertion (e.g., *c-myc*), mutations (e.g., *ras*), or amplification (e.g., *HER2/neu*). More than 100 oncogenes have been identified.

Oncogenes may be growth factors (e.g., platelet-derived growth factor), growth factor receptors (e.g., *HER2/neu*), intracellular signal transduction molecules (e.g., *ras*), nuclear transcription factors (e.g., *c-myc*), or other molecules involved in the regulation of cell growth and proliferation. Growth factors are proteins that are produced and secreted by cells locally and that stimulate cell proliferation by binding specific cell-surface receptors on the same cells (autocrine stimulation) or on neighboring cells (paracrine stimulation). Persistent overexpression of growth factors can lead to uncontrolled autostimulation and neoplastic transformation. Alternatively, growth factor

receptors can be aberrantly activated (turned on) through mutations, or over-expressed (continually presenting cells with growth-stimulatory signals, even in the absence of growth factors), leading cells to respond as if growth factor levels are altered. The growth-stimulating effect of growth factors and other mitogens is mediated through postreceptor signal transduction molecules. These molecules mediate the passage of growth signals from the outside to the inside of the cell and then to the cell nucleus, initiating the cell cycle and deoxyribonucleic acid (DNA) transcription. Aberrant activation or expression of cell-signaling molecules, cell-cycle molecules, or transcription factors may play an important role in neoplastic transformation.

Alterations in Apoptosis in Cancer Cells

Apoptosis (programmed cell death) is a genetically regulated program to dispose of cells. Cancer cells must avoid apoptosis if tumors are to arise. The growth of a tumor mass is dependent not only on an increase of proliferation of tumor cells but also on a decrease in their apoptotic rate. Apoptosis is distinguished from necrosis because it leads to several characteristic changes. In early apoptosis, the changes in membrane composition lead to extracellular exposure of phosphatidylserine residues, which avidly bind annexin, a characteristic used to discriminate apoptotic cells in laboratory studies. Late in apoptosis there are characteristic changes in nuclear morphology, such as chromatin condensation, nuclear fragmentation, and DNA laddering, and membrane blebbing. Apoptotic cells are then engulfed and degraded by phagocytic cells. The effectors of apoptosis are a family of proteases called caspases (cysteine-dependent and aspartate-directed proteases). The initiator caspases (e.g., 8, 9, and 10), which are upstream, cleave the downstream executioner caspases (e.g., 3, 6, and 7) that carry out the destructive functions of apoptosis.

Two principal molecular pathways signal apoptosis by cleaving the initiator caspases with the potential for cross-talk: the mitochondrial pathway and the death receptor pathway. In the mitochondrial pathway, sometimes referred to as the intrinsic pathway, death results from the release of cytochrome c from the mitochondria. Cytochrome c, procaspase-9, and apoptotic protease-activating factor-1 (Apaf-1) form an enzyme complex, referred to as the apoptosome, which activates the effector caspases. In addition to these proteins, the mitochondria contain other proapoptotic proteins such as SMAC/DIABLO. The mitochondrial pathway can be stimulated by many factors, including DNA damage, reactive oxygen species, or withdrawal of survival factors. The mitochondrial membrane permeability determines whether the apoptotic pathway will proceed. The Bcl-2 family of regulatory proteins includes proapoptotic proteins (e.g., Bax, Bad, and Bak) and antiapoptotic proteins (e.g., Bcl-2 and Bcl-xL); the activity of the Bcl-2 proteins is centered on the mitochondria, in which they regulate membrane permeability.

The second principal apoptotic pathway is the death receptor pathway, sometimes referred to as the extrinsic pathway. Cell-surface death receptors include Fas/APO1/CD95, tumor necrosis factor receptor 1 (TNFR1), and KILLER/DR5, which bind their ligands FasL, TNF, and TRAIL, respectively. When the receptors are bound by their ligands, they form a death-inducing signaling complex (DISC). At the DISC, procaspase-8 and procaspase-10 are cleaved, yielding active initiator caspases. The death receptor pathway may be regulated at the cell surface by the expression of "decoy" receptors for Fas and TRAIL.

The decoy receptors are closely related to the death receptors but lack a functional death domain, therefore they bind death ligands, but do not transmit a death signal. Another regulatory group is the FADD-like interleukin-1 protease-inhibitory proteins (FLIPs). FLIPs have homology to caspase-8; they bind to the DISC and inhibit the activation of caspase-8. Finally, inhibitors of apoptosis proteins (IAPs) block caspase-3 activation and have the ability to regulate both the death receptor and the mitochondrial pathway. The IAP family includes XIAP, cIAP1, cIAP2, NAIP, ML-IAP, ILP2, livin, apollon, and survivin. NF- κ B also induces cellular resistance to apoptosis by transcriptionally activating cIAP1 and cIAP2, and other specific antiapoptotic proteins such as A20 and Mn-SOD.

In human cancers, aberrations in the apoptotic program include increased expression of Fas and TRAIL decoy receptors; increased expression of antiapoptotic Bcl-2; increased expression of IAP-related protein survivin; increased expression of c-FLIP; mutations or downregulation of proapoptotic Bax, caspase-8, APAF1, XAF1, and death receptors CD95, TRAIL-R1, and TRAIL-R2; alterations of the p53 pathway; overexpression of growth factors and growth factor receptors; and activation of the PI3-K/Akt survival pathway.

Cancer Invasion

A feature of malignant cells is their ability to invade the surrounding normal tissue. Tumors in which the malignant cells appear to lie exclusively above the basement membrane are referred to as *in situ* cancer, although tumors in which the malignant cells are demonstrated to breach the basement membrane, penetrating into surrounding stroma, are termed *invasive cancer*. The ability to invade involves changes in adhesion, initiation of motility, and proteolysis of the extracellular matrix (ECM).

Cell-to-cell adhesion in normal cells involves interactions between cell-surface proteins. Calcium adhesion molecules of the cadherin family (E-cadherin, P-cadherin, and N-cadherin) are thought to enhance the cells' ability to bind to one another and suppress invasion. Migration occurs when cancer cells penetrate and attach to the basal matrix of the tissue being invaded; this allows the cancer cell to pull itself forward within the tissue. Attachment to glycoproteins of the ECM such as fibronectin, laminin, and collagen is mediated by tumor cell integrin receptors. Integrins are a family of glycoproteins that form heterodimeric receptors for ECM molecules. In addition to regulating cell adhesion to the ECM, integrins relay molecular signals regarding the cellular environment that influence shape, survival, proliferation, gene transcription, and migration.

Serine, cysteine, and aspartic proteinases and matrix metalloproteinases (MMPs) have all been implicated in cancer invasion. Urokinase plasminogen activators (uPA) and tissue plasminogen activators (tPA) are serine proteases that convert plasminogen into plasmin. Plasmin, in return, can degrade several ECM components. Plasmin also may activate several MMPs. Plasminogen activator inhibitors (PAI-1 and PAI-2) are produced in tissues and counteract the activity of plasminogen activators.

MMPs are upregulated in almost every type of cancer. Some of the MMPs are expressed by cancer cells, although others are expressed by the tumor stromal cells. Experimental models have demonstrated that MMPs promote cancer progression by increasing cancer cell growth, migration, invasion, angiogenesis, and metastasis. The activity of MMPs is regulated by their endogenous

inhibitors, including α_2 -macroglobulin, membrane-bound inhibitors RECK (reversion-inducing cysteine-rich protein with kazal domains), and tissue inhibitors of MMPs (TIMP-1, -2, -3, and -4). Thus regulation of MMPs occurs at three levels: alterations of gene expression, activation of latent zymogens, and inhibition by endogenous inhibitors. Alterations of all three levels of control have been associated with tumor progression.

Angiogenesis

Angiogenesis is the establishment of new blood vessels from a preexisting vascular bed. This neovascularization is essential for tumor growth and metastasis. Tumors develop an angiogenic phenotype as a result of accumulated genetic alterations and in response to local selection pressures such as hypoxia. Many of the common oncogenes and tumor suppressor genes have been shown to play a role in inducing angiogenesis, including *ras*, *myc*, *HER2/neu*, and mutations in *p53*.

Angiogenesis is mediated by factors produced by various cells including tumor cells, endothelial cells, stromal cells, and inflammatory cells. Several factors have been shown to be proangiogenic or antiangiogenic. Of the angiogenic stimulators, the best studied are the vascular endothelial growth factors (VEGF). The VEGF family consists of six growth factors (VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor) and three receptors (VEGFR1 or Flt-1, VEGFR2 or KDR/FLK-1, and VEGFR3 or FLT4). Neupilin 1 and 2 also may act as receptors for VEGF. VEGF is induced by hypoxia and by different growth factors and cytokines, including EGF, PDGF, TNF- α , TGF- β , and interleukin 1 β (IL-1 β). VEGF has various functions including increasing vascular permeability, inducing endothelial cell proliferation and tube formation, and inducing endothelial cell synthesis of proteolytic enzymes such as uPA, PAI-1, UPAR, and MMP-1. Furthermore, VEGF may mediate blood flow by its effects on the vasodilator nitric oxide and act as an endothelial survival factor, thus protecting the integrity of the vasculature. The proliferation of new lymphatic vessels, lymphangiogenesis, is also thought to be controlled by the VEGF family. Signaling in lymphatic cells is thought to be modulated by VEGFR3. Experimental studies with VEGF-C and VEGF-D have shown that they can induce tumor lymphangiogenesis and direct metastasis via the lymphatic vessels and lymph nodes.

PDGFs A, B, C, and D also play important roles in angiogenesis. PDGFs can not only enhance endothelial cell proliferation directly but also upregulate VEGF expression in vascular smooth muscle cells, promoting endothelial cell survival via a paracrine effect. The angiopoietins, angiopoietin 1 (Ang-1) and angiopoietin 2 (Ang-2), in return, are thought to regulate blood vessel maturation. Ang-1 and Ang-2 both bind endothelial cell receptor Tie-2, but only the binding of Ang-1 activates signal transduction; thus Ang-2 is an Ang-1 antagonist. Ang-1, via the Tie-2 receptor, induces remodeling and stabilization of blood vessels. Upregulation of Ang-2 by hypoxic induction of VEGF inhibits Ang-1-induced Tie-2 signaling, resulting in destabilization of vessels and making endothelial cells responsive to angiogenic signals, thus promoting angiogenesis in the presence of VEGF. Therefore the balance between these factors determines the angiogenetic capacity of a tumor. Tumor angiogenesis is regulated by several factors in a coordinated fashion. In addition to upregulation of proangiogenic molecules, angiogenesis also can be encouraged by

suppression of naturally occurring inhibitors. Such inhibitors of angiogenesis include thrombospondin 1 and angiostatin.

Angiogenesis is a prerequisite not only for primary tumor growth but also for metastasis. Angiogenesis in the primary tumor, as determined by microvessel density, has been demonstrated to be an independent predictor of distant metastatic disease and survival in several cancers. Expression of angiogenic factors such as VEGFs has had prognostic value in many studies. These findings further emphasize the importance of angiogenesis in cancer biology.

Metastasis

Metastases arise from the spread of cancer cells from the primary site and the formation of new tumors in distant sites. The metastatic process consists of a series of steps that need to be successfully completed. First, the primary cancer must develop access to the circulation through either the blood circulatory system or the lymphatic system. After the cancer cells are shed into the circulation, they must survive. Next, the circulating cells lodge in a new organ and extravasate into the new tissue. Next, the cells need to initiate growth in the new tissue and eventually establish vascularization to sustain the new tumor. Overall, metastasis is an inefficient process, although the initial steps of hematogenous metastasis (the arrest of tumor cells in the organ and extravasation) are believed to be performed efficiently.

Metastases can sometimes arise several years after the treatment of primary tumors. This phenomenon is referred to as dormancy, and it remains one of the biggest challenges in cancer biology. Persistence of solitary cancer cells in a secondary site such as the liver or bone marrow is one possible contributor to dormancy. Another explanation of dormancy is that cells remain viable in a quiescent state and then get reactivated by a physiologically perturbing event. An alternate explanation is that cells establish preangiogenic metastases in which they continue to proliferate but that the proliferative rate is balanced by the apoptotic rate. Therefore, when these small metastases acquire the ability to be vascularized, substantial tumor growth can be achieved at the metastatic site, leading to clinical detection.

Several types of tumors metastasize in an organ-specific pattern. One explanation for this is mechanical and is based on the different circulatory drainage patterns of the tumors. The other explanation for preferential metastasis is what is referred to as the “seed and soil” theory, the dependence of the seed (the cancer cell) on the soil (the secondary organ). According to this theory, once cells have reached a secondary organ, their growth efficiency in that organ is based on the compatibility of the cancer cell’s biology with its new microenvironment. The ability of cancer cells to grow in a specific site likely depends on features inherent to the cancer cell, features inherent to the organ, and the interplay between the cancer cell and its microenvironment.

Many of the oncogenes discovered to date, such as HER2/neu, ras, and myc, are thought to potentiate not only malignant transformation but also one or more of the steps required in the metastatic process. Metastasis also may involve the loss of metastasis suppressor genes. Laboratory work involving cancer cell lines that have been selected to have a higher metastatic potential have led to the realization that these more highly metastatic cells have a different gene expression profile than their less metastatic parental counterparts. This in turn has led to the currently held belief that the ability of a primary tumor to metastasize may be predictable by analysis of its gene expression profile.

Indeed, several studies have recently focused on identifying a gene expression profile or a “molecular signature” that is associated with metastasis. It has been shown that such a gene expression profile can be used to predict the probability of remaining free of distant metastasis. Notably, this hypothesis differs from the multistep tumorigenesis theory in that the ability to metastasize is considered an inherent quality of the tumor from the beginning. It is assumed that metastasis develops not from a few rare cells in the primary tumor that develop the ability to metastasize but that all cells in tumors with such molecular signatures develop the ability to metastasize. The reality probably lies in between in that some early genetic changes detectable in the entire tumor can give tumors an advantage in the metastatic process, although additional genetic changes can give a clone of cells additional advantages, thus allowing them to succeed in metastasis.

CANCER ETIOLOGY

Cancer Genetics

One widely held opinion is that cancer is a genetic disease that arises from an accumulation of mutations that leads to the selection of cells with increasingly aggressive behavior. These mutations may lead either to a gain of function by oncogenes or to a loss of function by tumor suppressor genes. Most of our information on human cancer genes has been gained from hereditary cancers. In the case of hereditary cancers, the individual carries a particular germline mutation in every cell. In the past decade, more than 30 genes for autosomal dominant hereditary cancers have been identified (Table 9-1). A few of these hereditary cancer genes are oncogenes, but most are tumor suppressor genes. Although hereditary cancer syndromes are rare, somatic mutations that occur in sporadic cancer have been found to disrupt the cellular pathways altered in hereditary cancer syndromes, suggesting that these pathways are critical to normal cell growth, cell cycle, and proliferation.

The following criteria may suggest the presence of a hereditary cancer:

1. Tumor development at a much younger age than usual
2. Presence of bilateral disease
3. Presence of multiple primary malignancies
4. Presentation of a cancer in the less affected sex (e.g., male breast cancer)
5. Clustering of the same cancer type in relatives
6. Cancer associated with other conditions such as mental retardation or pathognomonic skin lesions

It is crucial that all surgeons taking care of cancer patients be aware of hereditary cancer syndromes, because a patient's genetic background has significant implications for patient counseling, planning of surgical therapy, and cancer screening and prevention. Some of the more commonly encountered hereditary cancer syndromes are discussed here.

rb1 Gene and Hereditary Retinoblastoma

The *rb1* gene was the first tumor suppressor to be cloned. Retinoblastoma has long been known to occur in hereditary and nonhereditary forms. In approximately 40 percent of cases of retinoblastoma in the United States, the individual has a predisposition conferred by a germline mutation. Dr. Alfred Knudson hypothesized that hereditary retinoblastoma involves two mutations, one of which is germline, although the other, nonhereditary retinoblastoma,

TABLE 9-1 Genes Associated with Hereditary Cancer

Genes	Location	Syndrome	Cancer sites and associated traits
<i>APC</i>	17q21	Familial adenomatous polyposis (FAP)	Colorectal adenomas and carcinomas, duodenal and gastric tumors, desmoids, medullablastomas, osteomas
<i>BMPRIA</i>	10q21-q22	Juvenile polyposis coli	Juvenile polyps of the gastrointestinal tract, gastrointestinal and colorectal malignancy
<i>BRCA1</i>	17q21	Breast/ovarian syndrome	Breast cancer, ovarian cancer, colon cancer, prostate cancer
<i>BRCA2</i>	13q12.3	Breast/ovarian syndrome	Breast cancer, ovarian cancer, colon cancer, prostate cancer, cancer of the gallbladder and bile duct, pancreatic cancer, gastric cancer, melanoma
<i>p16; CDK4</i>	9p21; 12q14	Familial melanoma	Melanoma, pancreatic cancer, dysplastic nevi, atypical moles
<i>CDH1</i>	16q22	Hereditary diffuse gastric cancer	Gastric cancer
<i>hCHK2</i>	22q12.1	Li-Fraumeni and hereditary breast cancer	Breast cancer, soft-tissue sarcoma, brain tumors
<i>hMLH1; hMSH2; hMSH6; hPMS1; hPMS2</i>	3p21; 2p22-21; 2p16; 2q31-33; 7p22	Hereditary nonpolyposis colorectal cancer	Colorectal cancer, endometrial cancer, transitional cell carcinoma of the ureter and renal pelvis, and carcinomas of the stomach, small bowel, ovary, and pancreas
<i>MEN1</i>	11q13	Multiple endocrine neoplasia type 1	Pancreatic islet cell cancer, parathyroid hyperplasia, pituitary adenomas
<i>MET</i>	7q31	Hereditary papillary renal cell carcinoma	Renal cancer
<i>NF1</i>	17q11	Neurofibromatosis type 1	Neurofibroma, neurofibrosarcoma, acute myelogenous leukemia, brain tumors
<i>NF2</i>	22q12	Neurofibromatosis type 2	Acoustic neuromas, meningiomas, gliomas, ependymomas

(continued)

TABLE 9-1 *Continued*

Genes	Location	Syndrome	Cancer sites and associated traits
<i>PTC</i>	9q22.3	Nevoid basal cell carcinoma	Basal cell carcinoma
<i>PTEN</i>	10q23.3	Cowden disease	Breast cancer, thyroid cancer, endometrial cancer
<i>rb</i>	13q14	Retinoblastoma	Retinoblastoma, sarcomas, melanoma, and malignant neoplasms of brain and meninges
<i>RET</i>	10q11.2	Multiple endocrine neoplasia type 2	Medullary thyroid cancer, pheochromocytoma, parathyroid hyperplasia
<i>SDHB</i> ; <i>SDHC</i> ; <i>SDHD</i>	1p363.1-p35; 1q21; 11q23	Hereditary paraganglioma and pheochromocytoma	Paraganglioma, pheochromocytoma
<i>SMAD4/DPC4</i>	18q21.1	Juvenile polyposis coli	Juvenile polyps of the gastrointestinal tract, gastrointestinal and colorectal malignancy
<i>STK11</i>	19p13.3	Peutz-Jeghers syndrome	Gastrointestinal tract carcinoma, breast carcinoma, testicular cancer, pancreatic cancer, benign pigmentation of the skin and mucosa
<i>p53</i>	17p13	Li-Fraumeni syndrome	Breast cancer, soft-tissue sarcoma, osteosarcoma, brain tumors, adrenocortical carcinoma, Wilms tumor, phyllodes tumor of the breast, pancreatic cancer, leukemia, neuroblastoma
<i>TSC1</i> ; <i>TSC2</i>	9q34;16p13	Tuberous sclerosis	Multiple hamartomas, renal cell carcinoma, astrocytoma
<i>VHL</i>	3p25	von Hippel-Lindau disease	Renal cell carcinoma, hemangioblastomas of retina and central nervous system, pheochromocytoma
<i>WT</i>	11p13	Wilms' tumor	Wilms' tumor, aniridia, genitourinary abnormalities, mental retardation

is because of two somatic mutations. Thus both hereditary and nonhereditary forms of retinoblastoma involve the same number of mutations, a hypothesis known as Knudson's "two-hit" hypothesis. A "hit" may be a point mutation, a chromosomal deletion referred to as allelic loss, or a loss of heterozygosity (LOH), or silencing of an existing gene.

The *rb1* gene product, the Rb protein, is a regulator of transcription that controls the cell cycle, differentiation, and apoptosis in normal development. Besides hereditary retinoblastoma, Rb protein is commonly inactivated directly by mutation in many sporadic tumors. Moreover, other molecules in the Rb pathway, such as p16, CDK4, and CDK6, have been identified in a number of sporadic tumors, suggesting that the Rb pathway is critical in malignant transformation.

p53 and Li-Fraumeni Syndrome

Li-Fraumeni syndrome (LFS) was first defined on the basis of observations of clustering of malignancies, including early onset breast cancer, soft-tissue sarcomas, brain tumors, adrenocortical tumors, and leukemia. Criteria for classic LFS in an individual (the proband) include: (1) a bone or soft-tissue sarcoma when younger than 45 years, (2) a first-degree relative with cancer before age 45 years, and (3) another first- or second-degree relative with either a sarcoma diagnosed at any age or any cancer diagnosed before age 45 years. Approximately 70 percent of LFS families have been shown to have germline mutations in the tumor suppressor p53 gene. Breast carcinoma, soft-tissue sarcoma, osteosarcoma, brain tumors, adrenocortical carcinoma, Wilms tumor, and phyllodes tumor of the breast are strongly associated; pancreatic cancer is moderately associated; and leukemia and neuroblastoma are weakly associated with germline p53 mutations. Mutations of p53 have not been detected in approximately 30 percent of LFS families, and it is hypothesized that genetic alterations in other proteins interacting with p53 function may play a role in these families.

p53 is the most commonly mutated known gene in human cancer. The p53 protein regulates cell-cycle progression and apoptotic cell death as part of stress response pathways following ionizing or ultraviolet (UV) irradiation, chemotherapy, acidosis, growth factor deprivation, or hypoxia.

BRCA1, BRCA2, and Hereditary Breast-Ovarian Cancer Syndrome

It is estimated that 5–10 percent of breast cancers are hereditary. Of women with early onset breast cancer (aged 40 years or younger), nearly 10 percent have a germline mutation in BRCA1 or BRCA2. Mutation carriers are more prevalent among women who have a first- or second-degree relative with premenopausal breast cancer or ovarian cancer at any age. The likelihood of a BRCA mutation is higher in patients who belong to a population in which founder mutations may be prevalent, such as in the Ashkenazi Jewish population. The cumulative risks for a female BRCA1 mutation carrier of developing breast cancer and ovarian cancer by age 70 have been estimated to be 87 and 44 percent, respectively. The cumulative risks of breast cancer and ovarian cancer by age 70 in BRCA2 families were estimated to be 84 and 27 percent, respectively. Besides breast and ovarian cancer, BRCA1 and BRCA2 may be associated with increased risks for several other cancers. BRCA1 confers a 4-fold increased risk for colon cancer and 3-fold increased risk for prostate cancer. BRCA2 confers a 5-fold increased risk for prostate cancer, 7-fold in men younger than 65 years. Furthermore, BRCA2 confers a 5-fold increased

risk for gallbladder and bile duct cancers, 4-fold increased risk for pancreatic cancer, and 3-fold increased risk for gastric cancer and malignant melanoma.

BRCA1 was the first breast cancer susceptibility gene identified; BRCA2, was reported shortly afterward. BRCA1 and BRCA2 encode for large nuclear proteins, which have been implicated in processes fundamental to all cells, including DNA repair and recombination, checkpoint control of the cell cycle, and transcription.

APC Gene and Familial Adenomatous Polyposis

Patients affected with familial adenomatous polyposis (FAP) characteristically develop hundreds to thousand of polyps in the colon and rectum. The polyps usually appear in adolescence and, if left untreated, progress to colorectal cancer. FAP is associated with benign extracolonic manifestations that may be useful in identifying new cases, including congenital hypertrophy of the retinal pigment epithelium, epidermoid cysts, and osteomas. In addition to colorectal cancer, patients with FAP are at risk for upper intestinal neoplasms (gastric and duodenal polyps, duodenal and periampullary cancer), hepatobiliary tumors (hepatoblastoma, pancreatic cancer, and cholangiocarcinoma), thyroid carcinomas, desmoid tumors, and medulloblastomas.

The adenomatous polyposis coli (APC) tumor suppressor gene product is widely expressed in many tissues and plays an important role in cell-cell interactions, cell adhesion, regulation of β catenin, and maintenance of cytoskeletal microtubules. Alterations in APC lead to dysregulation of several physiologic processes that govern colonic epithelial cell homeostasis, including cell-cycle progression, migration, differentiation, and apoptosis. Mutations in the APC gene have been identified in FAP and in 80 percent of sporadic colorectal cancers. Furthermore, APC mutations are the earliest known genetic alterations in colorectal cancer progression, emphasizing its importance in cancer initiation.

Mismatch Repair Genes and Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC), also referred to as Lynch syndrome, is an autosomal dominant hereditary cancer syndrome that predisposes to a wide spectrum of cancers, including colorectal cancer without polyposis. Some have proposed that HNPCC consists of at least two syndromes: Lynch syndrome I, which entails hereditary predisposition for colorectal cancer with early age of onset (approximately age 44 years) and an excess of synchronous and metachronous colonic cancers; and Lynch syndrome II, featuring a similar colonic phenotype accompanied by a high risk for carcinoma of the endometrium, transitional cell carcinoma of the ureter and renal pelvis, and carcinomas of the stomach, small bowel, ovary, and pancreas. The diagnostic criteria for HNPCC are referred to as the Amsterdam criteria, or the "3-2-1-0 rule." These criteria are met when three or more family members have histologically verified, HNPCC-associated cancers (one of whom is a first-degree relative of the other two), two or more generations are involved, at least one individual was diagnosed before age 50 years, and no individuals have FAP.

During DNA replication, DNA polymerases may introduce single nucleotide mismatches or small insertion or deletion loops. These errors are corrected through a process referred to as mismatch repair. When mismatch repair genes are inactivated, DNA mutations in other genes that are critical to cell growth and proliferation accumulate rapidly. In HNPCC, germline mutations have been identified in several genes that play a key role in DNA nucleotide mismatch repair: hMLH1 (human mutL homologue 1), hMSH2 (human mutS

homologue 2), hMSH6, and hPMS1 and hPMS2 (human postmeiotic segregation 1 and 2), of which hMLH1 and hMSH2 are the most common. The hallmark of HNPCC is microsatellite instability, which occurs on the basis of unrepaired mismatches and small insertion or deletion loops. Microsatellite instability can be tested by comparing the DNA of a patient's tumor with DNA from adjacent normal epithelium, amplifying the DNA with polymerase chain reaction (PCR) using a standard set of markers, comparing the amplified genomic DNA sequences, and classifying the degree of microsatellite instability as high, low, or stable. Such microsatellite instability testing may help select patients who are more likely to have germline mutations.

PTEN and Cowden Disease

Somatic deletions or mutations in the tumor suppressor gene PTEN (phosphatase and tensin homologue deleted on chromosome 10) have been observed in a number of glioma, breast, prostate, and renal carcinoma cell lines and several primary tumor specimens. PTEN was identified as the susceptibility gene for the autosomal dominant syndrome Cowden disease (CD) or multiple hamartoma syndrome. Trichilemmomas, benign tumors of the hair follicle infundibulum, and mucocutaneous papillomatosis are pathognomonic of CD. Other common features include thyroid adenomas and multinodular goiters, breast fibroadenomas, and hamartomatous gastrointestinal polyps. The diagnosis of CD is made when an individual or family has a combination of pathognomonic major and/or minor criteria proposed by the International Cowden Consortium. CD is associated with an increased risk of breast and thyroid cancers. Breast cancer develops in 25–50 percent of affected women, and thyroid cancer develops in 3–10 percent of all affected individuals.

PTEN encodes a tyrosine phosphatase which negatively controls the PI3K signaling pathway for the regulation of cell growth and survival by dephosphorylating phosphoinositol 3,4,5-triphosphate; thus mutation of PTEN leads to constitutive activation of the PI3K/AKT signaling pathway.

RET Protooncogene and Multiple Endocrine Neoplasia Type 2

The RET gene encodes for a receptor tyrosine kinase that plays a role in proliferation, migration, and differentiation of cells derived from the neural crest. Gain-of-function mutations in the RET gene are associated with medullary thyroid carcinoma in isolation or multiple endocrine neoplasia type 2 (MEN2) syndromes. MEN2A is associated with medullary thyroid carcinoma and pheochromocytoma (in 50 percent) or parathyroid adenoma (in 20 percent), although MEN2B is associated with medullary thyroid carcinoma, marfanoid habitus, mucosal neuromas, and ganglioneuromatosis. RET mutations lead to uncontrolled growth of the thyroid c cells, and in familial medullary cancer, c-cell hyperplasia progresses to bilateral, multicentric medullary thyroid cancer. Mutations in the RET gene have also been identified in 40–60 percent of sporadic medullary thyroid cancers.

Genetic Modifiers of Risk

Individuals carrying identical germline mutations vary in regard to cancer penetrance (whether cancer will develop or not) and cancer phenotype (the tissues involved). It is thought that this variability may be because of environmental influences or, if genetic, to genetic modifiers of risk. Similarly, genetic modifiers of risk also can play a role in determining whether an individual will develop cancer after exposure to carcinogens.

Chemical Carcinogens

The first report that cancer could be caused by environmental factors was by John Hill in 1761, who reported the association between nasal cancer and excessive use of tobacco snuff. Currently, approximately 60–90 percent of cancers are thought to be because of environmental factors. Any agent that can contribute to tumor formation is referred to as a carcinogen and can be chemical, physical, or viral agents. Chemicals are classified into three groups based on how they contribute to tumor formation. The first group of chemical agents, the genotoxins, can initiate carcinogenesis by causing a mutation. The second group, the co-carcinogens, by themselves cannot cause cancer, but potentiate carcinogenesis by enhancing the potency of genotoxins. The third group, tumor promoters, enhance tumor formation when given after exposure to genotoxins.

Physical Carcinogens

Physical carcinogenesis can occur through induction of inflammation and cell proliferation over a period of time or through exposure to physical agents that induce DNA damage. In humans, clinical scenarios associated with chronic irritation and inflammation such as chronic nonhealing wounds, burns, and inflammatory bowel syndrome have all been associated with an increased risk of cancer. *H. pylori* is associated with gastritis and gastric cancer; and the liver fluke *Opisthorchis viverrini* leads to local inflammation and cholangiocarcinoma. The induction of lung and mesothelial cancers from asbestos fibers and nonfibrous particles such as silica are other examples of foreign-body-induced physical carcinogenesis.

Radiation is the best known agent of physical carcinogenesis and is classified as ionizing radiation (x-rays, gamma rays, and α and β particles) or nonionizing radiation (UV). The carcinogenic potential of ionizing radiation was recognized soon after Roentgen's discovery of x-rays in 1895. Long-term follow-up of survivors of the Hiroshima and Nagasaki atom bombs revealed that virtually all tissues exposed to radiation are at risk for cancer.

Viral Carcinogens

One of the first observations that cancer may be caused by transmissible agents was by Peyton Rous in 1911 when he demonstrated that cell-free extracts from sarcomas in chickens could transmit sarcomas to other animals injected with these extracts. This was subsequently discovered to represent viral transmission of cancer by the Rous sarcoma virus (RSV). At present, it is estimated that 15 percent of all human tumors worldwide are caused by viruses.

Viruses may cause or increase the risk of malignancy through several mechanisms, including direct transformation, expression of oncogenes that interfere with cell-cycle checkpoints or DNA repair, expression of cytokines or other growth factors, and alteration of the immune system. Oncogenic viruses may be ribonucleic acid (RNA) or DNA viruses. Oncogenic RNA viruses are retroviruses and contain a reverse transcriptase. After the viral infection, the single-stranded RNA viral genome is transcribed into a double-stranded DNA copy, which is then integrated into the chromosomal DNA of the cell. Retroviral infection of the cell is permanent, thus integrated DNA sequences remain in the host chromosome. Oncogenic transforming retroviruses carry oncogenes

derived from cellular genes. These cellular genes, referred to as protooncogenes, usually are involved in mitogenic signaling and growth control.

Unlike the oncogenes of the RNA viruses, those of the DNA tumor viruses are viral, not cellular in origin. These genes are required for viral replication using the host cell machinery. In permissive hosts, infection with an oncogenic DNA virus may result in a productive lytic infection, leading to cell death and the release of newly formed viruses. In nonpermissive cells, the viral DNA can be integrated into the cellular chromosomal DNA, and some of the early viral genes can be synthesized persistently, leading to transformation of cells to a neoplastic state.

Like other types of carcinogenesis, viral carcinogenesis is a multistep process. Although immunocompromised individuals are at elevated risk, most patients infected with oncogenic viruses do not develop cancer. When cancer does develop, it usually occurs several years after the viral infection. It is estimated, for example, that the risk of hepatocellular carcinoma among hepatitis C virus–infected individuals is 1–3 percent after 30 years. There may be synergy between various environmental factors and viruses in carcinogenesis. Factors that predispose to hepatocellular carcinoma among hepatitis C virus–infected patients include heavy alcohol intake and hepatitis B co-infection.

CANCER RISK ASSESSMENT

Cancer risk assessment starts with a complete history that includes history of environmental exposures to potential carcinogens and a detailed family history. Risk assessment for breast cancer, for example, includes a family history to determine whether another member of the family is known to carry a breast cancer susceptibility gene; whether there is familial clustering of breast cancer, ovarian cancer, thyroid cancer, sarcoma, adrenocortical carcinoma, endometrial cancer, brain tumors, dermatologic manifestations, leukemia, or lymphoma; and whether the patient is from a population at increased risk such as individuals of Ashkenazi Jewish descent. Patients who have a family history suggestive of a cancer susceptibility syndrome would benefit from genetic counseling and possibly genetic testing.

Patients who do not seem to have a strong hereditary component of risk can be evaluated on the basis of their age, race, personal history, and exposures. One of the most commonly used models for risk assessment in breast cancer is the Gail model. The model uses risk factors such as an individual's age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer, and number of previous breast biopsies and histology. This tool allows a health professional to project a woman's individualized estimated risk for invasive breast cancer over a 5-year period and over her lifetime (to age 90 years). These risk assessment tools have been validated and are now in widespread clinical use. Similar models are in development or being validated for other cancers.

CANCER SCREENING

Early detection is the key to success in cancer therapy. Screening for common cancers using relatively noninvasive tests is expected to lead to early diagnosis, allow more conservative surgical therapies with decreased morbidity, and potentially improve surgical cure rates and overall survival rates. Key factors that influence screening guidelines are the prevalence of the cancer in the population, the risk associated with the screening measure, and whether early

diagnosis actually affects outcome. The value of a widespread screening measure is likely to go up with the prevalence of the cancer in a population, often determining the age cutoffs for screening, and explaining why only common cancers are screened for. The risks involved with the screening measure are a significant consideration, especially with more invasive screening measures such as colonoscopy. The consequences of a false-positive screening test also need to be considered. For example, when 1000 screening mammograms are performed, only two to four new incidences of cancer will be identified; this number is slightly higher (6–10 prevalent cancers per 1000 mammograms) in the initial screening mammograms performed. However, as many as 10 percent of screening mammograms may be potentially suggestive of abnormality, requiring further imaging (i.e., a 10-percent recall rate). Of those women with abnormal mammograms, only 5–10 percent will be determined to have a breast cancer. Among women for whom biopsy is recommended, 25–40 percent will have a breast cancer. A false-positive screen is likely to induce significant emotional distress in patients, leads to unnecessary biopsies, and has cost implications for the health care system.

Screening guidelines are developed for the general baseline-risk population. These guidelines need to be modified for patients who are at high risk.

CANCER DIAGNOSIS

The definitive diagnosis of solid tumors is usually obtained with a biopsy of the lesion. Biopsy determines the tumor histology and grade and thus assists in definitive therapeutic planning. Biopsies of mucosal lesions usually are obtained endoscopically (e.g., via colonoscope). Lesions that are easily palpable, such as those of the skin, can either be excised or sampled by punch biopsy. Deep-seated lesions can be localized with CT scan or ultrasound guidance for biopsy.

A sample of a lesion can be obtained with a needle or with an open incisional or excisional biopsy. Fine-needle aspiration is easy and relatively safe, but has the disadvantage of not giving information on tissue architecture. For example, fine-needle aspiration biopsy of a breast mass can make the diagnosis of malignancy, but cannot differentiate between an invasive and noninvasive tumor. Therefore core-needle biopsy is more advantageous when the histology will affect the recommended therapy. Core biopsy, like fine-needle aspiration, is relatively safe and can be performed either by direct palpation (e.g., a soft-tissue mass) or can be guided by an imaging study. Core biopsies, like fine-needle aspirations, have the disadvantage of introducing sampling error. It is crucial to ensure that the histologic findings are consistent with the clinical scenario, and to know the appropriate interpretation of each histologic finding. A needle biopsy in which the report is inconsistent with the clinical scenario should be either repeated or followed by an open biopsy.

Open biopsies have the advantage of providing more tissue for histologic evaluation and the disadvantage of being an operative procedure. Incisional biopsies are reserved for very large lesions in which a definitive diagnosis cannot be made with needle biopsy.

Excisional biopsies are performed for lesions in which core biopsy is either not possible or is nondiagnostic. Excisional biopsies should be performed with curative intent, that is, by obtaining adequate tissue around the lesion to ensure negative surgical margins. Orientation of the margins by sutures or clips by the

surgeon and inking of the specimen margins by the pathologist will allow for determination of the surgical margins and will guide surgical re-excision if one or more of the margins are positive for microscopic tumor or close. The biopsy incision should be oriented to allow for excision of the biopsy scar if repeat operation is necessary. The biopsy incision should directly overlie the area to be removed. Finally, meticulous hemostasis during a biopsy is essential.

CANCER STAGING

Cancer staging is a system used to describe the anatomic extent of a malignant process in an individual patient. Staging systems may incorporate relevant clinical prognostic factors such as tumor size, location, extent, grade, and dissemination to regional lymph nodes or distant sites.

Cancer patients who are considered to be at high risk for distant metastasis usually undergo a preoperative staging work-up. This involves a set of imaging studies of sites of preferential metastasis for a given cancer type. For example, for a patient with breast cancer, a staging work-up would include a chest radiograph, bone scan, and scan of the abdomen to evaluate for lung, bone, and liver metastases, respectively.

Standardization of staging systems is essential to allow for comparison of different studies worldwide. The staging systems proposed by the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre Cancer (International Union Against Cancer, UICC) are among the most widely accepted staging systems. Both the AJCC and the UICC have adopted a shared TNM staging system that defines the cancer in terms of the anatomic extent of disease and is based on assessment of three components: the primary tumor (T), the presence (or absence) and extent of nodal metastases (N), and the presence (or absence) and extent of distant metastases (M).

The TNM staging applies only to cases that have been microscopically confirmed to be malignant. Standard TNM staging (clinical and pathologic) is completed at initial diagnosis. Clinical staging (cTNM or TNM) is based on information gained up until the initial definitive treatment. Pathologic staging (pTNM) includes clinical information and information obtained from pathologic examination of the resected primary tumor and regional lymph nodes.

The clinical measurement of tumor size (T) is the one judged to be the most accurate for each individual case based on physical examination and imaging studies. If even one lymph node is involved by tumor, the N component is at least N1. For many solid tumor types, simply the absence or presence of lymph node involvement is recorded and the tumor is categorized either as N0 or N1. For other tumor types, the number of lymph nodes involved, the size of the lymph nodes or the lymph node metastasis, or the regional lymph node basin involved also has been shown to have prognostic value. In these cancers, N1, N2, N3, or N4 suggests an increasing abnormality of lymph nodes based on size, characteristics, and location. NX indicates that the lymph nodes cannot be fully assessed.

Cases in which there is no distant metastasis are designated M0, cases in which one or more distant metastases are detected are designated M1, and cases in which the presence of distant metastasis cannot be assessed are designated MX.

The practice of dividing cancer cases into groups according to stage is based on the observation that the survival rates are higher for localized (lower

stage) tumors than for tumors that have extended beyond the organ of origin. Therefore staging is used to analyze and compare groups of patients. Such staging assists in (1) selection of therapy, (2) estimation of prognosis, (3) evaluation of treatments, (4) exchange of information among treatment centers, and (5) continued investigation of human cancers. For example, melanoma staging system can distinguish different prognostic groups on the basis of 15-year survival curves. Notably, the AJCC regularly updates its staging system to incorporate advances in prognostic technology to improve the predictive accuracy of the TNM system. Therefore it is important to know which revision of a staging system is being used when evaluating studies.

TUMOR MARKERS

Prognostic and Predictive Tissue Markers

Tumor markers are substances that can be detected in higher than normal amounts in the serum, urine, or tissues of patients with certain types of cancer. Tumors markers are produced either by the cancer cells themselves or by the body as a response to the cancer.

Over the past decade, there has been an especially large interest in identifying tissue tumor markers that can be used as prognostic or predictive markers. Although the terms prognostic marker and predictive marker are sometimes used interchangeably, the term prognostic marker usually is used to describe molecular markers that predict disease-free survival, disease-specific survival, and overall survival, although the term predictive marker is often used in the context of predicting response to certain therapies.

The goal is to identify prognostic markers that can give information on prognosis independent of other clinical characteristics, and therefore can provide information in addition to what can be projected on the basis of clinical presentation. This would allow us to further classify patients as being at higher or lower risk within clinical subgroups and to identify patients who may benefit most from adjuvant therapy.

Predictive markers are markers that can prospectively identify patients who will benefit from a certain therapy. Some of the best predictive markers are estrogen receptor and HER2/ neu, which can identify patients who can benefit from antiestrogen therapies (e.g., tamoxifen) and anti-HER2/ neu therapies (e.g., trastuzumab), respectively. There is increasing interest in identifying predictive markers for chemotherapy so that patients can be given the regimens they are most likely to benefit from, although those who are not likely to benefit from existing conventional therapies can be spared the toxicity of the therapy and be offered investigational therapies.

Serum Markers

Serum markers are under active investigation as they may allow early diagnosis of a new cancer or may be used to follow a cancer's response to therapy or monitor for recurrence. Unfortunately, identification of serum markers of clinical value has been challenging. Many of the tumor markers proposed so far have had low sensitivities and specificities (Table 9-2).

Tumor markers may not be elevated in all patients with cancer, especially in the early stages, when a serum marker would be most useful for diagnosis. Therefore when using a tumor marker to monitor recurrence, it is important to be certain that the tumor marker was elevated prior to primary therapy.

TABLE 9-2 Sensitivity and Specificity of Some Common Tumor Markers

Marker	Cancer	Sensitivity	Specificity
Prostate-specific antigen (4 μ g/L)	Prostate	57–93 percent	55–68 percent
Carcinoembryonic antigen	Colorectal	40–47 percent	90 percent
	Breast	45 percent	81 percent
	Recurrent disease	84 percent	100 percent
Alpha-fetoprotein	Hepatocellular	98 percent	65 percent
	Pancreatic	78–90 percent	95 percent
CA 19.9	Breast	62 percent	83 percent
CA 27.29	Breast	57 percent	87 percent
CA 15.3	Breast

Tumor Marker Overview, 1996, Laboratory Medicine Newsletter.

Moreover, tumor markers can be elevated in benign conditions. Many tumor markers are not specific for a certain type of cancer and can be elevated with more than one type of tumor. Because there may be significant laboratory variability, it is important to obtain serial results from the same laboratory. Despite these many clinical limitations, several serum markers are in clinical use. A few of the commonly measured serum tumor markers are discussed below.

Circulating Cancer Cells

It has been suggested that circulating cancer cells can be an effective tool in selecting patients who have a high risk of relapse. One methodology widely used to detect cancer cells in the peripheral blood is reverse transcriptase (RT)-PCR. The use of this methodology to detect circulating cancer cells as a prognostic marker is under active investigation by many groups; however, its high sensitivity and potential for contamination leading to false-positive results has made investigation especially challenging. A recent promising approach is the use of the number of circulating tumor cells as an early predictor of response to systemic therapy.

SURGICAL APPROACHES TO CANCER THERAPY

Multidisciplinary Approach to Cancer

Although surgery is the most effective therapy for most solid tumors, most patients die of metastatic disease. Therefore, to improve patient survival rates, a multimodality approach with systemic therapy and radiation therapy is key for most tumors. It is important that surgeons involved in cancer care know not only how to perform a cancer operation but also the alternatives to surgery and be well versed in reconstructive options. It is also crucial that the surgeon be familiar with the indications for and complications of preoperative and postoperative chemotherapy and radiation therapy. As such, the surgeon often is responsible for determining the most appropriate adjuvant therapy for a given patient, and the best sequence for therapy. In most instances, a multidisciplinary approach beginning at the patient's initial presentation is likely to yield the best result.

Surgical Management of Primary Tumors

The goal of surgical therapy for cancer is to achieve oncologic cure. A curative operation presupposes that the tumor is confined to the organ of origin, or to the

organ and the regional lymph node basin. Patients in whom the primary tumor is not resectable with negative surgical margins are considered to have inoperable disease. The operability of primary tumors is best determined before surgery with appropriate imaging studies that can define the extent of local-regional disease. Disease involving multiple distant metastases is deemed inoperable because it is usually not curable with surgery of the primary tumor. Therefore patients who are at high risk of having distant metastasis should have a staging work-up prior to surgery for their primary tumor. On occasion, primary tumors are resected in these patients for palliative reasons, such as improving the quality of life by alleviating pain, infection, or bleeding. Patients with limited metastases from a primary tumor on occasion are considered surgical candidates if the natural history of isolated distant metastases for that cancer type is favorable, or the potential complications associated with leaving the primary tumor intact are significant.

In the past it was presumed that the more radical the surgery, the better the oncologic outcome would be. Over the past 20 years, this has been recognized as not necessarily being true, leading to more conservative operations, with wide local excisions replacing compartmental resections of sarcomas; and breast-conserving therapies replacing radical mastectomies for breast cancer. The uniform goal for all successful oncologic operations seems to be achieving widely negative margins with no evidence of macroscopic or microscopic tumor at the surgical margins. Inking of the margins, orientation of the specimen by the surgeon, and immediate gross evaluation of the margins by the pathologist with frozen section analysis where necessary may assist in achieving negative margins at the first operation. In the end, although radiation therapy and systemic therapy can assist in decreasing local recurrence rates in the setting of positive margins, adjuvant therapy cannot substitute for adequate surgery.

Surgical Management of the Regional Lymph Node Basin

Most neoplasms metastasize via the lymphatics. Therefore, most oncologic operations have been designed to remove the primary tumor and draining lymphatics en bloc. This type of operative approach is usually undertaken when the lymph nodes draining the primary tumor site lie adjacent to the tumor bed, as is the case for colorectal cancers and gastric cancers. For tumors where the regional lymph node basin is not immediately adjacent to the tumor (e.g., melanomas), lymph node surgery can be performed through a separate incision.

It is generally accepted that a formal lymphadenectomy is likely to minimize the risk of regional recurrence of most cancers. On the other hand, there have been two opposing views regarding the role of lymphadenectomy on survival of cancer patients. The traditional Halsted view states that lymphadenectomy is important for staging and survival. The opposing view counters that cancer is systemic at inception and that lymphadenectomy, although useful for staging, does not affect survival. For most cancers, involvement of the lymph nodes is one of the most significant prognostic factors. Interestingly, the number of lymph nodes removed has been found to have an inverse relationship with overall survival rate in many solid tumors, including breast cancer, colon cancer, and lung cancer. There may be alternate explanations for the same finding. For example, the surgeon who performs a more extensive lymphadenectomy may obtain wider margins around the tumor, or even provide better overall

care such as ensuring that patients receive the appropriate adjuvant therapy or undergo a more thorough staging work-up.

Alternatively, the pathologist may perform a more thorough examination, identifying more nodes and more accurately staging the nodes. The effect of appropriate staging on survival is twofold. Patients with nodal metastases may be offered adjuvant therapy, improving their survival chances. Further, the improved staging can improve perceived survival rates through a "Will Rogers effect," meaning identification of metastases that had formerly been silent and unidentified leads to a stage migration and thus to a perceived improvement in chances of survival. Clearly the impact of lymphadenectomy on survival will not be easily resolved. Because minimizing regional recurrences as much as possible is a goal of cancer treatment, the standard of care remains lymphadenectomy for most tumors.

A relatively new development in the surgical management of the clinically negative regional lymph node basin is the introduction of lymphatic mapping technology. Lymphatic mapping and sentinel lymph node biopsy were first reported in 1977 by Cabanas for penile cancer. Now sentinel node biopsy is the standard of care for the management of melanoma and is rapidly becoming the standard of care in breast cancer. The first node to receive drainage from the tumor site is termed the sentinel node. This node is the node most likely to contain metastases, if metastases to that regional lymph node basin are present. The goal of lymphatic mapping and sentinel lymph node biopsy is to identify and remove the lymph node most likely to contain metastases in the least invasive fashion. The practice of sentinel lymph node biopsy followed by selective regional lymph node dissection for patients with a positive sentinel lymph node avoids the morbidity of lymph node dissections in patients with negative nodes. An additional advantage of the sentinel lymph node technique is that it directs attention to a single node, allowing more careful analysis of the lymph node most likely to have a positive yield and increasing the accuracy of nodal staging.

Two criteria are used to assess the efficacy of a sentinel lymph node biopsy: the sentinel lymph node identification rate and the false-negative rate. The sentinel lymph node identification rate is the proportion of patients in whom a sentinel lymph node was identified and removed among all patients undergoing an attempted sentinel lymph node biopsy. The false-negative rate is the proportion of patients with regional lymph node metastases in whom the sentinel lymph node was found to be negative. False-negative biopsies may be because of identification of the wrong node or to missing the sentinel node (i.e., surgical error), or they may be because of the cancer cells establishing metastases not in the first encountered node, but in a second echelon node (i.e., biologic variation). Alternatively, false-negative biopsies may be because of inadequate histologic evaluation of the lymph node.

Lymphatic mapping is performed by using isosulfan blue dye, technetium-labeled sulfur colloid or albumin, or a combination of both techniques to detect sentinel nodes. The combination of blue dye and technetium has been reported to improve the capability of detecting sentinel lymph nodes. The nodal drainage pattern usually is determined with a preoperative lymphoscintigram, and the "hot" and/or blue nodes are identified with the assistance of a gamma probe and careful nodal basin exploration. Careful manual palpation is a crucial part of the procedure to minimize the false-negative rate. The nodes are evaluated with serial sectioning, hematoxylin and eosin staining, and immunohistochemical

staining with S-100 and HMB-45 for melanoma and cytokeratin for breast cancer.

Surgical Management of Distant Metastases

The treatment of a patient with distant metastases depends on the number and sites of metastases, the cancer type, the rate of tumor growth, the previous treatments delivered and the responses to these treatments, and the patient's age, physical condition, and desires. Although once a tumor has metastasized it is usually not curable with surgical therapy, such therapy has resulted in cure in selected cases with isolated metastases to the liver, lung, or brain.

Patient selection is the key to success of surgical therapy for distant metastases. The cancer type is a major determinant in surgical decision making. The growth rate of the tumor also plays an important role and can be determined in part by the disease-free interval and the time between treatment of the primary tumor and detection of the distant recurrence. Patients with longer disease-free intervals have a higher survival rate after surgical metastasectomy than those with a short disease-free interval. The natural history of metastatic disease is so poor in some tumors (e.g., pancreatic cancer) that there is no role at this time for surgical metastasectomy. In cancers with more favorable outlooks, observation for several weeks or months, potentially with initial treatment with systemic therapy, can allow the surgeon to monitor for metastases at other sites.

In curative surgery for distant metastases, as with surgery for primary tumors, the goal is to resect the metastases with negative margins. In patients with hepatic metastases that are unresectable because their location near intrahepatic blood vessels precludes a margin-negative resection, or because of multifocality or inadequate hepatic function, tumor ablation with cryotherapy or radiofrequency ablation is an alternative. Curative resections or ablative procedures should be attempted only if the lesions are accessible and the procedure can be performed safely.

CHEMOTHERAPY

Clinical Use of Chemotherapy

In patients with documented distant metastatic disease, chemotherapy is usually the primary modality of therapy. The goal of therapy in this setting is to decrease the tumor burden, thus prolonging survival. It is rare to achieve cure with chemotherapy for metastatic disease in most solid tumors. Chemotherapy administered to a patient who is at high risk for distant recurrence, but has no evidence of distant disease, is referred to as adjuvant chemotherapy. The goal of adjuvant chemotherapy is eradication of micrometastatic disease, with the intent of decreasing relapse rates and improving survival rates.

Adjuvant therapy can be given after surgery (postoperative chemotherapy) or before surgery (preoperative chemotherapy, neoadjuvant chemotherapy, or induction therapy). A portion or all of the planned adjuvant chemotherapy can be administered prior to the surgical removal of the primary tumor. Preoperative chemotherapy has three potential advantages. The first is that preoperative regression of tumor can facilitate resection of tumors that were initially inoperable or allow more conservative surgery for patients whose cancer was operable to begin with. The second advantage of preoperative chemotherapy is the treatment of micrometastases without the delay of postoperative recovery. The third goal is the ability to assess a cancer's response to treatment clinically,

after a number of courses of chemotherapy, and pathologically, after surgical resection. This is especially important if alternative treatment regimens are available to be offered to patients whose disease responded inadequately.

Response to chemotherapy is monitored clinically with imaging studies and physical examinations. Response usually is defined as complete response, partial response, minimal response or stable disease, or progression. Complete response is defined as the disappearance of all evidence of disease and no evidence of new disease for a specified interval, usually 4 weeks. Partial response is defined as a 50 percent or more decrease of the product of the two largest perpendicular tumor diameters (relative to the initial product), determined by two observations not less than 4 weeks apart. Additionally, there can be no appearance of new lesions or progression of any lesion. Stable disease refers to the situation in which neither complete or partial response nor progression has been demonstrated. Progressive disease refers to a 25 percent or greater increase in the product of one or more measurable lesions (relative to the smallest size measured because treatment start) or the appearance of new lesions.

Cancer is usually not detectable until 10^9 cancer cells (1 g) are present. A 3-log increase in cancer cells produces 10^{12} cells (1 kg), which can be fatal. A clinical "complete response" (i.e., disappearance of all clinically detectable disease) can be achieved with millions of cancer cells still remaining.

Principles of Chemotherapy

Chemotherapy destroys cells by first-order kinetics, meaning that with the administration of a drug a constant percentage of cells are killed, not a constant number of cells. If a patient with 10^{12} tumor cells is treated with a dose that results in 99.9 percent cell kill (3-log cell kill), the tumor burden will be reduced from 10^{12} to 10^9 cells (or 1 kg to 1 g). If the patient is retreated with the same drug, which theoretically could result in another 3-log cell kill, the number of cells would decrease from 10^9 to 10^6 (1 g to 1 mg) rather than being eliminated totally.

Chemotherapeutic agents can be classified according to the phase of the cell cycle they are effective in. Cell-cycle phase–nonspecific agents (e.g., alkylating agents) have a linear dose-response curve, such that the fraction of cells killed increases with dose of the drug. In contrast, the cell-cycle phase–specific drugs have a plateau with respect to cell killing ability, and cell kill will not increase with further increases in drug dose.

Anticancer Agents

Alkylating Agents

Alkylating agents are cell-cycle–nonspecific agents, meaning that they are able to kill cells in any phase of the cell cycle. They act by cross-linking the two strands of the DNA helix or by other direct damage to the DNA. The damage to the DNA prevents cell division and, if severe enough, leads to apoptosis. The alkylating agents comprise three main subgroups: classic alkylators, nitrosoureas, and miscellaneous DNA-binding agents.

Antitumor Antibiotics

Antitumor antibiotics are the products of fermentation of microbial organisms. Like the alkylating agents, these agents are cell-cycle nonspecific. Antitumor

antibiotics damage the cell by interfering with DNA or RNA synthesis, although the exact mechanism of action may differ by agent.

Antimetabolites

Antimetabolites are generally cell-cycle-specific agents that have their major activity during the S phase of the cell cycle and have little effect on cells in G₀. These drugs are most effective, therefore, in tumors that have a high growth fraction. Antimetabolites are structural analogues of naturally occurring metabolites involved in DNA and RNA synthesis. Therefore, they interfere with normal synthesis of nucleic acids by substituting for purines or pyrimidines in the metabolic pathway to inhibit critical enzymes in nucleic acid synthesis. The antimetabolites include folate antagonists, purine antagonists, and pyrimidine antagonists.

Plant Alkaloids

Plant alkaloids are derived from plants such as the periwinkle plant, *Vinca rosea* (e.g., vincristine, a vinca alkaloid), or the root of mandrake, *Podophyllum peltatum* (e.g., etoposide, a podophyllotoxin). Vinca alkaloids affect the cell by binding to tubulin in the S phase. This blocks microtubule polymerization, resulting in impaired mitotic spindle formation in the M phase. Taxanes such as paclitaxel, on the other hand, cause excess polymerization and stability of microtubules, blocking the cell cycle in mitosis. The epipodophyllotoxins act to inhibit a DNA enzyme called topoisomerase II by stabilizing the DNA–topoisomerase II complex. This results in an inability to synthesize DNA, thus the cell cycle is stopped in G₁ phase.

Combination Chemotherapy

Combination chemotherapy may provide greater efficacy than single-agent therapy by three mechanisms: (1) it provides maximum cell kill within the range of toxicity for each drug that can be tolerated by the host, (2) it offers a broader range of coverage of resistant cell lines in a heterogeneous population, and (3) it prevents or delays the emergence of drug-resistant cell lines. Drugs with different mechanisms of action are combined to allow for additive or synergistic effects. Combining cell-cycle-specific and cell-cycle-nonspecific agents may be especially advantageous. Drugs with differing dose-limiting toxic effects are combined to allow for each drug to be given at therapeutic doses. Drugs with different patterns of resistance are combined whenever possible to minimize cross-resistance. The treatment-free interval between cycles is kept at the shortest possible time that will allow for recovery of the most sensitive normal tissue.

Drug Resistance

Several tumor factors influence tumor cell kill. Tumors are heterogeneous, and, according to the Goldie Coldman hypothesis, tumor cells are genetically unstable and tend to mutate to form different cell clones. This has been used as an argument for giving chemotherapy as soon as possible in treatment, to reduce the likelihood of resistant clones emerging. Tumor size is another important variable. The greater the tumor, the larger the heterogeneity. Because of the larger proportion of cells dividing, smaller tumors may be more chemosensitive.

Multiple mechanisms of chemotherapy resistance have been identified. Cells may exhibit reduced sensitivity to drugs by virtue of their cell-cycle distribution. For example, cells in G0 phase are resistant to drugs active in the S phase. Alternatively, tumor cells may exhibit “pharmacologic resistance,” when the failure to kill cells is because of insufficient drug concentration. This may occur when tumor cells are located in sites where effective drug concentrations are difficult to achieve (such as the central nervous system), or can be because of enhanced metabolism of the drug after its administration, decreased conversion of the drug to active form, or a decrease in the intracellular drug level because of increased removal of the drug from the cell associated with enhanced expression of P-glycoprotein, the protein product of the multidrug resistance gene 1 (MDR-1). Other mechanisms of resistance include decreased affinity of the target enzyme for the drug, altered amount of the target enzyme, or enhanced repair of the drug-induced defect.

Drug Toxicity

Tumors are more susceptible than normal tissue to chemotherapeutic agents, in part because they have a higher proportion of dividing cells. Normal tissues with a high growth fraction, such as the bone marrow, oral and intestinal mucosa, and hair follicles are also sensitive to chemotherapeutic effects. Therefore, treatment with chemotherapeutic agents can produce toxic effects such as bone marrow suppression, stomatitis, ulceration of the gastrointestinal tract, and alopecia. Toxic effects are usually graded from 0 to 4 on the basis of World Health Organization (WHO) standard criteria. Significant drug toxicity may necessitate a dose reduction. A toxic effect requiring a dose modification or change in dose intensity is referred to as a dose-limiting toxic effect. As maintaining dose intensity is important to maintaining as high a tumor cell kill as possible, several supportive strategies have been developed, such as administration of colony-stimulating factors and erythropoietin for poor bone marrow reserve and administration of cytoprotectants such as sodium 2-mercaptoethane sulfonate (MESNA) and amifostine to prevent renal dysfunction.

Administration of Chemotherapy

Chemotherapy usually is administered systemically (intravenously, intramuscularly, subcutaneously, or orally). Systemic administration treats micrometastases at widespread sites and prevents systemic recurrence. However, it increases the drug's toxicity to a wide range of organs throughout the body. One method to minimize systemic toxicity while enhancing target organ delivery of chemotherapy is regional administration of chemotherapy. Many of these approaches require surgical access, such as intrahepatic delivery of chemotherapy for hepatic carcinomas or metastatic colorectal cancer with a hepatic artery infusion pump, limb perfusion for extremity melanoma and sarcoma, or intraperitoneal hyperthermic perfusion for pseudomyxoma peritonei.

HORMONAL THERAPY

Some tumors, most notably breast and prostate cancers, originate from tissues whose growth is under hormonal control. The first attempts at hormonal therapy were through surgical ablation of the organ producing the hormones of interest, such as oophorectomy for breast cancer. Hormones or hormone-like agents can be administered to inhibit tumor growth by blocking or antagonizing

the naturally occurring substance, such as estrogen antagonist tamoxifen. Other substances that block the synthesis of the natural hormone can be administered as alternatives. Aromatase inhibitors, for example, block the peripheral conversion of endogenous androgens to estrogens in postmenopausal women.

BIOLOGIC THERAPY

Over the past decade, increasing understanding of cancer biology has fostered the emerging field of molecular therapeutics. The basic principle of molecular therapeutics is to exploit the molecular differences between normal cells and cancer cells to develop targeted therapies. The ideal molecular target would be exclusively expressed in the cancer cells, be the driving force of the proliferation of the cancer cells, and be critical to their survival. A large number of molecular targets are currently being explored, both preclinically and in clinical trials. The major groups of targeted therapies include inhibitors of growth factor receptors, inhibitors of intracellular signal transduction, cell-cycle inhibitors, apoptosis-based therapies, and antiangiogenic compounds.

Protein kinases have come to the forefront as attractive therapeutic targets with the success of STI571 (imatinib mesylate, Gleevec) in chronic myelogenous leukemia and gastrointestinal stromal tumors and trastuzumab (Herceptin) in breast cancer, which work by targeting bcr-abl, c-kit, and HER2/neu, respectively. Therefore, protein kinases involving these aberrantly activated pathways are being aggressively pursued in molecular therapeutics. Most of the compounds in development are monoclonal antibodies like trastuzumab or small-molecule kinase inhibitors like STI-571. Some of the kinase inhibitors in clinical development include inhibitors of EGFR, Ras, Raf, MEK, mammalian target of rapamycin (mTOR), CDK, PKC, and 3-phosphoinositide-dependent protein kinase 1 (PDK-1).

IMMUNOTHERAPY

The aim of immunotherapy is to induce or potentiate inherent antitumor immunity that can destroy cancer cells. Central to the process of antitumor immunity is the ability of the immune system to recognize tumor-associated antigens present on human cancers and to direct cytotoxic responses through humoral or T-cell-mediated immunity. Overall, T-cell-mediated immunity appears to have the greater potential of the two for eradicating tumor cells. T cells recognize antigens on the surfaces of target cells as small peptides presented by class I and class II major histocompatibility complex (MHC) molecules.

One approach to antitumor immunity is nonspecific immunotherapy, which stimulates the immune system as a whole by administering bacterial agents or their products, such as bacille Calmette-Guérin (BCG). This approach is thought to activate the effectors of antitumor response such as natural killer cells and macrophages, and polyclonal lymphocytes. Another approach to nonspecific immunotherapy is systemic administration of cytokines such as IL-2, interferon α , and interferon γ .

Antigen-specific immunotherapy can be active, achieved through antitumor vaccines, or passive. In passive immunotherapy, antibodies to specific tumor-associated antigens can be produced by hybridoma technique and then administered to patients whose cancers express these antigens, inducing antibody-dependent cellular cytotoxicity.

The early attempts at vaccination against cancers used allogeneic cultured cancer cells, including irradiated cells, cell lysates, or shed antigens isolated from tissue culture supernatants. An alternate strategy is the use of autologous tumor vaccines, which have the potential advantage of being more likely to contain antigens relevant for the individual patient, but have the disadvantage of needing a large amount of tumor tissue for preparation, which restricts eligibility of patients for this modality. Strategies to enhance immunogenicity of tumor cells include the introduction of genes encoding cytokines or chemokines, or fusion of the tumor cells to allogeneic MHC II-bearing cells.

Identification of tumor antigens has made it possible to perform antigen-specific vaccination. Vaccines directed at defined tumor antigens aim to combine selected tumor antigens and appropriate routes for delivering these antigens to the immune system to optimize antitumor immunity. Several different vaccination approaches are under study including tumor cell-based vaccines, peptide-based vaccines, recombinant virus-based vaccines, DNA-based vaccines, and dendritic cell vaccines.

In adoptive transfer, antigen-specific cytotoxic T lymphocytes or antigen-nonspecific natural killer cells can be transferred to a patient. These effector cells can be obtained from the tumor (tumor-infiltrating lymphocytes) or the peripheral blood.

Clinical experience in patients with metastatic disease has shown objective tumor responses to a variety of immunotherapeutic modalities. It is thought, however, that the immune system is overwhelmed with the tumor burden in this setting, and thus adjuvant therapy may be preferable, reserving immunotherapy for decreasing tumor recurrences. How to best integrate immunotherapy with other therapies are not well understood for most cancer types.

GENE THERAPY

Gene therapy is being pursued as a possible approach to modifying the genetic program of cancer cells and for treatment of metabolic diseases. The field of cancer gene therapy uses a variety of strategies, ranging from replacement of mutated or deleted tumor suppressor genes to enhancement of immune responses to cancer cells.

As the goal in cancer therapy is to eradicate systemic disease, optimization of delivery systems is the key to success for gene therapy strategies. Gene therapy is likely to be most successful when combined with standard therapies, but it will provide the advantage of customization of therapy based on the molecular status of an individual's tumor.

RADIATION THERAPY

Physical Basis of Radiation Therapy

Ionizing radiation is energy strong enough to remove an orbital electron from an atom. This radiation can be electromagnetic, such as a high-energy photon, or particulate, such as an electron, proton, neutron, or alpha particle. Radiation therapy is delivered primarily as high-energy photons (gamma rays and x-rays) and charged particles (electrons). Gamma rays are photons that are released from the nucleus of a radioactive atom. X-rays are photons that are created electronically, such as with a clinical linear accelerator. Currently, high-energy radiation is delivered to tumors primarily with linear accelerators. X-rays traverse the tissue, depositing the maximum dose beneath the surface, and thus

spare the skin. Electrons are used to treat superficial skin lesions, superficial tumors, or surgical beds to a depth of 5 cm. Gamma rays typically are produced by radioactive sources used in brachytherapy.

The dose of radiation absorbed correlates with the energy of the beam. The basic unit is the amount of energy absorbed per unit of mass (joules per kilogram) and is known as a gray (Gy). One gray is equivalent to 100 rads, the unit of radiation measurement used in the past.

Biologic Basis of Radiation Therapy

Radiation deposition results in DNA damage manifested by single- and double-strand breaks in the sugar phosphate backbone of the DNA molecule. Cross-linking between the DNA strands and chromosomal proteins also occurs. The mechanism of DNA damage differs by the type of radiation delivered. Electromagnetic radiation is indirectly ionizing through short-lived hydroxyl radicals produced primarily by the ionization of cellular hydrogen peroxide (H_2O_2). Protons and other heavy particles are directly ionizing and directly damage DNA.

Radiation damage is manifested primarily by the loss of cellular reproductive integrity. Most cell types do not show signs of radiation damage until they attempt to divide, so slowly proliferating tumors may persist for months and appear viable. Some cell types, however, undergo apoptosis.

The extent of DNA damage following radiation is dependent on several factors. The most important of these is cellular oxygen. Hypoxic cells are significantly less radiosensitive than aerated cells.

The extent of DNA damage from indirectly ionizing radiation is also dependent on the phase of the cell cycle. The most radiation-sensitive phases are G2 and M, although G1 and late S phases are less sensitive. Thus irradiation of a population of tumor cells results in killing of a greater proportion of cells in G2 and M phases. However, delivery of radiation in divided doses, a concept referred to as fractionation, allows the surviving G1 and S phase cells to progress to more sensitive phases, a process referred to as reassortment. In contrast to DNA damage following indirectly ionizing radiation, that following exposure to directly ionizing radiation is less dependent on the cell-cycle phase.

Several chemicals can modify the effects of ionizing radiation. These include hypoxic cell sensitizers such as metronidazole and misonidazole, which mimic oxygen and increase cell kill of hypoxic cells. A second category of radiation sensitizers are thymidine analogues iododeoxyuridine and bromodeoxyuridine. These molecules are incorporated into the DNA in place of thymidine and render the cells more susceptible to radiation damage. Furthermore, several chemotherapeutic agents sensitize cells to radiation through various mechanisms, including 5-fluorouracil, actinomycin D, gemcitabine, paclitaxel, topotecan, doxorubicin, and vinorelbine.

Radiation Therapy Planning

Radiation therapy is delivered in a homogeneous dose to a well-defined region that includes tumor and/or surrounding tissue at risk for subclinical disease. The first step in planning is to define the target to be irradiated and the dose-limiting organs in the vicinity. Treatment planning includes evaluation of alternative treatment techniques, which is done through a process referred to as simulation. Once the beam distribution is determined that will best achieve homogenous delivery to the target volume and minimize the dose to the normal

tissue, immobilization devices and markings or tattoos on the patient's skin are used to ensure that each daily treatment is given in the same way. Conventional fractionation is 1.8–2 Gy per day, administered 5 days each week for 3–7 weeks.

Another mode of postoperative radiation therapy is brachytherapy. In brachytherapy, unlike external beam therapy, the radiation source is in contact with the tissue being irradiated. The radiation source may be cesium, gold, iridium, or radium. Brachytherapy is administered with temporary or permanent implants such as needles, seeds, or catheters. Temporary brachytherapy catheters are placed either during open surgery or percutaneously soon after surgery. The implants are loaded interstitially and treatment usually is given postoperatively for a short duration such as 1–3 days. Although brachytherapy has the advantage of patient convenience owing to the shorter treatment duration, it has the disadvantages of leaving scars at the catheter insertion site and requiring special facilities for inpatient brachytherapy therapy.

Side Effects

Both tumor and normal tissue have radiation dose-response relationships that can be plotted on a sigmoidal curve. A minimum dose of radiation must be given before any response is seen. The response to radiation then increases slowly with an increase in dose. At a certain dose level the curves become exponential, with increases in tumor response and normal tissue toxicity with each incremental dose increase. The side effects of radiation therapy can be acute, occurring during or 2–3 weeks after therapy, or chronic, occurring weeks to years after therapy. The side effects depend on the tissue included in the target volume.

CANCER PREVENTION

The old axiom “an ounce of prevention is worth a pound of cure” is being increasingly recognized in oncology. Cancer prevention can be divided into three categories: (1) primary prevention (i.e., preventing initial cancers in healthy individuals); (2) secondary prevention (i.e., preventing cancer in individuals with premalignant conditions); and (3) tertiary prevention (i.e., preventing second primary cancers in patients cured of their initial disease).

The administration of systemic or local therapies to prevent the development of cancer, called chemoprevention, is being actively explored for several cancer types. Tamoxifen reduces the risk of breast cancer by one half in high-risk patients. Therefore tamoxifen has been approved by the FDA for breast cancer chemoprevention. Celecoxib has been shown to reduce polyps in patients with familial adenomatous polyposis. In head and neck cancer, 13-cis-retinoic acid was shown to both reverse oral leukoplakia and reduce second primary tumor development. Thus the chemoprevention trials completed so far have demonstrated success in primary, secondary, and tertiary prevention. It is important for surgeons to be aware of these preventive options because they are likely to be involved in the diagnosis of premalignant and malignant conditions, and will be the ones to counsel patients about their chemopreventive options.

In selected scenarios, the risk of cancer is high enough to justify surgical prevention. These high-risk scenarios include hereditary cancer syndromes such as hereditary breast ovarian cancer syndrome, hereditary diffuse gastric cancer, multiple endocrine neoplasia type 2, FAP, and HNPCC, and some nonhereditary scenarios such as chronic ulcerative colitis. Most prophylactic surgeries are

large ablative surgeries (e.g., bilateral risk-reducing mastectomy or total proctocolectomy). Therefore it is important that the patient be completely informed about potential surgical complications and long-term lifestyle consequences. Further, the conservative options of close surveillance and chemoprevention need to be discussed. The patient's cancer risk needs to be assessed accurately and implications for survival discussed. Ultimately, the decision to proceed with surgical prevention should be individualized and made with caution.

TRENDS AND EVOLVING TECHNOLOGIES IN ONCOLOGY

Cancer Screening and Diagnosis

It is clear that the practice of oncology will change dramatically over the next few decades as our understanding of the molecular basis of cancer and available technologies are evolving rapidly. One of the critical changes expected is earlier detection of cancers. With improvements in available imaging modalities and development of newer functional imaging technologies, it is likely that many tumors may be detected at earlier, more curable stages in the near future.

Another area of rapid development is the identification of serum markers. High-throughput technologies such as matrix-assisted laser-desorption-ionization time of flight (MALDI-TOF) mass spectroscopy and liquid chromatography-ion-spray tandem mass spectroscopy (LC-MS/MS) have revolutionized the field of proteomics and identification of unique proteins and unique proteomic profiles for most cancer types is being pursued actively by many researchers, which if successful, could dramatically enhance our ability to detect cancers early.

Surgical Therapy

The current trend in surgery is moving toward more conservative resections. With earlier identification of tumors, more conservative surgeries may be possible. The goal, however, is always to remove the tumor en bloc with wide negative margins. Another interesting area being explored is the destruction of tumors by such techniques as radiofrequency ablation, cryoablation, and heat-producing technologies such as lasers, microwaves, or focused ultrasound. Pilot studies have demonstrated that radiofrequency ablation is effective for destruction of small primary breast cancers. Although this approach remains experimental and potentially of limited applicability, with the development of imaging technologies that can accurately map the extent of cancer cells, these types of noninvasive interventions are likely to come to the forefront.

Systemic Therapy

The current trend in systemic therapy is moving toward individualized therapy. It now is presumed that all cancers of a certain cell origin are the same, thus all patients are offered the same systemic therapy. Not all patients respond to these therapies, however, emphasizing the biologic variability within the groups. Therefore the intent is to determine the underlying biology of each tumor to tailor therapy accordingly. The approaches used include high-throughput techniques such as proteomics, or more frequently, transcriptional profiling. It is likely that in the near future tumors can be tested and treatments individualized. Patients who will respond to conventional therapies can be given these regimens, although patients who will not respond are not, sparing them the toxicity. Instead, these patients can be offered novel therapies.

Furthermore, with emerging biologic therapies, it is likely that patients may be given a combination of biologic therapies specifically targeting the alterations in their own tumors. Finally, stratification of patients by gene expression profile for prognosis may assist in determining which patients are at higher risk of relapse, sparing patients whose tumors have less aggressive biologic characteristics further therapy.

The field of organ transplantation has made remarkable progress in a short period of time. From an experimental procedure just 50 years ago, transplantation has evolved to become the treatment of choice for end-stage organ failure resulting from almost any of a wide variety of causes. Transplantation of the kidney, liver, pancreas, intestine, heart, and lungs has now become commonplace in all parts of the world.

Definitions

Transplantation is the act of transferring an organ, tissue, or cell from one place to another. Broadly speaking, transplants are divided into three categories based on the similarity between the donor and the recipient: autotransplants, allotransplants, and xenotransplants. Autotransplants involve the transfer of tissue or organs from one part of an individual to another part of the same individual. They are the most common type of transplants and include skin grafts and vein grafts for bypasses. Because the donor and the recipient are the same person and no immunologic disparity exists, no immunosuppression is required. Allotransplants involve transfer from one individual to a different individual of the same species—the most common scenario for most solid organ transplants performed today. Immunosuppression is required for allograft recipients to prevent rejection. Finally, xenotransplants involve transfer across species barriers. Currently, xenotransplants are largely relegated to the laboratory, given the complex, potent immunologic barriers to success.

TRANSPLANT IMMUNOBIOLOGY

It was only after a basic understanding of transplant immunobiology was obtained could the obstacle of rejection posttransplant be overcome, thus making clinical transplants possible. The success of transplants today is due in large part to control of the rejection process, thanks to an ever-deepening understanding of the immune process triggered by a transplant.

The immune system is important not only in graft rejection, but also in the body's defense system against viral, bacterial, fungal, and other pathogens. It also helps prevent tumor growth and helps the body respond to shock and trauma. As with the body's reaction to an infection, graft rejection is triggered when specific cells of the transplant recipient, namely T and B lymphocytes, recognize foreign antigens.

Transplant Antigens

The main antigens involved in triggering rejection are coded for by a group of genes known as the major histocompatibility complex (MHC). These antigens and hence genes define the "foreign" nature of one individual to another within the same species. In humans, the MHC complex is known as the human leukocyte antigen (HLA) system. It comprises a series of genes located on chromosome 6.

In a nontransplant setting, the function of the HLA gene product is to present antigens as fragments of foreign proteins that can be recognized

by T lymphocytes. In the transplant setting, HLA molecules can initiate rejection and graft damage, via either humoral or cellular mechanisms. Humoral rejection occurs if the recipient has circulating antibodies specific to the donor's HLA from prior exposure (i.e., blood transfusion, previous transplant, or pregnancy), or if posttransplant, the recipient develops antibodies specific to the donor's HLA. The antibodies then bind to the donor's recognized foreign antigens, activating the complement cascade and leading to cell lysis. The blood group antigens of the ABO system, although not part of the HLA system, may also trigger this form of humoral rejection.

Cellular rejection is the more common type of rejection after organ transplants. Mediated by T lymphocytes, it results from their activation and proliferation after exposure to donor MHC molecules.

Allorecognition and Destruction

The recognition of foreign HLA antigens by the recipient T cells is referred to as allorecognition. This process may occur by either a direct or an indirect pathway. In the direct pathway, the recipient's T cells directly interact with donor HLA molecules, leading to the generation of activated cytotoxic T cells. In the indirect pathway, the recipient's own antigen-presenting cells (APCs) first process the donor's antigens (which may be shed from the parenchymal cells of the graft into the recipient's circulation, or alternatively may be encountered by the recipient's APCs in the graft itself); then the recipient's APCs present the donor's antigens to the recipient T cells, leading to the activation of those T cells.

Regardless of the method of presentation of foreign MHC, the subsequent steps are similar. Binding of the T cell to the foreign molecule occurs at the T-cell receptor (TCR)-CD3 complex on the surface of the lymphocyte. This binding leads to transduction of a signal to the cell, named signal 1. This signal by itself, however, is not sufficient to result in T-cell activation. Full activation requires transduction of a second signal that is not antigen-dependent. Signal 2 is provided by the binding of accessory molecules on the T cell to corresponding molecules (ligands) on the APC. An example is CD25 on the T lymphocytes binding with its ligand B7 on the surface of the APC. Transmission of signal 1 and 2 to the cell nucleus leads to interleukin-2 (IL-2) gene expression and to production of this important cytokine. IL-2 then permits the entire cascade of T-cell activation to proceed, leading to proliferation and differentiation of these cells into cells capable of causing damage to the graft.

T-cell activation is key in initiating the rejection process, but B-cell activation and antibody production also play a role. Foreign antigens are acquired by immunoglobulin receptors on the surface of B cells. These antigens are then processed similarly to the way that APCs process the donor's antigens. The antigen-presenting B cells can then interact with activated T-helper cells. This interaction leads to B-cell proliferation, differentiation into plasma cells, and to antibody production.

Clinical Rejection

Graft rejection is a complex process involving several components, including T lymphocytes, B lymphocytes, macrophages, and cytokines, with resultant local inflammatory injury and graft damage. Rejection can be classified into

the following types based on timing and pathogenesis: hyperacute, acute, and chronic.

Hyperacute

This type of rejection, which usually occurs within min after the transplanted organ is reperfused, is because of the presence of preformed antibodies in the recipient, antibodies that are specific to the donor. These bind to the vascular endothelium in the graft and activate the complement cascade, leading to platelet activation and to diffuse intravascular coagulation. The result is a swollen, darkened graft, which undergoes ischemic necrosis.

Acute

This used to be the most common type of rejection, but with modern immunosuppression it is becoming less and less common. Acute rejection is usually seen within days to a few months posttransplant. It is predominantly a cell-mediated process, with lymphocytes being the main cells involved. With current immunosuppressive drugs, most acute rejection episodes are generally asymptomatic. They usually manifest with abnormal laboratory values (e.g., elevated creatinine in kidney transplant recipients, and elevated transaminase levels in liver transplant recipients).

Acute rejection episodes may also be mediated by a humoral, rather than cellular, immune response. B cells may generate antidonor antibodies, which can damage the graft. Establishing the diagnosis may be difficult, as biopsy may not demonstrate a significant cellular infiltrate; special immunologic stains may be necessary.

Chronic

This form of rejection occurs months to years posttransplant. Now that short-term graft survival rates have improved so markedly, chronic rejection is an increasingly common problem. Histologically, the process is characterized by atrophy, fibrosis, and arteriosclerosis. Both immune and nonimmune mechanisms are likely involved. Clinically, graft function slowly deteriorates over months to years.

CLINICAL IMMUNOSUPPRESSION

The success of modern transplantation is in large part because of the successful development of effective immunosuppressive agents. Over 15 agents are now approved in the United States by the Food and Drug Administration (FDA) for clinical immunosuppression (Table 10-1), with scores of others in various stages of clinical trials. Table 10-2 shows characteristics of some common immunosuppressive agents and their location of action.

Induction immunosuppression refers to the drugs administered immediately posttransplant to induce immunosuppression. Maintenance immunosuppression refers to the drugs administered to maintain immunosuppression once recipients have recovered from the operative procedure. Individual drugs can be categorized as either biologic or nonbiologic agents. Biologic agents consist of antibody preparations directed at various cells or receptors involved in the rejection process; they are generally used in induction (rather than maintenance) protocols. Nonbiologic agents form the mainstay of maintenance protocols.

TABLE 10-1 Immunosuppressive Drugs by Classification

Immunophilin binders
Calcineurin inhibitors
Cyclosporine
Tacrolimus (FK506)
Noninhibitors of calcineurin
Sirolimus (rapamycin)
Antimetabolites
Inhibitors of de novo purine synthesis
Azathioprine
Mycophenolate mofetil (MMF)
Inhibitors of de novo pyrimidine synthesis
Leflunomide
Biologic immunosuppression
Polyclonal antibodies
ATGAM
Thymoglobulin
Monoclonal antibodies
OKT3
IL-2R (humanized)
Others
Deoxyspergualin
Corticosteroids
FTY720

ATGAM = antithymocyte gamma-globulin; OKT3 = anti-CD3 monoclonal antibody; IL-2R = interleukin-2 receptor.

Nonbiologic Agents

Corticosteroids

Steroids have both antiinflammatory and immunosuppressive properties as the two are closely related. Their effects on the immune system are complex. Historically, corticosteroids represent the first family of drugs used for clinical immunosuppression. Today steroids remain an integral component of most immunosuppressive protocols, and often are the first-line agents in the treatment of acute rejection. Despite their proven benefit, steroids have significant side effects, especially with long-term use. Hence there has been considerable interest recently in withdrawing steroids from long-term maintenance protocols. The newer immunosuppressive agents may make doing so possible.

Azathioprine

An antimetabolite, azathioprine (AZA) is a derivative of 6-mercaptopurine, the active agent. Until the introduction of cyclosporine, it was the most widely used immunosuppressive drug, but now has become an adjunctive component of immunosuppressive drug regimens. With the introduction of newer agents, the use of AZA may be discontinued altogether.

AZA acts late in the immune process, affecting the cell cycle by interfering with DNA synthesis, thus suppressing proliferation of activated B and T lymphocytes. AZA is valuable in preventing the onset of acute rejection, but is not effective in the treatment of rejection episodes themselves.

TABLE 10-2 Characteristics of Common Immunosuppressive Drugs

Drug	Mechanism of action	Adverse effects	Clinical uses	Dosage
Cyclosporine	Binds to cyclophilin; inhibits calcineurin and IL-2 synthesis	Nephrotoxicity; tremor; hypertension; hirsutism	Improved bioavailability of microemulsion form; used as mainstay of maintenance protocols	Oral dose is 8 to 10 mg/kg/day (given in 2 divided doses)
Tacrolimus (FK506)	Binds to FKBP; inhibits calcineurin and IL-2 synthesis	Nephrotoxicity; hypertension; neurotoxicity; GI toxicity (nausea, diarrhea)	Improved patient and graft survival in (liver) primary and rescue therapy; used as mainstay of maintenance, like cyclosporine	IV 0.05 to 0.1 mg/kg/day; PO 0.15 to 0.3 mg/kg/day (given q12h)
Mycophenolate mofetil (MMF)	Antimetabolite; inhibits enzyme necessary for de novo purine synthesis	Leukopenia; GI toxicity	Effective for primary and rescue therapy in kidney transplants; may replace azathioprine	1.0 g bid PO (may need 1.5 g in black recipients)
Sirolimus (rapamycin)	Inhibits lymphocyte effects driven by IL-2 receptor	Thrombocytopenia; increased serum cholesterol/LDL; vasculitis (animal studies)	May allow early withdrawal of steroids and decreased calcineurin doses	3 to 5 mg/day, adjusted to trough drug levels
Corticosteroids	Multiple actions; antiinflammatory; inhibit lymphokine production	Cushingoid state; glucose intolerance; osteoporosis	Used in induction, maintenance, and treatment of acute rejection	Varies from milligrams to several grams per day; maintenance doses, 5 to 10 mg/day
Azathioprine (AZA)	Antimetabolite; interferes with DNA and RNA synthesis	Thrombocytopenia; neutropenia; liver dysfunction	Used in maintenance protocols	1 to 3 mg/kg/day for maintenance

bid = two times daily; FKBP = FK506-binding proteins; GI = gastrointestinal; IL-2 = interleukin-2; LDL = low-density lipoproteins.

Cyclosporine

The introduction of cyclosporine in the early 1980s dramatically altered the field of transplantation. It significantly improved results after kidney transplants, but its greatest impact was on extrarenal transplants. When it was introduced, cyclosporine was the most specific immunosuppressive agent available. Currently, cyclosporine plays a central role in maintenance immunosuppression in almost all types of organ transplants.

Adverse effects of cyclosporine can be classified as renal or nonrenal. Nephrotoxicity is the most important and troubling adverse effect of cyclosporine. Cyclosporine has a vasoconstrictor effect on the renal vasculature. This vasoconstriction (likely a transient, reversible, and dose-dependent phenomenon) may cause early posttransplant graft dysfunction or may exaggerate existing poor graft function. Also, long-term cyclosporine use may result in interstitial fibrosis of the renal parenchyma, coupled with arteriolar lesions. The exact mechanism is unknown, but renal failure may eventually result.

A number of nonrenal side effects may also be seen with the use of cyclosporine. Cosmetic complications, most commonly hirsutism and gingival hyperplasia, may result in considerable distress, possibly leading to non-compliant behavior, especially in adolescents and women. Several neurologic complications, including headaches, tremor, and seizures, also have been reported. Other nonrenal side effects include hyperlipidemia, hepatotoxicity, and hyperuricemia.

Tacrolimus

Tacrolimus (FK506) is a metabolite of the soil fungus *Streptomyces tsukubaensis*, found in Japan. Released in the United States in April 1994 for use in liver transplantation, it is currently used in a fashion similar to cyclosporine. Tacrolimus, like cyclosporine, is a calcineurin inhibitor and has a very similar mechanism of action.

Adverse effects of tacrolimus and cyclosporine are similar. The most common problems include nephrotoxicity, neurotoxicity, impaired glucose metabolism, hypertension, infection, and gastrointestinal (GI) disturbances. Nephrotoxicity is dose-related and reversible with dose reduction. Neurotoxicity seen with tacrolimus ranges from mild symptoms (tremors, insomnia, and headaches) to more severe events (seizures and coma); it is usually related to high levels and resolves with dose reduction. These side effects are most common early posttransplant and subsequently tend to decrease in incidence.

Sirolimus

A macrolide antibiotic derived from a soil actinomycete originally found on Easter Island (Rapa Nui), sirolimus (previously known as rapamycin) is structurally similar to tacrolimus and binds to the same immunophilin (FKBP). Unlike tacrolimus, it does not affect calcineurin activity.

To date, sirolimus has been used in a variety of combinations and situations. It is most commonly used in conjunction with one of the calcineurin inhibitors. In such combinations, sirolimus is usually used to help withdraw or avoid the use of steroids completely in maintenance immunosuppressive regimens. It also has been used as an alternative to tacrolimus or cyclosporine, as part of a calcineurin-sparing protocol. The advantage of this type of protocol is that it is not associated with long-term

nephrotoxicity (as may be seen with the calcineurin agents). Hence, sirolimus may prove to be better for long-term preservation of renal function in transplant recipients.

The major side effects of sirolimus include neutropenia, thrombocytopenia, and a significant elevation of the serum triglyceride and cholesterol levels. It also has been associated with impaired wound healing, leading to a higher incidence of wound-related complications.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) was approved in May 1995 by the FDA for use in the prevention of acute rejection after kidney transplants. It has since been rapidly incorporated into routine clinical practice at many centers as part of maintenance regimens. It works by inhibiting inosine monophosphate dehydrogenase, which is a crucial, rate-limiting enzyme in de novo synthesis of purines. The net result is a selective, reversible antiproliferative effect on T and B lymphocytes.

MMF differs from cyclosporine, tacrolimus, and sirolimus in that it does not affect cytokine production or the events immediately after antigen recognition. Rather, MMF works further distally in the chain of activation events to prevent proliferation of the stimulated T cell. Like AZA, it is an antimetabolite; unlike AZA, its impact is selective: it only affects lymphocytes, not neutrophils or platelets. In several clinical trials, it has proven to be more effective than AZA, and has largely replaced it.

The incidence and types of adverse events with MMF are similar to those seen with AZA. Notable exceptions are GI side effects (diarrhea, gastritis, and vomiting), which are more common with MMF. Clinically significant leukopenia also is more common, affecting about one third of recipients.

Biologic Agents

Polyclonal antibodies directed against lymphocytes have been used in clinical transplantation since the 1960s. Monoclonal antibody techniques, developed later, allowed in turn for the development of biologic agents (such as OKT3) targeted to specific subsets of cells. A number of different monoclonal antibodies (MABs) are currently under development or have been recently approved for use in clinical transplantation. Many are directed against functional secreted molecules of the immune system or their receptors, rather than against actual groups of cells.

Polyclonal Antibodies

Polyclonal antibodies are produced by immunizing animals (such as horses, goats, or rabbits) with human lymphoid tissue, allowing for an immune response, removing the resultant immune sera, and purifying the sera in an effort to remove unwanted antibodies. What remain are antibodies that will recognize human lymphocytes.

After administration of these antibodies into a transplant recipient, the total lymphocyte count should fall. Lymphocytes, especially T cells, are either lysed after antibody binding and complement deposition at the cell surface, inactivated by binding to T-cell receptors, or are cleared from the circulation and deposited into the reticuloendothelial system. Currently available polyclonal preparations include antithymocyte globulin (obtained by immunizing horses

with human thymocytes) and thymoglobulin (obtained by immunizing rabbits with human thymocytes).

Monoclonal Antibodies

MABs are produced by the hybridization of murine antibody-secreting B lymphocytes with a nonantibody-secreting myeloma cell line. A number of MABs have been produced that are active against different stages of the immune response. OKT3 remains the most commonly used MAB, but the last few years have seen the introduction of a number of “humanized” MABs (genetically engineered to possess large domains of human antibody while retaining the murine antigen binding site), which have a significantly lower potential for toxicity than OKT3.

OKT3 is highly effective and versatile. Most commonly, it is used to treat severe acute rejection episodes (i.e., those resistant to steroids). OKT3 also has been used as prophylaxis against rejection, as induction therapy, and as primary rejection treatment.

Significant, even life-threatening adverse effects may be seen after OKT3 administration, most commonly immediately after one of the first several doses. Such effects may occur when cytokines (such as tumor necrosis factor, IL-2, and γ -interferon) are released by T cells from the circulation. The most common symptoms are fever, chills, and headaches. The most serious side effect of OKT3 is a rapidly developing, noncardiogenic pulmonary edema; the risk of this side effect significantly increases if the patient is fluid-overloaded at the time of OKT3 treatment. Other serious side effects include encephalopathy, aseptic meningitis, and nephrotoxicity.

Several other monoclonal antibodies (MABs) targeting different steps of the immune process are available for clinical use. As noted, IL-2 is an important cytokine necessary for the proliferation of cytotoxic T cells. Two MABs are currently approved to target the IL-2 receptor (IL-2R): basiliximab and daclizumab. Both are humanized products and therefore are not associated with significant first-dose reactions or drug-specific adverse events. They have been proven effective as induction agents, decreasing the incidence of acute rejection in kidney transplant recipients when compared to placebo in clinical trials. They have not been used to treat established acute rejection. More recently, alemtuzumab, a MAB directed against the CD52 antigen found on B and T cells, has been used, usually as an induction agent.

Organ Procurement and Preservation

The biggest problem facing transplant centers today is the shortage of organ donors. Mechanisms that might increase the number of available organs include: (1) optimizing the current donor pool (e.g., the use of multiple organ donors or marginal donors); (2) increasing the number of living-donor transplants (e.g., the use of living unrelated donors); (3) using unconventional and controversial donor sources (e.g., using deceased donors without cardiac activity or anencephalic donors); and (4) performing xenotransplants.

Deceased Donors

Most extrarenal transplants performed today, and roughly one half of all renal transplants, are from deceased donors. These donors are deceased individuals who meet the criteria for brain death, but whose organs are being perfused by life-support measures, allowing adequate time for referral to an organ

procurement organization. A member of that organization can then ascertain whether donation is possible, and if so, approach the potential donor's family and possibly obtain consent to procure suitable organs.

Once the diagnosis of brain death has been established, the process of organ donation can be initiated. The focus then switches from the treatment of elevated intracranial pressure to preserving organ function and optimizing peripheral oxygen delivery. It is important to keep in mind that management of the deceased organ donor is an active process, requiring aggressive monitoring and intervention to ensure that perfusion to the organs of interest is not compromised.

Living Donors

Living-donor transplantation is unique in that surgeons commonly operate on a healthy individual (i.e., a living donor) who has no medical disorders and does not require an operation. The use of living donors is an integral and important part of the field of transplantation today. But living-donor transplants pose a unique set of medical, ethical, financial, and psychosocial problems that must be dealt with by the transplant team.

The use of living donors offers numerous advantages. Primary is the availability of a life-saving organ. A certain percentage of transplant candidates die while waiting for a deceased donor organ as a direct result of a complication, or of progression of their underlying disease. For such ill candidates, the advantage of a living donor is obvious. Even for candidates who would receive a deceased donor organ, a living-donor transplant may significantly shorten the waiting time. A shorter waiting time generally implies a healthier candidate—one whose body has not been ravaged by prolonged end-stage organ failure. Lastly, long-term results may be superior with living-donor transplants, which is certainly the case with kidney transplants.

The disadvantages of a living-donor transplant for the potential recipient are minimal. With some organ transplants (e.g., living donor liver or lung) the procedure may be more technically complex, resulting in an increased incidence of surgical complications. However, this disadvantage is offset by numerous advantages. The major disadvantage is to the donor. Medically, there is no possibility of benefit for the donor, only potential for harm. The risk of death associated with donation depends on the organ being removed. For nephrectomy, the mortality risk is estimated to be less than 0.05 percent. However, for partial hepatectomy, it is about 0.5 percent. Risks for surgical and medical complications also depend on the procedure being performed. Additionally, long-term complications or problems may be associated with partial loss of organ function through donation.

The kidney, the first organ to be used for living-donor transplants, is the most common type of organ donated by living donors today. Potential donors are first evaluated to ensure that they have normal renal function with two equally functioning kidneys and that they do not have any significant risk factors for developing renal disease (e.g., hypertension or diabetes). The anatomy of their kidneys and the vasculature can be determined by using various radiologic imaging techniques. Nephrectomy can be performed through a flank incision, by an anterior retroperitoneal approach, or by a laparoscopic technique. With the laparoscopic technique, an intraperitoneal approach is used.

Living-donor liver transplants have been performed for almost 15 years. Initially, they involved adult donors and pediatric recipients. In such cases, the

left lateral segment of the donor's liver is resected. Inflow to the graft occurs via the donor's left hepatic artery and left portal vein; outflow is via the left hepatic vein. For adult recipients, a larger piece of the liver is required; usually the right lobe is chosen. The risks for living liver donors are higher than those for living kidney donors. The risks are also generally higher for right lobe donors than for left lateral segment donors. The most worrisome complication for living liver donors is a bile leak, either from the cut surface of the liver or from the bile duct stump.

Living-donor transplants with organs besides the kidney and liver are not as common, but are performed at various centers. Living-donor pancreas transplants involve a distal pancreatectomy, with the graft consisting of the body and tail of the pancreas; vascular inflow and outflow are provided by the splenic artery and splenic vein. Living-donor intestinal transplants usually involve removal of about 200 cm of the donor's ileum, with inflow and outflow provided by the ileocolic vessels. Living-donor lung transplants involve removal of one lobe of one lung from each of two donors; both grafts are then transplanted into the recipient.

Preservation

Organ preservation methods have played an important role in the success of cadaver donor transplants. They have resulted in improved graft function immediately posttransplant and have diminished the incidence of primary non-function of organs. By prolonging the allowable cold ischemia times, they have also allowed for better organ allocation and for safer transplants.

The most common methods involve the use of hypothermia and pharmacologic inhibition to slow down metabolic processes in the organ once it has been removed from the deceased donor. Hypothermia very effectively slows down enzymatic reactions and metabolic activity, allowing the cell to make its limited energy reserves last much longer. Cold storage solutions have been developed to improve organ preservation by ameliorating some of the detrimental effects of hypothermia alone. Essentially, these solutions suppress hypothermia-induced cellular swelling and minimize the loss of potassium from the cell.

The most commonly used fluid worldwide is the University of Wisconsin solution. It contains lactobionate, raffinose, and hydroxyethyl starch. Lactobionate is impermeable and prevents intracellular swelling; it also lowers the concentration of intracellular calcineurin and free iron, which may be beneficial in reducing reperfusion injury. Hydroxyethyl starch, a synthetic colloid, may help decrease hypothermia-induced cell swelling of endothelial cells and reduce interstitial edema.

Although cold preservation has improved cadaver donor transplant results, the amount of time that an organ can be safely preserved is limited. After that, the incidence of organ nonfunction starts to increase. With kidneys, exceeding the preservation time limit results in delayed graft function, requiring dialysis support for the recipient until function improves. With livers, the result is primary nonfunction, requiring an urgent retransplant. How long an organ can be safely preserved depends on the type of organ and on the condition of the donor. With kidneys, cold ischemic times should be kept below 36–40 h; after that, delayed graft function significantly increases. With pancreata, more than 24 h of ischemia increases problems because of pancreatitis and duodenal leaks. With livers, more than 16 h of ischemia increases the risk for primary nonfunction and biliary complications. Hearts and lungs tolerate preservation

poorly; ideally, ischemia times should be below 6 h. With marginal donors, all of these times should be adjusted further downward.

KIDNEY TRANSPLANTATION

A kidney transplant now represents the treatment of choice for patients with end-stage renal disease (ESRD). It offers the greatest potential for restoring a healthy, productive life in most such patients. Compared with dialysis, it is associated with better patient survival and superior quality of life, and is more cost-effective.

Preoperative Evaluation

Very few absolute contraindications to kidney transplants exist. Therefore, most patients with ESRD should be considered as potential transplant candidates. However, the surgery and general anesthesia impose a significant cardiovascular stress. Subsequent lifelong immunosuppression also is associated with some risk. Pretransplant evaluation should identify any factors that would contraindicate a transplant or any risk factors that could be minimized pretransplant.

The preoperative evaluation can be divided into four parts: medical, surgical, immunologic, and psychosocial. The purpose of the medical evaluation is to identify risk factors for the surgical procedure. Mortality posttransplant usually is because of underlying cardiovascular disease, so a detailed cardiac evaluation is necessary. Untreated malignancy and active infection are absolute contraindications to a transplant, because of the requisite lifelong immunosuppression. After curative treatment of malignancy, an interval of 2–5 years is recommended pretransplant. The medical evaluation also should concentrate on GI problems such as peptic ulcer disease, symptomatic cholelithiasis, and hepatitis. Patients who demonstrate serologic evidence of hepatitis C or B, but without evidence of active hepatic inflammation or cirrhosis, are acceptable transplant candidates.

The surgical evaluation should identify vascular or urologic abnormalities that may contraindicate or complicate a transplant. Evidence of vascular disease that is revealed by the history (claudication or rest pain) or the physical examination (diminished or absent pulse or bruit) should be evaluated further by Doppler studies or angiography. Urologic evaluation should exclude chronic infection in the native kidney, which may require nephrectomy pretransplant. Other indications for nephrectomy include huge polycystic kidneys, significant vesicoureteral reflux, or uncontrollable renovascular hypertension.

The immunologic evaluation involves determining blood type, tissue type (HLA-A, -B, or -DR antigens), and presence of any cytotoxic antibodies against HLA antigens (because of prior transplants, blood transfusions, or pregnancies). If a living-donor transplant is planned, a cross-match should be performed early on during the initial evaluation.

The psychosocial evaluation is necessary to ensure that transplant candidates understand the nature of the transplant procedure and its attendant risk. They must be capable of rigorously adhering to the medical regimen posttransplant. Patients who have not been compliant with their medical regimen in the past must demonstrate a willingness and capability to do so before they undergo the transplant.

One important aspect of the preoperative evaluation is the search for and evaluation of potential living donors. Living-donor kidney recipients enjoy

improved long-term success, avoid a prolonged wait, and are able to plan the timing of their transplant in advance. Moreover, they have a significantly decreased incidence of ATN and increased potential for HLA matching. As a result, living-donor transplants generally have better short- and long-term results, as compared with cadaver donor transplants. Of course, the risks to the living donor must be acceptably low. The donor must be fully aware of potential risks and must freely give informed consent. The search for a living donor should not be restricted to immediate family members. Results with living, unrelated donors are comparable to those with living, related (non-HLA-identical) donors.

Surgical Procedure

The transplanted kidney is usually placed in a heterotopic position, with no need for native nephrectomy except in select circumstances. Retroperitoneal placement is preferred, to allow for easy access for percutaneous renal biopsy. With the standard approach, the dissection is extraperitoneal. The iliac vessels are identified and assessed for suitability for anastomosis. The internal iliac artery can be used as the inflow vessel, with an end-to-end anastomosis, or the external iliac artery can be used with an end-to-side anastomosis. To minimize the risk of lymphocele formation after surgery, only a modest length of artery is dissected free and the lymphatics overlying the artery are ligated. The donor renal vein is anastomosed end to side to the external iliac vein.

After the vascular anastomosis is completed and the kidney perfused, urinary continuity can be restored by a number of well-described techniques. The important principles are to attach the ureter to the bladder mucosa in a tension-free manner and to cover the distal 1 cm of the ureter with a submucosal tunnel, thus protecting against reflux during voiding.

Early Postoperative Care

The immediate postoperative care of all recipients involves (1) stabilizing the major organ systems (e.g., cardiovascular, pulmonary, and renal); (2) evaluating graft function; (3) achieving adequate immunosuppression; and (4) monitoring and treating complications directly and indirectly related to the transplant.

Careful attention to fluid and electrolyte management is crucial. In general, recipients should be kept euvolemic or slightly hypervolemic. If initial graft function is good, fluid replacement can be regulated by hourly replacement of urine. Half-normal saline is a good solution to use for urine replacement. Aggressive replacement of electrolytes, including calcium, magnesium, and potassium, may be necessary, especially for recipients undergoing brisk diuresis. Those with acute tubular necrosis (ATN) and fluid overload or hyperkalemia may need fluid restriction and even hemodialysis. Magnesium levels should be kept above 2 mEq/L to prevent seizures, and phosphate levels kept between 2 and 5 mEq/L for proper support of the respiratory and alimentary tracts.

A critical aspect of postoperative care is the repeated evaluation of graft function, which in fact begins intraoperatively, soon after the kidney is reperfused. Signs of good kidney function include appropriate color and texture, along with evidence of urine production. Postoperatively, urine output is the most readily available and easily measured indicator of graft function. Urine volume may range from none (anuria) to large quantities (polyuria). When using posttransplant urine volume to monitor graft function, the clinician must

have at least some knowledge of the recipient's pretransplant urine volume, if any. Laboratory values of obvious use in assessing graft function include serum blood urea nitrogen (BUN) and creatinine levels.

Recipients can be divided into three groups (by initial graft function as indicated by their urine output and serum creatinine) as those with: (1) immediate graft function (IGF), characterized by a brisk diuresis posttransplant and rapidly falling serum creatinine level; (2) slow graft function (SGF), characterized by a moderate degree of kidney dysfunction posttransplant, with modest amounts of urine and a slowly falling creatinine level, but no need for dialysis at any time posttransplant; and (3) delayed graft function (DGF), which represents the far end of the spectrum of posttransplant graft dysfunction and is defined by the need for dialysis posttransplant.

Decreased or minimal urine output is a frequent concern posttransplant. Most commonly, it is because of an alteration in volume status. Other causes include a blocked urinary catheter, vascular thrombosis, a urinary leak or obstruction, early acute rejection, drug toxicity, or DGF. Early diagnosis is important, and begins with an assessment of the recipient's volume status. The urinary catheter is checked to exclude the presence of occlusion with clots or debris. Other diagnostic tests that may be warranted, on the suspected cause, include a Doppler ultrasound, nuclear medicine scan, or a biopsy.

Complications

Monitoring for potential surgical and medical complications is important. Early diagnosis and appropriate intervention can minimize the detrimental impact on the graft and recipient. Potential complications that may occur early after surgery include hemorrhage, vascular complications, urologic complications, lymphocele, and several others.

Bleeding is uncommon after a kidney transplant; it usually occurs from unligated vessels in the graft hilum or from the retroperitoneum of the recipient. A falling hematocrit level, hypotension, or tachycardia should all raise the possibility of bleeding. Surgical exploration is seldom required because bleeding often tamponades. Vascular complications can involve the donor vessels (renal artery thrombosis or stenosis, renal vein thrombosis), the recipient vessels (iliac artery thrombosis, pseudoaneurysms, and deep venous thrombosis), or both. Renal artery thrombosis usually occurs early posttransplant; it is uncommon, with an incidence of less than 1 percent. However, it is a devastating complication, usually resulting in graft loss. Diagnosis is easily made with color flow Doppler studies. Urgent thrombectomy is indicated, but most such grafts cannot be salvaged and require removal. Renal vein thrombosis is not as common as its arterial counterpart, but again, graft loss is the usual end result. Causes include angulation or torsion of the vein, compression by hematomas or lymphoceles, anastomotic stenosis, and extension of an underlying deep venous thrombosis. Again, Doppler studies are the best diagnostic test. Urgent thrombectomy is rarely successful, and nephrectomy is usually required.

Urinary tract complications, manifesting as leakage or obstruction, generally occur in 2–10 percent of kidney recipients. The underlying cause is often related to poor blood supply and ischemia of the transplant ureter. Leakage most commonly occurs from the anastomotic site. Causes other than ischemia include undue tension created by a short ureter, and direct surgical injury. Presentation is usually early (before the fifth posttransplant week); symptoms include fever, pain, swelling at the graft site, increased creatinine level,

decreased urine output, and cutaneous urinary drainage. Early surgical exploration with ureteral re-implantation is usually indicated, although small leaks may be managed by percutaneous nephrostomy and stent placement with good results.

The reported incidence of lymphoceles (fluid collections of lymph that generally result from cut lymphatic vessels in the recipient) is 0.6–18 percent. Lymphoceles usually do not occur until at least two weeks posttransplant. Symptoms are generally related to the mass effect and compression of nearby structures (e.g., ureter, iliac vein, allograft renal artery), and patients develop hypertension, unilateral leg swelling on the side of the transplant, and elevated serum creatinine. The standard surgical treatment is creation of a peritoneal window to allow for drainage of the lymphatic fluid into the peritoneal cavity where it can be absorbed. Either a laparoscopic or an open approach may be used. Another option is percutaneous insertion of a drainage catheter, with or without sclerotherapy.

Late Posttransplant Care

The goal of late posttransplant care of the kidney transplant recipient is to optimize immunosuppression, carefully monitor graft function, and screen and monitor for complications that are directly or indirectly related to immunosuppressive medications. Optimizing immunosuppression entails fitting it to the individual recipient's needs. Recipients at low risk for rejection should have their immunosuppression lowered to minimize side effects and complications. Careful attention should be paid to compliance; it is often easy for recipients to become less attentive to their medications as they progress through the post-transplant period. Monitoring kidney function may help detect noncompliance, but is also important to detect late rejection episodes, recurrence of disease, or late technical problems (such as renal artery stenosis or ureteric stricture). Other potential problems in these recipients include hypercholesterolemia, hypertriglyceridemia, and increased blood pressure, which may or may not be related to the immunosuppressive drugs. Screening for malignancy (especially skin, colorectal, breast, cervical, and prostate) is important, although the incidence of many of these malignancies is equivalent to those seen in the general population.

PANCREAS TRANSPLANTATION

Diabetes mellitus is a very common medical condition with immense medical, social, and financial costs. In North America, it is the leading cause of kidney failure, blindness, nontraumatic amputations, and impotence. A successful pancreas transplant can establish normoglycemia and insulin independence in diabetic recipients, with glucose control similar to that seen with a functioning native pancreas. A pancreas transplant also has the potential to halt progression of some secondary complications of diabetes. No current method of exogenous insulin administration can produce a euglycemic, insulin-independent state akin to that achievable with a technically successful pancreas graft.

Currently, the main drawback of a pancreas transplant is the need for immunosuppression. Pancreas transplants are now preferentially performed in diabetic patients with kidney failure who also are candidates for a kidney transplant, as they already require immunosuppression to prevent kidney rejection. However, a pancreas transplant alone (PTA) is appropriate for nonuremic

diabetics if their day-to-day quality of life is so poor (e.g., labile serum glucose with ketoacidosis and/or hypoglycemic episodes, or progression of severe diabetic retinopathy, nephropathy, neuropathy, and/or enteropathy) that chronic immunosuppression is justified to achieve insulin independence.

Preoperative Evaluation

The preoperative evaluation for pancreas transplant recipients does not differ substantially from that for diabetic kidney transplant recipients. Examination of the cardiovascular system is most important because significant coronary artery disease may be present. Noninvasive testing may not identify coronary artery disease, so coronary angiography is routinely performed. Detailed neurologic, ophthalmologic, metabolic, and kidney function testing may be needed to assess the degree of progression of secondary complications. A thorough evaluation of the peripheral vascular system is essential, given the high incidence of peripheral vascular disease in diabetics.

Once a patient is determined to be a good candidate for a pancreas transplant, with no obvious contraindications, it is important to decide which type of pancreas transplant is best for that individual. First, the degree of kidney dysfunction and the need for a kidney transplant must be determined. Patients with stable kidney function (creatinine less than 2.0 mg/dL and minimal protein in the urine) are candidates for a PTA. However, patients with moderate kidney insufficiency will likely require a kidney transplant as well; further deterioration of kidney function often occurs once calcineurin inhibitors are started for immunosuppression.

For patients requiring both a kidney and a pancreas transplant, various options are available. The two transplants can be performed either simultaneously or sequentially. A living donor or a deceased donor can be used, or both. Which option is best for the individual patient depends on the degree of kidney dysfunction, the availability of donors, and personal preference. The following options are currently possible:

1. Deceased-donor, simultaneous pancreas-kidney transplant (SPK): The most common option worldwide, deceased-donor SPK transplants have well-documented long-term survival results for both the kidney and the pancreas grafts.
2. Living-donor kidney transplant, followed weeks to months later by a deceased-donor pancreas transplant (pancreas after kidney [PAK] transplant): If a living donor is available for the kidney transplant, then this is a good option for uremic diabetic patients. It offers the possibility of performing the kidney transplant as soon as the living-donor evaluation is complete, rendering the recipient dialysis-free within a short period.
3. Simultaneous deceased-donor pancreas and living-donor kidney (SPLK) transplant: Candidates with a suitable living donor for the kidney transplant who have not yet progressed to dialysis can be placed on the deceased-donor pancreas transplant waiting list. When a deceased-donor pancreas becomes available, the living donor for the kidney is called in at the same time, and both procedures are performed simultaneously.
4. Living-donor, simultaneous pancreas-kidney transplant: If a single individual is suitable to donate both a kidney and a hemipancreas, then this potential option exists.

Surgical Procedure

The initial preparation of the donor pancreas is a crucial component of a successful transplant. Direct physical examination of the pancreas often is the best or only way to confirm its suitability. If it is sclerotic, calcific, or markedly discolored, it should not be used. Before implantation, a surgical procedure is undertaken to remove the spleen and any excess duodenum and to ligate blood vessels at the root of the mesentery. The inflow vessels to the graft are the splenic and superior mesenteric arteries; outflow is via the portal vein. Arterial reconstruction is performed before implanting the graft in the recipient. The donor superior mesenteric and splenic arteries are connected, most commonly using a reversed segment of donor iliac artery as a Y-graft. The pancreas graft is then implanted via an anastomosis of the aforementioned arterial graft to the recipient common iliac artery or distal aorta, and, via a venous anastomosis of the donor portal vein to the recipient iliac vein (for systemic drainage), or to the superior mesenteric vein (for portal drainage).

Once the pancreas is revascularized, a drainage procedure must be performed to handle the pancreatic exocrine secretions. Options include anastomosing the donor duodenum to the recipient bladder or to the small bowel, with the small bowel either in continuity or connected to a Roux-en-Y limb. Both enteric drainage and bladder drainage now have a relatively low surgical risk. The main advantage of bladder drainage is the ability to directly measure enzyme activity in the pancreatic graft exocrine secretions by measuring the amount of amylase in the urine. The leak rate is the same whether the pancreas is drained to the bladder or to the bowel, but the consequences of a bladder leak are much less severe than those associated with a bowel leak. The disadvantages of bladder drainage include complications such as dehydration and acidosis (from loss of alkalotic pancreatic secretions in the urine), and local problems with the bladder such as infection, hematuria, stones, and urethritis.

Postoperative Care

In general, pancreas recipients do not require intensive care monitoring in the postoperative period. Laboratory values—serum glucose, hemoglobin, electrolytes, and amylase—are monitored daily. The serum glucose level is monitored even more frequently if normoglycemia is not immediately achieved. Nasogastric suction and IV fluids are continued for the first several days until bowel function returns. In the early postoperative period, regular insulin is infused to maintain plasma glucose levels less than 150 mg/dL, because chronic hyperglycemia may be detrimental to beta cells.

Complications

One crucial aspect of posttransplant care is monitoring for rejection and complications (both surgical and medical). Rejection episodes may be identified by an increase in serum creatinine (in SPK recipients), a decrease in urinary amylase (in recipients with bladder drainage), an increase in serum amylase, or by an increase in serum glucose levels. Unfortunately, complications are common after pancreas transplants. The pancreas graft is susceptible to a unique set of complications because of its exocrine secretions and low blood flow. Potential complications include:

Thrombosis

The incidence of thrombosis is approximately 6 percent for pancreas transplants reported to the UNOS registry. Low-dose heparin, dextran, or antiplatelet agents are administered routinely in the early postoperative period at many centers, although these agents slightly increase the risk of postoperative bleeding. Treatment consists of graft removal.

Hemorrhage

Postoperative bleeding may be minimized by meticulous intraoperative control of bleeding sites. Hemorrhage may be exacerbated by anticoagulants and antiplatelet drugs, but their benefits seem to outweigh the risks. Bleeding is a much less significant cause (<1 percent) of graft loss than is thrombosis, according to United Network for Organs Sharing (UNOS) registry data. Significant bleeding is treated by immediate re-exploration.

Pancreatitis

Most cases of graft pancreatitis occur early, tend to be self-limited, and are probably because of ischemic preservation injury. Clinical manifestations may include graft tenderness and fever, to hyperamylasemia. Treatment consists of intravenous (IV) fluid replacement and keeping the recipient fasting.

Urologic Complications

Urologic complications are almost exclusively limited to recipients with bladder drainage. Hematuria is not uncommon in the first several months posttransplant, but it is usually transient and self-limiting. Bladder calculi may develop because exposed sutures or staples along the duodenocystostomy serve as a nidus for stone formation. Recurrent urinary tract infections commonly occur concurrently. Urinary leaks, most commonly from the proximal duodenal cuff or from the duodenal anastomosis to the bladder, typically occur during the first several weeks posttransplant. Small leaks can be successfully managed by prolonged (at least 2 weeks) urinary catheter drainage; larger leaks require surgical intervention.

Infections

Infections remain a significant problem after pancreas transplants. Most common are superficial wound infections and intraabdominal infections, often related to graft complications such as leaks. Thanks to appropriate perioperative antimicrobial regimens (for prophylaxis against gram-positive bacteria, gram-negative bacteria, and yeast) the incidence of significant infections has decreased.

Results

The International Pancreas Transplant Registry (IPTR) maintains data on pancreas transplants. The results (particularly as measured by long-term insulin independence) have continually improved over time. Patient survival rates are not significantly different between the three main recipient categories and are greater than 90 percent at 3 years posttransplant. Most deaths are because of preexisting cardiovascular disease; the mortality risk of a pancreas transplant per se is extremely low (e.g., patient survival at 1 year for PTA recipients is >95 percent). Pancreas graft survival rates at 1 year remain higher in the SPK

(approximately 90 percent) than in the PAK (approximately 85 percent) and PTA (approximately 75 percent) categories, according to IPTR data.

Islet Cell Transplantation

The pancreas consists of two separate functional systems (endocrine and exocrine), but it is only the endocrine component that is of use in the transplant process. However, many of the complications seen with whole-organ pancreas transplants are because of the exocrine component. Therefore, the concept of transplanting simply the cells responsible for the production of insulin is very logical and attractive.

Islet cell transplantation involves extracting islets of Langerhans from a donor's pancreas and then injecting them into a diabetic recipient. These islet cells then engraft into the recipient and secrete insulin, providing excellent moment-to-moment control of blood glucose, as is seen with a whole-organ pancreas transplant. Compared with exogenous insulin injections, an islet cell transplant offers advantages similar to those of a whole-organ pancreas transplant. A successful islet transplant provides perfect glucose homeostasis, freeing the diabetic patient from the burden of frequent glucose monitoring and insulin injections. It potentially prevents secondary complications of diabetes and significantly improves quality of life.

Unlike a whole-organ pancreas transplant, an islet cell transplant is not a major surgical procedure. It can generally be performed as an outpatient procedure, with minimal recovery time for the recipient. It avoids a major surgical procedure, with its associated mortality and morbidity. Given this significantly lower surgical risk, islet cell transplants could theoretically have much wider application than whole-organ transplants.

One major disadvantage of an islet cell transplant (similar to that of a whole-organ transplant) is the need for long-term immunosuppression. This disadvantage has limited the use of islet cell transplants to patients with kidney failure who require immunosuppression because of a kidney transplant.

Islet cell transplants have been a possibility for many years, but the results have generally been poor. In 1995, a report of the International Islet Transplant Registry indicated that of 270 recipients, only 5 percent were insulin-independent at 1 year posttransplant. Recently, however, significantly improved results have been reported by using steroid-free immunosuppression and islet injections from multiple donors. These recent successes have stimulated a flurry of islet transplant activity at centers across the world. As results are likely to continue to improve, it is possible that islet cell transplants may come to replace whole-organ pancreas transplants.

LIVER TRANSPLANTATION

The field of liver transplantation has undergone remarkable advances in the last two decades. An essentially experimental procedure in the early 1980s, a liver transplant is now the treatment of choice for patients with acute and chronic liver failure. Patient survival at 1 year posttransplant has increased from 30 percent in the early 1980s to more than 85 percent at present. The major reasons for this dramatic increase include refined surgical and preservation techniques, better immunosuppressive protocols, more effective treatment of infections, and improved care during the critical perioperative period. However, a liver transplant remains a major undertaking, with the potential for complications affecting every major organ system.

Preoperative Evaluation

A liver transplant is indicated for liver failure, whether acute or chronic. Liver failure is signaled by a number of clinical symptoms (e.g., ascites, variceal bleeding, hepatic encephalopathy, and malnutrition), and by biochemical liver test results that suggest impaired hepatic synthetic function (e.g., hypoalbuminemia, hyperbilirubinemia, and coagulopathy). The cause of liver failure often influences its presentation. For example, patients with acute liver failure generally have hepatic encephalopathy and coagulopathy, whereas patients with chronic liver disease most commonly have ascites, GI bleeding, and malnutrition.

A host of diseases are potentially treatable by a liver transplant. Broadly, they can be categorized as acute or chronic, and then subdivided by the cause of the liver disease. Chronic liver diseases account for the majority of liver transplants today. The most common cause in North America is chronic hepatitis, usually because of hepatitis C and less commonly to hepatitis B. Chronic alcohol abuse accelerates the process, especially with hepatitis C. Cholestatic disorders also account for a significant percentage of transplant candidates with chronic liver disease. In adults, the most common causes are primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). A variety of metabolic diseases can result in progressive, chronic liver injury and cirrhosis, including hereditary hemochromatosis, alpha1-antitrypsin deficiency, and Wilson's disease. Hepatocellular carcinoma (HCC) may be a complication of cirrhosis from any cause, most commonly with hepatitis B, hepatitis C, hemochromatosis, and tyrosinemia.

Acute liver disease, more commonly termed fulminant hepatic failure (FHF), is defined as the development of hepatic encephalopathy and profound coagulopathy shortly after the onset of symptoms, such as jaundice, in patients without preexisting liver disease. The most common causes include acetaminophen overdose, acute hepatitis B infection, various drugs and hepatotoxins, and Wilson disease; often, however, no cause is identified.

Indications for Transplant

The presence of chronic liver disease alone with established cirrhosis is not an indication for a transplant. Some patients have well-compensated cirrhosis with a low expectant mortality. Patients with decompensated cirrhosis, however, have a poor prognosis without transplant. The signs and symptoms of decompensated cirrhosis include: hepatic encephalopathy (HE), ascites, spontaneous bacterial peritonitis (SBP), portal hypertensive bleeding, hepatorenal syndrome (HRS), and other signs and symptoms such as severe weakness and fatigue.

Generally, FHF patients are more acutely ill than chronic liver failure patients, and thus require more intensive care pretransplant. Indications for transplant include worsening coagulopathy and encephalopathy. Cerebral edema is substantially more common in FHF patients. As many as 80 percent of the patients who die secondary to FHF have evidence of cerebral edema. The pathogenesis is unclear, but it may be because of potential neurotoxins that are normally cleared by the liver.

Once the indications for a transplant and the absence of contraindications have been established, a careful search for underlying medical disorders must be made. Unique to patients with chronic liver disease, the pretransplant

evaluation must assess for any evidence of hepatopulmonary syndrome, pulmonary hypertension, and hepatorenal syndrome. Hepatopulmonary syndrome is characterized by impaired gas exchange, resulting from intrapulmonary arteriovenous shunts. A transplant may be contraindicated if intrapulmonary shunting is severe, as manifested by hypoxemia that is only partially improved with high inspired oxygen concentrations. Pulmonary hypertension is seen in a small proportion of patients with established cirrhosis. Diagnosing pulmonary hypertension pretransplant is critical, because major surgical procedures in the presence of nonreversible pulmonary hypertension are associated with a very high risk of mortality.

Surgical Procedure

The surgical procedure is divided into three phases: preanhepatic, anhepatic, and postanhepatic. The preanhepatic phase involves mobilizing the recipient's diseased liver in preparation for its removal. The basic steps include isolating the supra- and infrahepatic vena cava, portal vein, and hepatic artery, and then dividing the bile duct. Once the above structures have been isolated, vascular clamps are applied. The recipient's liver is removed, thus beginning the anhepatic phase. With the recipient liver removed, the donor liver is anastomosed to the appropriate structures to place it in an orthotopic position. The suprahepatic caval anastomosis is performed first, followed by the infrahepatic cava and the portal vein. The portal and caval clamps may be removed at this time. The new liver is then allowed to reperfuse. Either before or after this step, the hepatic artery may be anastomosed.

With the clamps removed and the new liver reperfused, the postanhepatic phase begins, often characterized by marked changes in the recipient's status. The most dramatic changes in hemodynamic parameters usually occur on reperfusion, namely hypotension and the potential for serious cardiac arrhythmias. Severe coagulopathy may also develop because of the release of natural anticoagulants from the ischemic liver or because of active fibrinolysis.

Variations on the Standard Procedure

Several variations of the standard operation have been described. With the "piggyback technique," the recipient's inferior vena cava is preserved, the infrahepatic donor cava is oversewn, and the suprahepatic cava is anastomosed to the confluence of the recipient hepatic veins. With this technique, the recipient's vena cava does not have to be completely cross-clamped during anastomosis, thus allowing blood from the lower body to return to the heart uninterrupted, without the need for venovenous bypass (VVB).

Another important variation of the standard operation is a partial transplant, either a living-donor transplant or a deceased-donor split-liver transplant. Both have developed in response to the donor shortage and are gaining in popularity. Usually, in living-donor liver transplants for pediatric recipients, the left lateral segment or left lobe is used; for adult recipients, the right lobe is used. Split-liver transplants from deceased donors involve dividing the donor liver into two segments, each of which is subsequently transplanted.

Living-Donor Liver Transplant

The greatest advantage of a living-donor liver transplant is that it avoids the often lengthy waiting period experienced with deceased-donor organ transplants. A partial hepatectomy in an otherwise healthy donor is a significant

undertaking, so all potential donors must be carefully evaluated. Detailed medical screening must ensure that the donor is medically healthy, radiologic evaluation must ensure that the anatomy of the donor's liver is suitable, and a psychosocial evaluation must ensure that the donor is mentally fit and not being coerced in any way. If the recipient is a child, the lateral segment of the donor's liver (about 25 percent of the total liver) is removed. If the recipient is an adult, a larger portion of the liver needs to be removed. Usually the right lobe of the liver, which comprises approximately 60 percent of the total liver, is used. The operative procedure involves isolating the blood vessels supplying the portion of the liver to be removed, transecting the hepatic parenchyma, and then removing the portion to be transplanted.

Split-Liver Transplants

Another method to increase the number of liver transplants is to split the liver from a deceased donor into two grafts, which are then transplanted into two recipients. Thus, a whole adult liver from such a donor can be divided into two functioning grafts. The vast majority of split-liver transplants have been between one adult and one pediatric recipient. Usually the liver is split into a smaller portion (the left lateral segment, which can be transplanted into a pediatric recipient) and a larger portion (the extended right lobe, which can be transplanted into a normal-sized adult recipient). With appropriate donor and recipient selection criteria, a small percentage of livers from deceased donors could be split and transplanted into two adult recipients also.

Postoperative Care

The immediate postoperative care for liver recipients involves: (1) stabilizing the major organ systems (e.g., cardiovascular, pulmonary, and renal); (2) evaluating graft function and achieving adequate immunosuppression; and (3) monitoring and treating complications directly and indirectly related to the transplant. This initial care should generally be performed in an intensive care unit (ICU) setting because recipients usually require mechanical ventilatory support for the first 12–24 h. The goal is to maintain adequate oxygen saturation, acid-base equilibrium, and stable hemodynamics.

A crucial aspect of postoperative care is to repeatedly evaluate graft function. In fact, doing so begins intraoperatively, soon after the liver is reperfused. Signs of hepatic function include good texture and good color of the graft, evidence of bile production, and restoration of hemodynamic stability. Postoperatively, hepatic function can be assessed using clinical signs and laboratory values. Patients who rapidly awaken from anesthesia and whose mental status progressively improves likely have a well-functioning graft. Laboratory indicators of good graft function include normalization of the coagulation profile, resolution of hypoglycemia and hyperbilirubinemia, and clearance of serum lactate. Adequate urine production and good output of bile through the biliary tube (if present) are also indicators of good graft function.

Another important aspect of postoperative care is to monitor for any surgical and medical complications. The incidence of complications tends to be high after liver transplants, especially in patients who were severely debilitated pretransplant. Surgical complications related directly to the operation include postoperative hemorrhage and anastomotic problems.

The incidence of vascular complications after liver transplants ranges from 8–12 percent. Thrombosis is the most common early event, with stenosis and pseudoaneurysm formation occurring later. Hepatic artery thrombosis (HAT) has a reported incidence of about 3 to 5 percent in adults and about 5–10 percent in children. The incidence tends to be higher in partial liver transplant recipients. After HAT, liver recipients may be asymptomatic or may develop severe liver failure secondary to extensive necrosis. Doppler ultrasound evaluation is the initial investigative method of choice, with more than 90 percent sensitivity and specificity. If HAT is suggested by radiologic imaging, urgent re-exploration is indicated, with thrombectomy and revision of the anastomosis. If hepatic necrosis is extensive, a retransplant is indicated.

Thrombosis of the portal vein is less common. Signs include liver dysfunction, tense ascites, and variceal bleeding. Doppler evaluation should be used to establish the diagnosis. If thrombosis is diagnosed early, operative thrombectomy and revision of the anastomosis may be successful. If thrombosis occurs late, liver function is usually preserved because of the presence of collaterals; a retransplant is then unnecessary and attention is directed toward relieving the left-sided portal hypertension.

Biliary complications remain a significant problem after liver transplants, affecting 10–35 percent of all recipients. A higher incidence generally is seen after partial liver transplants, in which bile leaks may occur from the anastomoses or from the cut surface of the liver. Biliary complications manifest either as leaks or as obstructions. Leaks tend to occur early postoperatively and often require surgical repair; obstructions usually occur later and can be managed with radiologic or endoscopic techniques.

One devastating complication posttransplant is primary nonfunction of the hepatic allograft, with an attendant mortality rate of greater than 80 percent without a retransplant. By definition, primary nonfunction results from poor or no hepatic function from the time of the transplant procedure. The incidence in most centers is about 3–5 percent. Factors associated with primary nonfunction include advanced donor age, increased fat content of the donor liver, prolonged donor hospitalization prior to organ procurement, prolonged cold ischemia time, and partial liver donation.

Infectious complications after liver transplant are common and can be devastating. Early infections (within the first month posttransplant) usually are related to surgical complications, initial graft function, or preexisting comorbid conditions. Risk factors include prolonged surgery, large-volume blood transfusions, primary nonfunction requiring a retransplant, and reoperations for bleeding or bile leaks. The most common early infections are intraabdominal and wound infections. Intraabdominal infections should always lead the surgeon to consider the possibility of a bile leak. If an intraabdominal infection is suspected, a CT scan should be performed, with aspiration and culture of any fluid collections that are identified. The biliary tree should be evaluated to exclude the presence of a bile leak. Patients with FHF are at high risk for fungal infections, usually secondary to *Candida* or *Aspergillus* species. Common sites include the abdomen, lungs, and central nervous system.

Disease recurrence is a significantly more important problem after liver transplants than with other solid organ transplants. Recurrence of hepatitis C is almost universal after transplants for this condition. Fortunately, only a minority of recipients experience aggressive recurrence leading to cirrhosis and liver failure. Ribavirin and α -interferon therapy should be considered in recipients with evidence of significant recurrence, as indicated by liver biopsy

findings. Recurrence of hepatitis B has been significantly decreased by the routine use of hepatitis B immune globulin and the antiviral agent lamivudine posttransplant, but recurrence may still be seen with resistant viral strains. Other diseases that may recur posttransplant are primary sclerosing cholangitis, primary hepatic malignancy, and autoimmune hepatitis.

Pediatric Liver Transplants

The clinical indications for a pediatric liver transplant are similar to those already mentioned for adults. Endpoints that require a transplant include evidence of portal hypertension as manifested by variceal bleeding and ascites, significant jaundice, intractable pruritus, encephalopathy, failing synthetic function (e.g., hypoalbuminemia or coagulopathy), poor quality of life, and failure to thrive (as manifested by poor weight gain or poor height increase).

Biliary atresia is the most common indication for a pediatric liver transplant. The incidence of biliary atresia is about 1 in 10,000 infant births. Once the diagnosis is established, a portoenterostomy, or Kasai procedure, is indicated to drain microscopic ducts within the porta hepatis. Successful bile flow can be achieved in 40–60 percent of patients whose Kasai procedure takes place early in their life. However, even with a Kasai procedure, 75 percent of children with biliary atresia eventually require a liver transplant because of progressive cholestasis followed by cirrhosis. Other cholestatic disorders that may eventually require a transplant include sclerosing cholangitis, familial cholestasis syndromes, and paucity of intrahepatic bile ducts (as seen with Alagille syndrome).

The surgical procedure for children does not differ significantly from that used in adults. The recipient's size is a more important variable in pediatric transplants, and it has an impact on both the donor and the recipient operations. For pediatric patients (especially infants and small children), the chance of finding a size-matched graft from a deceased donor may be very small, as the vast majority of such donors are adults. With adult grafts for pediatric patients, options include reduced-size liver transplants, in which a portion of the liver, such as the right lobe or extended right lobe, is resected and discarded; split-liver transplants in which a whole liver is divided into two functional grafts; and living-donor liver transplants in which a portion, usually the left lateral segment, is resected from a living donor. Graft implantation may be more demanding in pediatric patients, given the small caliber and delicate nature of the vessels. Use of venovenous bypass is usually not technically possible because of the small size of the vessels. For that reason, and given the increasing use of partial transplants, vena cava-sparing procedures are generally performed in children.

Surgical complications, especially those related to the vascular anastomoses, tend to be more frequent in pediatric recipients. HAT is three to four times more common in children. Factors associated with this increased risk include small recipient weight (less than 10 kg), use of just the left lateral segment (rather than the whole liver), and complex arterial reconstructions.

Patient survival rates have improved dramatically for pediatric liver recipients since the early 1990s. Most centers now report patient survival of close to 90 percent at 1 year posttransplant. Even for small recipients, patient survival rates at 1 year are 80–85 percent. Also, pediatric recipients enjoy close to normal growth and development posttransplant. Usually, growth accelerates immediately posttransplant.

Results

Patient and graft survival rates after liver transplants have improved significantly since the mid-1990s, with most centers now reporting graft survival rates of 85–90 percent at 1 year. The main factors affecting short-term (within the first year posttransplant) patient and graft survival are the medical condition of the patient at the time of transplant and the development of early postoperative surgical complications. Severely debilitated patients with numerous comorbid conditions such as kidney dysfunction, coagulopathy, and malnutrition, have a significantly higher risk of early posttransplant mortality. Such patients are more likely to develop surgical and medical complications (especially infections) and are unable to tolerate them. National U.S. data show that for 2001, patient survival at 1 year was 86.4 percent, although graft survival was 80.2 percent.

INTESTINAL TRANSPLANTATION

Intestinal transplants have been performed in the laboratory for years. The first human intestinal transplant was performed in 1966, but it remained essentially an experimental procedure, producing dismal results well into the 1980s. Newer immunosuppressive drugs have played a significant role in the success with the procedure since the mid-1990s. However, intestinal transplants remain the least frequently performed of all transplants, with the highest rejection rates and the lowest graft survival rates.

Preoperative Evaluation

Currently an intestinal transplant is indicated for irreversible intestinal failure that is not successfully managed by TPN (because of malnutrition and failure to thrive) or that has life-threatening complications (e.g., hepatic dysfunction, repeated episodes of sepsis secondary to central access, loss of central venous access sites).

The causes of intestinal failure are different in adult than in pediatric patients. Most commonly, although, the underlying disease results in extensive resection of the small bowel with resultant short bowel syndrome. The development of short bowel syndrome depends not only on the length of bowel resected, but also on the location of the resection, on the presence or absence of the ileocecal valve, and on the presence or absence of the colon. As a rough guideline, most patients can tolerate resection of 50 percent of their intestine with subsequent adaptation, avoiding the need for long-term parenteral nutritional support. Loss of greater than 75 percent of the intestine, however, usually necessitates some type of parenteral nutritional support. The most common causes of intestinal failure in children are necrotizing enterocolitis, gastroschisis, and volvulus. In adults, Crohn disease, massive resection of ischemic bowel because of mesenteric vascular thrombosis, and trauma are the most common causes.

The pretransplant evaluation does not differ greatly from that for other transplants. Absolute contraindications such as malignancy and active infection must be ruled out, and hepatic function should be evaluated carefully. If there is evidence of significant liver dysfunction and cirrhosis, a combined liver and intestinal transplant is indicated.

Surgical Procedure

The operative procedure varies, depending on whether or not a liver transplant is also performed. In the case of an isolated intestinal transplant, the graft may be from a living or deceased donor. With a living donor, about 200 cm of the distal small bowel is used; inflow to the graft is via the ileocolic artery, and outflow via the ileocolic vein. With a deceased donor, the graft is based on the superior mesenteric artery for inflow and on the superior mesenteric vein for outflow. For a combined liver and intestinal transplant, the graft is usually procured intact with an aortic conduit that contains both the celiac and superior mesenteric arteries. The common bile duct can be maintained intact in the hepatoduodenal ligament along with the first part of the duodenum and a small rim of the head of the pancreas. Doing so avoids a biliary reconstruction in the recipient.

Postoperative Care

The early posttransplant care for intestinal transplant patients is in many ways similar to that of other transplant recipients. Initial care should take place in an ICU so that fluid, electrolytes, and blood product replacement can be carefully monitored. Broad-spectrum antibiotics are routinely administered, given the high risk for infectious complications.

A number of different immunosuppressive protocols have been described. Many involve some form of induction therapy, followed by tacrolimus-based maintenance immunosuppression. Regardless of the protocol, intestinal transplants clearly have a high risk of rejection. Therefore, careful monitoring for rejection is imperative and involves endoscopy with biopsy of the graft mucosa. Acute rejection episodes are often associated with infections. Rejection results in damage to the intestinal mucosa, leading to impaired barrier function and bacterial translocation. Therefore, advanced rejection can be very difficult to treat as concurrent infection invariably is present.

HEART AND LUNG TRANSPLANTATION

Heart transplantation is a well-established therapy for end-stage heart failure, and is performed in age groups from neonates to senior citizens. Lung transplantation is a newer field than heart transplantation, and far fewer lung transplants (about 1000) are performed each year. Results have improved since the early 1990s, mainly because of improvements in immunosuppression and refinements in surgical techniques, in particular with modification of the airway anastomosis. A combined heart-lung transplant is usually reserved for patients who have pulmonary hypertension and obvious right-sided heart failure.

Preoperative Evaluation

A heart transplant is generally indicated in the presence of end-stage heart failure. The most common cause is ischemic or dilated cardiomyopathy, followed by intractable angina, valvular disease, congenital heart disease, life-threatening recurrent ventricular arrhythmias, and isolated intracardiac tumors. Isolated lung transplants are performed for a number of indications, including chronic obstructive pulmonary disease, idiopathic pulmonary fibrosis, cystic fibrosis, and pulmonary hypertension (without right-sided heart failure). Patients with chronic obstructive pulmonary disease or idiopathic pulmonary

fibrosis generally are treated with a single-lung transplant; those with cystic fibrosis or pulmonary hypertension (without right-sided heart failure) usually require a bilateral single-lung transplant. Patients with pulmonary hypertension with significant right-sided heart failure, or those with Eisenmenger syndrome, usually require a combined heart-lung transplant.

Surgical Procedure

A heart transplant is an orthotopic procedure. Therefore the first step of the procedure for heart or heart-lung recipients is removal of their corresponding thoracic organs. The recipient's aorta and vena cava are cannulated, an aortic cross-clamp is applied, and the diseased heart is excised along the atrioventricular groove. The recipient is maintained on cardiopulmonary bypass during this time. The new heart is then placed in an orthotopic position, with anastomoses performed in the following order: left atrium, right atrium, pulmonary artery, and aorta. Several variations to the original technique have been described, such as performing the aortic anastomosis before the pulmonary artery anastomosis to allow reperfusion of the heart and to minimize the ischemic time. Another variation is to perform selective anastomoses of the inferior and superior vena cava (rather than just of the right atrium); doing so is believed to allow for better geometry of the right atrium and to decrease the incidence of posttransplant atrial arrhythmias.

In heart-lung transplants, the new organs are implanted en bloc. Right and left pneumonectomies are carried out, with isolation and division of the trachea just above the carina. Anastomoses are then performed between the donor and recipient trachea, right atrium, and aorta.

Single-lung transplants are performed through a standard posterolateral thoracotomy. The superior and inferior pulmonary veins, pulmonary artery, and main stem bronchus are dissected. The pulmonary artery is then clamped to assess the recipient's hemodynamic status; cardiopulmonary bypass is used if necessary, although most recipients do not require bypass support. The bronchus and appropriate vascular structures are then clamped and the pneumonectomy completed. The bronchial anastomosis is performed first, followed by the pulmonary arterial and left atrial anastomoses. A telescoped bronchial anastomosis reduces the incidence of complications, most notably leaks. A pedicle of vascularized omentum can also be wrapped around the anastomosis for further reinforcement. Bilateral single-lung transplants are performed in a similar fashion, each side sequentially.

Postoperative Care

The immediate postoperative care does not differ significantly from any other major cardiac or pulmonary procedure. However, heart or lung recipients are at greater risk for infections than their nontransplant counterparts, and require appropriate precautions and prophylaxis regimens. As with other transplant recipients, maintenance immunosuppressive therapy is started immediately posttransplant.

After heart or heart-lung transplants, cardiac output is sustained by establishing a heart rate of 90–110 beats per minute, using either temporary epicardial atrial pacing or low-dose isoproterenol. For recipients who may suffer transient right-sided heart failure, adequate preload is important. Use of an oximetric Swan-Ganz catheter can be helpful to monitor pulmonary artery pressure and measure cardiac output. Urine output and arterial blood gases must be

carefully monitored. Hypotension and a low cardiac output usually respond to an infusion of volume and to minor adjustments in inotropic support.

Complications can be surgical or medical, and may occur early or late post-transplant. Many of the complications, especially those occurring late, are medical in nature and are similar to those seen after other types of transplants. Generally, they are related to the medications and to the immunosuppressed state. Examples include hypertension, hyperglycemia, osteoporosis, and malignancy. Certain complications, such as airway problems, are unique to lung and heart recipients. Rejection, both acute and chronic, can occur, but manifests in very different ways as compared with abdominal organ transplants.

Early attempts at lung transplantation were severely hampered by a high incidence of airway complications. This anastomosis is at high risk for problems because of the poor blood supply. However, increased experience and refinements in surgical technique have dramatically reduced airway complications. Nonetheless, about 10–15 percent of lung recipients develop some airway complication, often resulting in significant morbidity and occasional mortality.

INFECTION AND MALIGNANCY

Infections

Transplant recipients exhibit an increased risk for infectious complications posttransplant, which can lead to significant morbidity and mortality. Numerous risk factors include long-standing end-stage organ failure (which can lead to an immunosuppressed state even before any immunosuppressive drugs are begun), impaired tissue healing, and poor vascular flow because of coexisting illnesses such as diabetes. The transplant surgery itself, which may involve opening nonsterile viscera such as the bladder or bowel, and the posttransplant need for powerful immunosuppressive agents further increase the risk for infections.

The spectrum of possible infections in transplant recipients is wide. Infections are classified by the type of pathogen involved into bacterial, viral, or fungal infections. However, more than one type of pathogen may be involved in several different types of infections (e.g., pneumonia may be caused by a viral, bacterial, or fungal pathogen). Moreover, a number of different pathogens may be involved in a single infection (e.g., an intraabdominal abscess can be because of several different bacterial and fungal pathogens).

Infections can also be classified by the primary method of treatment into surgical or medical infections. Surgical infections require some surgical intervention as an integral part of their treatment. They generally occur soon after the transplant operation and are usually related directly to it, or to some complication occurring as a result of it. Surgical infections are less likely to be related to the recipient's overall immunosuppressed state, although obviously this plays some role. Typical examples of surgical infections include generalized peritonitis, intraabdominal abscesses, and wound infections. In contrast, medical infections do not generally require an invasive intervention for treatment, but rather are primarily treated with antiviral, antibacterial, or antifungal agents. They tend to occur later posttransplant and are usually related to the recipient's overall immunosuppressive state. Typical examples of medical infections include those secondary to cytomegalovirus (CMV), polyomavirus-induced nephropathy, pneumonias, and Epstein-Barr virus (EBV)-related problems.

The most common surgical infections, especially in liver and pancreas transplant recipients, are intraabdominal infections. They are also the most likely to be life-threatening. They may range from diffuse peritonitis to localized abscesses. Their presentation, management, and clinical course will in part depend on their underlying cause, their location, and on the recipient's overall medical condition. The clinical presentation of intraabdominal infections will depend on their severity and location. Generalized peritonitis is usually associated with some catastrophic event such as biliary disruption or graft duodenal leak with spillage of enteric contents or urine into the peritoneal cavity. It may also occur as a result of perforation of some other viscus, unrelated to the transplant (e.g., perforated gastric ulcer or perforated cecum). Fortunately, most intraabdominal infections do not fall into the generalized peritonitis category. Instead, most of them consist of localized fluid collections in and around the graft. Patients usually develop symptoms such as fever, nausea, vomiting, and abdominal distention, with localized pain and guarding over the region of the fluid collection. A computed tomography (CT) scan with contrast is the best diagnostic tool in this clinical situation. Treatment of localized intraabdominal infections involves adequate drainage and administration of appropriate antibacterial or antifungal agents.

Medical infections posttransplant tend to be more varied compared to surgical infections, and can involve bacterial, viral, or fungal pathogens. Bacterial infections primarily occur in the first few weeks posttransplant. The major sites are the incisional wound, respiratory tract, urinary tract, and bloodstream. Administration of perioperative systemic antibiotics decreases the risk and incidence of some infections. Viral infections in transplant recipients often involve the herpesvirus group; CMV is clinically the most important. Fungal infections are most commonly caused by *Candida* species; *Aspergillus*, *Cryptococcus*, *Blastomyces*, *Mucor*, *Rhizopus*, and other species account for a much smaller percentage of fungal infections, but are more serious.

Malignancy

Transplant recipients are at increased risk for developing certain types of de novo malignancies, including nonmelanomatous skin cancers (3–7-fold increased risk), lymphoproliferative disease (2–3-fold increased risk), gynecologic and urologic cancers, and Kaposi sarcoma. The risk ranges from 1 percent among renal allograft recipients to approximately 5–6 percent among recipients of small bowel and multivisceral transplants.

The most common malignancies in transplant recipients are skin cancers. They tend to be located on sun-exposed areas and are usually squamous or basal cell carcinomas. Often they are multiple and have an increased predilection to metastasize. Diagnosis and treatment are the same as for the general population. Patients are encouraged to use sunscreen liberally and avoid significant sun exposure.

Lymphomas constitute the largest group of noncutaneous neoplasms in transplant recipients. The vast majority (> 95 percent) of these lymphomas consist of a spectrum of B-cell proliferation disorders associated with EBV, known collectively as posttransplant lymphoproliferative disorder (PTLD). Risk factors include a high degree of immunosuppression, anti-T-cell antibody therapy, tacrolimus, and primary EBV infection posttransplant. A wide variety of clinical manifestations may be seen. Symptoms may be systemic

and include fever, fatigue, weight loss, or progressive encephalopathy. Lymphadenopathy may be localized, diffuse, or absent.

A variety of other malignancies occur with increased incidence in transplant recipients. Conventional treatment is appropriate for most malignancies post-transplant. Immunosuppression should be reduced, particularly if bone marrow suppressive chemotherapeutic agents are administered. However, allograft function should be maintained for those organs that are critical to survival, such as the heart, liver, and lung. For other types of transplants with alternative therapies to fall back on if necessary (e.g., hemodialysis for kidney transplants, exogenous insulin for pancreas or islet cell transplants, and TPN for intestinal transplants), the risks of ongoing immunosuppression must be weighed against the benefits of organ function compared to the alternative therapies.

Surgical complications prolong the course of illness, lengthen hospital stay, and increase morbidity and mortality rates. Although complications occur that are caused by a surgical disease, complications also occur because of lapses in the processes of care of disease. The issue of medical errors has received much attention since the Institute of Medicine (IOM) issues its 2000 report stating that between 45,000 and 98,000 medical error-related deaths occur annually. It is the processes of care that are increasingly recognized as the etiology for complications and errors, not the diseases or treatments themselves.

ISSUES PERTINENT TO ERRORS AND COMPLICATIONS

Patient Safety Initiatives

Most surgical quality improvement (QI) programs have been oriented toward patient diseases and their complications (e.g., postoperative abscesses following perforated viscus repair), provider decisions (e.g., a delay in diagnosis or errors in decision making), and to a lesser extent, the system processes related to patient care. Recently, the focus of QI programs has begun to shift toward patient safety.

The increasing complexity of health care carries an inherent risk that system failures may occur. An improvement in patient safety, accomplished through stronger vigilance and refinement of the processes of care, is the primary thrust for current QI initiatives.

Processes of Care

The simplicity of the phrase “processes of care” belies the complex set of systems involved. Even the simplest of processes, when broken into component parts and analyzed, becomes complex. The root causes of process failures are notoriously difficult to identify and resolve.

Recently, groups such as The Joint Commission for Accreditation of Healthcare Organizations (JCAHO), The Leapfrog Group, and The Institute for Healthcare Improvement (IHI) have begun offering new QI approaches to health care, and a new culture of patient safety awareness is occurring.

Quality Improvement Processes

QI systems focus on the recognition of problems, errors, system inefficiency, or patient safety concerns. Most QI programs, however, are reactive in the analysis and management of problems that are identified. A shift toward a forward-thinking system of QI needs to occur in order for ongoing improvements in care to become an inherent goal for practitioners, and for the mentality in health care to move from one of satisfaction to one of continued improvement.

A strong QI program has the following characteristics: (1) any employee/caregiver can identify problems and issues, (2) reporting a problem does not threaten job or position security, (3) problems are recorded and feedback

is provided to the reporter and those affected by the reporting, (4) all problems are addressed after they are clarified, evaluated for significance, and prioritized, (5) databases are used to help analyze the identified problem, (6) organized discussion forums are held to evaluate the problem and to propose solutions, (7) the reporting system is integrated with other QI programs and process improvement initiatives, (8) there is an oversight committee for institutional QI programs, (9) institutional resources are available when solutions are beyond simple restructuring or behavior change, (10) the success or failure of solutions is monitored, and the entire QI process is documented and reviewed, (11) there is ongoing communication with the employees who are affected by the changes instituted by the QI program, and (12) an incentive or reward system exists to facilitate change in human behavior.”

Communication Strategies and the Importance of Care Plans

Communication failures are the most frequent cause of errors and complications in health care. An integrated communication system is essential for high quality care to flourish.

Traditionally, individual surgeons have been able to establish their practice preferences, and institutions have attempted to cater to all surgeons on an individual basis. This often leads to a chaotic organizational environment in terms of how to best manage surgical patients as an overall group. Surgeons are taught to retain their individual preferences (i.e., adhering to their best-known and most successful technique), although all groups of practitioners remain untrained regarding how to work within an integrated structure. Therefore, it is not surprising that the net result is poor communication and subsequent system failures.

One of the basic tenets for minimizing communications errors is to “speak the same language” through the use of protocols or clinical care plans that are based on sound evidence and are used by everyone. Protocols of care reduce misunderstanding, incorrect assumptions, and communications errors. Although common problems, such as a fractured hip or cholelithiasis, lend themselves to the development of clinical protocols, other surgical problems do not. When clinical variability exists, or outcome data are equivocal, randomized trials of treatment options can and should be established. Although the physician’s autonomy will suffer in these regimented approaches to care, patient safety will improve because of a lower potential for complications and medical errors.

Documentation of Care and Evolving Issues

Careful and complete documentation is the essence of high-quality patient care. Although at times documentation remains an arduous task, the medical record must be rigorously maintained; procedures should never be presumed to have been performed if they have not been documented properly. The medical record is the only legal document that maintains a long-term transcription of patient care activity, and as such its maintenance should be considered a priority. The confidentiality of each patient’s medical information is also a priority. Optimal medical record keeping includes all patient interactions. For outpatient care, the office chart needs to document all patient visits and correspondence, examination results, laboratory and radiology investigations, and assessment of the medical problems with a proposed plan of care, and records of procedures, pathology results, and any complications

encountered. Inpatient medical records need to be equally thorough, and need to document the interactions between all care providers with patients and their families.

Medical records are not the forum for open discussion, inflammatory remarks on care, or denigrating comments on the patient, their family, friends and/or other health care providers. The records should always be clear, objective, and up-to-date. All entries must be dated and timed, and should not be back-dated at a later review of the record. Discussions related to ethically sensitive issues must also be stated clearly and advanced care directives and do-not-resuscitate (DNR) status should be clearly documented.

Complications Related to Surgery and Anesthesia Relationships

The relationships between surgeons and anesthesiologists are critical for the quality of care received by surgical patients. Although the fund of knowledge and skill sets of anesthesiologists have dramatically expanded in recent decades, the interrelationship and communication between surgical and anesthesia teams is often deficient, because of radically different patterns of care continuity and on-call availability.

Peri-operative care should involve a continuous, inclusive knowledge of a patient's surgical and comorbid conditions such that all medical providers are cognizant of all issues throughout the management of a patient's surgical disease state. An open line of communication between surgeons and anesthesiologists needs to occur during the preoperative, intraoperative, and postoperative management of patients. When issues, errors, or complications are developing for any particular patient, communication and decision making should be simplified so a minimum of redundant discussion or relearning of data occurs.

Intraoperatively, an open and continuous dialogue between the surgical and anesthesia teams is essential for optimal care. The two teams should be mutually and concurrently aware of the physiologic status of the patient, the effects of surgical or anesthetic interventions, and the postoperative care plans including analgesia. This is well recognized for vascular and cardiothoracic operations, but is equally important for unstable trauma cases, septic shock cases, patients with metabolic or intravascular volume abnormalities, or for patients at either extreme of age.

Ethics of Reporting Your Complications (and Those of Others)

Because of the very personal nature of medical care, patients enter into a trust relationship (and an informal contract or covenant) with their surgeon (and the associated institution). Both parties should expect that open communication will occur so that this trust relationship is not violated at any time during the relationship. When problems or complications occur, open communication must be maintained as the only morally, ethically, and legally correct action.

The reporting of complications to one's peers is an important component of quality assurance and improvement. However, it is equally important that the patient and their family members are included in the dialogue related to complications. Similarly, to the extent that the reporting of complications of one's peers is important for the care of the patient, the patient is entitled to these details of their care. Minor errors and missteps are common but may have

no impact or consequence on a patient's care; these are discussed, in detail, if the patient or their family inquires about them. Major complications should be discussed with the patient if they are clearly identified as complications or errors, and if they affect the patient's care or prognosis.

All procedures carry the potential for unforeseen difficulties or complications. Problems may arise as a result of a patient's primary surgical disease and their comorbid conditions, or may arise because of technical problems, medication delivery errors, system process errors, communication errors, or other unexpected developments.

During the process of obtaining informed consent for any procedure, it is always prudent to describe for the patient and their significant others potential complications that may occur. Although it is not necessary to detail all of the possible problems or difficulties that may arise, it is important to state that no procedure should be assumed to be risk-free.

In general, patients are fairly accepting of medical errors when they have been informed ahead of time that the possibility for errors and complications exists, and when open and direct communication is provided after a procedural complication or error.

COMPLICATIONS IN MINOR PROCEDURES

Central Venous Access Catheters

Complications of central venous access catheters are common. Steps to decrease complications include the following:

1. Ensure that central venous access is indicated.
2. Experienced (credentialed) personnel should insert the catheter, or should supervise the insertion.
3. Use proper positioning and sterile technique. Controversy exists regarding whether or not placing the patient in Trendelenburg position facilitates access.
4. Central venous catheters should be exchanged only for specific indications (not as a matter of routine) and should be removed as soon as possible.

Common complications of central venous access include:

Pneumothorax. Occurrence rates from both subclavian and internal jugular vein approaches are 1–6 percent. Pneumothorax rates appear to be higher among the inexperienced but occur with experienced operators as well. If the patient is stable, and the pneumothorax is small (<15 percent) close expectant observation may be adequate. If the patient is symptomatic, a thoracostomy tube should be placed. Occasionally, pneumothorax will occur as late as 48–72 h after central venous access attempts. This usually creates sufficient compromise that a tube thoracostomy is required. Prevention requires proper positioning of the patient and correct technique. A postprocedure chest radiograph is mandatory to confirm the presence or absence of a pneumothorax, regardless of whether a pneumothorax is suspected.

Arrhythmias. Arrhythmias result from myocardial irritability secondary to guidewire placement, and usually resolve when the catheter or guidewire is withdrawn from the right heart. Prevention requires electrocardiogram (EKG) monitoring whenever possible during catheter insertion.

Arterial puncture. The inadvertent puncture or laceration of an adjacent artery with bleeding can occur, but the majority will resolve with direct pressure on or near the arterial injury site. Rarely will angiography, stent placement, or surgery be required to repair the puncture site, but close observation and a chest radiograph are indicated. Prevention requires careful attention to insertion technique.

Lost guidewire. A guidewire or catheter that migrates into the vascular space completely can be readily retrieved with interventional angiography techniques. A prompt chest x-ray and close monitoring of the patient until retrieval is indicated.

Air embolus. Although estimated to occur in only 0.2–1 percent of patients, an air embolism can be dramatic and fatal. Treatment may prove futile if the air bolus is larger than 50 mL. Auscultation over the precordium may reveal a “crunching” noise, but a portable chest radiograph is required for diagnosis. If an embolus is suspected, the patient should immediately be placed into a left lateral decubitus Trendelenburg position, so the entrapped air can be stabilized within the right ventricle. Aspiration via a central venous line accessing the heart may decrease the volume of gas in the right side of the heart, and minimize the amount traversing into the pulmonary circulation. Subsequent recovery of intracardiac and intrapulmonary air may require open surgical or angiographic techniques. Prevention requires careful attention to technique.

Pulmonary artery rupture. Flow-directed, pulmonary artery (“Swan-Ganz”) catheters can cause pulmonary artery rupture because of excessive advancement of the catheter into the pulmonary circulation. There usually is a sentinel bleed noted when a pulmonary artery catheter balloon is inflated, and then the patient begins to have uncontrolled hemothysis. Reinflation of the catheter balloon is the initial step in management, followed by immediate airway intubation with mechanical ventilation, an urgent portable chest radiograph, and notification of the operating room that an emergent thoracotomy may be required. If there is no further bleeding after the balloon is reinflated, the radiograph shows no significant consolidation of lung fields from ongoing bleeding and the patient is easily ventilated, then a conservative nonoperative approach may be considered. This approach might include observation alone if the patient has no signs of bleeding or hemodynamic compromise; however, more typically a pulmonary angiogram with angioembolization or vascular stenting is required. Hemodynamically unstable patients rarely survive because of the time needed to perform the thoracotomy and identify the branch of the pulmonary artery that has ruptured.

Central venous line infection. The Centers for Disease Control and Prevention (CDC) reports mortality rates of 12–25 percent when a central venous line infection becomes systemic, and this carries a cost of approximately \$25,000 per episode. The CDC does not recommend routine central line changes, but when the clinical suspicion is high, the site of venous access must be changed. Additionally, nearly 15 percent of hospitalized patients will acquire central venous line sepsis. In many instances, once an infection is recognized as central line sepsis, removing the line is adequate. *Staphylococcus aureus* infections, however, present a unique problem because of the potential for metastatic seeding of bacterial emboli. The required treatment is 4–6 weeks of tailored antibiotic therapy.

Arterial Lines

Arterial lines are placed to facilitate arterial blood gas sampling and hemodynamic monitoring. They are often left in place to make routine blood sampling easier, but this practice leads to higher complication rates.

Arterial access requires a sterile Seldinger technique, and a variety of arteries are used, such as the radial, femoral, brachial, axillary, dorsal pedis, or superficial temporal arteries. Although complications occur less than 1 percent of the time, they can be catastrophic. Complications include thrombosis, bleeding, hematoma, arterial spasm (nonthrombotic pulselessness), and infection. Thrombosis or embolization of an extremity arterial catheter can result in the loss of a digit, hand, or foot, and the risk is nearly the same for both femoral and radial cannulation. Thrombosis with distal tissue ischemia is treated with anticoagulation, but occasionally surgical intervention is required to reestablish adequate inflow. Pseudo-aneurysms and arteriovenous fistulae can also occur.

Endoscopy and Bronchoscopy

The principal risk of gastrointestinal endoscopy is perforation. Perforations occur in 1:10,000 patients with endoscopy alone, but have a higher incidence rate when biopsies are performed (up to 10 percent). This increased risk is because of complications of intubating a gastrointestinal diverticulum (either esophageal or colonic), or from the presence of weakened or inflamed tissue in the intestinal wall (e.g., diverticulitis, glucocorticoid use, or inflammatory bowel disease).

Patients will usually complain of diffuse abdominal pain shortly after the procedure, and then will quickly progress with worsening abdominal discomfort on examination. In obtunded or older adult patients, a change in clinical status may take several h, and occasionally as long as 24–48 h, to become manifest. Radiologic studies to look for free intraperitoneal air, retroperitoneal air, or a pneumothorax are diagnostic. A delay in diagnosis results in ongoing contamination and sepsis.

Open or laparoscopic exploration locates the perforation, and allows repair and local decontamination of the surrounding tissues. The patient who may be a candidate for nonoperative management is one in which perforation arises during an elective, bowel-prepped, endoscopy, and yet the patient does not have significant pain or clinical signs of infection. The patient may be closely observed in a monitored setting, on strict dietary restriction and broad-spectrum antibiotics.

The complications of bronchoscopy include bronchial plugging, hypoxemia, pneumothorax, lobar collapse, and bleeding. When diagnosed in a timely fashion, they are rarely life-threatening. Bleeding usually resolves and rarely requires surgery, but may require repeat endoscopy for thermocoagulation or fibrin glue application. The presence of a pneumothorax necessitates placement of a thoracostomy tube when significant deoxygenation occurs or the pulmonary mechanics are compromised. Lobar collapse or mucous plugging responds to aggressive pulmonary toilet, but occasionally requires repeat bronchoscopy.

Tracheostomy

Tracheostomy facilitates weaning from a ventilator, decreases length of intensive care unit (ICU) or hospital stay, and improves pulmonary toilet.

Tracheostomies are now performed open, percutaneously, with or without bronchoscopy, and with or without Doppler guidance, and yet complications still arise.

Recent studies do not support obtaining a routine posttracheostomy chest radiograph after either percutaneous or open tracheostomy. However, significant lobar collapse can occur from copious tracheal secretions or mechanical obstruction.

The most dramatic complication of tracheostomy is tracheoinnominate artery fistula (TIAF). These occur rarely (approximately 0.3 percent), but carry a 50–80 percent mortality rate. TIAFs can occur as early as 2 days or as late as 2 months after tracheostomy. The prototypical patient is a thin woman with a long, gracile neck. The patient may have a sentinel bleed, which occurs in 50 percent of TIAF cases, followed by a most spectacular bleed. Should a TIAF be suspected, the patient should be transported immediately to the operating room for fiberoptic evaluation. If needed, remove the tracheostomy, and place a finger through the tracheostomy site to apply direct pressure anteriorly for compression of the innominate artery.

Percutaneous Endogastrostomy

A misplaced percutaneous endogastrostomy (PEG) may create intraabdominal sepsis with peritonitis and/or an abdominal wall abscess with necrotizing fasciitis. As in other minor procedures, the initial placement technique must be fastidious to avoid complications. Transillumination of the abdomen may decrease the risk for error. Inadvertent colotomies, intraperitoneal leakage of tube feeds with peritonitis, and abdominal wall abscesses require surgery to correct the complications and to replace the PEG with an alternate feeding tube, usually a jejunostomy.

A dislodged or prematurely removed PEG tube must be replaced within 8 h of dislodgment, because the gastrostomy site closes rapidly. A contrast radiograph should be performed to confirm the tube's intragastric position prior to feeding.

Tube Thoracostomy

Tube thoracostomy (chest tube insertion) is performed for pneumothorax, hemothorax, pleural effusions or empyema. A chest tube can be easily placed with a combination of local analgesia and light conscious sedation. Common complications include inadequate analgesia or sedation, incomplete penetration of the pleura with formation of a subcutaneous track for the tube, lacerations to the lung or diaphragm, intraperitoneal placement of the tube through the diaphragm, and bleeding related to these various lacerations or injury to pleural adhesions. Additional problems include slippage of the tube out of position, or mechanical problems related to the drainage system. All of these complications can be avoided with proper initial insertion techniques, plus a daily review of the drainage system and follow-up radiographs. Tube removal can create a residual pneumothorax if the patient does not maintain positive intrapleural pressure by Valsalva maneuver during tube removal and dressing application.

Diagnostic Peritoneal Lavage

Diagnostic peritoneal lavage (DPL) is performed in the emergent trauma setting for the hemodynamically unstable patient with neurologic impairment and

an uncertain etiology for blood loss, when an abdominal trauma ultrasound is not available or is unreliable. Nasogastric and bladder catheter decompression is mandatory prior to DPL to avoid injury during the procedure. The small or large bowel, or the major vessels of the retroperitoneum also can be punctured inadvertently, and these injuries require surgical exploration and repair.

Complications of Angiography

Intramural dissection of a cannulated artery can lead to complications such as ischemic stroke from a carotid artery dissection or occlusion, mesenteric ischemia from dissection of the superior mesenteric artery, or a more innocuous finding of “blue toe syndrome” from a dissected artery in a peripheral limb. Invasive or noninvasive imaging studies confirm the suspected problem. The severity of the ischemia and the extent of the dissection determine if anticoagulation therapy or urgent surgical exploration is indicated.

Bleeding from the vascular access site usually is obvious, but may not be visible when the blood loss is tracking into the retroperitoneal tissue planes after femoral artery cannulation. These patients can present with hemorrhagic shock; an abdominopelvic computed tomography (CT) scan delineates the extent of bleeding into the retroperitoneum. The initial management is direct compression at the access site and clinical observation with resuscitation as indicated. Urgent surgical exploration may be required to control the bleeding site.

Renal complications of angiography occur in 1–2 percent of patients. Contrast nephropathy is a temporary and preventable complication of radiologic studies such as CT, angiography, and/or venography. Some studies suggest a benefit of n-acetylcysteine for this condition. For the patient with impaired renal function or dehydration prior to contrast studies, twice-daily dosing 24 h before and on the day of the radiographic study is suggested. Nonionic contrast also may be of benefit in higher-risk patients. Intravenous hydration before and after the procedure is the most efficient method for preventing contrast nephropathy.

Complications of Biopsies

Lymph node biopsies have direct and indirect complications which include bleeding, infection, lymph leakage, and seromas. Measures to prevent direct complications include proper surgical hemostasis, proper skin preparation, and a single preoperative dose of antibiotic to cover skin flora 30–60 min before incision. Bleeding at a biopsy site usually can be controlled with direct pressure. Infection at a biopsy site will appear 5–10 days postoperatively, and may require opening of the wound to drain the infection. Seromas or lymphatic leaks resolve with aspiration of seromas and the application of pressure dressings, but may require repeated treatments.

ORGAN SYSTEM COMPLICATIONS

Neurologic System

Neurologic complications that occur after surgery include motor or sensory deficits and mental status changes. Peripheral motor and sensory deficits are

often because of neurapraxia secondary to improper positioning and/or padding during operations. Treatment is largely clinical observation, and the majority will resolve spontaneously within 1–3 months.

Direct injury to nerves during a surgical intervention is a well-known complication of several specific operations, including superficial parotidectomy (facial nerve), carotid endarterectomy (hypoglossal nerve), prostatectomy (nervi erigentes) and inguinal herniorrhaphy (ilioinguinal nerve). The nerve injury may simply be a stretch injury, or an unintentionally severed nerve. In addition to loss of function, severed nerves can result in a painful neuroma, which may require subsequent surgery.

Mental status changes in the postoperative patient can have numerous causes (Table 11-1). Mental status changes must be carefully documented and continually assessed. CT scanning should be employed early to detect intracranial causes.

Atherosclerotic disease increases the risk for intraoperative and postoperative stroke (cerebrovascular accident or CVA). Postoperatively, hypotension and hypoxemia are the most likely causes of CVA. Management is largely supportive once the diagnosis is made, and includes adequate intravascular volume replacement plus optimal oxygen delivery. Neurologic consultation should be obtained so that decisions regarding thrombolysis or anticoagulation can be made in a timely fashion.

Eyes, Ears, and Nose

Corneal abrasions are unusual, but are due to inadequate protection of the eyes during anesthesia. Overlooked contact lenses in a trauma patient may cause conjunctivitis.

Persistent epistaxis can occur after nasogastric tube placement or removal, and nasal packing is the best treatment option if prolonged persistent direct pressure on the external nares fails. Anterior and posterior nasal gauze packing with balloon tamponade, angiembolization, and fibrin glue placement may be required in refractory cases. The use of antibiotics for posterior packing is controversial, but the incidence of toxic shock syndrome is documented at approximately 17:100,000 cases.

External otitis and otitis media occasionally occur postoperatively. Patients complain of ear pain or decreased hearing, and treatment includes topical antibiotics and nasal decongestion for symptomatic improvement.

Ototoxicity because of aminoglycoside administration occurs in up to 10 percent of patients, and is often irreversible. Recent data show that iron chelating agents and alpha-tocopherol may be protective against ototoxicity. Vancomycin-related ototoxicity occurs about 3 percent of the time when used alone, and as high as 6 percent when used with other ototoxic agents, but is self-limited.

Vascular Problems of the Neck

Complications of carotid endarterectomy include central or regional neurologic deficits or bleeding with an expanding neck hematoma. An acute change in mental status or the presence of localized neurologic deficit may require an immediate return to the operating room to correct an iatrogenic occlusion. An expanding hematoma may warrant emergent airway intubation and subsequent transfer to the operating room for control of hemorrhage. Intraoperative anticoagulation with heparin during carotid surgery makes bleeding

TABLE 11-1 Common Causes of Mental Status Changes

Electrolyte imbalance	Toxins	Trauma	Metabolic	Medications
Sodium	Ethanol	Closed head injury	Thyrotoxicosis	Aspirin
Magnesium	Methanol	Pain	Adrenal insufficiency	Beta blockers
Calcium	Venoms and poisons	Shock	Hypoxemia	Narcotics
Inflammation	Ethylene glycol	Psychiatric	Acidosis	Antiemetics
Sepsis	Carbon monoxide	Dementia	Severe Anemia	MAOIs
AIDS		Depression	Hyperammonemia	TCAs
Cerebral abscess		ICU psychosis	Poor glycemic control	Amphetamines
Meningitis		Schizophrenia	Hypothermia	Antiarrhythmics
Fever/hyperpyrexia			Hyperthermia	Corticosteroids
				Anabolic steroids

AIDS = acquired immunodeficiency syndrome; ICU = intensive care unit; MAOI = monoamine oxidase inhibitor; TCA = tricyclic antidepressant.

a postoperative risk. Other complications can arise, such as arteriovenous fistulae, pseudoaneurysms, and infection, all of which are treated surgically.

Intraoperative hypotension during manipulation of the carotid bifurcation can occur, and is related to increased tone from baroreceptors that reflexly cause bradycardia. Should hypotension occur when manipulating the carotid bifurcation, an injection of 1 percent lidocaine solution around this structure should attenuate this reflexive response.

The most common late complication following carotid endarterectomy is myocardial infarction. The possibility of a postoperative myocardial infarction should be considered as a cause of labile blood pressure and arrhythmias in high-risk patients.

Thyroid and Parathyroid Glands

Surgery of the thyroid and parathyroid glands can result in hypocalcemia in the immediate postoperative period. Manifestations include electrocardiogram changes (shortened PR interval), muscle spasm (tetany, Chvostek sign, and Trousseau sign), paresthesias, and laryngospasm. Treatment includes calcium gluconate infusion, and if tetany ensues, chemical paralysis with intubation. Maintenance treatment is thyroid hormone replacement (after thyroidectomy) in addition to calcium carbonate and vitamin D.

Recurrent laryngeal nerve (RLN) injury occurs in less than 5 percent of patients. Of those with injury, approximately 10 percent are permanent. As the thyroid gland is dissected from lateral to medial, the dissection near the inferior thyroid artery is a common area for RLN injury. At the conclusion of the operation direct laryngoscopy confirms normal vocal cord apposition. The cord on the affected side will be in the paramedian position. If bilateral RLN has occurred, the chance of a successful extubation is poor. The cords are found to be in the midline, and an early sign of respiratory distress is stridor with labored breathing. If paralysis of the cords is not permanent, function may return 1–2 months after injury. Permanent RLN injury can be treated by various techniques to stent the cords in a position of function.

Superior laryngeal nerve injury is less debilitating, as the common symptom is loss of projection of the voice. The glottic aperture is asymmetrical on direct laryngoscopy and management is limited to clinical observation.

Respiratory System

Surgical complications that put the respiratory system in jeopardy are not always confined to technical errors. Malnutrition, inadequate pain control, inadequate mechanical ventilation, inadequate pulmonary toilet, and aspiration can cause serious pulmonary problems.

Pneumothorax can occur from central line insertion during anesthesia or from a diaphragmatic injury during an abdominal procedure. Hypotension, hypoxemia, and tracheal deviation away from the affected side may be present. A tension pneumothorax can cause complete cardiovascular collapse. Treatment is by needle thoracostomy, followed by tube thoracostomy. A large-bore needle is placed either in the midclavicular line in the second rib interspace, or where the chest tube will be inserted, the fifth intercostal space in the anterior axillary line.

Hemothorax because of trauma or intrathoracic disease should be evacuated completely. A delay in evacuation of the hemothorax leaves the patient at risk for empyema and entrapped lung. If evacuation is incomplete with tube

thoracostomy, video-assisted thoracoscopy or open evacuation and pleurodesis may be required.

Pulmonary atelectasis results in a loss of functional residual capacity (FRC) of the lung, and can predispose to pneumonia. Poor pain control in the postoperative period contributes to poor inspiratory effort and collapse of the lower lobes in particular. An increase in FRC by 700 mL or more can be accomplished by sitting patients up to greater than 45 degrees. For mechanically ventilated patients, simply placing the head of the bed at 30–45 degrees in elevation improves pulmonary outcomes. The prevention of atelectasis is facilitated by delivering adequate tidal volumes (8–10 mL/kg), preventing the abdominal domain from impinging on the thoracic cavity, and by sitting the patient up as much as possible. This includes having the ventilated patient out of bed and sitting in a chair if possible.

Aspiration complications include pneumonitis and pneumonia. The treatment of pneumonitis is similar to that for acute lung injury (see below), and includes oxygenation with general supportive care. Antibiotics are usually contraindicated unless known organisms are detected with bacteriologic analysis. Hospitalized patients who develop aspiration pneumonia carry a mortality rate as high as 70–80 percent. Early, aggressive, and repeated bronchoscopy for suctioning of aspirated material from the tracheobronchial tree will help to minimize the inflammatory reaction of pneumonitis and facilitate improved pulmonary toilet.

Patients with inadequate pulmonary toilet are at increased risk for bronchial plugging and lobar collapse. Patients with copious and tenacious secretions develop these plugs most often, but foreign bodies in the bronchus can be the cause of lobar collapse as well. The diagnosis of bronchial plugging is based on chest radiograph and clinical suspicion when there is acute pulmonary decompensation with increased work of breathing and hypoxemia. Fiberoptic bronchoscopy can be useful to clear mucous plugs and secretions.

Pneumonia is the second most common nosocomial infection and is the most common infection in ventilated patients. Ventilator-associated pneumonia (VAP) occurs in 15–40 percent of ventilated ICU patients, and accrues at a daily probability rate of 5 percent per day, up to 70 percent at 30 days. The 30-day mortality rate of nosocomial pneumonia can be as high as 40 percent, and depends on the microorganisms involved and the timeliness of initiating appropriate treatment.

Once the diagnosis of pneumonia is suspected (an abnormal chest radiograph, fever, productive cough with purulent sputum, and no other obvious fever sources), it is invariably necessary to initially begin treatment with broad-spectrum antibiotics until proper identification, colony count ($\geq 100,000$ colony-forming units [CFU]), and sensitivity of the microorganisms are determined. The spectrum of antibiotic coverage should be narrowed as soon as the culture sensitivities are determined. Double-coverage antibiotic strategy for the two pathogens, *Pseudomonas* and *Acinetobacter* species, may be appropriate if the local prevalence of these particularly virulent organisms is high. One of the most helpful tools in treating pneumonia and other infections is the tracking of a medical center's antibiogram every 6–12 months.

Epidural analgesia decreases the risk of perioperative pneumonia. This method of pain control improves pulmonary toilet and the early return of bowel function; both have a significant impact on the potential for aspiration and for acquiring pneumonia. The routine use of epidural analgesia has a lower incidence of pneumonia than patient-controlled analgesia.

Acute lung injury (ALI) is a diagnosis applied to patients with similar findings to those with acute respiratory distress syndrome (ARDS). These should be considered a spectrum of the same disease process, with the difference being in the degree of oxygenation deficits of patients. The pathology, pathophysiology, and the mechanism of lung injury for ALI are the same as for ARDS, except that the arterial oxygen to inspired oxygen (PaO_2 -to- Fio_2) ratio is >200 for ALI and <200 for ARDS. Both types of patients will require some form of positive pressure ventilatory assistance to improve the oxygenation deficits, although simultaneously treating the primary etiology of the initiating disease.

The definition of ARDS includes five criteria (see Table 11-2). The recent multicenter ARDS Research Network (ARDSnet) research trial demonstrated improved clinical outcomes for ARDS patients ventilated at tidal volumes of only 5–7 mL/kg. It is important to note that these ventilator setting recommendations are for patients with ARDS, and not for patients requiring ventilatory support for a variety of other reasons. The beneficial effects of positive end-expiratory pressure (PEEP) for ARDS were confirmed in this study as well. The maintenance of PEEP during ventilatory support is determined based on blood gas analysis, pulmonary mechanics, and requirements for supplemental oxygen. As gas exchange improves with resolving ARDS, the initial step in decreasing ventilatory support should be to decrease the levels of supplemental oxygen first, and then to slowly bring the PEEP levels back down to minimal levels. This is done to minimize the potential for recurrent alveolar collapse and a worsening gas exchange.

Not all patients can be weaned easily from mechanical ventilation. When the respiratory muscle energy demands are not balanced, or there is an ongoing active disease state external to the lungs, patients may require prolonged ventilatory support. Protocol-driven ventilator weaning strategies are successful and have become part of the standard of care. The use of a weaning protocol for patients on mechanical ventilation greater than 48 h reduces the incidence of VAP and the overall length of time on mechanical ventilation, when compared with nonprotocol managed ventilator weaning. Unfortunately there is still no reliable way of predicting which patient will be successfully extubated after a weaning program, and the decision for extubation is based on a combination of clinical parameters and measured pulmonary mechanics. The Tobin Index (frequency-to-tidal volume ratio), also known as the rapid shallow breathing index (RSBI), is perhaps the best negative predictive instrument. If the result equals <105 , then there is nearly a 70 percent chance the patient will pass extubation. If the score is >105 , the patient has an approximately 80 percent chance of failing extubation. Other parameters such as the negative inspiratory force, minute ventilation, and respiratory rate are used, but individually have no better predictive value than the RSBI.

TABLE 11-2 Definition of Adult Respiratory Distress Syndrome

-
1. A known etiology or disease exists that would predispose to ARDS
 2. Pulmonary artery occlusion pressures are less than 18 mmHg
 3. No clinical evidence exists for right heart failure, subsequent to left heart failure
 4. Diffuse bilateral pulmonary infiltrates are found on chest radiograph
 5. The PaO_2 -to- Fio_2 ratio is less than 200
-

Malnutrition and poor nutritional support may adversely affect the respiratory system. The respiratory quotient (RQ), or respiratory exchange ratio (RER), is the ratio of the rate of carbon dioxide produced to the rate of oxygen uptake ($RQ = V_{CO_2}/V_{O_2}$). Lipids, carbohydrates, and protein have differing effects on carbon dioxide production. Patients consuming a diet consisting mostly of carbohydrates would have an RQ of 1 or greater. The RQ for a diet mostly of lipids would be closer to 0.7, and that for a diet of mostly protein would be closer to 0.8. Ideally, an RQ of 0.75–0.85 suggests adequate balance and composition of nutrient intake. An excess of carbohydrate may negatively affect ventilator weaning because of the abnormal RQ because of higher CO_2 production and altered pulmonary gas exchange.

Although not without risk, tracheostomy will decrease the pulmonary dead space and provides for improved pulmonary toilet. When performed prior to the tenth day of ventilatory support, tracheostomy may decrease the incidence of VAP, the overall length of ventilator time, and the number of ICU patient days.

The occurrence of pulmonary embolism (PE) is probably underdiagnosed. Its etiology stems from deep vein thrombosis (DVT). The diagnosis of PE is made when a high degree of clinical suspicion for PE leads to imaging techniques such as ventilation-to-perfusion nuclear scans (VQ scans) or CT pulmonary angiogram. Clinical findings include elevated central venous pressure, hypoxemia, shortness of breath, hypocarbia secondary to tachypnea, and right heart strain noted on electrocardiogram. VQ scans are often indeterminate in patients who have an abnormal chest radiograph. The pulmonary angiogram remains the gold standard for diagnosing PE, but spiral CT angiogram has become an alternative method because of its relative ease of use and reasonable rates of diagnostic accuracy. For cases without clinical contraindications to therapeutic anticoagulation, patients should be empirically started on heparin infusion until the imaging studies are completed if the suspicion of a PE is strong.

Sequential compression devices on the lower extremities, and low-dose subcutaneous heparin administration are routinely used to prevent DVT, and, by inference, the risk of PE. Neurosurgical and orthopedic patients have higher rates of PE, as do obese patients and those at prolonged bed rest.

When anticoagulation is contraindicated, or when a known clot exists in the inferior vena cava (IVC), therapy for PE includes insertion of an IVC filter. The Greenfield filter has been most widely studied, and it has a failure rate of less than 4 percent. Newer devices include those with nitinol wire that expands with body temperature and retrievable filters. Patients with spinal cord injury and multiple long-bone or pelvic fractures frequently receive IVC filters, and there appears to be a low long-term complication rate with their use.

Cardiac System

Arrhythmias are often seen preoperatively in older adult patients, but may occur postoperatively in any age group. Atrial fibrillation is the most common arrhythmia and occurs between postoperative days 3 to 5 in high-risk patients. This is typically when patients begin to mobilize their interstitial fluid into the vascular fluid space. Contemporary evidence suggests that rate control is more important than rhythm control for atrial fibrillation. The first-line treatment includes beta blockade and/or calcium channel blockade. B blockade must be

used judiciously, because hypotension, and withdrawal from β blockade with rebound hypertension, is possible. Calcium channel blockers are an option if β blockers are not tolerated by the patient, but caution must be exercised in those with a history of congestive heart failure. Although digoxin is still a faithful standby medication, it has limitations because of the need for optimal dosing levels. Cardioversion may be required if patients become hemodynamically unstable and the rhythm cannot be controlled.

Ventricular arrhythmias and other tachyarrhythmias may occur in surgical patients as well. Similar to atrial rhythm problems, these are best controlled with beta blockade, but the use of other antiarrhythmics or cardioversion may be required if patients become hemodynamically unstable. Formal cardiac electrophysiology studies may be needed to clarify the etiology of the arrhythmias so that medical or surgical treatment can be tailored.

Cardiac ischemia is a cause of postoperative mortality. Acute myocardial infarction (AMI) can present insidiously or it can be more dramatic with the classic presentation of shortness of breath (SOB), severe angina, and sudden cardiogenic shock. The work-up to rule out an AMI includes an EKG and cardiac enzyme measurements. The patient should be transferred to a monitored (telemetry) floor as soon as a bed is available. Morphine, supplemental Oxygen, Nitroglycerine, and Aspirin (MONA) are the initial therapeutic maneuvers for those who are being investigated for AMI.

Hypertension in the immediate postoperative period may be merely a failure of adequate pain control, but other causes include hypoxia, volume overload, and rebound hypertension from failure to resume β blockade and/or clonidine. Perioperative hypertension carries significant morbidity and aggressive control is warranted. Twenty to 50 percent of patients with chronic atherosclerotic disease present with hypertension, and causes of perioperative hypertension include cerebrovascular disease, renal artery stenosis, aorto-occlusive disease, and rarely pheochromocytoma. Routine perioperative cardiac protection with β blockade is the standard of care for patients with a history of cardiovascular disease.

Gastrointestinal System

Surgery of the esophagus is potentially complicated because of its anatomic location and blood supply. The two primary types of esophageal resection performed are the transhiatal resection and the transthoracic (Ivor-Lewis) resection. The transhiatal resection has the advantage that a formal thoracotomy incision is avoided. The dissection of the esophagus is blind, however, and an anastomotic leak occurs more than with other resections. However, when a leak does occur, simple opening of the cervical incision and draining the leak is all that is usually required.

The transthoracic Ivor-Lewis resection includes an esophageal anastomosis performed in the chest near the level of the azygos vein. These resections tend not to leak as often, but when they do, they can be difficult to control. The reported mortality is about 50 percent with an anastomotic leak, and the overall mortality is about 5 percent, which is similar to transhiatal resection. Nutritional support strategies must be considered for esophageal resection patients to maximize the potential for survival.

Nissen fundoplication is an operation that is fraught with possibilities for error. Bleeding is always a potential hazard, so dissection of the short gastric

vessels must be done with care. Laparoscopic port site bleeding, injury to the aorta, and liver lacerations can also contribute to significant blood loss. The fundoplication may be too tightly wrapped or become unwrapped postoperatively. Postoperative edema and patient noncompliance will produce symptoms of odynophagia and dysphagia.

Postoperative ileus is related to dysfunction of the neural reflex axis of the intestine. Excessive narcotic use may delay return of bowel function. Epidural anesthesia results in better pain control, and there is an earlier return of bowel function, and a shorter length of hospital stay. The limited use of nasogastric tubes and the initiation of early postoperative feeding are associated with an earlier return of bowel function.

Numerous studies have shown a decreased length of stay and improved pain control when bowel surgery is performed laparoscopically. In one study, however, patients with open colon resection were fed at the same time as the laparoscopically treated patients and had no difference in hospital length of stay.

Pharmacologic agents commonly used to stimulate bowel function include metoclopramide and erythromycin. Metoclopramide's action is limited to the stomach, and it may help primarily with gastroparesis. Erythromycin is a motilin-agonist that works throughout the stomach and bowel. Several studies demonstrate significant benefit from the administration of erythromycin in those suffering from an ileus.

Small bowel obstruction occurs in less than 1 percent of early postoperative patients. When it does occur, adhesions are usually the cause. Internal and external hernias, technical errors, and infections or abscesses are also causative. No one can accurately predict which patients will form obstructive postoperative adhesions, because all patients who undergo surgery form adhesions to some extent, and there is little that can limit this natural healing process. Hyaluronidase is a mucolytic enzyme that degrades connective tissue, and the use of a methylcellulose form of hyaluronidase, Sefrafil, has been shown to result in a 50 percent decrease in adhesion formation in some patients. This should translate into a lower occurrence of postoperative bowel obstruction, but this has yet to be proven.

Fistulae are the abnormal communication of one structure to an adjacent structure or compartment, and are associated with extensive morbidity and mortality. Common causes for fistula formation are summarized in the mnemonic FRIENDS (Foreign body, Radiation, Ischemia/Inflammation/Infection, Epithelialization of a tract, Neoplasia, Distal obstruction, and Steroid use). The cause of the fistula must be recognized early, and treatment may include non-operative management with observation and nutritional support, or a delayed operative management strategy that also includes nutritional support and wound care.

Gastrointestinal bleeding can occur perioperatively (Table 11-3). Technical errors such as a poorly tied suture, a nonhemostatic staple line, or a missed injury can all lead to postoperative intestinal bleeding. The source of bleeding is in the upper gastrointestinal tract about 85 percent of the time, and is usually detected and treated endoscopically. Surgical control of intestinal bleeding is required in up to 40 percent of patients.

When patients in the ICU have a major bleed from stress gastritis, the mortality risk is as high as 50 percent. It is important to keep the gastric pH greater than 4 to decrease the overall risk for stress gastritis, particularly in patients mechanically ventilated for 48 h or greater and patients who are coagulopathic.

TABLE 11-3 Common Causes of Upper and Lower Gastrointestinal Hemorrhage

Upper GI bleed	Lower GI bleed
Erosive esophagitis	Angiodysplasia
Gastric varices	Radiation proctitis
Esophageal varices	Hemangioma
Dieulafoy's lesion	Diverticulosis
Aortoduodenal fistula	Neoplastic diseases
Mallory-Weiss tear	Trauma
Peptic ulcer disease	Vasculitis
Trauma	Hemorrhoids
Neoplastic disease	Aortoenteric fistula
	Intussusception
	Ischemic colitis
	Inflammatory bowel disease
	Postprocedure bleeding

Proton pump inhibitors, H₂ receptor antagonists, and intragastric antacid installation are all effective measures.

Hepatobiliary-Pancreatic System

Complications involving the hepatobiliary tree are usually because of technical errors. Laparoscopic cholecystectomy has become the standard of care for cholecystectomy, but common bile duct injury remains a nemesis of this approach. Intraoperative cholangiography has not been shown to decrease the incidence of common bile duct injuries, because the injury to the bile duct usually occurs prior to the cholangiogram. Early recognition of an injury is important, because delayed bile duct leaks often require a more complex repair.

Ischemic injury due to devascularization of the common bile duct has a delayed presentation days to weeks after an operation. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates a stenotic, smooth common bile duct. Liver function studies are elevated. The recommended treatment is a Roux-en-Y hepaticojejunostomy.

A bile leak because of an unrecognized injury to the ducts may present after cholecystectomy as a biloma. These patients may present with abdominal pain and hyperbilirubinemia. The diagnosis of a biliary leak can be confirmed by CT scan, ERCP, or radionuclide (HIDA) scan. Once a leak is confirmed, a retrograde biliary stent and external drainage is the treatment of choice.

Hyperbilirubinemia in the surgical patient can be a complex problem. Cholestasis makes up the majority of causes for hyperbilirubinemia, but other mechanisms of hyperbilirubinemia include reabsorption of blood (e.g., hematoma from trauma), decreased bile excretion (e.g., sepsis), increased unconjugated bilirubin because of hemolysis, hyperthyroidism, and impaired excretion because of congenital abnormalities or acquired disease. Errors in surgery that cause hyperbilirubinemia largely involve missed or iatrogenic injuries.

The presence of cirrhosis predisposes to postoperative complications. Abdominal or hepatobiliary surgery is problematic in the cirrhotic patient. Ascites leak in the postoperative period can be an issue when any abdominal operation has been performed. Maintaining proper intravascular oncotic pressure in the immediate postoperative period can be difficult, and resuscitation should be

maintained with crystalloid solutions. Prevention of renal failure and the management of the hepatorenal syndrome can be difficult, as the demands of fluid resuscitation and altered glomerular filtration become competitive. Spironolactone with other diuretic agents may be helpful in the postoperative care. These patients often have a labile course and bleeding complications because of coagulopathy is common. The operative mortality in cirrhotic patients is 10 percent for Child class A, 30 percent for Child class B, and 82 percent for Child class C patients.

Pyogenic liver abscess occurs in less than 0.5 percent of adult admissions, because of retained necrotic liver tissue, occult intestinal perforations, benign or malignant hepatobiliary obstruction, and hepatic arterial occlusion. The treatment is long-term antibiotics with percutaneous drainage of large abscesses.

Pancreatitis can occur following injection of contrast during cholangiography and ERCP. These episodes range from a mild elevation in amylase and lipase with abdominal pain, to a fulminant course of pancreatitis with necrosis requiring surgical débridement. Traumatic injuries to the pancreas during surgical procedures on the kidneys, gastrointestinal tract, or spleen comprise the most common causes. Treatment involves serial CT scans and percutaneous drainage to manage infected fluid and abscess collections. A pancreatic fistula may respond to antisecretory therapy with a somatostatin analog, Octreotide. Management of these fistulae initially includes ERCP with or without pancreatic stenting, percutaneous drainage of any fistula fluid collections, total parenteral nutrition with bowel rest, and repeated CT scans. The majority of pancreatic fistulae will eventually heal spontaneously.

Renal System

Renal failure can be classified as prerenal failure, intrinsic renal failure, and postrenal failure. Postrenal failure, or obstructive renal failure, should always be considered when low urine output (oliguria) or anuria occurs. The most common cause is a misplaced or clogged urinary catheter. Other, less-common causes to consider are unintentional ligation or transection of ureters during a difficult surgical dissection (e.g., colon resection for diverticular disease), or a large retroperitoneal hematoma (e.g., ruptured aortic aneurysm).

Oliguria is evaluated by flushing the Foley catheter using sterile technique. When this fails to produce the desired response, it is reasonable to administer an intravenous fluid challenge with a crystalloid fluid bolus of 500–1000 mL. However, the immediate postoperative patient must be examined and have recent vital signs recorded with total intake and output tabulated, and urinary electrolytes measured (Table 11-4). A hemoglobin and hematocrit level should be checked immediately. Patients in compensated shock from acute blood loss may manifest anemia and end-organ malperfusion as oliguria.

TABLE 11-4 Urinary Electrolytes Associated with Acute Renal Failure and Their Possible Etiologies

	FE _{Na}	Osmolarity	UR _{Na}	Etiology
Prerenal	< 1	> 500	< 20	CHF, cirrhosis
Intrinsic failure	> 1	< 350	> 40	Sepsis, shock

CHF = congestive heart failure; FE_{Na} = fractional excretion of sodium; UR_{Na} = urinary excretion of sodium.

Acute tubular necrosis (ATN) carries a mortality risk of 25–50 percent because of the many complications that can cause, or result from, this insult. When ATN is due to poor inflow (prerenal failure), the remedy begins with intravenous administration of crystalloid or colloid fluids as needed. If cardiac insufficiency is the problem, the optimization of vascular volume is achieved first, followed by inotropic agents as needed. Intrinsic renal failure and subsequent ATN are often the result of direct renal toxins. Aminoglycosides, vancomycin, and furosemide, among other commonly used agents, contribute directly to nephrotoxicity. Contrast-induced nephropathy usually leads to a subtle or transient rise in creatinine. In patients who are volume depleted or have poor cardiac function, contrast nephropathy may permanently impair renal function.

The treatment of renal failure because of myoglobinuria in severe trauma patients has shifted away from the use of sodium bicarbonate for alkalinizing the urine, to merely maintaining brisk urine output of 100 mL/h with crystalloid fluid infusion. Mannitol and furosemide are not recommended as long as the intravenous fluid achieves the goal rate of urinary output.

Musculoskeletal System

A compartment syndrome can develop in any compartment of the body. Compartment syndrome of the extremities generally occurs after a closed fracture. The injury alone may predispose the patient to compartment syndrome, but aggressive fluid resuscitation can exacerbate the problem. Pain with passive motion is the hallmark of compartment syndrome, and the anterior compartment of the leg is usually the first compartment to be involved. Confirmation of the diagnosis is obtained by direct pressure measurement of the individual compartments. If the pressures are greater than 20–25 mmHg in any of the compartments, then a four-compartment fasciotomy is considered. Compartment syndrome can be caused by ischemia-reperfusion injury, after an ischemic time of 4 to 6 h. Renal failure (because of myoglobinuria), foot drop, tissue loss, and a permanent loss of function are possible results of untreated compartment syndrome.

Decubitus ulcers are preventable complications of prolonged bedrest because of traumatic paralysis, dementia, chemical paralysis, or coma. Ischemic changes in the microcirculation of the skin can be significant after 2 h of sustained pressure. Routine skin care and turning of the patient helps ensure a reduction in skin ulceration. This can be labor intensive and special mattresses and beds are available to help with this ubiquitous problem. The treatment of a decubitus ulcer in the noncoagulopathic patient is surgical débridement. Once the wound bed has a viable granulation base without an excess of fibrinous debris, a vacuum-assisted closure (VAC) dressing can be applied. Wet to moist dressings with frequent dressing changes is the alternative, and is labor intensive. Expensive topical enzyme preparations are also available. If the wounds fail to respond to these measures, soft tissue coverage by flap is considered.

Contractures are the result of muscle disuse. Whether from trauma, amputation, or from vascular insufficiency, contractures can be prevented by physical therapy and splinting. If not attended to early, contractures will prolong rehabilitation and may lead to further wounds and wound healing issues. Depending on the functional status of the patient, contracture releases may be required for long-term care.

Hematologic System

The transfusion guideline of maintaining the hematocrit level in all patients at greater than 30 percent is no longer valid. Only those patients with symptomatic anemia, or those who have significant cardiac disease, or the critically ill patient who requires increased oxygen-carrying capacity to adequately perfuse end-organs, requires higher levels of hemoglobin. Other than these select patients, the decision to transfuse should generally not occur until the hemoglobin level reaches 7.0 mg/dL or the hematocrit reaches 21 percent.

Transfusion reactions are common complications of blood transfusion. These can be attenuated with a leukocyte filter, but not completely prevented. The manifestations of a transfusion reaction include simple fever, pruritus, chills, muscle rigidity, and renal failure because of myoglobinuria secondary to hemolysis. Discontinuing the transfusion and returning the blood products to the blood bank is an important first step, but administration of antihistamine and possibly steroids may be required to control the reaction symptoms. Severe transfusion reactions are rare but can be fatal.

Infectious complications in blood transfusion range from cytomegalovirus transmission, which is benign in the nontransplant patient, to human immunodeficiency virus (HIV) infection, to passage of the hepatitis viruses, which can lead to subsequent hepatocellular carcinoma. Although the efficiency of infectious agent screening in blood products has improved, universal precautions should be rigidly maintained for all patients (Table 11-5).

Patients on Coumadin (warfarin) who require surgery can have anticoagulation reversal by administration of fresh frozen plasma (FFP). Each unit of FFP contains 200–250 mL of plasma and includes 1 unit of coagulation factor per mL of plasma.

Thrombocytopenia may require platelet transfusion for a platelet count less than 20,000/mL when invasive procedures are performed, or when platelet counts are low and ongoing bleeding from raw surface areas persists. One unit of platelets will increase the platelet count by 5000–7500 per mL in adults. It is important to delineate the cause of the low platelet count. Usually there is a self-limiting or reversible condition such as sepsis. Rarely, it is because of heparin-induced thrombocytopenia (HIT I and HIT II). Complications of HIT II can be serious because of the diffuse thrombogenic nature of the disorder. Simple precautions to limit this hypercoagulable state include saline solution flushes instead of heparin solutions, and to limit the use of heparin-coated catheters. The treatment is anticoagulation with synthetic agents such as argatroban.

TABLE 11-5 Rate of Viral Transmission in Blood Product Transfusions^a

HIV	1:1.9 million
HBV ^b	1:137,000
HCV	1:1 million

HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus.

^aPostnucleic acid amplification technology (1999). Earlier rates were erroneously reported higher due to lack of contemporary technology.

^bHBV is reported with prenucleic acid amplification technology. Statistical information is unavailable in postnucleic acid amplification technology at this writing.

Note that bacterial transmission is 50–250 times higher than viral transmission per transfusion.

For patients with uncontrollable bleeding because of disseminated intravascular coagulopathy (DIC), an expensive but useful drug is factor VIIa. Largely used in hepatic trauma and obstetric emergencies, this agent may mean the difference between life or death in some circumstances. The combination of ongoing, nonsurgical bleeding and renal failure can sometimes be successfully treated with desmopressin (DDAVP).

In addition to classic hemophilia, other inherited coagulation factor deficiencies can be difficult to manage in surgery. When required, transfusion of appropriate replacement products is coordinated with the regional blood bank center prior to surgery. Other blood dyscrasias seen by surgeons include hypercoagulopathic patients. Those who carry congenital anomalies such as the most common, Factor V Leiden deficiency, and protein C and S deficiencies, are likely to form thromboses if inadequately anticoagulated.

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) and intraabdominal hypertension represent the same problem. Multi-system trauma, thermal burns, retroperitoneal injuries, and surgery related to the retroperitoneum are the major initial causative factors that may lead to ACS. Ruptured abdominal aortic aneurysm, major pancreatic injury and resection, or multiple intestinal injuries are also examples of clinical situations in which a large volume of IV fluid resuscitation puts these patients at risk for intraabdominal hypertension. Manifestations of ACS typically include progressive abdominal distention followed by increased peak airway ventilator pressures, oliguria followed by anuria, and an insidious development of intracranial hypertension. These findings are related to elevation of the diaphragm and inadequate venous return from the vena cava or renal veins secondary to the transmitted pressure on the venous system.

Measurement of abdominal pressures is easily accomplished by transducing bladder pressures from the urinary catheter after instilling 100 mL of sterile saline into the urinary bladder. A pressure greater than 20 mmHg constitutes intraabdominal hypertension, but the diagnosis of ACS requires intraabdominal pressure greater than 25–30 mmHg, with at least one of the following: compromised respiratory mechanics and ventilation, oliguria or anuria, or increasing intracranial pressures.

The treatment of ACS is to open any recent abdominal incision to release the abdominal fascia, or to open the fascia directly if no abdominal incision is present. Immediate improvement in mechanical ventilation pressures, intracranial pressures, and renal output is usually noted. When expectant management for ACS is considered in the operating room, the abdominal fascia should be left open and covered under sterile conditions with plans made for a second-look operation and delayed fascial closure. Patients with intraabdominal hypertension should be monitored closely with repeated examinations and measurements of bladder pressure, so that any further deterioration is detected and operative management can be initiated. Left untreated, ACS may lead to multiple system end-organ dysfunction or failure, and has a high mortality.

Abdominal wall closure should be attempted every 48–72 h until the fascia can be reapproximated. If the abdomen cannot be closed within 5–7 days following release of the abdominal fascia, a large incisional hernia is the net result.

WOUNDS, DRAINS, AND INFECTION

Wound (Surgical Site) Infection

There exist no prospective, randomized, double-blind, controlled studies that demonstrate that antibiotics used beyond 24 h in the perioperative period prevent infections. There is a general trend toward providing a single preoperative dose, as antibiotic prophylaxis may not impart any benefit at all beyond the initial dosing. Irrigation of the operative field and the surgical wound with saline solution has shown benefit in controlling wound inoculum. Irrigation with an antibiotic-based solution has not demonstrated significant benefit in controlling postoperative infection.

Antibacterial-impregnated polyvinyl placed over the operative wound area for the duration of the surgical procedure has not been shown to decrease the rate of wound infection. Although skin preparation with 70 percent isopropyl alcohol has the best bacteriocidal effect, it is flammable, and could be hazardous when electrocautery is used. The contemporary formulae of chlorhexidine gluconate with isopropyl alcohol or povidone-iodine and iodophor with alcohol are more advantageous.

There is a difference between wound colonization and infection. Overtreating colonization is just as injurious as undertreating infection (Table 11-6). The strict definition of wound (soft tissue) infection is more than 10^5 CFU per g of tissue. This warrants expeditious and proper antibiotic/antifungal treatment. Often, however, clinical signs raise enough suspicion that the patient is treated before a confirmatory culture is undertaken. The clinical signs of wound infection include rubor, tumor, calor, and dolor (redness, swelling, heat, and pain), and once the diagnosis of wound infection has been established, the most definitive treatment remains open drainage of the wound to facilitate wound dressing care. The use of antibiotics for wound infection treatment should be limited.

One type of wound dressing/drainage system that is gaining popularity is the VAC dressing. The principle of the system is to decrease local wound edema and to promote healing through the application of a sterile dressing that is then covered and placed under controlled suction for a period of 2–4 days at a time. Although costly, the benefits are frequently dramatic and may offset the costs of nursing care, frequent dressing changes, and operative wound débridement.

Drain Management

The indications for applying a surgical drain are:

1. To collapse surgical dead space in areas of redundant tissue (e.g., neck and axilla).
2. To provide focused drainage of an abscess or grossly infected surgical site.

TABLE 11-6 Common Causes of Leukocytosis

Infection
Systemic inflammatory response syndrome
Glucocorticoid administration
Splenectomy
Leukemia
Medications
Physiologic stress
Increases in interleukin-1 and tumor necrosis factor

3. To provide early warning notice of a surgical leak (either bowel contents, secretions, urine, air, or blood)—the so-called sentinel drain.
4. To control an established fistula leak.

Open drains are often used for large contaminated wounds such as perirectal or perianal fistulas and subcutaneous abscess cavities. They prevent premature closure of an abscess cavity in a contaminated wound, but do not address the fact that bacteria are free to travel in either direction along the drain tract. More commonly, surgical sites are drained by closed suction drainage systems, but data do not support closed suction drainage to “protect an anastomosis,” or to “control a leak” when placed at the time of surgery. Closed suction devices can exert a negative pressure of 70–170 mmHg at the level of the drain, therefore the presence of this excess suction may call into question whether an anastomosis breaks down on its own, or if the drain creates a suction injury that promotes leakage.

On the other hand, CT- or ultrasound-guided placement of percutaneous drains is now the standard of care for abscesses, loculated infections, and other isolated fluid collections such as pancreatic leaks. The risk of surgery is far greater than the placement of an image-guided drain, and the risk can often be reduced in these instances by a brief course of antibiotics.

The use of antibiotics when drains are placed should be examined from a cost-benefit perspective. Antibiotics are rarely necessary when a wound is drained widely. Twenty-four to 48 h of antibiotic use after drain placement is prophylactic, and after this period only specific treatment of positive cultures should be performed, to avoid increased drug resistance and superinfection.

Urinary Catheters

Several complications of urinary (Foley) catheters can occur that lead to an increased length of hospital stay and morbidity. It is recommended that the catheter be inserted its full length up to the hub, and that urine flow is established before the balloon is inflated, because misplacement of the catheter in the urethra with premature inflation of the balloon can lead to tears and disruption of the urethra.

Enlarged prostatic tissue can make catheter insertion difficult, and a coude catheter may be required. If this attempt is also unsuccessful, then a urologic consultation for endoscopic placement of the catheter may be required to prevent harm to the urethra. For patients with urethral strictures, filiform-tipped catheters and followers may be used, but these can potentially cause bladder injury. If endoscopic attempts fail, the patient may require a percutaneously placed suprapubic catheter to obtain decompression of the bladder. Follow-up investigations of these patients are recommended so definitive care of the urethral abnormalities can be pursued.

The most frequent nosocomial infection is urinary tract infection (UTI). These infections are classified into complicated and uncomplicated forms. The uncomplicated type is a UTI that can be treated with trimethoprim-sulfamethoxazole for 3 days. The complicated UTI usually involves the hospitalized patient with an indwelling catheter whose UTI is diagnosed as part of a fever work-up. The interpretation of urine culture results of less than 100,000 CFU/mL is controversial. Before treating such a patient, one should change the catheter and then repeat the culture to see if the catheter was simply colonized with organisms. On the other hand, an argument can be made that

until the foreign body (catheter) is removed, the bladder will continue to be the nidus of infection, and antibiotics should be started. Cultures with more than 100,000 CFU/mL should be treated with the appropriate antibiotics and the catheter removed as soon as possible. Undertreatment or misdiagnosis of a UTI can lead to urosepsis and septic shock.

Recommendations are mixed on the proper way to treat *Candida albicans* fungal bladder infections. Continuous bladder washings with fungicidal solution for 72 h have been recommended, but this is not always effective. Replacement of the urinary catheter and a course of fluconazole are appropriate treatments, but some infectious disease specialists claim that *C. albicans* in the urine may serve as an indication of fungal infection elsewhere in the body. If this is the case, then screening cultures for other sources of fungal infection should be performed whenever a fungal UTI is found.

Empyema

One of the most debilitating infections is an empyema, or infection of the pleural space. Frequently, an overwhelming pneumonia is the source of an empyema, but a retained hemothorax, systemic sepsis, esophageal perforation from any cause, and infections with a predilection for the lung (e.g., tuberculosis) are potential etiologies as well. The diagnosis is confirmed by chest radiograph or CT scan, followed by aspiration of pleural fluid for bacteriologic analysis. Gram's stain, lactate dehydrogenase, protein, pH, and cell count are obtained, and broad-spectrum antibiotics are initiated while the laboratory studies are performed. Once the specific organisms are confirmed, anti-infective agents are tailored appropriately. Placement of a thoracostomy tube is needed to evacuate and drain the infected pleural fluid, but depending on the specific nidus of infection, video-assisted thoracoscopy (VATS) may also be helpful for irrigation and drainage of the infection.

Abdominal Abscesses

Postsurgical intraabdominal abscesses can present with vague complaints of intermittent abdominal pain, fever, leukocytosis, and a change in bowel habits. Depending on the type and timing of the original procedure, the clinical assessment of these complaints is sometimes difficult, and a CT scan is usually required. When a fluid collection within the peritoneal cavity is found on CT scan, antibiotics and percutaneous drainage of the collection is the treatment of choice. There should still be a determination regarding what the cause of the infection was, so tailored antibiotic therapy can be initiated. Initial antibiotic treatment is usually with broad-spectrum antibiotics such as piperacillin-tazobactam or imipenem. Should the patient exhibit signs of peritonitis and/or have free air on radiograph or CT scan, then reexploration should be considered.

For patients who present primarily (i.e., not postoperatively) with the clinical and radiologic findings of an abscess but are clinically stable, the etiology of the abscess must be determined. A plan for drainage of the abscess and decisions about further diagnostic studies with consideration of the timing of any definitive surgery all need to be balanced. This can be a complex set of decisions, depending on the etiology (e.g., appendicitis or diverticulitis); but if the patient exhibits signs of peritonitis, urgent surgical exploration should be performed.

Necrotizing Fasciitis

Postoperative infections that progress to the fulminant soft tissue infection known as necrotizing fasciitis are uncommon. Group A streptococcal (M types 1, 3, 12, and 28) soft tissue infections, and infections with *Clostridium perfringens* and *C. septicum* carry a mortality of 30–70 percent. Septic shock can be present and patients can become hypotensive less than 6 h following inoculation. Manifestations of a group A *Streptococcus pyogenes* infection in its most severe form include hypotension, renal insufficiency, coagulopathy, hepatic insufficiency, ARDS, tissue necrosis, and erythematous rash.

These findings constitute a surgical emergency and the mainstay of treatment remains wide débridement of the necrotic tissue to the level of bleeding, viable tissue. A grey serous fluid at the level of the necrotic tissue is usually noted, and as the infection spreads, thrombosed blood vessels are noted along the tissue planes involved with the infection. Typically, the patient requires serial trips to the operating room for wide débridement until the infection is under control. Antibiotics are an important adjunct to surgical débridement and broad-spectrum coverage should be used because these infections may be polymicrobial (i.e., so-called mixed-synergistic infections). *S. pyogenes* is eradicated with penicillin, and it should still be used as the initial drug of choice.

Systemic Inflammatory Response Syndrome, Sepsis, and Multiple-Organ Dysfunction Syndrome

The systemic inflammatory response syndrome (SIRS) and the multiple-organ dysfunction syndrome (MODS) carry significant mortality risks (Table 11-7). Specific criteria have been established for the diagnosis of SIRS (Table 11-8), but two criteria are not required for the diagnosis of SIRS: lowered blood pressure and blood cultures positive for infection. SIRS is the result of proinflammatory cytokines related to tissue malperfusion or injury. The dominant cytokines implicated in this process include interleukin (IL)-1, IL-6, and tissue necrosis factor (TNF). Other mediators include nitric oxide, inducible macrophage-type nitric oxide synthase (iNOS), and prostaglandin I₂ (PGI₂).

Sepsis is categorized as sepsis, severe sepsis, and septic shock. An oversimplification of sepsis would be to define it as SIRS plus infection. Severe sepsis is defined as sepsis plus signs of cellular hypoperfusion or end-organ dysfunction. Septic shock would then be sepsis associated with hypotension after adequate fluid resuscitation.

MODS is the culmination of septic shock and multiple end-organ failure. Usually there is an inciting event (e.g., perforated sigmoid diverticulitis), and as the patient undergoes resuscitation, he or she develops cardiac hypokinesia and oliguric or anuric renal failure, followed by the development of ARDS and eventually septic shock with death.

TABLE 11-7 Mortality Associated with Patients Exhibiting Two or More Criteria for Systemic Inflammatory Response Syndrome (SIRS)

Prognosis	Mortality
2 SIRS criteria	5 percent
3 SIRS criteria	10 percent
4 SIRS criteria	15–20 percent

TABLE 11-8 Inclusion Criteria for the Systemic Inflammatory Response Syndrome (SIRS)

Temperature >38 or $<36^{\circ}\text{C}$
Heart rate >90 beats/min
Respiratory rate >20 breaths/min or $\text{Paco}_2 <32$ mm Hg
White blood cell count <4000 or $>12,000$ cells/ mm^3 or $>10\%$ immature forms

Management of SIRS/MODS includes aggressive global resuscitation and support of end-organ perfusion, correction of the inciting etiology, control of infectious complications, and management of iatrogenic complications. Drotrecogin α , or recombinant activated protein C, appears to specifically counteract the cytokine cascade of SIRS/MODS, but its use is still limited. Other adjuncts for supportive therapy include tight glucose control, low tidal volumes in ARDS, vasopressin in septic shock, and steroid replacement therapy.

NUTRITIONAL AND METABOLIC SUPPORT COMPLICATIONS

Nutrition-Related Complications

A basic principle is to use enteral feeding whenever possible, but complications can intervene such as aspiration, ileus, and to a lesser extent, sinusitis. There is no difference in aspiration rates when a small-caliber feeding tube is placed transpylorically into the duodenum or if it remains in the stomach. Patients who are fed via nasogastric tubes are at risk for aspiration pneumonia, because these relatively large-bore tubes stent open the esophagus, creating the possibility of gastric reflux. The use of enteric and gastric feeding tubes obviates complications of total parenteral nutrition (TPN), such as pneumothorax, line sepsis, upper extremity deep venous thrombosis, and the related expense. There is growing evidence to support the initiation of enteral feeding in the early postoperative period, prior to the return of bowel function, where it is usually well tolerated.

In patients who have had any type of nasal intubation that are having high, unexplained fevers, sinusitis must be entertained as a diagnosis. CT scan of the sinuses is warranted, followed by aspiration of sinus contents so the organism(s) are appropriately treated.

Patients who have not been enterally fed for prolonged periods secondary to multiple operations, those who have had enteral feeds interrupted for any other reason, or those with poor enteral access are at risk for the refeeding syndrome, which is characterized by severe hypophosphatemia and respiratory failure. Slow progression of the enteral feeding administration rate can avoid this complication.

Common TPN problems are mostly related to electrolyte abnormalities that may develop. These electrolyte errors include deficits or excesses in sodium, potassium, calcium, magnesium, and phosphate. Acid-base abnormalities can also occur with the improper administration of acetate or bicarbonate solutions.

The most common cause for hyponatremia in hospitalized patients is underresuscitation, and conversely, hyponatremia is most often caused by fluid overload. Treatment for hyponatremia is fluid restriction in mild or moderate cases and the administration of hypertonic saline for severe cases. An overly rapid correction of the sodium abnormality may result in central pontine myelinolysis, which results in a severe neurologic deficit. Treatment

for hyponatremic patients includes fluid restriction to correct the free water deficit by 50 percent in the first 24 h. An overcorrection of hyponatremia can result in severe cerebral edema, a neurologic deficit or seizures.

Glycemic Control

In 2001, Van den Berghe and associates demonstrated that tight glycemic control by insulin infusion is associated with a 50 percent reduction in mortality in the critical care setting. This prospective, randomized, controlled trial of 1500 patients had two study arms: the intensive-control arm, where the serum glucose was maintained between 80 and 110 mg/dL with insulin infusion; and the control arm, in which patients received an insulin infusion only if blood glucose was > 215 mg/dL, but serum glucose was then maintained at 180 to 200 mg/dL.

The tight glycemic control group had an average serum glucose level of 103 mg/dL, and the average glucose level in the control group was 153 mg/dL. Hypoglycemic episodes (glucose < 40 mg/dL) occurred in 39 patients in the tightly controlled group, although the control group had episodes in 6 patients. The overall mortality was reduced from 8 percent to 4.6 percent, but the mortality of those patients whose ICU stay lasted longer than 5 days was reduced from 20 percent to 10 percent. Secondary findings included an improvement in overall morbidity, a decreased percentage of ventilator days, less renal impairment, and a lower incidence of bloodstream infections. These findings have been corroborated by subsequent similar studies, and the principal benefit appears to be a greatly reduced incidence of nosocomial infections and sepsis. It is not known whether the benefits are because of strict euglycemia, to the anabolic properties of insulin, or both, but the maintenance of strict euglycemia appears to be a powerful therapeutic strategy.

Metabolism-Related Complications

“Stress dose steroids” have been advocated for the perioperative treatment of patients on corticosteroid therapy, but recent studies strongly discourage the use of supraphysiologic doses of steroids when patients are on low or maintenance doses (e.g., 5–15 mg) of prednisone daily. Parenteral glucocorticoid treatment need only replicate physiologic replacement steroids in the perioperative period. When patients are on steroid replacement doses equal to or greater than 20 mg per day of prednisone, it may be appropriate to administer additional glucocorticoid doses for no more than two perioperative days.

Adrenal insufficiency may be present in patients with a baseline serum cortisol less than 20 μ g/dL. A rapid provocative test with synthetic adrenocorticotrophic hormone (ACTH) may confirm the diagnosis. After a baseline serum cortisol level is drawn, 250 μ g of cosyntropin is administered. At exactly 30 and 60 min following the dose of cosyntropin, serum cortisol levels are obtained. There should be an incremental increase in the cortisol level of between 7 and 10 μ g/dL for each half hour. If the patient is below these levels, a diagnosis of adrenal insufficiency is made, and glucocorticoid and mineralocorticoid administration is then warranted. Mixed results are common, but the complication of performing major surgery on an adrenally insufficient patient is sudden or profound hypotension.

Thyroid hormone abnormalities usually consist of previously undiagnosed thyroid abnormalities. Hypothyroidism and the so-called “sick-euthyroid syndrome” are more commonly recognized in the critical care setting. When

surgical patients are not progressing satisfactorily in the perioperative period, screening for thyroid abnormalities should be performed. If the results show mild to moderate hypothyroidism, then thyroid replacement should begin immediately and thyroid function studies monitored closely. All patients should be reassessed after the acute illness has subsided regarding the need for chronic thyroid replacement therapy.

PROBLEMS WITH THERMOREGULATION

Hypothermia

Hypothermia is defined as a core temperature less than 35°C (95°F), and is divided into subsets of mild (35–32°C [95–89.6°F]), moderate (32–28°C [89.6–82.4°F]), and severe (<28°C [82.4°F]) hypothermia. Shivering, the body's attempt to reverse the effects of hypothermia, occurs between 37 (98.6°F) and 31°C (87.8°F), but ceases at temperatures below 31°C (87.8°F). Patients who are moderately hypothermic are at higher risk for complications than are those who are more profoundly hypothermic.

Hypothermia creates a coagulopathy that is related to platelet and clotting cascade enzyme dysfunction. This triad of metabolic acidosis, coagulopathy, and hypothermia is commonly found in long operative cases, and in patients with blood dyscrasias. The enzymes that contribute to the clotting cascade and platelet activity are most efficient at normal body temperatures; therefore all measures must be used to reduce heat loss intraoperatively.

The most common cardiac abnormality is the development of arrhythmias when body temperature drops below 35°C (95°F). Bradycardia occurs with temperatures below 30°C (86°F). It is well known that hypothermia may induce carbon dioxide retention resulting in respiratory acidosis. Renal dysfunction of hypothermia manifests itself as a paradoxical polyuria, and is related to an increased glomerular filtration rate, as peripheral vascular constriction creates central shunting of blood. This is potentially perplexing in patients that are undergoing resuscitation for hemodynamic instability, because the brisk urine output provides a false sense of an adequate intravascular fluid volume.

Neurologic dysfunction is inconsistent in hypothermia, but a deterioration in reasoning and decision-making skills progresses as body temperature falls, and profound coma (and a flat EEG) occurs as the temperature drops below 30°C (86°F). The diagnosis of hypothermia is important, so accurate measurement techniques are required to get a true core temperature.

Methods used to warm patients include warm air circulation over the patient, and heated intravenous fluids, and more aggressive measures such as bilateral chest tubes with warm solution lavage, intraperitoneal rewarming lavage, and extracorporeal membrane oxygenation. A rate of temperature rise of 2–4°C (35.6–39.2°F)/h is considered adequate, but the most common complication for nonbypass rewarming is arrhythmia with ventricular arrest.

Hyperthermia

Hyperthermia is a core temperature greater than 38.6°C (101.48°F), and has a host of etiologies (Table 11-9). Hyperthermia can be environmentally induced (e.g., summer heat with inability to dissipate heat or control exposure), iatrogenically induced (e.g., heat lamps and medications), endocrine in origin (e.g., thyrotoxicosis), or neurologically induced (i.e., hypothalamic).

TABLE 11-9 Common Causes of Elevated Temperature in Surgical Patients

Hyperthermia	Hyperpyrexia
Environmental	Sepsis
Malignant hyperthermia	Infection
Neuroleptic malignant syndrome	Drug reaction
Thyrotoxicosis	Transfusion reaction
Pheochromocytoma	Collagen disorders
Carcinoid syndrome	Factitious syndrome
Iatrogenic	Neoplastic disorders
Central/hypothalamic responses	
Pulmonary embolism	
Adrenal insufficiency	

Malignant hyperthermia (MH) occurs after exposure to agents such as succinylcholine and some halothane-based inhalational anesthetics. The presentation is dramatic, with rapid onset of increased temperature, rigors, and myoglobinuria related to myonecrosis. Medications must be discontinued immediately and dantrolene administered (2.5 mg/kg every 5 min) until symptoms subside. Aggressive cooling methods are also implemented, such as an alcohol bath, or packing in ice. In cases of severe malignant hyperthermia, the mortality rate is nearly 30 percent.

Thyrotoxicosis can occur after surgery, because of undiagnosed Graves disease. Hyperthermia ($> 40^{\circ}\text{C}$ [104°F]), anxiety, copious diaphoresis, congestive heart failure (present in about one-fourth of episodes), tachycardia (most commonly atrial fibrillation), and hypokalemia (up to 50 percent of patients), are hallmarks of the disease. The treatment of thyrotoxicosis includes glucocorticoids, propylthiouracil, β blockade, and iodide (Lugol solution) delivered in an emergent fashion. As the name suggests, these patients are usually toxic and require supportive measures as well. Acetaminophen, cooling modalities noted above, and vasoactive agents are often indicated.

ISSUES IN CARING FOR OBESE PATIENTS AND PATIENTS AT THE EXTREMES OF AGE

Surgery in the obese patient has multiple risks, and it is important to optimize these patients before surgery to minimize these risks. Optimization begins preoperatively with teaching about dietary modifications, exercise and pulmonary toilet issues. Obese patients often have eccentric left ventricular hypertrophy, right ventricular hypertrophy, and congestive heart failure. Sleep studies and patient history may also reveal significant sleep apnea and gastroesophageal reflux disease. Glycemic control is often poor and contributes significantly to infection and diabetes. The obese patient has a decrease in antithrombin III levels, and a higher risk of DVT and pulmonary embolism (PE). Measures to optimize physiologic function in obese patients include keeping the head of the bed elevated at all times. This can improve the functional residual capacity of the lungs by almost a liter, thereby decreasing complications associated with atelectasis and pneumonia. Proper glycemic control via a tight insulin sliding scale is also recommended. Finally, the risk of DVT may be attenuated by immediate use of prophylactic doses of low molecular weight heparin (LMWH) and early ambulation.

Issues for surgery in the very young and the very old have many similarities when it comes to potential errors and complications. Perhaps the most notable

similarity is the lack of physiologic reserve. The older adult may have end-organ insufficiency, although the young can have underdeveloped or anomalous organ function that may not yet have become manifest. Similarly, the immune responses at the extremes of age are often compromised. This makes diagnosing an infection difficult; older adults may not be capable of mounting a febrile response, and young children can often resolve fevers overnight, and the cause may remain undiagnosed.

Other alterations in these groups include the amount and distribution of total body water and total body fat. This is important to consider because some medications are predominantly distributed to fat stores, and this deposition may lead to altered drug clearance. Similarly, total body water is decreased and serum concentrations of medications may be higher than anticipated. In both groups there is a lower lean body mass, which may potentiate the adverse effects of some anesthetic agents. Metabolism of various analgesic and anesthetic agents can be protracted, leading to postoperative problems such as prolonged intubation and the need for the administration of reversal agents.

Other issues that can lead to complex decision making include those related to communication. Whether because of neurologic impairments, agitation, confusion, or an inability to comprehend a language, these factors associated with the extremes of age increase the potential for medical errors. Open and direct communication with the supporting family members is critical for optimal outcomes in these patient groups.

Physiologic Monitoring of the Surgical Patient

Louis H. Alarcon and Mitchell P. Fink

Patients are monitored to detect alterations in various physiologic parameters, providing advanced warning of impending deterioration in organ function. With this knowledge, appropriate and timely intervention may be taken to prevent or ameliorate physiologic derangement.

Synthesis of adenosine triphosphate (ATP), the energy “currency” of cells, requires the continuous delivery of oxygen from hemoglobin in red blood cells to the oxidative machinery within mitochondria. In essence, the goal of hemodynamic monitoring is to ensure that the flow of oxygenated blood through the microcirculation is sufficient to support aerobic metabolism at the cellular level. Under normal conditions when the supply of oxygen is plentiful, aerobic metabolism is determined by factors other than the availability of oxygen. These factors include the hormonal milieu and mechanical workload of contractile tissue. However, in pathologic circumstances when oxygen availability is inadequate, oxygen utilization (Vo_2) becomes dependent on oxygen delivery (Do_2). This is the point of critical oxygen delivery ($\text{Do}_{2\text{crit}}$) in which the transition from supply independent to supply dependent oxygen uptake occurs, and is approximately 300 mL/min per square meter.

ARTERIAL BLOOD PRESSURE

Arterial blood pressure is a complex function of both cardiac output and vascular input impedance. Blood pressure can be determined directly by measuring the pressure within the arterial lumen or indirectly using a cuff around an extremity.

Noninvasive Measurement of Arterial Blood Pressure

Both manual and automated means for the noninvasive determination of blood pressure use an inflatable cuff to increase pressure around an extremity. Erroneous measurements can be obtained from inappropriate sized cuffs. Noninvasive measurement of blood pressure requires detection of the arterial pulsations. The auscultation of the Korotkoff sounds is a time-honored method. Systolic pressure is defined as the pressure in the cuff when tapping sounds are first audible. Diastolic pressure is the pressure in the cuff when audible pulsations first disappear.

Another means for pulse detection when measuring blood pressure noninvasively depends on the detection of oscillations in the pressure within the bladder of the cuff. This approach is simple and can be performed even in a noisy environment, however, it is neither accurate nor reliable. Other methods for pulse detection are use of a Doppler stethoscope (reappearance of the pulse produces an audible amplified signal) or a pulse oximeter (reappearance of the pulse is indicated by flashing of a light-emitting diode).

Invasive Monitoring of Arterial Blood Pressure

Direct monitoring of arterial pressure is performed by using fluid-filled tubing to connect an intraarterial catheter to a transducer. The signal generated by the transducer is amplified and displayed as a continuous waveform by an oscilloscope. Digital values for systolic, diastolic and mean pressure, calculated by averaging the amplitude of the pressure waveform, can be displayed.

The fidelity of the catheter-tubing-transducer system is determined by the compliance of the tubing, the surface area of the transducer diaphragm, and the compliance of the diaphragm. If the system is underdamped, the inertia of the system, which is a function of the mass of the fluid in the tubing and the mass of the diaphragm, causes overshoot of the points of maximum positive and negative displacement of the diaphragm. Thus in an underdamped system, systolic pressure will be overestimated and diastolic pressure will be underestimated. In an overdamped system, displacement of the diaphragm fails to track the rapidly changing pressure waveform, and systolic pressure will be underestimated and diastolic pressure will be overestimated. Even in an underdamped or overdamped system, mean pressure will be accurately recorded, provided the system has been properly calibrated.

The radial artery is the site most commonly used for intraarterial pressure monitoring. It should be noted that central (aortic) and peripheral (radial artery) pressures are different as a result of the impedance and inductance of the arterial tree. Systolic pressures typically are higher and diastolic pressures are lower in the periphery, whereas mean pressure is approximately the same in the aorta and distal sites. Complications of arterial cannulation include: distal ischemia, retrograde embolization of air bubbles or thrombi into the intracranial circulation, and catheter-related infections.

ELECTROCARDIOGRAPHIC MONITORING

The electrocardiogram (ECG) records the electrical activity associated with cardiac contraction by detecting voltages on the body surface. A standard 3-lead ECG is obtained by placing electrodes that correspond to the left arm (LA), right arm (RA), and left leg (LL). The ECG waveforms can be continuously displayed on a monitor, and an alarm sounds if an abnormality of rate or rhythm is detected. Monitoring of the ECG waveform is essential in patients with acute coronary syndromes or blunt myocardial injury, because dysrhythmias are the most common lethal complication. In patients with shock or sepsis, dysrhythmias can occur as a consequence of inadequate myocardial oxygen delivery or as a complication of vasoactive or inotropic drugs used to support blood pressure and cardiac output.

Additional information can be obtained from a 12-lead ECG, which is essential for patients with potential acute coronary syndromes or other cardiac complications in acutely ill patients. Continuous monitoring of the 12-lead ECG provides greater sensitivity than 3-lead ECG for the detection of acute myocardial ischemia.

CARDIAC OUTPUT AND RELATED PARAMETERS

Bedside catheterization of the pulmonary artery was introduced to manage patients with cardiogenic shock and other acute cardiac diseases. Indications for this form of invasive hemodynamic monitoring have expanded to encompass a wide variety of clinical conditions.

Determinants of Cardiac Performance

Preload

According to Starling's law the force of muscle contraction depends on the initial length of the cardiac fibers, which represents preload and is determined by end-diastolic volume (EDV). For the right ventricle, central venous pressure (CVP) approximates right ventricular end-diastolic pressure (EDP). For the left ventricle, pulmonary artery occlusion pressure (PAOP), which is measured by transiently inflating a balloon at the end of a pressure monitoring catheter positioned in a small branch of the pulmonary artery, approximates left ventricular end-diastolic pressure. The presence of atrioventricular valvular stenosis will alter this relationship.

EDP is used as a surrogate for EDV, but EDP is determined not only by volume but also by the diastolic compliance of the ventricular chamber. Ventricular compliance is altered by various pharmacologic agents and pathologic conditions. Furthermore, the relationship between EDP and true preload is not linear, but rather is exponential.

Afterload

Afterload is defined as the force resisting fiber shortening once systole begins. Several factors contribute to ventricular afterload, including ventricular intracavitary pressure, wall thickness, chamber radius, and chamber geometry. Because these factors are difficult to assess clinically, afterload is commonly approximated by calculating systemic vascular resistance (SVR), defined as mean arterial pressure (MAP) divided by cardiac output.

Contractility

Contractility is defined as the inotropic state of the myocardium. Contractility is said to increase when the force of ventricular contraction increases at constant preload and afterload. Contractility is difficult to quantify, because the available measures are dependent to a certain degree on preload and afterload. If pressure-volume loops are constructed for each cardiac cycle, small changes in preload and/or afterload will result in shifts of the point defining the end of systole. These end-systolic points on the pressure-versus-volume diagram describe a straight line, known as the isovolumic pressure line. A steeper slope of this line indicates greater contractility.

Placement of Pulmonary Artery Catheters

In its simplest form, the pulmonary artery catheter (PAC) has four channels. One channel terminates in a balloon at the tip of the catheter which permits inflation of the balloon with air. A second channel contains wires that are connected to a thermistor located near the tip of the catheter to permit calculation of cardiac output using the thermodilution technique (see below). The final two channels are used for pressure monitoring and the injection of the thermal indicator for determinations of cardiac output. One of these channels terminates at the tip of the catheter; the other terminates 20 cm proximal to the tip.

Placement of a PAC requires access to the central venous circulation (antecubital, femoral, jugular, and subclavian veins). Cannulation of the vein is normally performed percutaneously, using the Seldinger technique (described elsewhere). An introducer sheath is placed, which is equipped with a diaphragm that permits insertion of the PAC whereas preventing the backflow of blood.

The proximal terminus of the distal port of the PAC is connected to a strain-gauge transducer. Although constantly observing the pressure tracing on an oscilloscope, the PAC is advanced with the balloon deflated until respiratory excursions are observed. The balloon is then inflated, and the catheter advanced further, although monitoring pressures sequentially in the right atrium and right ventricle en route to the pulmonary artery. The catheter is advanced out the pulmonary artery until a damped tracing indicative of the “wedged” position is obtained. The balloon is then deflated, taking care to ensure that a normal pulmonary arterial tracing is again observed on the monitor; leaving the balloon inflated can increase the risk of pulmonary infarction or perforation of the pulmonary artery. Unnecessary measurements of the pulmonary artery occlusion pressure are discouraged as rupture of the pulmonary artery may occur.

Hemodynamic Measurements

The PAC is capable of providing a remarkable amount of information about the hemodynamic status of patients. Additional information may be obtained if various modifications of the standard PAC are employed. By combining data obtained through use of the PAC with results obtained by other means (i.e., blood hemoglobin concentration and oxyhemoglobin saturation), derived estimates of systemic oxygen transport and utilization can be calculated. Table 12-1 summarizes the equations used to calculate the derived parameters and Table 12-2 gives the normal ranges for the measured and calculated hemodynamic values.

Measurement of Cardiac Output by Thermodilution

Measurement of cardiac output (QT) using the thermodilution technique is simple and reasonably accurate. If a bolus of an indicator is rapidly and thoroughly mixed with a moving fluid upstream from a detector, then the concentration of the indicator at the detector will increase sharply and then exponentially diminish back to zero. The area under the resulting time-concentration curve is a function of the volume of indicator injected and the flow rate of the moving stream of fluid. Larger volumes of indicator result in greater areas under the curve, and faster flow rates of the mixing fluid result in smaller areas under the curve. When QT is measured by thermodilution, the indicator is heat and the detector is a temperature-sensing thermistor at the distal end of the PAC. The relationship used for calculating QT is called the Stewart-Hamilton equation:

$$QT = [V \times (TB - TI) \times K1 \times K2] \times \int TB(t)dt$$

in which V is the volume of the indicator injected, TB is the temperature of blood (i.e., core body temperature), TI is the temperature of the indicator, K1 is a constant that is the function of the specific heats of blood and the indicator, K2 is an empirically derived constant that accounts for several factors (the dead space volume of the catheter, heat lost from the indicator as it traverses the catheter, and the injection rate of the indicator), and $\int TB(t)dt$ is the area under the time-temperature curve. In clinical practice, the Stewart-Hamilton equation is solved by a microprocessor.

Determination of cardiac output by the thermodilution method is generally quite accurate, although it tends to overestimate QT at low values. The results

TABLE 12-1 Formulas for Calculation of Hemodynamic Parameters That Can Be Derived by Using Data Obtained by Pulmonary Artery Catheterization

 $Q_T^* (L \cdot \min^{-1} \cdot m^{-2}) = Q_T / BSA$, where BSA is body surface area (m^2)

 $SV (mL) = Q_T / HR$, where HR is heart rate (\min^{-1})

 $SVR (\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5}) = [(MAP - CVP) \times 80] / Q_T$, where MAP is mean arterial pressure (mmHg)

 $SVRI (\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot m^{-2}) = [(MAP - CVP) \times 80] / Q_T^*$
 $PVR (\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5}) = [(PAP - PAOP) \times 80] / Q_T$, where PPA is mean pulmonary artery pressure

 $PVRI (\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot m^{-2}) = [(PAP - PAOP) \times 80] / Q_T^*$
 $RVEDV (mL) = SV / RVEF$
 $\dot{D}O_2 (mL \cdot \min^{-1} \cdot m^{-2}) = Q_T^* \times CaO_2 \times 10$, where CaO_2 is arterial oxygen content (mL/dL)

 $\dot{V}O_2 (mL \cdot \min^{-1} \cdot m^{-2}) = Q_T^* \times (CaO_2 - C\bar{V}O_2) \times 10$, where $C\bar{V}O_2$ is mixed venous oxygen content (mL/dL)

 $CaO_2 = (1.36 \times Hgb \times Sao_2) + (0.003 \times Pao_2)$, where Hgb is hemoglobin concentration (g/dL), Sao_2 is fractional arterial hemoglobin saturation, and Pao_2 is the partial pressure of oxygen in arterial blood

 $C\bar{V}O_2 = (1.36 \times Hgb \times S\bar{V}O_2) + (0.003 \times P\bar{V}O_2)$, where $P\bar{V}O_2$ is the partial pressure of oxygen in pulmonary arterial (mixed venous) blood

 $Q_S / Q_T = (Cco_2 - CaO_2) / (Cco_2 - Cvo_2)$, where Cco_2 (mL/dL) is the content of oxygen in pulmonary end capillary blood

 $Cco_2 = (1.36 \times Hgb) + (0.003 \times PAO_2)$, where PAO_2 is the alveolar partial pressure of oxygen

 $PAO_2 = [FIO_2 \times (P_B - P_{H_2O})] - PaCO_2 / RQ$, where FIO_2 is the fractional concentration of inspired oxygen, P_B is the barometric pressure (mmHg), P_{H_2O} is the water vapor pressure (usually 47 mmHg), $PaCO_2$ is the partial pressure of carbon dioxide in arterial blood (mmHg), and RQ is respiratory quotient (usually assumed to be 0.8)

 $C\bar{V}O_2$ = central venous oxygen pressure; CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; PAOP = pulmonary artery occlusion (wedge) pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_S / Q_T = fractional pulmonary venous admixture (shunt fraction); Q_T = cardiac output; Q_T^* = cardiac output indexed to body surface area (cardiac index); RVEDV = right ventricular end-diastolic volume; RVEF = right ventricular ejection fraction; SV = stroke volume; SVI = stroke volume index; $S\bar{V}O_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; $\dot{V}O_2$ = systemic oxygen utilization. Hgb = concentration of hemoglobin in blood.

generally should be recorded as the mean of two or three determinations obtained at random points in the respiratory cycle. Using cold injectate widens the difference between TB and TI and thereby increases signal-to-noise ratio. Nevertheless, most authorities recommend using room temperature injectate (normal saline or 5 percent dextrose in water) to minimize errors resulting from warming of the fluid as it is transferred from its reservoir to a syringe for injection.

Continuous measurement of QT by thermodilution is possible using a PAC with a heating element that heats the passing blood located upstream from the thermistor. It is then possible to estimate the average blood flow across the

TABLE 12-2 Approximate Normal Ranges for Selected Hemodynamic Parameters in Adults

Parameter	Normal range
CVP	0–6 mmHg
Right ventricular systolic pressure	20–30 mmHg
Right ventricular diastolic pressure	0–6 mmHg
PAOP	6–12 mmHg
Systolic arterial pressure	100–130 mmHg
Diastolic arterial pressure	60–90 mmHg
MAP	75–100 mmHg
Q_T	4–6 L/min
Q_T^*	$2.5\text{--}3.5 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$
SV	40–80 mL
SVR	$800\text{--}1400 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$
SVRI	$1500\text{--}2400 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot \text{m}^{-2}$
PVR	$100\text{--}150 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$
PVRI	$200\text{--}400 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot \text{m}^{-2}$
CaO_2	16–22 mL/dL
CvO_2	~15 mL O ₂ dL blood
$\dot{\text{D}}\text{O}_2$	$400\text{--}660 \text{ mL} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$
$\dot{\text{V}}\text{O}_2$	$115\text{--}165 \text{ mL} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$

CaO_2 = arterial oxygen content; CvO_2 = central venous oxygen pressure; CVP = mean central venous pressure; $\dot{\text{D}}\text{O}_2$ = systemic oxygen delivery; MAP = mean arterial pressure; PAOP = pulmonary artery occlusion (wedge) pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_T = cardiac output; Q_T^* = cardiac output indexed to body surface area (cardiac index); SV = stroke volume; SVI = stroke volume index; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; VO_2 = systemic oxygen utilization.

filament and thereby calculate Q_T . Continuous determinations of Q_T using this approach agree well with data generated by conventional measurements.

Mixed Venous Oximetry

The Fick equation can be written as $Q_T = \text{VO}_2 / (\text{CaO}_2 - \text{CvO}_2)$, in which CaO_2 is the content of oxygen in arterial blood and CvO_2 is the content of oxygen in mixed venous blood. The Fick equation can be rearranged as: $\text{C}\bar{\text{v}}\text{O}_2 = \text{CaO}_2 - \text{VO}_2 / Q_T$. If the small contribution of dissolved oxygen to $\text{C}\bar{\text{v}}\text{O}_2$ and CaO_2 is ignored, the equation can be rewritten as $\text{S}\bar{\text{v}}\text{O}_2 = \text{SaO}_2 - \text{VO}_2 / (Q_T \times \text{Hgb} \times 1.36)$, in which $\text{S}\bar{\text{v}}\text{O}_2$ is the fractional saturation of hemoglobin in mixed venous blood, SaO_2 is the fractional saturation of hemoglobin in arterial blood, and Hgb is the concentration of hemoglobin in blood. Accordingly, low values of $\text{S}\bar{\text{v}}\text{O}_2$ can be caused by a decrease in Q_T (e.g., heart failure or hypovolemia), a decrease in SaO_2 (e.g., intrinsic pulmonary disease), a decrease in Hgb (i.e., anemia), or an increase in metabolic rate (e.g., seizures or fever). With a conventional PAC, intermittent measurements of $\text{S}\bar{\text{v}}\text{O}_2$ require aspirating a sample of blood from the distal (i.e., pulmonary arterial) port of the catheter and injecting the sample into a blood gas analyzer.

By adding a fifth channel to the PAC, it is possible to monitor $S\bar{v}O_2$ continuously. This channel contains two fiber-optic bundles, which are used to transmit and receive light of the appropriate wavelengths to permit measurements of hemoglobin saturation by reflectance spectrophotometry. The device provides measurements of $S\bar{v}O_2$ that agree quite closely with those obtained by conventional analyses of pulmonary arterial blood.

The saturation of oxygen in the right atrium or superior vena cava ($Sc\bar{v}O_2$) correlates closely with $S\bar{v}O_2$ over a wide range of conditions. Because measurement of $Sc\bar{v}O_2$ requires placement of a central venous catheter rather than a PAC, it is somewhat less invasive and easier to carry out. By using a central venous catheter equipped to permit fiber-optic monitoring of $Sc\bar{v}O_2$, it may be possible to improve the resuscitation of patients with shock during the first few critical h after presentation to the hospital.

Right Ventricular Ejection Fraction

Ejection fraction (EF) is calculated as $(EDV - ESV)/EDV$, in which ESV is end-systolic volume. EF is an ejection-phase measure of myocardial contractility. By equipping a PAC with a thermistor with a short time constant, the thermodilution method can be used to estimate right ventricular (RV) EF. Measurements of RVEF by thermodilution agree reasonably well with those obtained by other means. Stroke volume (SV) is calculated as $EDV - ESV$. Left ventricular (LV) SV also equals QT/HR , in which HR is heart rate. Because $LVS\bar{V}$ is equal to $RVS\bar{V}$, it is possible to estimate right ventricular end-diastolic volume (RVEDV) by measuring RVEF, QT, and HR.

Effect of Pulmonary Artery Catheterization on Outcome

Connors and colleagues reported surprising results in a major observational study evaluating the value of pulmonary artery catheterization in critically ill patients. They compared two groups of patients: those who did and those who did not undergo placement of a PAC during their first 24 h of intensive care unit (ICU) care. A critical assessment of this study reveals that the groups were well-matched with respect to a large number of pertinent clinical parameters. They concluded that placement of a pulmonary artery catheter during the first 24 h of stay in an ICU is associated with a significant increase in the risk of mortality, even when statistical methods are used to account for severity of illness.

This study confirmed the results of two prior similar observational studies. The first of these studies used as a database 3263 patients with acute myocardial infarction. Hospital mortality was significantly greater for patients treated using a PAC, even when multivariate statistical methods were employed to control for key potential confounding factors such as age, peak circulating creatine kinase concentration, and presence or absence of new Q waves on the electrocardiogram. The second large observational study of patients with acute myocardial infarction also found that hospital mortality was significantly greater for patients managed with the assistance of a PAC, even when the presence or absence of "pump failure" was considered in the statistical analysis. In neither of these earlier reports did the authors conclude that placement of a PAC was truly the cause of worsened survival after myocardial infarction. As a result of the study by Connors and colleagues, experts in

the field questioned the value of bedside pulmonary artery catheterization, and some even called for a moratorium on the use of the PAC. Relatively few prospective, randomized controlled trials of pulmonary artery catheterization have been performed. All of these studies are flawed in one or more ways.

In the largest randomized controlled trial of the PAC, Sandham and associates randomized American Society of Anesthesiologists (ASA) class III and IV patients undergoing major thoracic, abdominal, or orthopedic surgery to placement of a PAC or CVP catheter. In the patients assigned to receive a PAC, physiologic goal-directed therapy was implemented by protocol. There were no differences in mortality at 30 days, 6 months, or 12 months between the two groups, and ICU length of stay was similar. There was a significantly higher rate of pulmonary emboli in the PAC group (0.9 vs. 0 percent).

Thus, the weight of current evidence suggests that routine pulmonary artery catheterization is not useful for the vast majority of patients undergoing cardiac, major peripheral vascular, or ablative surgical procedures.

One of the reasons for using a PAC is to optimize cardiac output and systemic oxygen delivery. Defining what constitutes the optimum cardiac output, however, has proven to be difficult. Based on an extensive observational database and comparisons of the hemodynamic and oxygen transport values recorded in survivors and nonsurvivors, Bland and colleagues proposed that "goal-directed" hemodynamic resuscitation should aim to achieve a QT greater than 4.5 L/min per square meter and VO_2 greater than 600 mL/min per square meter. A number of investigators have conducted randomized trials designed to evaluate the effect on outcome of goal-directed as compared to conventional hemodynamic resuscitation. Some studies provide support for the notion that interventions designed to achieve supraphysiologic goals for DO_2 , VO_2 , and QT improve outcome. However, other published studies do not support this view, and a meta-analysis concluded that interventions designed to achieve supraphysiologic goals for oxygen transport do not significantly reduce mortality rates in critically ill patients. At this time, supraphysiologic resuscitation of patients in shock cannot be endorsed.

Connors has offered several explanations for the apparent lack of effectiveness of the PAC. First, even though bedside pulmonary artery catheterization is quite safe, the procedure is associated with a finite incidence of serious complications, including ventricular arrhythmias, catheter-related sepsis, central venous thrombosis, pulmonary arterial perforation and pulmonary embolism. The adverse effects of these complications on outcome may equal or even outweigh any benefits associated with using a PAC to guide therapy. Second, the data generated by the PAC may be inaccurate, leading to inappropriate therapeutic interventions. Third, the measurements, even if accurate, are often misinterpreted in practice. Even well-trained intensivists are capable of misinterpreting results provided by pulmonary artery catheterization. Furthermore, the current state of understanding is primitive when it comes to deciding what is the best management for certain hemodynamic disturbances. Taking all of this into consideration, it may be that interventions prompted by measurements obtained with a PAC are actually harmful to patients. As a result, the marginal benefit now available by placing a PAC may be quite small. Less invasive modalities are available that can provide clinically useful hemodynamic information.

Minimally Invasive Alternatives to the Pulmonary Artery Catheter

There has been increasing interest in the development of less invasive methods for monitoring of hemodynamic parameters. None of these methods render the standard thermodilution technique of the PAC obsolete. However, these strategies may contribute to improvements in the hemodynamic monitoring of critically ill patients.

Doppler Ultrasonography

When ultrasonic sound waves are reflected by moving erythrocytes in the bloodstream, the frequency of the reflected signal is increased or decreased, depending on whether the cells are moving toward or away from the ultrasonic source. This change in frequency is called the Doppler shift, and its magnitude is determined by the velocity of the moving red blood cells. Using the cross-sectional area of a vessel and the mean red blood cell velocity of the blood flowing through it, one can calculate blood flow rate. If the vessel in question is the aorta, then QT can be calculated as:

$$QT = HR \times A \times \int V(t)dt$$

in which A is the cross-sectional area of the aorta and $\int V(t)dt$ is the red blood cell velocity integrated over the cardiac cycle.

Two approaches have been developed for using Doppler ultrasonography to estimate QT. The first approach uses an ultrasonic transducer, which is manually positioned in the suprasternal notch and focused on the root of the aorta. Although this approach is completely noninvasive, it requires a highly skilled operator to obtain meaningful results. Moreover, unless QT measured using thermodilution is used to back-calculate aortic diameter, accuracy using the suprasternal notch approach is not acceptable. Accordingly, the method is useful only for obtaining very intermittent estimates of QT, and has not been widely adopted by clinicians.

In the other approach blood flow velocity is continuously monitored in the descending thoracic aorta using a transducer introduced into the esophagus. The device consists of a continuous-wave Doppler transducer mounted at the tip of a transesophageal probe, and continuously measures the blood flow velocity in the descending aorta and the calculated QT. Results using these methods appear to be reasonably accurate across a broad spectrum of patients and are clinically useful. In a multicenter study, good correlation was found between esophageal Doppler and thermodilution ($r = 0.95$), with a small systematic underestimation (bias 0.24 L/min) using esophageal Doppler.

Impedance Cardiography

The impedance to flow of alternating electrical current in regions of the body is commonly called bioimpedance. In the thorax, changes in the volume and velocity of blood in the thoracic aorta lead to detectable changes in bioimpedance. The first derivative of the oscillating component of thoracic bioimpedance (dZ/dt) is linearly related to aortic blood flow. Empirically derived formulas have been developed to estimate SV, and subsequently QT. The approach is attractive because it is noninvasive and provides a continuous readout of QT. However, measurements of QT obtained by impedance cardiography

are not sufficiently reliable to be used for clinical decision-making and have poor correlation with standard methods such as thermodilution and ventricular angiography.

Pulse Contour Analysis

Pulse contour analysis was originally described for estimating SV on a beat-to-beat basis. The mechanical properties of the arterial tree and the SV determine the shape of the arterial pulse waveform. The pulse contour method of estimating QT uses the arterial pressure waveform as an input for a model of the systemic circulation to determine beat-to-beat flow through the circulatory system. The parameters of resistance, compliance, and impedance are initially estimated based on the patient's age and sex, and can be subsequently refined by using a reference standard measurement of QT.

Measurements of QT based on pulse contour monitoring are comparable in accuracy to standard PAC-thermodilution methods, but it uses an approach that is less invasive because arterial and central venous, but not transcardiac, catheterization is needed. Using on-line pressure waveform analysis, the computerized algorithms can calculate SV, QT, systemic vascular resistance, and an estimate of myocardial contractility, the rate of rise of the arterial systolic pressure (dP/dT).

The use of pulse contour analysis has been applied using an even less invasive technology based on totally noninvasive photoplethysmographic measurements of arterial pressure. However, the accuracy of this technique has been questioned and its clinical utility remains to be determined.

Partial Carbon Dioxide Rebreathing

Partial carbon dioxide (CO₂) rebreathing uses the Fick principle to estimate QT noninvasively. By intermittently altering the dead space within the ventilator circuit via a rebreathing valve, changes in CO₂ production (Vco₂) and end-tidal CO₂ (etco₂) are used to determine cardiac output using a modified Fick equation ($QT = \Delta V_{CO_2} / \Delta et_{CO_2}$). Changes in intrapulmonary shunt and hemodynamic instability impair the accuracy of QT estimated by partial CO₂ rebreathing. Continuous in-line pulse oximetry and inspired fraction of inspired O₂ (Fio₂) are used to estimate shunt fraction to correct QT. Some studies suggest that the partial CO₂ rebreathing method for determination of QT compares favorably to measurements made using a PAC in critically ill patients.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) has made the transition from operating room to intensive care unit. TEE requires that the patient be sedated and usually intubated for airway protection. Using this powerful technology, global assessments of LV and RV function can be made, including determinations of ventricular volume, EF, and QT. Segmental wall motion abnormalities, pericardial effusions, and tamponade can be readily identified with TEE. Doppler techniques allow estimation of atrial filling pressures. The technique is somewhat cumbersome and requires considerable training and skill to obtain reliable results.

Assessing Preload Responsiveness

Although pulse contour analysis or partial CO₂ rebreathing may be able to provide fairly reliable estimates regarding SV and QT, these approaches alone offer little or no information about the adequacy of preload. Most clinicians determine preload by measuring CVP or PAOP. However, neither CVP nor PAOP correlate well with the true parameter of interest, left ventricular end-diastolic volume (LVEDV). Extremely high or low CVP or PAOP results are informative, but readings in a large middle zone (i.e., 5–20 mmHg) are not very useful. Furthermore, changes in CVP or PAOP fail to correlate well with changes in stroke volume. Echocardiography can be used to estimate LVEDV, but this approach is dependent on the skill and training of the individual using it, and isolated measurements of LVEDV fail to predict the hemodynamic response to alterations in preload.

When intrathoracic pressure increases during the application of positive airway pressure in mechanically ventilated patients, venous return decreases, and as a consequence, left ventricular stroke volume (LVS_V) also decreases. Therefore, pulse pressure variation (PPV) during a positive pressure episode can be used to predict the responsiveness of cardiac output to changes in preload. PPV is defined as the difference between the maximal pulse pressure and the minimum pulse pressure divided by the average of these two pressures. Patients are considered as being preload responsive if their cardiac index increases by at least 15 percent after rapid infusion of a standard volume of intravenous fluid. Although atrial arrhythmias can interfere with the usefulness of this technique, PPV remains a useful approach for assessing preload responsiveness in most patients because of its simplicity and reliability.

Tissue Capnometry

Global indices of QT, DO₂, or VO₂ provide little useful information regarding the adequacy of cellular oxygenation and mitochondrial function. In theory, measuring tissue pH to assess the adequacy of perfusion is an attractive concept because anaerobiosis is associated with the net accumulation of protons. The detection of tissue acidosis should alert the clinician to the possibility that perfusion is inadequate. Tonometric measurements of tissue Pco₂ in the stomach or sigmoid colon could be used to estimate mucosal pH (pHi) and thereby monitor visceral perfusion in critically ill patients.

Unfortunately, using tonometric estimates of gastrointestinal mucosal pHi for monitoring perfusion is predicated on a number of assumptions, some of which may be invalid. Furthermore, methods for performing measurements of gastric mucosal Pco₂ in the clinical setting remain rather cumbersome and expensive. For these reasons gastric tonometry has primarily been used as a research tool. Some recent developments in the field may change this situation, and monitoring tissue Pco₂ may become common in the near future.

Tonometric determination of mucosal carbon dioxide tension, Pco₂muc, can be used to calculate pHi by using the Henderson-Hasselbalch equation as follows: $pHi = \log ([HCO_3^-]_{muc}/0.03 \times Pco_{2muc})$, in which [HCO₃⁻]_{muc} is the concentration of bicarbonate anion in the mucosa. [HCO₃⁻]_{muc} cannot be measured directly, but must be estimated by assuming that the concentration of bicarbonate anion in arterial blood, [HCO₃⁻]_{art}, is approximately equal to [HCO₃⁻]_{muc}. Under pathologic conditions, however, the assumption that [HCO₃⁻]_{art} \cong [HCO₃⁻]_{muc} is almost certainly invalid.

There is another inherent problem in using pHi as an index of perfusion. As noted above, pHi calculated using the Henderson-Hasselbalch equation is a function of both Pco_2muc and $[\text{HCO}_3^-]_{\text{art}}$. Under steady-state conditions Pco_2muc , reflects the balance between inflow of CO_2 into the interstitial space and outflow of CO_2 from the interstitial space. An increase in Pco_2muc can reflect a decrease in mucosal perfusion, but may also can be caused by arterial hypercarbia, leading to increased diffusion of CO_2 from arterial blood into the interstitium. Thus, tonometrically derived estimates of pHi are not a reliable way to assess mucosal perfusion.

Despite the problems noted above, measurements of gastric pHi and/or mucosal-arterial Pco_2 gap have been proven to be a reliable predictor of outcome in a wide variety of critically ill patients. Moreover, in a landmark prospective, randomized, multicentric clinical trial by Gutierrez and associates of monitoring in medical intensive care unit patients, titrating resuscitation to a gastric pHi endpoint rather than conventional hemodynamic indices resulted in higher 30-day survival rate. In trauma patients, it has been shown that failure to normalize gastric pHi within 24 h was associated with a high mortality rate.

Monitoring tissue Pco_2 (tissue capnometry) will play an increasingly important role in the management of critically ill patients because it provides more reliable information about perfusion than does the derived parameter, pHi . By eliminating the potentially confounding effects of systemic hypocarbia or hypercarbia, calculating and monitoring the gap between tissue Pco_2 and arterial Pco_2 may prove to be even more valuable than simply following changes in tissue Pco_2 . Additionally, monitoring tissue Pco_2 in sites such as the space under the tongue may be as informative as measuring Pco_2 in the wall of the esophagus or the gut and less invasive.

Increased sublingual Pco_2 (Pslco_2) is associated with decreases in arterial blood pressure and QT in patients with shock because of hemorrhage or sepsis. In a study of critically ill patients with septic or cardiogenic shock, the Pslco_2 - Paco_2 gradient was found to be a good prognostic indicator. This study also demonstrated that sublingual capnography was superior to gastric tonometry in predicting patient survival. The Pslco_2 - Paco_2 gradient also correlated with the mixed venous-arterial Pco_2 gradient, but failed to correlate with blood lactate level, mixed venous O_2 saturation ($\text{S}\bar{\text{v}}\text{O}_2$), or systemic DO_2 . These latter findings suggest that the Pslco_2 - Paco_2 gradient may be a better marker of tissue hypoxia than are these other parameters.

RESPIRATORY MONITORING

The ability to monitor various parameters of respiratory function is important in critically ill patients, to assess the adequacy of oxygenation and ventilation, guide weaning and liberation from mechanical ventilation, and detect adverse events associated with respiratory failure and mechanical ventilation.

Arterial Blood Gases

Blood gas analysis provides useful information when caring for patients with respiratory failure and to detect alterations in acid-base balance because of low QT, sepsis, renal failure, severe trauma, medication or drug overdose, or altered mental status. Arterial blood can be analyzed for pH, Po_2 , Pco_2 , HCO_3^- -concentration and calculated base deficit. When indicated, carboxy-hemoglobin and methemoglobin levels also can be measured. Efforts have

been made to decrease the unnecessary use of arterial blood gas analysis. For example, arterial blood gas determinations are not necessary for routine weaning from mechanical ventilation in the majority of postoperative patients.

Blood gas analyses involve the removal of an aliquot of blood from the patient, although continuous bedside arterial blood gas determinations are now possible via an indwelling arterial catheter that contains a biosensor. Excellent agreement between the two methods has been demonstrated.

Determinants of Oxygen Delivery

The primary goal of the cardiovascular and respiratory systems is to deliver oxygenated blood to the tissues. DO_2 is dependent to a greater degree on the oxygen saturation of hemoglobin (Hgb) in arterial blood (Sao_2) than on the partial pressure of oxygen in arterial blood (Pao_2). DO_2 also is dependent on QT and Hgb. Dissolved oxygen in blood, which is proportional to the Pao_2 , makes only a negligible contribution to DO_2 , as is apparent from the equation: $\text{DO}_2 = \text{QT} \times [(\text{Hgb} \times \text{Sao}_2 \times 1.36) + (\text{Pao}_2 \times 0.0031)]$.

Sao_2 in mechanically ventilated patients depends on the mean airway pressure, the fraction of inspired oxygen (Fio_2), and SVO_2 . Thus, when Sao_2 is low, the clinician has only a limited number of ways to improve this parameter. The clinician can increase mean airway pressure by increasing positive-end expiratory pressure (PEEP) or inspiratory time. Fio_2 can be increased to a maximum of 1.0 by decreasing the amount of room air mixed with the oxygen supplied to the ventilator.

Peak and Plateau Airway Pressure

Airway pressures are routinely monitored in mechanically ventilated patients. The peak airway pressure measured at the end of inspiration (Ppeak) is a function of the tidal volume, the resistance of the airways, lung/chest wall compliance, and peak inspiratory flow. The airway pressure measured at the end of inspiration when the inhaled volume is held in the lungs by briefly closing the expiratory valve is termed the plateau airway pressure (Pplateau). Plateau airway pressure is independent of the airways resistance, and is related to the lung/chest wall compliance and tidal volume. Mechanical ventilators monitor Ppeak with each breath and can be set to trigger an alarm if the Ppeak exceeds a predetermined threshold. Pplateau is not measured routinely with each delivered tidal volume, but rather is measured intermittently by setting the ventilator to close the exhalation circuit briefly at the end of inspiration and record the airway pressure when airflow is zero.

If both Ppeak and Pplateau are increased (and tidal volume is not excessive), then the problem is a decrease in the compliance in the lung/chest wall unit. Common causes of this problem include pneumothorax, lobar atelectasis, pulmonary edema, pneumonia, acute respiratory distress syndrome (ARDS), active contraction of the chest wall or diaphragmatic muscles, abdominal distention, and intrinsic PEEP, such as occurs in patients with bronchospasm and insufficient expiratory times. When Ppeak is increased but Pplateau is relatively normal, the primary problem is an increase in airway resistance, such as occurs with bronchospasm, use of a small-caliber endotracheal tube, or kinking or obstruction of the endotracheal tube. A low Ppeak also should trigger an alarm, as it suggests a discontinuity in the airway circuit involving the patient and the ventilator.

Ventilator-induced lung injury (VILI) is now an established clinical entity of great relevance to the care of critically ill patients. Excessive airway pressure and tidal volume adversely affect pulmonary and possibly systemic responses to critical illness. Subjecting the lung parenchyma to excessive pressure, known as barotrauma, can result in parenchymal lung injury, diffuse alveolar damage similar to ARDS, and pneumothorax, and can impair venous return and therefore limit cardiac output. Lung-protective ventilation strategies have been developed to prevent the development of VILI and improve patient outcomes. In a large, multicenter randomized trial of patients with ARDS from a variety of etiologies, limiting plateau airway pressure to less than 30 cm H₂O and tidal volume to less than 6 mL/kg of ideal body weight reduced 28-day mortality by 22 percent relative to a ventilator strategy that used a tidal volume of 12 mL/kg. For this reason, monitoring of plateau pressure and using a low tidal volume strategy in patients with ARDS is now the standard of care.

Pulse Oximetry

Continuous, noninvasive monitoring of arterial oxygen saturation is possible using light-emitting diodes and sensors placed on the skin. Pulse oximetry employs two wavelengths of light (i.e., 660 nm and 940 nm) to analyze the pulsatile component of blood flow between the light source and sensor. Because oxyhemoglobin and deoxyhemoglobin have different absorption spectra, differential absorption of light at these two wavelengths can be used to calculate the fraction of oxygen saturation of hemoglobin. Under normal circumstances, the contributions of carboxyhemoglobin and methemoglobin are minimal. However, if carboxyhemoglobin levels are elevated, the pulse oximeter will incorrectly interpret carboxyhemoglobin as oxyhemoglobin and the arterial saturation displayed will be falsely elevated. When the concentration of methemoglobin is markedly increased, the SaO_2 will be displayed as 85 percent, regardless of the true arterial saturation. The accuracy of pulse oximetry begins to decline at SaO_2 values less than 92 percent, and tends to be unreliable for values less than 85 percent.

Because of its clinical relevance, ease of use, noninvasive nature, and cost-effectiveness, pulse oximetry has become a routine monitoring strategy in patients with respiratory disease, intubated patients, and those undergoing surgical intervention under sedation or general anesthesia. Pulse oximetry is especially useful in the titration of F_{IO_2} and PEEP for patients receiving mechanical ventilation, and during weaning from mechanical ventilation. The widespread use of pulse oximetry has decreased the need for arterial blood gas determinations in critically ill patients.

Capnometry

Capnometry is the measurement of P_{CO_2} in the airway throughout the respiratory cycle. In healthy subjects, end-tidal P_{CO_2} (P_{etCO_2}) is about 1–5 mmHg less than P_{aCO_2} . Thus, P_{etCO_2} can be used to estimate P_{aCO_2} without the need for blood gas determination. However, changes in P_{etCO_2} may not correlate with changes in P_{aCO_2} during a number of pathologic conditions (see below).

Capnography allows the confirmation of endotracheal intubation and continuous assessment of ventilation, integrity of the airway, operation of the ventilator, and cardiopulmonary function. Continuous monitoring with capnography has become routine during surgery under general anesthesia and

for some intensive care patients. A number of situations can be promptly detected with continuous capnography. A sudden reduction in Petco_2 suggests either obstruction of the sampling tubing with water or secretions, or a catastrophic event such as loss of the airway, airway disconnection or obstruction, ventilator malfunction, or a marked decrease in QT. If the airway is connected and patent and the ventilator is functioning properly, then a sudden decrease in Petco_2 should prompt efforts to rule out cardiac arrest, massive pulmonary embolism, or cardiogenic shock. Petco_2 can be persistently low during hyperventilation or with an increase in dead space such as occurs with pulmonary embolization (even in the absence of a change in QT). Causes of an increase in Petco_2 include reduced minute ventilation or increased metabolic rate.

RENAL MONITORING

Urine Output

Bladder catheterization allows the monitoring of urine output, usually recorded hourly. With a patent Foley catheter, urine output is a crude indicator of renal perfusion. The generally accepted normal urine output is 0.5 mL/kg per hour for adults and 1 to 2 mL/kg per hour for neonates and infants. Oliguria may reflect inadequate renal artery perfusion because of hypotension, hypovolemia, or low QT. Low urine flow also can be a sign of intrinsic renal dysfunction. It is important to recognize that normal urine output does not exclude the possibility of impending renal failure.

Bladder Pressure

The triad of oliguria, elevated peak airway pressures, and elevated intraabdominal pressure is known as the abdominal compartment syndrome (ACS). ACS is associated with interstitial edema of the abdominal organs, resulting in elevated intraabdominal pressure. When intraabdominal pressure exceeds venous or capillary pressures, perfusion of the kidneys and other intraabdominal viscera is impaired. Oliguria is a cardinal sign. Although the diagnosis of ACS is a clinical one, measuring intraabdominal pressure is useful to confirm the diagnosis. Ideally, a catheter inserted into the peritoneal cavity could measure intraabdominal pressure to substantiate the diagnosis. In practice, transurethral bladder pressure measurement reflects intraabdominal pressure and is most often used to confirm the presence of ACS. After instilling 50–100 mL of sterile saline into the bladder via a Foley catheter, the tubing is connected to a transducing system to measure bladder pressure. Most authorities agree that a bladder pressure greater than 20–25 mmHg confirms the diagnosis of ACS.

NEUROLOGIC MONITORING

Intracranial Pressure

Because the brain is rigidly confined within the bony skull, cerebral edema or mass lesions increase intracranial pressure (ICP). Monitoring of ICP is currently recommended in patients with severe traumatic brain injury (TBI), defined as a Glasgow Coma Scale (GCS) score ≤ 8 with an abnormal CT scan, and in patients with severe TBI and a normal CT scan if two or more of the following are present: age older than 40 years, unilateral or bilateral

motor posturing, or systolic blood pressure less than 90 mmHg. ICP monitoring also is indicated in patients with acute subarachnoid hemorrhage with coma or neurologic deterioration, intracranial hemorrhage with intraventricular blood, ischemic middle cerebral artery stroke, fulminant hepatic failure with coma and cerebral edema on CT scan, and global cerebral ischemia or anoxia with cerebral edema on CT scan. The goal of ICP monitoring is to ensure that cerebral perfusion pressure (CPP) is adequate to support perfusion of the brain. CPP is equal to the difference between MAP and ICP: $CPP = MAP - ICP$.

Ventriculostomy catheters are one type of ICP measuring device which consist of a fluid-filled catheter inserted into a ventricle and connected to an external pressure transducer. This device permits measurement of ICP and allows drainage of cerebrospinal fluid (CSF) as a means to lower ICP and sample CSF for laboratory studies. Other devices locate the pressure transducer within the central nervous system and are used only to monitor ICP. These devices can be placed in the intraventricular, parenchymal, subdural, or epidural spaces. Ventriculostomy catheters are the accepted standard for monitoring ICP in patients with TBI because of their accuracy, ability to drain CSF, and low complication rate. The associated complications include infection (5 percent), hemorrhage (1.4 percent), catheter malfunction or obstruction (6.3–10.5 percent), and malposition with injury to cerebral tissue.

The purpose of ICP monitoring is to detect and treat abnormal elevations of ICP that may be detrimental to cerebral perfusion and function. In TBI patients, ICP greater than 20 mmHg is associated with unfavorable outcomes. In patients with low CPP, therapeutic strategies to correct CPP can be directed at increasing MAP or decreasing ICP. Although it often has been recommended that CPP be maintained above 70 mmHg, data to support this recommendation are not convincing.

Electroencephalogram and Evoked Potentials

Electroencephalography offers the capacity to monitor global neurologic electrical activity, although evoked potential monitoring can assess pathways not detected by the conventional EEG. Continuous EEG (CEEG) monitoring in the intensive care unit permits ongoing evaluation of cerebral cortical activity. It is especially useful in obtunded and comatose patients. CEEG also is useful for monitoring of therapy for status epilepticus and detecting early changes associated with cerebral ischemia. CEEG can be used to adjust the level of sedation, especially if high-dose barbiturate therapy is being used to manage elevated ICP. Somatosensory and brain stem evoked potentials are less affected by the administration of sedatives than is the EEG. Evoked potentials are useful for localizing brain stem lesions or proving the absence of such structural lesions in cases of metabolic or toxic coma. They also can provide prognostic data in posttraumatic coma.

A recent advance in EEG monitoring is the use of the bispectral index (BIS) to titrate the level of sedative medications. The BIS device is often used in the operating room to continuously monitor the depth of anesthesia. The BIS is an empiric measurement statistically derived from a database of bifrontal EEG recordings and analyzed for burst suppression ratio, relative alpha-to-beta ratio, and bicoherence. The BIS ranges from 0 (isoelectric EEG) to 100 (fully awake). Its use has been associated with lower consumption of anesthetics

during surgery and earlier awakening and faster recovery from anesthesia. The BIS also has been validated as a useful approach for monitoring the level of sedation for ICU patients, using the revised Sedation-Agitation Scale as a gold standard.

Transcranial Doppler Ultrasonography

This modality provides a noninvasive method for evaluating cerebral hemodynamics. Transcranial Doppler (TCD) measurements of middle and anterior cerebral artery blood flow velocity are useful for the diagnosis of cerebral vasospasm after subarachnoid hemorrhage. Although some have proposed using TCD to estimate ICP, studies have shown that TCD is not a reliable method for estimating ICP and CPP. TCD is useful to confirm the clinical examination for determining brain death in patients with confounding factors such as the presence of CNS depressants or metabolic encephalopathy.

Jugular Venous Oximetry

When the arterial oxygen content, hemoglobin concentration, and the oxyhemoglobin dissociation curve are constant, changes in jugular venous oxygen saturation (SjO_2) reflect changes in the difference between cerebral oxygen delivery and demand. Generally, a decrease in SjO_2 reflects cerebral hypoperfusion, whereas an increase in SjO_2 indicates the presence of hyperemia. SjO_2 monitoring cannot detect decreases in regional cerebral blood flow if overall perfusion is normal or above normal. This technique requires the placement of a catheter in the jugular bulb, usually via the internal jugular vein. Catheters that permit intermittent aspiration of jugular venous blood for analysis or continuous oximetry catheters are available.

Low SjO_2 is associated with poor outcomes after TBI. Nevertheless, the value of monitoring SjO_2 remains unproven, and should be used in conjunction with ICP and CPP monitoring.

Transcranial Near-Infrared Spectroscopy

Transcranial near-infrared spectroscopy is a noninvasive continuous monitoring method to determine cerebral oxygenation. It employs technology similar to that of pulse oximetry to determine the concentrations of oxy- and deoxyhemoglobin with near-infrared light and sensors, and takes advantage of the relative transparency of the skull to light in the near-infrared region of the spectrum. This form of monitoring remains largely a research tool at the present time.

Minimally invasive surgery (MIS) describes an area of surgery that crosses all traditional disciplines, from general surgery to neurosurgery. It is not a discipline unto itself, but more a philosophy of surgery, a way of thinking. Minimally invasive surgery is a means of performing major operations through small incisions, often using miniaturized, high-tech imaging systems, to minimize the trauma of surgical exposure.

HISTORICAL BACKGROUND

Although the term minimally invasive surgery is relatively recent, the history of its component parts is nearly 100 years old. What is considered the newest and most popular variety of MIS, laparoscopy, is in fact the oldest. Primitive laparoscopy, placing a cystoscope within an inflated abdomen, was first performed by Kelling in 1901. Illumination of the abdomen required hot elements at the tip of the scope and was dangerous. In the late 1950s, Hopkins described the rod lens, a method of transmitting light through a solid quartz rod with no heat and little light loss. Around the same time, thin quartz fibers were discovered to be capable of trapping light internally and conducting it around corners, opening the field of fiberoptics and allowing the rapid development of flexible endoscopes. In the 1970s, the application of flexible endoscopy grew faster than that of rigid endoscopy except in a few fields such as gynecology and orthopedics. By the mid-1970s, rigid and flexible endoscopes made a rapid transition from diagnostic instruments to therapeutic ones. The explosion of video-assisted surgery in the past 10 years was a result of the development of compact, high-resolution, charge-coupled devices which could be mounted on the internal end of flexible endoscopes or on the external end of a Hopkins telescope. Coupled with bright light sources, fiberoptic cables, and high-resolution video monitors, the videoendoscope has changed our understanding of surgical anatomy and reshaped surgical practice.

THE MINIMALLY INVASIVE TEAM

A typical MIS team may consist of a laparoscopic surgeon and an operating room nurse with an interest in laparoscopic surgery. Adding dedicated laparoscopic assistants and circulating staff with an intimate knowledge of the equipment will add to and enhance the team nucleus. Studies have demonstrated that having a designated laparoscopic team reduces the conversion rate and overall operative time, which is translated into a cost savings for patient and hospital.

PHYSIOLOGY

Even with the least invasive of the MIS procedures, physiologic changes occur. Many minimally invasive procedures require minimal or no sedation, and there are few alterations to the cardiovascular, endocrinologic, or immunologic systems. Minimally invasive procedures that require general anesthesia have a

greater physiologic impact because of the anesthetic agent, the incision (even if small), and the induced pneumoperitoneum.

Laparoscopy

Carbon dioxide and nitrous oxide are used for inflating the abdomen. N_2O had the advantage of being physiologically inert and rapidly absorbed. It also provided better analgesia for laparoscopy performed under local anesthesia when compared with CO_2 or air. Despite initial concerns that N_2O would not suppress combustion, controlled clinical trials have established its safety within the peritoneal cavity. Additionally, nitrous oxide has recently been shown to reduce the intraoperative end-tidal CO_2 and minute ventilation required to maintain homeostasis when compared to CO_2 pneumoperitoneum. The safety of N_2O pneumoperitoneum in pregnancy has yet to be elucidated.

The physiologic effects of CO_2 pneumoperitoneum can be divided into two areas: (1) gas-specific effects and (2) pressure-specific effects. CO_2 is rapidly absorbed across the peritoneal membrane into the circulation. In the circulation, CO_2 creates a respiratory acidosis by the generation of carbonic acid. Body buffers, the largest reserve of which lies in bone, absorb CO_2 (up to 120 L) and minimize the development of hypercarbia or respiratory acidosis during brief endoscopic procedures. Once the body buffers are saturated, respiratory acidosis develops rapidly, and the respiratory system assumes the burden of keeping up with the absorption of CO_2 and its release from these buffers.

In patients with normal respiratory function this is not difficult; the anesthesiologist increases the ventilatory rate or vital capacity on the ventilator. If the respiratory rate required exceeds 20 breaths per min, there may be less efficient gas exchange and increasing hypercarbia. Conversely, if vital capacity is increased substantially, there is a greater opportunity for barotrauma and greater respiratory motion-induced disruption of the upper abdominal operative field. In some situations it is advisable to evacuate the pneumoperitoneum or reduce the intraabdominal pressure to allow time for the anesthesiologist to adjust for hypercarbia. Hypercarbia also causes tachycardia and increased systemic vascular resistance, which elevates blood pressure and increases myocardial oxygen demand.

The pressure effects of the pneumoperitoneum on cardiovascular physiology also have been studied. In the hypovolemic individual, excessive pressure on the inferior vena cava and a reverse Trendelenburg position with loss of lower extremity muscle tone may cause decreased venous return and cardiac output. The most common arrhythmia created by laparoscopy is bradycardia. A rapid stretch of the peritoneal membrane often causes a vagovagal response with bradycardia and occasionally hypotension. With the increased intraabdominal pressure compressing the inferior vena cava, there is diminished venous return from the lower extremities. This has been well documented in the patient placed in the reverse Trendelenburg position for upper abdominal operations. Venous engorgement and decreased venous return promote venous thrombosis. Many series of advanced laparoscopic procedures in which deep venous thrombosis (DVT) prophylaxis was not used demonstrate the frequency of pulmonary embolus. This usually is an avoidable complication with the use of sequential compression stockings, subcutaneous heparin, or low-molecular-weight heparin. The direct effect of the pneumoperitoneum on increasing intrathoracic pressure increases peak inspiratory pressure, pressure across the chest wall,

and also the likelihood of barotrauma. Despite these concerns, disruption of blebs and consequent pneumothoraces are rare after uncomplicated laparoscopic surgery.

Increased intraabdominal pressure decreases renal blood flow, glomerular filtration rate, and urine output. These effects may be mediated by direct pressure on the kidney and the renal vein. The secondary effect of decreased renal blood flow is to increase plasma renin release, thereby increasing sodium retention. Increased circulating antidiuretic hormone (ADH) levels also are found during the pneumoperitoneum, increasing free water reabsorption in the distal tubules. Although the effects of the pneumoperitoneum on renal blood flow are immediately reversible, the hormonally mediated changes, such as elevated ADH levels, decrease urine output for up to 1 h after the procedure has ended. Intraoperative oliguria is common during laparoscopy, but the urine output is not a reflection of intravascular volume status. Early it was predicted that the surgical stress response would be significantly lessened with laparoscopic surgery, but this is not always the case. Serum cortisol levels after laparoscopic operations are often higher than after the equivalent operation performed through an open incision. In terms of endocrine balance, the greatest difference between open and laparoscopic surgery is the more rapid equilibration of most stress-mediated hormone levels after laparoscopic surgery. Immune suppression also is less after laparoscopy than after open surgery. There is a trend toward more rapid normalization of cytokine levels after a laparoscopic procedure than after the equivalent procedure performed by celiotomy.

Thoracoscopy

The physiology of thoracic MIS (thoracoscopy) is different from that of laparoscopy. Because of the bony confines of the thorax it is unnecessary to use positive pressure when working in the thorax. The disadvantages of positive pressure in the chest include decreased venous return, mediastinal shift, and the need to keep a firm seal at all trocar sites. Without positive pressure, it is necessary to place a double-lumen endotracheal tube so that the ipsilateral lung can be deflated when the operation starts. By collapsing the ipsilateral lung, working space within the thorax is obtained. Because insufflation is unnecessary in thoracoscopic surgery, it can be beneficial to use standard instruments via extended port sites in conjunction with thoracoscopic instruments. This approach is particularly useful when performing advanced procedures such as thoracoscopic anatomic pulmonary resection.

Extracavitary Minimally Invasive Surgery

Many new MIS procedures are creating working spaces in extrathoracic and extraperitoneal locations. Laparoscopic inguinal hernia repair usually is performed in the anterior extraperitoneal Retzius space. Laparoscopic nephrectomy often is performed with retroperitoneal laparoscopy. Recently, an endoscopic retroperitoneal approach to pancreatic necrosectomy has been introduced. Lower extremity vascular procedures and plastic surgical endoscopic procedures require the development of working space in unconventional planes, often at the level of the fascia, sometimes below the fascia, and occasionally in nonanatomic regions. Some of these techniques use insufflation of gas, but many use balloon inflation to develop the space, followed by low-pressure gas insufflation or lift devices to maintain the space. These techniques

produce fewer and less severe adverse physiologic consequences than does the pneumoperitoneum, but the insufflation of gas into extraperitoneal locations can spread widely, causing subcutaneous emphysema and metabolic acidosis.

Anesthesia

MIS procedures usually are outpatient procedures, and short-acting anesthetic agents are preferable. Because the factors that require hospitalization after laparoscopic procedures include the management of nausea, pain, and urinary retention, the anesthesiologist should minimize the use of agents that provoke these conditions and maximize the use of medications that prevent such problems. Critical to the anesthesia management of these patients is the use of nonnarcotic analgesics (e.g., ketorolac) and the liberal use of antiemetic agents.

GENERAL PRINCIPLES OF ACCESS AND EQUIPMENT

The most natural ports of access for MIS are the anatomic portals of entry and exit. The nares, mouth, urethra, and anus are used to access the respiratory, gastrointestinal, and urinary systems. The advantage of using these points of access is that no incision is required. The disadvantages lie in the long distances between the orifice and the region of interest.

Increasingly, vascular access is obtained with percutaneous techniques using a small incision, a needle, and a guidewire, over which are passed a variety of different sized access devices. This approach, known as the Seldinger technique, is most frequently used by general surgeons for placement of Hickman catheters, but also is used to gain access to the arterial and venous system for performance of minimally invasive procedures. Guidewire-assisted, Seldinger-type techniques also are helpful for gaining access to the gut for procedures such as percutaneous endoscopic gastrostomy, for gaining access to the biliary system through the liver, and for gaining access to the upper urinary tract.

In thoracoscopic surgery, the access technique is similar to that used for placement of a chest tube. In these procedures general anesthesia and split-lung ventilation are essential. A small incision is made over the top of a rib and, under direct vision, carried down through the pleura. The lung is collapsed, and a trocar is inserted across the chest wall to allow access with a telescope. Once the lung is completely collapsed, subsequent access may be obtained with direct puncture, viewing all entry sites through the videoendoscope. Because insufflation of the chest is unnecessary, simple ports that keep the small incisions open are all that is required to allow repeated access to the thorax.

Laparoscopic Access

The requirements for laparoscopy are more involved, because the creation of a pneumoperitoneum requires that instruments of access (trocars) contain valves to maintain abdominal inflation.

Two methods are used for establishing abdominal access during laparoscopic procedures. The first, direct puncture laparoscopy, begins with the elevation of the relaxed abdominal wall with two towel clips or a well-placed hand. A small incision is made in the umbilicus, and a specialized spring-loaded (Veress) needle is placed in the abdominal cavity. With the Veress needle, two distinct pops are felt as the surgeon passes the needle through the

abdominal wall fascia and the peritoneum. The umbilicus usually is selected as the preferred point of access because in this location the abdominal wall is quite thin, even in obese patients. The abdomen is inflated with a pressure-limited insufflator. CO₂ gas is usually used, with maximal pressures in the range of 14–15 mmHg. During the process of insufflation it is essential that the surgeon observe the pressure and flow readings on the monitor to confirm an intraperitoneal location of the Veress needle tip. Laparoscopic surgery can be performed under local anesthesia, but general anesthesia is preferable. Under local anesthesia, N₂O is used as the insufflating agent, and insufflation is stopped after 2 L of gas is insufflated or when a pressure of 10 mmHg is reached.

After peritoneal insufflation, direct access to the abdomen is obtained with a 5- or 10-mm trocar. The critical issues for safe direct-puncture laparoscopy include the use of a vented stylet for the trocar, or a trocar with a safety shield or dilating tip. The trocar must be pointed away from the sacral promontory and the great vessels. Patient position should be surveyed prior to trocar placement to ensure a proper trajectory. For performance of laparoscopic cholecystectomy, the trocar is angled toward the right upper quadrant.

Occasionally the direct peritoneal access (Hasson) technique is advisable. With this technique, the surgeon makes a small incision just below the umbilicus and under direct vision locates the abdominal fascia. Two Kocher clamps are placed on the fascia, and with a curved Mayo scissors a small incision is made through the fascia and underlying peritoneum. A finger is placed into the abdomen to make sure that there is no adherent bowel. A sturdy suture is placed on each side of the fascia and secured to the wings of a specialized trocar, which is then passed directly into the abdominal cavity. For safe access to the abdominal cavity, it is critical to visualize all sites of trocar entry. At the completion of the operation, all trocars are removed under direct vision and the insertion sites are inspected for bleeding. If bleeding occurs, direct pressure with an instrument from another trocar site or balloon tamponade with a Foley catheter placed through the trocar site generally stops the bleeding within 3–5 min. It generally is agreed that 5-mm trocars need no site suturing. Ten-mm trocars placed off the midline and above the transverse mesocolon do not require repair. Conversely, if the fascia has been dilated to allow the passage of the gallbladder, all midline 10-mm trocar sites should be repaired at the fascial level with interrupted sutures.

Access for Subcutaneous and Extraperitoneal Surgery

There are two methods for gaining access to nonanatomic spaces. For retroperitoneal locations, balloon dissection is effective. This access technique is appropriate for the extraperitoneal repair of inguinal hernias and for retroperitoneal surgery for adrenalectomy, nephrectomy, lumbar discectomy, pancreatic necrosectomy, or para-aortic lymph node dissection. The initial access to the extraperitoneal space is performed in a way similar to direct puncture laparoscopy, except that the last layer (the peritoneum) is not traversed. Once the transversalis fascia has been punctured, a specialized trocar with a balloon on the end is introduced. The balloon is inflated in the extraperitoneal space to create a working chamber. The balloon then is deflated and a Hasson trocar is placed. An insufflation pressure of 10 mmHg usually is adequate to

keep the extraperitoneal space open for dissection and will limit subcutaneous emphysema.

Hand-Assisted Laparoscopic Access

Hand-assisted laparoscopic surgery (HALS) is thought to combine the tactile advantages of open surgery with the minimal access of laparoscopy and thoracoscopy. This approach is commonly used to assist with difficult cases before conversion to celiotomy is necessary. Additionally, HALS is employed to help surgeons negotiate the steep learning curve associated with advanced laparoscopic procedures. This technology employs a “port” for the hand which preserves the pneumoperitoneum and enables endoscopic visualization in combination with the use of minimally invasive instruments.

Port Placement

Trocars for the surgeon’s left and right hand should be placed at least 10 cm apart. For most operations it is possible to orient the telescope between these two trocars and slightly retract from them. The ideal trocar orientation creates an equilateral triangle between the surgeon’s right hand, left hand, and the telescope, with 10–15 cm on each leg. If one imagines the target of the operation (e.g., the gallbladder or gastroesophageal junction) oriented at the apex of a second equilateral triangle built on the first, these four points of reference create a diamond. The surgeon stands behind the telescope, which provides optimal ergonomic orientation but frequently requires that a camera operator (or robotic arm) reach between the surgeon’s hands to guide the telescope.

The position of the operating table should permit the surgeon to work with both elbows in at the sides, with arms bent 90 degrees at the elbow. It usually is necessary to alter the operating table position with left or right tilt with the patient in the Trendelenburg or reverse Trendelenburg position, depending on the operative field.

Imaging Systems

Two methods of videoendoscopic imaging are widely used. Both methods use a camera with a charge-coupled device (CCD), which is an array of photo-sensitive sensor elements (pixels) that convert the incoming light intensity to an electric charge. The electric charge is subsequently converted into a black-and-white image. The first of these is flexible videoendoscopy, in which the CCD camera is placed on the internal end of a long, flexible endoscope. In the second method, thin quartz fibers are packed together in a bundle, and the CCD camera is mounted on the external end of the endoscope. Most standard gastrointestinal endoscopes have the CCD chip at the distal end, but small, delicate choledochoscopes and nephroscopes are equipped with fiberoptic bundles. Distally mounted CCD chips were developed for laparoscopy, but are unpopular.

Video cameras come in two basic designs. The one-chip camera has a black-and-white video chip that has an internal processor capable of converting gray scales to approximate colors. Perfect color representation is not possible with a one-chip camera, but perfect color representation is rarely necessary for endosurgery. The most accurate color representation is obtained using a three-chip video camera. A three-chip camera has red, green, and blue (RGB) input, and is identical to the color cameras used for television production. RGB

imaging provides the highest fidelity, but is probably not necessary for everyday use. Priorities in a video system for MIS are illumination first, resolution second, and color third. Without the first two attributes, video surgery is unsafe. Imaging for laparoscopy, thoracoscopy, and subcutaneous surgery uses a rigid metal telescope, usually 30 cm in length. This telescope contains a series of quartz optical rods with differing optical characteristics that provide a specific character to each telescope. These metal telescopes vary in size from 2–10 mm in diameter. Because light transmission is dependent on the cross-sectional area of the quartz rod, when the diameter of a rod/lens system is doubled, the illumination is quadrupled.

Rigid telescopes may have a flat or angled end. The flat end provides a straight view (0 degrees), and the angled end provides an oblique view (30 or 45 degrees). Angled scopes allow greater flexibility in viewing a wider operative field through a single trocar site; rotating an angled telescope changes the field of view. The use of an angled telescope has distinct advantages for most videoendoscopic procedures, particularly in visualizing the common bile duct during laparoscopic cholecystectomy or visualizing the posterior esophagus or the tip of the spleen during laparoscopic fundoplication.

Light is delivered to the endoscope through a fiberoptic light cable. These light cables are highly inefficient, losing more than 90 percent of the light delivered from the light source. Extremely bright light sources (300 watts) are necessary to provide adequate illumination for video endosurgery.

The quality of the videoendoscopic image is only as good as the weakest component in the imaging chain. Therefore it is important to use a video monitor that has a resolution equal to or greater than the camera being used. Resolution is the ability of the optical system to distinguish between line pairs. The larger the number of line pairs per millimeter, the sharper and more detailed the image. Most high-resolution monitors have up to 700 horizontal lines. High-definition television (HDTV) can deliver up to eight times more resolution than the standard NTSC/PAL monitors; when combined with digital enhancement, a very sharp and well-defined image can be achieved.

Energy Sources for Endoscopic and Endoluminal Surgery

MIS uses conventional energy sources, but the requirement of bloodless surgery to maintain optimal visualization has spawned new ways of applying energy. The most common energy source is radiofrequency (RF) electrosurgery using an alternating current with a frequency of 500,000 cycles/s (Hz). Tissue heating progresses through the well-known phases of coagulation (60°C [140°F]), vaporization and desiccation (100°C [212°F]), and carbonization (>200°C [392°F]).

The two most common methods of delivering RF electrosurgery are with monopolar and bipolar electrodes. With monopolar electrosurgery a remote ground plate on the patient's leg or back receives the flow of electrons that originate at a point source, the surgical electrode. A fine-tipped electrode causes a high current density at the site of application and rapid tissue heating. Monopolar electrosurgery is inexpensive and easy to modulate to achieve different tissue effects. A short-duration, high-voltage discharge of current (coagulation current) provides extremely rapid tissue heating. Lower-voltage, higher-wattage current (cutting current) is better for tissue desiccation and vaporization. When the surgeon desires tissue division with the least

amount of thermal injury and least coagulation necrosis, a cutting current is used.

With bipolar electrosurgery the electrons flow between two adjacent electrodes. The tissue between the two electrodes is heated and desiccated. There is little opportunity for tissue cutting when bipolar current is used, but the ability to coapt the electrodes across a vessel provides the best method of small-vessel coagulation without thermal injury to adjacent tissues.

To avoid thermal injury to adjacent structures, the laparoscopic field of view must include all uninsulated portions of the electrosurgical electrode. Additionally, the integrity of the insulation must be maintained and assured. Capacitive coupling occurs when a plastic trocar insulates the abdominal wall from the current; in turn the current is bled off of a metal sleeve or laparoscope into the viscera. This may result in thermal necrosis and a delayed fecal fistula. Another potential mechanism for unrecognized visceral injury may occur with the direct coupling of current to the laparoscope and adjacent bowel.

With endoscopic endoluminal surgery, radiofrequency alternating current in the form of a monopolar circuit represents the mainstay for procedures such as snare polypectomy, sphincterotomy, lower esophageal sphincter ablation, and "hot" biopsy. A grounding ("return") electrode is necessary for this form of energy. Bipolar electrocoagulation is used primarily for thermal hemostasis. The electrosurgical generator is activated by a foot pedal so the endoscopist may keep both hands free during the endoscopic procedure.

Methods of producing shock waves or heat with ultrasonic energy are also of interest. Extracorporeal shockwave lithotripsy creates focused shock waves that intensify as the focal point of the discharge is approached. When the focal point is within the body, large amounts of energy are capable of fragmenting stones. Slightly different configurations of this energy can be used to provide focused internal heating of tissues. Potential applications of this technology include the ability to noninvasively produce sufficient internal heating to destroy tissue without an incision.

A third means of using ultrasonic energy is to create rapidly oscillating instruments that are capable of heating tissue with friction; this technology represents a major step forward in energy technology. An example of its application is the laparoscopic coagulation shears (LCS) device (Harmonic Scalpel), which is capable of coagulating and dividing blood vessels by first occluding them and then providing sufficient heat to weld the blood vessel walls together and to divide the vessel. This nonelectric method of coagulating and dividing tissue with a minimal amount of collateral damage has facilitated the performance of numerous endosurgical procedures. It is especially useful in the control of bleeding from medium-sized vessels that are too big to manage with monopolar electrocautery and require bipolar desiccation followed by cutting.

Instrumentation

Hand instruments for MIS usually are duplications of conventional surgical instruments made longer, thinner, and smaller at the tip. It is important to remember that when grasping tissue with laparoscopic instruments, a greater force is applied over a smaller surface area, which increases the risk for perforation or injury.

Certain conventional instruments such as scissors are easy to reproduce with a diameter of 3–5 mm and a length of 20–45 cm, but other instruments, such as forceps and clamps, cannot provide remote access. Different configurations of graspers were developed to replace the various configurations of surgical forceps and clamps. Standard hand instruments are 5 mm in diameter and 30 cm in length, but smaller and shorter hand instruments are now available for pediatric surgery, for microlaparoscopic surgery, and for arthroscopic procedures.

Robotic Assistance

The term “robot” defines a device that has been programmed to perform specific tasks in place of those usually performed by people. The equipment that has been introduced under the heading of robotic assistance would perhaps be more aptly termed computer-assisted surgery, as it is controlled entirely by the surgeon for the purpose of improving team performance. An example of computer-assisted surgery includes laparoscopic camera holders, which enable the surgeon to maneuver the laparoscope either with head movements or voice activation. Randomized studies with such camera holders have demonstrated a reduction in operative time, steadier image, and a reduction in the number of required laparoscope cleanings. This device has the advantage of eliminating the need for a human camera holder, which serves to free valuable operating room personnel for other duties.

Room Setup and the Minimally Invasive Suite

Nearly all MIS, whether using fluoroscopic, ultrasound, or optical imaging, incorporates a video monitor as a guide. Occasionally two images are necessary to adequately guide the operation, as in procedures such as endoscopic retrograde cholangiopancreatography (ERCP), laparoscopic common bile duct exploration, and laparoscopic ultrasonography. When two images are necessary, the images should be displayed on two adjacent video monitors or projected on a single screen with a picture-in-picture effect. The video monitor(s) should be set across the operating table from the surgeon. The patient should be interposed between the surgeon and the video monitor; ideally, the operative field also lies between the surgeon and the monitor. In pelviscopic surgery it is best to place the video monitor at the patient’s feet, and in laparoscopic cholecystectomy, the monitor is placed at the 10 o’clock position (relative to the patient) while the surgeon stands on the patient’s left at the 4 o’clock position. The insufflating and patient-monitoring equipment ideally also is placed across the table from the surgeon, so that the insufflating pressure and the patient’s vital signs and end-tidal CO₂ tension can be monitored.

The development of the minimally invasive surgical suite has been a tremendous contribution to the field of laparoscopy in that it has facilitated the performance of advanced procedures and techniques. By having the core equipment (monitors, insufflators, and imaging equipment) located within mobile, ceiling-mounted consoles, the surgery team is able to accommodate and make small adjustments rapidly and continuously throughout the procedure. The specifically designed minimally invasive surgical suite serves to decrease equipment and cable disorganization, ease the movements of operative personnel around the room, improve ergonomics, and facilitate the use of advanced imaging equipment such as laparoscopic ultrasound.

Patient Positioning

Patients usually are placed in the supine position for laparoscopic surgery. When the operative field is the gastroesophageal junction or the left lobe of the liver, it is easiest to operate from between the legs. The legs may be elevated in Allen stirrups or abducted on leg boards to achieve this position. When pelvic procedures are performed, it usually is necessary to place the legs in Allen stirrups to gain access to the perineum. A lateral decubitus position with the table flexed provides the best access to the retroperitoneum when performing nephrectomy or adrenalectomy. For laparoscopic splenectomy, a 45-degree tilt of the patient provides excellent access to the lesser sac and the lateral peritoneal attachments to the spleen. For thoracoscopic surgery, the patient is placed in the lateral position with table flexion to open the intercostal spaces and the distance between the iliac crest and costal margin.

SPECIAL CONSIDERATIONS

Pediatric Considerations

The advantages of MIS in children may be more significant than in the adult population. MIS in the adolescent is little different from that in the adult, and standard instrumentation and trocar positions can usually be used. However, laparoscopy in the infant and young child requires specialized instrumentation. The instruments are shorter (15–20 cm), and many are 3 mm in diameter rather than 5 mm. Because the abdomen of the child is much smaller than that of the adult, a 5-mm telescope provides sufficient illumination for most operations. The development of 5-mm clippers and bipolar devices has obviated the need for 10-mm trocars in pediatric laparoscopy.

Pregnancy

Concerns about the safety of laparoscopic cholecystectomy or appendectomy in the pregnant patient have been eliminated. The pH of the fetus follows the pH of the mother linearly, and therefore fetal acidosis may be prevented by avoiding a respiratory acidosis in the mother. Experience in well over 100 cases of laparoscopic cholecystectomy in pregnancy have been reported with uniformly good results. The operation should be performed during the second trimester if possible. Access to the abdomen in the pregnant patient should take into consideration the height of the uterine fundus, which reaches the umbilicus at 20 weeks. In order not to damage the uterus or its blood supply, most surgeons feel that the open (Hasson) approach should be used in favor of direct puncture laparoscopy. The patient should be positioned slightly on the left side to avoid compression of the vena cava by the uterus. Because pregnancy poses a risk for thromboembolism, sequential compression devices are essential for all procedures.

Cancer

MIS techniques have been used for many decades to provide palliation for the patient with an obstructive cancer. Laser treatment, intracavitary radiation, stenting, and dilation are outpatient techniques that can be used to reestablish the continuity of an obstructed esophagus, bile duct, ureter, or airway. Laparoscopy also is used to assess the liver in patients being evaluated for pancreatic, gastric, or hepatic resection.

The most controversial role of MIS techniques is that of providing potentially curative surgery to the patient with cancer. It is possible to perform laparoscopy-assisted colectomy, gastrectomy, pancreatectomy, and hepatectomy in patients with intraabdominal malignant disease, and thoracoscopic esophagectomy and pneumonectomy in patients with intrathoracic malignant disease. There are not yet enough data to indicate whether minimally invasive surgical techniques provide survival rates or disease-free intervals comparable to those of conventional surgical techniques. It has been proven that in laparoscopy-assisted colectomy and gastrectomy a number of lymph nodes equal to that of an open procedure can be removed without any compromise of resection margins. A second concern centers on excessive tumor manipulation and the possibility that cancer cells would be shed during the dissection.

Cirrhosis and Portal Hypertension

Patients with hepatic insufficiency pose a significant challenge for any type of surgical intervention. The ultimate surgical outcome in this population relates directly to the degree of underlying hepatic dysfunction. Often, this group of patients has minimal reserve, and the stress of an operation will trigger complete hepatic failure or hepatorenal syndrome. These patients are at risk for major hemorrhage at all levels, including trocar insertion, operative dissection in a field of dilated veins, and secondary to an underlying coagulopathy. Additionally, ascitic leak from a port site may occur, leading to bacterial peritonitis. Therefore a watertight port site closure should be carried out in all patients.

It is essential that the surgeon be aware of the Child class of severity of cirrhosis of the patient prior to intervening so that appropriate preoperative optimization can be completed. For example, if a patient has an eroding umbilical hernia and ascites, a preoperative paracentesis or transjugular intrahepatic portosystemic shunt (TIPS) procedure in conjunction with aggressive diuresis may be considered. Because these patients commonly are intravascularly depleted, insufflation pressures should be reduced to prevent a decrease in cardiac output and minimal amounts of low-salt intravenous fluids should be given.

ROBOTIC SURGERY

Computer-enhanced ("robotic") surgery was developed with the intent of circumventing the limitations of laparoscopy and thoracoscopy, and to make minimally invasive surgical techniques accessible to those without a laparoscopic background. Additionally, remote site surgery (telesurgery), in which the surgeon is a great distance from the patient (e.g., combat or space), has potential future applications. This was recently exemplified when a team of surgeons located in New York performed a cholecystectomy on a patient located in France.

These devices offer a three-dimensional view with hand- and wrist-controlled instruments that possess multiple degrees of freedom, thereby facilitating surgery with a one-to-one movement ratio that mimics open surgery. Additionally, computer-enhanced surgery also offers tremor control. The surgeon is physically separated from the operating table and the working arms of the device are placed over the patient. An assistant remains at the bedside and changes the instruments as needed.

Because this equipment is very costly, a primary limitation to its uniform acceptance has been attempting to achieve increased value in the form of improved clinical outcomes. There have been two randomized controlled trials

that compared robotic and conventional laparoscopic approaches to Nissen fundoplication. Although there was a reduction in operative time, there was no difference in ultimate outcome. Similar results have been achieved for laparoscopic cholecystectomy. Finally, it may be too early in its development (because of bulky equipment, difficulty in accessing patients, and limited instrumentation) for widespread adoption of this technology.

ENDOLUMINAL SURGERY

The fields of vascular surgery, interventional radiology, neuroradiology, gastroenterology, general surgery, pulmonology, and urology all encounter clinical scenarios that require the urgent restoration of luminal patency of a “biologic cylinder.” Based on this need, fundamental techniques have been pioneered that are applicable to all specialties and virtually every organ system. As a result, all minimally invasive surgical procedures, from coronary artery angioplasty to palliation of pancreatic malignancy, involve the use of an endoluminal balloon, dilator, prostheses, biopsy forceps, chemical agent, or thermal technique (Table 13-1). Endoluminal balloon dilators may be inserted through an endoscope, or they may be fluoroscopically guided. Balloon dilators all have low compliance—that is, the balloons do not stretch as the pressure within the balloon is increased. The high pressures achievable in the balloon create radial expansion of the narrowed vessel or orifice, usually disrupting the atherosclerotic plaque, the fibrotic stricture, or the muscular band (e.g., esophageal achalasia).

Once the dilation has been attained, it is frequently beneficial to hold the lumen open with a stent. Stenting is particularly valuable in treating malignant lesions and in endovascular procedures. Stenting usually is not applicable for long-term management of benign gastrointestinal strictures except in patients with limited life expectancy.

A variety of stents are available that are divided into two basic categories, plastic stents and expandable metal stents. Plastic stents came first and are used widely as endoprostheses for temporary bypass of obstructions in the

TABLE 13-1 Modalities and Techniques of Restoring Luminal Patency

Modality	Technique
Core out	Photodynamic Therapy Laser Coagulation Endoscopic biopsy forceps Chemical Ultrasound
Fracture	Ultrasound Endoscopic biopsy Balloon
Dilate	Balloon Bougie Angioplasty Endoscope
Bypass	Transvenous intrahepatic portosystemic shunt Surgical (synthetic or autologous conduit)
Stent	Self-expanding metal stent Plastic stent

biliary or urinary systems. Metal stents generally are delivered over a balloon and expanded with the balloon to the desired size. These metal stents usually are made of titanium or nitinol. Although great progress has been made with expandable metal stents, two problems remain: propensity for tissue ingrowth through the interstices of the stent and stent migration. Most recently, anticoagulant-eluting coronary artery stents have been placed in specialized centers. This exciting technological advance may dramatically increase the long-term patency rates of stents placed in patients with coronary artery disease and peripheral atherosclerosis.

Intraluminal Surgery

The successful application of minimally invasive surgical techniques to the lumen of the gastrointestinal tract has hinged on the development of a port that maintains access to the gastrointestinal lumen while preventing intraperitoneal leakage of intestinal contents and facilitating adequate insufflation.

Procedures that are gaining acceptance include resection of benign and early malignant gastric tumors, transanal resection of polyps (transanal endoscopic microsurgery), pancreatic cyst gastrotomy, and biliary sphincterotomy.

The location of the lesion within the gastrointestinal tract is of utmost importance when considering an intraluminal approach. For example, a leiomyoma that is located on the anterior gastric wall may not be amenable to intraluminal resection because the working ports must also penetrate the anterior surface of the stomach. Preoperative endoscopy and endoscopic ultrasound should be routinely employed to determine resectability.

EDUCATION AND SKILL ACQUISITION

Surgeons in Training and Skill Acquisition

Surgeons in training acquire their skills in minimally invasive techniques through a series of operative experiences of graded complexity. This training occurs on patients. With the recent constraints placed on resident work hours, providing adequate minimally invasive training to future surgeons within a relatively brief time frame has become of paramount importance.

Laparoscopic surgery demands a unique set of skills that require the surgeon to function at the limit of his or her psychomotor abilities. The introduction of virtual reality training devices presents a unique opportunity to improve and enhance experiential learning in endoscopy and laparoscopy for all surgeons. This technology has the advantage of enabling objective measurement of psychomotor skills, which can be used to determine progress in skill acquisition, and ultimately technical competency. This technology will most likely be used to create benchmarks for the performance of future minimally invasive techniques. Additionally, virtual reality training enables the surgeon to build an experience base prior to venturing into the operating room. Be that as it may, no studies have demonstrated that simulator training improves overall patient outcome.

Some hospitals and training programs have established virtual reality and laparoscopic training centers that are accessible at all hours for surgeons' use.

Telementoring

In response to the Institute of Medicine's call for the development of unique technologic solutions to deliver health care to rural and underserved areas,

surgeons are beginning to explore the feasibility of telementoring. Teleconsultation or telementoring is two-way audio and visual communication between two geographically separated providers. This communication can take place in the office setting, or directly in the operating room when complex scenarios are encountered. Although local communication channels may limit its performance in rural areas, the technology is available and currently being employed.

INNOVATION AND INTRODUCTION OF NEW PROCEDURES

The revolution in minimally invasive general surgery, which occurred in 1990, created ethical challenges for the profession. The problem was: If competence is gained from experience, how was the surgeon to climb the competency curve (otherwise known as the learning curve) without injuring patients? If it was indeed impossible to achieve competence without making mistakes along the way, how should one effectively communicate this to patients such that they understand the weight of their decisions? Even more fundamentally important is determining the path that should be followed before one recruits the first patient for a new procedure.

Although procedure development is fundamentally different than drug development, adherence to a process similar to that used to develop a new drug is a reasonable path for a surgical innovator. At the outset the surgeon must identify the problem that is not solved with current surgical procedures. For example, although the removal of a gallbladder through a Kocher incision is certainly effective, it creates a great deal of disability, pain, and scarification. As a result of those issues, many patients with very symptomatic biliary colic delayed operation until life-threatening complications occurred. Clearly there was a need for developing a less invasive approach.

Once the opportunity has been established, the next step involves a search through other disciplines for technologies and techniques that might be applied. Again, this is analogous to the drug industry, in which secondary drug indications have often turned out to be more therapeutically important than the primary indication for drug development. The third step is in vivo studies in the most appropriate animal model. Certainly these types of studies are controversial because of the resistance to animal experimentation, and yet without such studies many humans would be injured or killed during the developmental phase of medical drugs, devices, and techniques. These steps are often called the preclinical phase of procedure development.

The decision regarding when such procedures are ready to come out of the lab is a difficult one. Put simply, the procedure should be reproducible, provide the desired effect, and not have serious side effects. Once these three criteria are reached, the time for human application has arrived. Before the surgeon discusses the new procedure with his patient, it is important to achieve full institutional support. The dialogue with the patient who is to be first must be thorough, brutally honest, and well documented. The psychology that allows a patient to decide to be first is quite interesting, and may under certain circumstances require psychiatric evaluation. Certainly if a dying cancer patient has a chance with a new drug, this makes sense. Similarly, if the standard surgical procedure has a high attendant morbidity and the new procedure offers a substantially better outcome, the decision to be first is understandable. On the other hand, when the benefits of the new approach are small and the risks

are largely unknown, a more complete psychological profile may be necessary before proceeding.

For new surgical procedures, it is generally wise to assemble the best possible operative team, including a surgeon experienced with the old technique, and assistants who have participated in the earlier animal work. This initial team of experienced physicians and nurses should remain together until full competence with the procedure is attained. This may take 10 procedures, or it may take 50 procedures. The team will know that it has achieved competence when the majority of procedures take the same length of time, and the team is relaxed and sure of the flow of the operation. This will complete phase I of the procedure development.

In phase II, the efficacy of the procedure is tested in a nonrandomized fashion. Ideally, the outcome of new techniques must be as good or better than the procedure that is being replaced. This phase should occur at several medical centers to prove that good outcomes are achievable outside of the pioneering institution. These same requirements may be applied to the introduction of new technology into the operating room. The value equation requires that the additional measurable procedure quality exceeds the additional measurable cost to the patient or health care system. In phase III, a randomized trial pits the new procedure against the old.

Once the competence curve has been climbed, it is appropriate for the team to engage in the education of others. During the ascension of the competence curve, other learners in the institution (i.e., surgical residents) may not have the opportunity to participate in the first case series. The second stage of learning occurs when the new procedure has proven its value and a handful of experts exist, but the majority of surgeons have not been trained to perform the new procedure. In this setting, it is relatively unethical for surgeons to forge ahead with a new procedure in humans as if they had spent the same amount of time in intensive study that the first team did. The fact that one or several surgical teams were able to perform an operation does not ensure that all others with the same medical degrees can perform the operation with equal skill. It behooves the learners to contact the experts and request their assistance to ensure an optimal outcome at the new center. Although it is important that the learners contact the experts, it is equally important that the experts be willing to share their experience with their fellow professionals. As well, the experts should provide feedback to the learners regarding whether they feel the learners are equipped to forge ahead on their own. If not, further observation and assistance from the experts are required. Although this approach may sound obvious, it is fraught with difficulties. In many situations ego, competitiveness, and monetary concerns have short-circuited this process and led to poor patient outcomes. To a large extent, MIS has recovered from the black eye that it received early in development, when inadequately trained surgeons caused an excessive number of significant complications.

Cell, Genomics, and Molecular Surgery

*Xin-Hua Feng, Jeffrey B. Matthews, Xia Lin,
and F. Charles Brunicardi*

Modern biology aims at the molecular interpretation and full understanding of how cells, organs, and entire organisms function, both in a normal state and under pathologic conditions. The advent of recombinant DNA technology, polymerase chain reaction (PCR) techniques, and completion of the Human Genome Project are positively affecting human society by not only broadening our knowledge and understanding of disease development but also by bringing about necessary changes in disease treatment. Today's practicing surgeons are becoming increasingly aware that many modern surgical procedures rely on the information gained through molecular research. Hence surgeons will benefit from a clear introduction to how basic biochemical and biologic principles relate to the developing area of molecular biology.

This chapter reviews the current information on modern molecular biology. First, it introduces or updates the readers about the general concepts of molecular cell biology, which are essential for comprehending the real power and potential of modern molecular technology. The second aim is to inform the reader about the modern molecular techniques commonly used for surgical research and to provide a fundamental introduction on how these techniques are developed and applied to benefit patients.

BASIC CONCEPTS OF MOLECULAR RESEARCH

The modern era of molecular biology began in 1953 when James D. Watson and Francis H. C. Crick discovered the double-helical structure of deoxyribonucleic acid, or DNA. Although DNA had been implicated as genetic material prior to 1953, it was the base-paired structure of DNA that provided a logical interpretation of how a "double helix" could "unzip" to make copies of itself. This DNA synthesis, termed replication, immediately gave rise to the notion that a template was involved in the transfer of information between generations.

Within cells DNA is packed into chromosomes. One important feature of DNA as genetic material is its ability to encode important information for all of a cell's functions. Based on the principles of base complementarity, scientists also discovered how information in DNA is accurately transferred into the protein structure. DNA serves as a template for ribonucleic acid (RNA) synthesis, termed transcription, including messenger RNA (mRNA, or the protein-encoding RNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). mRNA carries the information from DNA to make proteins, termed translation, with the assistance of rRNA and tRNA. Each of these steps is precisely controlled in such a way that genes are properly expressed in each cell at a specific time and location. Thus the differential gene activity in a cell determines its actions, properties, and functions.

DNA and Heredity

DNA forms a right-handed, double-helical structure that is composed of two antiparallel strands of unbranched polymeric deoxyribonucleotides. DNA is composed of four types of deoxyribonucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T). The deoxyribonucleotides are joined together by phosphodiester bonds between the 5' carbon of one deoxyribose moiety to the 3' carbon of the next. In the double-helical structure deduced by Watson and Crick, the two strands of DNA are complementary to each other. Because of size, shape, and chemical composition, A always pairs with T, and C with G, through the formation of hydrogen bonds between complementary bases that stabilize the double helix.

For cells to pass on the genetic material (DNA) to each progeny, the amount of DNA must be doubled. The complementary base-pair structure of DNA implies the existence of a template-like mechanism for the copying of genetic material. The transfer of DNA material from the mother cell to a daughter cell takes place during somatic cell division (also called mitosis). Before a cell divides, DNA must be precisely duplicated. During replication, the two strands of DNA separate and each strand creates a new complementary strand by precise base-pair matching. The two new double-stranded DNAs carry the same genetic information, which can then be passed on to two daughter cells. Proofreading mechanisms ensure that the replication process occurs in a highly accurate manner. The fidelity of DNA replication is absolutely crucial to maintaining the integrity of the genome from generation to generation. However, mistakes can still occur during this process, resulting in mutations, which may lead to a change of the DNA's encoded protein and, consequently, a change of the cell's behavior. For example, there are many mutations present in the genome of a cancer cell.

Gene Regulation

Living cells have the necessary machinery to enzymatically transcribe DNA into RNA and translate the mRNA into protein. This machinery accomplishes the two major steps required for gene expression in all organisms: transcription and translation. However, gene regulation is far more complex, particularly in eukaryotic organisms. For example, many gene transcripts must be spliced to remove the intervening sequences. The sequences that are spliced off are called introns, which appear to be useless, but in fact may carry some regulatory information. The sequences that are joined together, and are eventually translated into protein, are called exons. Additional regulation of gene expression includes modification of mRNA, control of mRNA stability, and its nuclear export into cytoplasm (where it is assembled into ribosomes for translation). After mRNA is translated into protein, the levels and functions of the proteins can be further regulated posttranslationally. However, the following sections will mainly focus on gene regulation at transcriptional and translational levels.

Transcription

Transcription is the enzymatic process of RNA synthesis from DNA. In bacteria, a single RNA polymerase carries out all RNA synthesis, including that of mRNA, rRNA, and tRNA. Transcription often is coupled with translation in such a way that an mRNA molecule is completely accessible to ribosomes, and bacterial protein synthesis begins on an mRNA molecule even while it is still being synthesized. Transcription mechanisms in eukaryotes differ from those

in prokaryotes. The unique features of eukaryotic transcription are as follows: (1) Three separate RNA polymerases are involved in eukaryotes: RNA polymerase I transcribes the precursor of 5.8S, 18S, and 28S rRNAs; RNA polymerase II synthesizes the precursors of mRNA; RNA polymerase III makes tRNAs and 5S rRNAs. (2) In eukaryotes, the initial transcript is often the precursor to final mRNAs, tRNAs, and rRNAs. The precursor is then modified and/or processed into its final functional form. RNA splicing is one type of processing to remove the noncoding introns (the region between coding exons) on an mRNA. (3) In contrast to bacterial DNA, eukaryotic DNA often is packaged with histone and nonhistone proteins into chromatin. Transcription will only occur when the chromatin structure changes in such a way that DNA is accessible to the polymerase. (4) RNA is made in the nucleus and transported into cytoplasm, in which translation occurs. Therefore, unlike bacteria, eukaryotes undergo uncoupled transcription and translation.

Eukaryotic gene transcription also involves the recognition and binding of RNA polymerase to the promoter DNA. However, the interaction between the polymerase and DNA is far more complex in eukaryotes than in prokaryotes. Because the majority of studies have been focused on the regulation and functions of proteins, this chapter primarily focuses on how protein-encoding mRNA is made by RNA polymerase II.

Translation

DNA directs the synthesis of RNA; RNA in turn directs the synthesis of proteins. Proteins are variable-length polypeptide polymers composed of various combinations of 20 different amino acids and are the working molecules of the cell. The genetic information on mRNA is composed of arranged sequences of four bases that are transferred to the linear arrangement of 20 amino acids on a protein. The process of decoding information on mRNA to synthesize proteins is called translation. Translation takes place in ribosomes composed of rRNA and ribosomal proteins. Amino acids are characterized by a central carbon unit linked to four side chains: an amino group ($-\text{NH}_2$), a carboxy group ($-\text{COOH}$), a hydrogen, and a variable group. The amino acid chain is assembled via peptide bonds between the amino group of one amino acid and the carboxy group of the next. Translation involves all three RNAs. The precise transfer of information from mRNA to protein is governed by genetic code; the set of rules by which codons are translated into an amino acid (Table 14-1). A codon, a triplet of three bases, codes for one amino acid. The codons on mRNA are sequentially recognized by tRNA adaptor proteins. Specific enzymes termed aminoacyl-tRNA synthetases link a specific amino acid to a specific tRNA. The translation of mRNA to protein requires the ribosomal complex to move stepwise along the mRNA until the start codon (encoding initiator methionine) is identified. Each new amino acid is added sequentially by the appropriate tRNA in conjunction with proteins called elongation factors. Protein synthesis proceeds in the amino-to-carboxy-terminus direction.

The biologic versatility of proteins is astounding. Among many other functions, proteins serve as enzymes that catalyze critical biochemical reactions, carry signals to and from the extracellular environment, and mediate diverse signaling and regulatory functions in the intracellular environment. They also transport ions and various small molecules across plasma membranes. Proteins make up the key structural components of cells and the extracellular matrix and are responsible for cell motility. The unique functional properties of proteins are largely determined by their structure.

TABLE 14-1 The Genetic Code

		Second Base in Codon												
		U			C			A			G			
First Base in Codon	U	UUU	Phe	[F]	UCU	Ser	[S]	UAU	Tyr	[Y]	UGU	Cys	[C]	U

Third Base in Codon														

A = adenine; C = cytosine; G = guanine; U = uracil; Ala = alanine; Arg = arginine; Asn = asparagine; Asp = aspartic acid; Cys = cysteine; Glu = glutamic acid; Gln = glutamine; Gly = glycine; His = histidine; Ile = isoleucine; Leu = leucine; Lys = lysine; Met = methionine; Phe = phenylalanine; Pro = proline; Ser = serine; Thr = threonine; Trp = tryptophan; Tyr = tyrosine; Val = valine. Letter in [] indicates single lettercode for amino acid.

Regulation of Gene Expression

The human organism is made up of a myriad of different cell types that, despite their vastly different characteristics, contain the same genetic material. This cellular diversity is controlled by the genome and accomplished by tight regulation of gene expression. This leads to the synthesis and accumulation of different complements of RNA and, ultimately, to the proteins found in different cell types. For example, muscle and bone express different genes or the same genes at different times. Moreover, the choice of which genes are expressed in a given cell at a given time depends on signals received from its environment. There are multiple levels at which gene expression can be controlled along the pathway from DNA to RNA to protein. Transcriptional control refers to the mechanism for regulating when and how often a gene is transcribed. Splicing of the primary RNA transcript (RNA processing control) and selection of which completed mRNAs undergo nuclear export (RNA transport control) represent additional potential regulatory steps. The mRNAs in the cytoplasm can be selectively translated by ribosomes (translational control), or selectively stabilized or degraded (mRNA degradation control). Finally, the resulting proteins can undergo selective activation, inactivation, or compartmentalization (protein activity control).

Because a large number of genes are regulated at the transcriptional level, regulation of gene transcripts (i.e., mRNA) often is referred to as gene regulation in a narrow definition. Each of the steps during transcription is properly regulated in eukaryotic cells. Because genes are differentially regulated from one another, one gene can be differentially regulated in different cell types or at different developmental stages. Therefore, gene regulation at the level of transcription is largely context-dependent. However, there is a common scheme that applies to transcription at the molecular level. Each gene promoter possesses unique sequences called TATA boxes that can be recognized and bound by a large complex containing RNA polymerase II, forming the basal transcription machinery. Usually located upstream of the TATA box (but sometimes longer distances) are a number of regulatory sequences referred to as enhancers that are recognized by regulatory proteins called transcription factors. These transcription factors specifically bind to the enhancers, often in response to environmental or developmental cues, and cooperate with each other and with basal transcription factors to initiate transcription. Regulatory sequences that negatively regulate the initiation of transcription also are present on the promoter DNA. The transcription factors that bind to these sites are called repressors, in contrast to the activators that activate transcription. The molecular interactions between transcription factors and promoter DNA, and between the cooperative transcription factors, are highly regulated. Specifically, the recruitment of transcription factors to the promoter DNA occurs in response to physiologic signals.

Human Genome

Genome is a collective term for all genes present in one organism. The human genome contains DNA sequences of 3 billion base pairs, carried by 23 pairs of chromosomes. The human genome has an estimated 25,000–30,000 genes, and overall it is 99.9 percent identical in all people. Approximately 3 million locations in which single-base DNA differences exist have been identified and termed single nucleotide polymorphisms (SNPs). SNPs may be critical

determinants of human variation in disease susceptibility and responses to environmental factors.

The medical field is building on the knowledge, resources, and technologies emanating from the human genome to further the understanding of the relationship of the genes and their mutations to human health and disease. This expansion of genomics into human health applications resulted in the field of genomic medicine and will consequently transform the practice of medicine and surgery in this century. In the 21st century, the goal is to use this information embedded in the human genome sequence to develop new ways to treat, cure, or even prevent the thousands of diseases that afflict humankind. By doing so, the genomic information can be used for diagnosing and predicting diseases and disease susceptibility. Furthermore, exploration into the function of each human gene is now possible, which will shed light on how faulty genes play a role in disease causation. This knowledge also makes possible the development of a new generation of therapeutics based on genes. Drug design is being revolutionized as researchers create new classes of medicines based on a reasoned approach to the use of information on gene sequence and protein structure function rather than the traditional trial-and-error method. Drugs targeted to specific sites in the body promise to have fewer side effects than many of today's medicines. Finally, other applications of genomics will involve the transfer of genes to replace defective versions or the use of gene therapy to enhance normal functions such as immunity.

Proteomics refers to the study of the structure and expression of proteins and the interactions among proteins encoded by a human genome. A number of Internet-based repositories for protein sequences exist, including Swiss-Prot (<http://www.expasy.ch>). These databases allow comparisons of newly identified proteins with previously characterized sequences to allow prediction of similarities, identification of splice variants, and prediction of membrane topology and posttranslational modifications. Tools for proteomic profiling include two-dimensional gel electrophoresis, mass spectrometry, and protein microarrays.

It is anticipated that a genomic and proteomic approach to human disease will lead to a new understanding of pathogenesis that will aid in the development of effective strategies for early diagnosis and treatment. For example, identification of altered protein expression in organs, cells, subcellular structures, or protein complexes may lead to development of new biomarkers for disease detection. Moreover, improved understanding of how protein structure determines function will allow rational identification of therapeutic targets, and thereby not only accelerate drug development, but also lead to new strategies to evaluate therapeutic efficacy and potential toxicity.

Cell Cycle and Apoptosis

Every organism has many different cell types. Many cells grow, although some cells such as nerve cells and striated muscle cells do not. All growing cells have the ability to duplicate their genomic DNA and pass along identical copies of this genetic information to every daughter cell. Thus the cell cycle is the fundamental mechanism to maintain tissue homeostasis. After a full cycle, two daughter cells with identical DNA are generated. The machinery that drives cell cycle progression is made up of a group of enzymes called cyclin-dependent kinases (CDK). Cyclins are essential for CDK activities and

form complexes with CDK, and their expression fluctuates during the cell cycle. There also are negative regulators for CDK termed CDK inhibitors (CKIs), which inhibit the assembly or activity of the cyclin-CDK complex. Expression of cyclins and CKIs often are regulated by developmental and environmental factors.

The cell cycle is connected with signal transduction pathways and gene expression. During the G1 phase (the phase before DNA duplication), cells receive signals to enter S phase (the phase of DNA duplication) or remain in G1, respectively. Growing cells proliferate only when supplied with appropriate mitogenic growth factors. Mitogenic signals stimulate the activity of CDKs. Meanwhile, cells also receive antiproliferative signals such as those from tumor suppressors. These antiproliferative signals stop cells progress into the S phase by inducing CKI production. For example, when DNA is damaged, cells will repair the damage before entering the S phase. Accelerated proliferation or improper cell cycle progression with damaged DNA would be disastrous. Genetic gain-of-function mutations in oncogenes or loss-of-function mutations in tumor suppressor are causal factors for malignant transformation.

In addition to cell cycle control, cells use genetically programmed mechanisms to kill cells. This cellular process, called apoptosis or programmed cell death, is essential for the maintenance of tissue homeostasis. Normal tissues undergo proper apoptosis to remove unwanted cells, those that have completed their jobs or have been damaged or improperly proliferated. Apoptosis can be activated by many physiologic stimuli such as death signals, growth factor deprivation, DNA damage, and stress signals. What is central to the apoptotic machinery is the activation of a cascade of proteinases called caspases. Similarly to CDK in the cell cycle, activities and expression of caspases are well controlled by positive and negative regulators. The complex machinery of apoptosis must be tightly controlled. Perturbations of this process can cause neoplastic transformation or other diseases.

Signal Transduction Pathways

Gene expression in a genome is controlled in a temporal and spatial manner, at least in part by signaling pathways. A signaling pathway generally begins at the cell surface and, after a signaling relay by a cascade of intracellular effectors, ends up in the nucleus. All cells have the ability to sense changes in their external environment. The bioactive substances to which cells can respond are many and include proteins, short peptides, amino acids, nucleotides/nucleosides, steroids, retinoids, fatty acids, and dissolved gases. Some of these substances are lipophilic and thereby can cross the plasma membrane by diffusion to bind to a specific target protein within the cytoplasm (intracellular receptor). Other substances bind directly with a transmembrane protein (cell-surface receptor). Binding of ligand to receptor initiates a series of biochemical reactions (signal transduction) typically involving protein-protein interactions, leading to various cellular end responses.

Control and specificity through simple protein-protein interactions is a common feature of signal transduction pathways in cells. Signaling also involves catalytic activities of signaling molecules such as protein kinases/phosphatases that modify the structures of key signaling proteins. On binding and/or modification by upstream signaling molecules, downstream effectors undergo a conformational (allosteric) change and, consequently, a change in function.

The signal that originates at the cell surface and is relayed by the cytoplasmic proteins often ultimately reaches the transcriptional apparatus in the nucleus. It alters the DNA binding and activities of transcription factors that directly turn genes on or off in response to the stimuli. Abnormal alterations in signaling activities and capacities in otherwise normal cells can lead to diseases such as cancer.

In a given cell, many signaling pathways operate simultaneously and cross-talk with one another. A cell generally may react to a hormonal signal in a variety of ways: (1) by changing its metabolite or protein, (2) by generating an electric current, or (3) by contracting. Cells are continually subject to multiple input signals that simultaneously and sequentially activate multiple receptor- and non-receptor-mediated signal transduction pathways. Although the regulators responsible for cell behavior are rapidly identified as a result of genomic and proteomic techniques, the specific functions of the individual proteins, how they assemble, and the networks that control cellular behavior remain to be defined. An increased understanding of cell regulatory pathways—and how they are disrupted in disease—will likely reveal common themes based on protein interaction domains that direct associations of proteins with other polypeptides, phospholipids, nucleic acids, and other regulatory molecules. Advances in the understanding of signaling networks will require multidisciplinary and transdisciplinary methodologies within the emerging disciplines of medical informatics and computational biology.

Signaling pathways often are grouped according to the properties of signaling receptors. Many hydrophobic signaling molecules are able to diffuse across plasma membranes and directly reach specific cytoplasmic targets. Steroid hormones, thyroid hormones, retinoids, and vitamin D are examples that exert their activity on binding to structurally related members of the nuclear hormone receptor superfamily. Ligand binding induces a conformational change that enhances transcriptional activity of these receptors.

Most extracellular signaling molecules interact with transmembrane protein receptors that couple ligand binding to intracellular signals, leading to biologic actions. There are three major classes of cell-surface receptors: transmitter-gated ion channels, seven-transmembrane G-protein coupled receptors (GPCRs), and enzyme-linked receptors. The superfamily of GPCRs is one of the largest families of proteins, representing over 800 genes of the human genome. Members of this superfamily share a characteristic seven-transmembrane configuration. The ligands for these receptors are diverse and include hormones, chemokines, neurotransmitters, proteinases, inflammatory mediators, and even sensory signals such as odorants and photons. Most GPCRs signal through heterotrimeric G-proteins, which are guanine-nucleotide regulatory complexes. Thus the receptor serves as the receiver, the G-protein serves as the transducer, and the enzyme serves as the effector arm. Enzyme-linked receptors possess an extracellular ligand-recognition domain and a cytosolic domain that either has intrinsic enzymatic activity or directly links with an enzyme. Structurally, these receptors usually have only one transmembrane-spanning domain. Of various classes of enzyme-linked receptors, the growth factor receptors such as tyrosine kinase receptor or serine/threonine kinase receptors mediate diverse cellular events including cell growth, differentiation, metabolism, and survival/apoptosis. Dysregulation (particularly mutations) of these receptors is thought to underlie conditions of abnormal cellular proliferation in the context of cancer. The following

sections further review two examples of growth factor signaling pathways and their connection with human diseases.

Insulin Pathway and Diabetes

Insulin is required for the growth and metabolism of most mammalian cells, which contain cell-surface insulin receptors (InsR). Insulin binding to InsR activates the tyrosine kinase activity of InsR. InsR then activates its immediate intracellular effector, called insulin receptor substrate (IRS). IRS plays a central role in coordinating the signaling of insulin by activating distinct signaling pathways, the PI3K-Akt pathway and mitogen-activated protein kinase (MAPK) pathway, both of which possess multiple protein kinases that can control transcription, protein synthesis, and glycolysis.

The primary physiologic role of insulin is in glucose homeostasis, which is accomplished through the stimulation of glucose uptake into insulin-sensitive tissues such as fat and skeletal muscle. Defects in insulin synthesis/secretion and/or responsiveness are major causal factors in diabetes, one of the leading causes of death and disability in the United States. Type 2 diabetes accounts for about 90 percent of all cases of diabetes. Clustering of type 2 diabetes in certain families and ethnic populations points to a strong genetic background for the disease. More than 90 percent of affected individuals have insulin resistance. The majority of type 2 diabetes cases may result from defects in InsR, IRS or downstream-signaling components in the insulin-signaling pathway. Type 2 diabetes is also associated with declining β -cell function, resulting in reduced insulin secretion. A full understanding of the basis of insulin resistance is crucial for the development of new therapies for type 2 diabetes. Furthermore, apart from type 2 diabetes, insulin resistance is a central feature of several other common human disorders, including atherosclerosis and coronary artery disease, hypertension, and obesity.

TGF- β Pathway and Cancers

B growth factor signaling controls cell growth, differentiation, and apoptosis. Although insulin and many mitogenic growth factors promote cell proliferation, some growth factors and hormones inhibit cell proliferation. Transforming growth factor- β (TGF- β) is one of them. The balance between mitogens and TGF- β plays an important role in controlling the proper pace of cell cycle progression. The growth inhibition function of TGF- β signaling in epithelial cells plays a major role in maintaining tissue homeostasis.

The TGF- β superfamily comprises a large number of structurally related growth and differentiation factors that act through a receptor complex at the cell surface. The complex consists of transmembrane serine/threonine kinases. The receptor signals through activation of downstream intracellular effectors called SMADs. Activated SMAD complexes translocate into the nucleus, in which they bind to gene promoters and cooperate with specific transcription factors to regulate the expression of genes that control cell proliferation and differentiation. For example, TGF- β strongly induces the transcription of a gene called p15INK4B (a type of CKI) and, at the same time, reduces the expression of many oncogenes such as c-Myc. The outcome of the altered gene expression leads to the inhibition of cell cycle progression. Therefore, activation of TGF- β signaling is an intrinsic mechanism for cells to ensure controlled proliferation.

Resistance to TGF- β 's anticancer action is one hallmark of human cancer cells. TGF- β receptors and SMADs are identified as tumor suppressors.

The TGF- β signaling circuit can be disrupted in different types of human tumors through various mechanisms such as downregulation or mutations of the TGF- β receptors or SMADs. In pancreatic and colorectal cancers, 100 percent of cells derived from these cancers carry genetic defects in the TGF- β signaling pathway. Therefore, the TGF- β antiproliferative pathway is disrupted in a majority of human cancer cells.

Gene Therapy and Molecular Drugs in Cancer

Human diseases arise from improper changes in the genome, thus the continuous understanding of how the genome functions will make it possible to tailor medicine on an individual basis. In this section, cancer is used as an example to elaborate some therapeutic applications of molecular biology.

Cancer is a complex disease, involving uncontrolled growth and spread of tumor cells. Cancer development depends on the acquisition and selection of specific characteristics that transform normal cells into cancerous ones by derailing a wide spectrum of regulatory pathways including signal transduction pathways, cell cycle machinery, or apoptotic pathways. The early notion that cancer was caused by mutations in genes critical for the control of cell growth implied that genome stability is important for preventing oncogenesis. There are two major classes of cancer genes in which alteration has been identified in human and animal cancer cells: oncogenes, with dominant gain-of-function mutations, and tumor suppressor genes, with recessive loss-of-function mutations. In normal cells, oncogenes promote cell growth by activating cell cycle progression, although tumor suppressors counteract oncogenes' functions. Therefore, the balance between oncogenes and tumor suppressors maintains a well-controlled state of cell growth.

During the development of most types of human cancer, cancer cells can break away from primary tumor masses, invade adjacent tissues, and hence travel to distant sites where they form new colonies. This spreading process of tumor cells, called metastasis, is the cause of 90 percent of human cancer deaths. Metastatic cancer cells that enter the blood stream can reach virtually all tissues of the body. Bones are one of the most common places for these cells to settle and start growing again. Bone metastasis is one of the most frequent causes of pain in people with cancer. It also can cause bones to break and create other symptoms and problems for patients.

As a result of explosive new discoveries, some modern treatments were developed. Understanding the biology of cancer cells has led to the development of designer therapies for cancer prevention and treatment. Gene therapy, immune system modulation, genetically engineered antibodies, and molecularly designed chemical drugs, are all promising fronts in the war against cancer.

Immunotherapy

The growth of the body is controlled by many natural signals through complex signaling pathways. Some of these natural agents have been used in cancer treatment and have been proven effective for fighting several cancers through the clinical trial process. These naturally occurring biologic agents such as interferons are given to patients to influence the natural immune response agents either by directly altering the cancer cell growth, or by acting indirectly to help healthy cells control the cancer. One of the most exciting applications of immunotherapy has come from the generation of antibodies aimed at tumor antigens. This was first used as a means of localizing tumors in the body for diagnosis, and was more recently used

to attack cancer cells. For example, Trastuzumab is a monoclonal antibody that neutralizes the mitogenic activity of cell-surface growth factor receptor HER-2, which is overexpressed in approximately 25 percent of breast cancers. These tumors tend to grow faster and are generally more likely to recur than tumors that do not overproduce HER-2. Trastuzumab slows or stops the growth of these cells and increases the survival of HER-2–positive breast cancer patients. Another significant example is the administration of interleukin-2 (IL-2) to patients with metastatic melanoma or kidney cancer, which has been shown to mediate the durable regression of metastatic cancer.

IL-2, a cytokine produced by human T-helper lymphocytes, has no direct impact on cancer cells, yet has a wide range of immune regulatory effects including the expansion of lymphocytes with antitumor activity. The expanded lymphocytes somehow recognize the antigen on cancer cells. Thus, the molecular identification of cancer antigens has opened new possibilities for the development of effective immunotherapies for patients with cancer. Clinical studies using immunization with peptides derived from cancer antigens have shown that high levels of lymphocytes with antitumor activity can be produced in cancer-bearing patients. Highly avid antitumor lymphocytes can be isolated from immunized patients and grown *in vitro* for use in cell-transfer therapies.

Chemotherapy

The primary function of anticancer chemicals is to block different steps involved in cell growth and replication. These chemicals often block a critical chemical reaction in a signal transduction pathway or during DNA replication or gene expression. For example, STI571, also known as Gleevec, is one of the first molecularly targeted drugs based on the changes that cancer causes in cells. STI571 offers promise for the treatment of chronic myeloid leukemia (CML) and may soon surpass α interferon- α as the standard treatment for the disease. In CML, STI571 is targeted at the Bcr-Abl kinase, an activated oncogene product in CML. Bcr-Abl is an overly activated protein kinase resulting from a specific genetic abnormality generated by chromosomal translocation that is found in the cells of patients with CML. STI571-mediated inhibition of Bcr-Abl-kinase activity not only prevents cell growth of Bcr-Abl–transformed leukemic cells, but also induces apoptosis. Clinically, the drug quickly corrects the blood cell abnormalities caused by the leukemia in a majority of patients, achieving a complete disappearance of the leukemic blood cells and the return of normal blood cells. Additionally, the drug appears to have some effect on other cancers including certain brain tumors and gastrointestinal stromal tumors (GISTs), a very rare type of stomach cancer.

Gene Therapy

Gene therapy is an experimental treatment that involves genetically altering a patient's own tumor cells or lymphocytes. For years, the concept of gene therapy has held promise as a new, potentially potent weapon to attack cancer. Several problems must be resolved to transform it into a clinically relevant form of therapy. The major issues that limit its translation to the clinic are improving the selectivity of tumor targeting, improving the delivery to the tumor, and the enhancement of the transduction rate of the cells of interest. An important aspect of effective gene therapy involves the choice of appropriate genes for manipulation. Genes that promote the production of messenger chemicals or other immune-active substances can be transferred into the patient's cells. These include genes that inhibit cell cycle progression, induce apoptosis,

enhance host immunity against cancer cells, and block the ability of cancer cells to metastasize. The mapping of genes responsible for human cancer is likely to provide new targets for gene therapy in the future. The preliminary results of gene therapy for cancer clinical trials are encouraging, and as advancements are made in the understanding of the molecular biology of human cancer, the future of this rapidly developing field holds great potential for treating cancer.

It is noteworthy that the use of multiple therapeutic methods has proven more powerful than a single method. The use of chemotherapy after surgery to destroy the few remaining cancerous cells in the body is called "adjuvant therapy." Adjuvant therapy was first tested and found to be effective in breast cancer. It was later adopted for use in other cancers. A major discovery in chemotherapy is the advantage of multiple chemotherapeutic agents (known as combination or cocktail chemotherapy) over single agents. Some types of fast-growing leukemias and lymphomas (tumors involving the cells of the bone marrow and lymph nodes) responded extremely well to combination chemotherapy, and clinical trials led to gradual improvement of the drug combinations used. Many of these tumors can be cured today by combination chemotherapy. As cancer cells carry multiple genetic defects, the use of combination chemotherapy, immunotherapy, and gene therapies may be more effective in treating cancers.

Stem Cell Research

Stem cell biology represents a cutting-edge scientific research field with potential clinical applications. It may have an enormous impact on human health by offering hope for curing human diseases such as diabetes mellitus, Parkinson disease, neurologic degeneration, and congenital heart disease. Stem cells are endowed with two remarkable properties. First, stem cells can self-renew. Second, they have the ability to differentiate into many specialized cell types. There are two groups of stem cells: embryonic stem (ES) cells and adult stem cells. Human ES cells are derived from early preimplantation embryos called blastocysts (5 days postfertilization), and are capable of generating all differentiated cell types in the body. Adult stem cells are present in adult tissues. They are often tissue-specific and can only generate the cell types comprising a particular tissue in the body; however, in some cases they can transdifferentiate into cell types found in other tissues. Hematopoietic stem cells are adult stem cells. They reside in bone marrow and are capable of generating all cell types of the blood and immune system.

With the recent and continually increasing improvement in culturing stem cells, scientists are beginning to understand the molecular mechanisms of stem cell self-renewal and differentiation in response to environmental cues. It is believed that discovery of the signals that control self-renewal versus differentiation will be extremely important for the therapeutic use of stem cells in treating disease. It is possible that success in the study of the changes in signal transduction pathways in stem cells will lead to the development of therapies to specifically differentiate stem cells into a particular cell type to replace diseased or damaged cells in the body.

MOLECULAR APPROACHES TO SURGICAL RESEARCH

Rapid advances in molecular and cellular biology over the past half-century have revolutionized the understanding of disease and will radically transform the practice of surgery. In the future, molecular techniques will be increasingly

applied to surgical disease and will lead to new strategies for the selection and implementation of operative therapy. Surgeons should be familiar with the fundamental principles of molecular and cellular biology so that emerging scientific information can be incorporated into improved care of the surgical patient.

The basic molecular approaches for modern surgical research include DNA cloning, cell manipulation, disease modeling in animals, and clinical trials in human patients. The greatest advances in the field of molecular biology have been in the areas of analysis and manipulation of DNA. Recombinant DNA technology in particular has drastically changed the world of biology. DNA molecules can be cloned for a variety of purposes including safeguarding DNA samples, facilitating sequencing, generating probes, and expressing recombinant proteins. Expression of recombinant proteins provides a method for analyzing gene regulation, gene functions, and in recent years for gene therapy and biopharmaceuticals. The basic molecular approaches for modern surgical research include DNA cloning, cell manipulation, disease modeling in animals, and clinical trials in human patients.

DNA Cloning

Recombinant DNA technology is the technology that uses advanced enzymatic and microbiologic techniques to manipulate DNA. This technology, often referred to as DNA cloning, is the basis of all other DNA analysis methods. It is only with the awesome power of recombinant DNA technology that the completion of the Human Genome Project was possible. It also has led to the identification of the entire gene complements of organisms such as viruses, bacteria, worms, flies, and plants.

Molecular cloning refers to the process of cloning a DNA of interest into a DNA vector that is ultimately delivered into bacterial or mammalian cells or tissues. This represents a very basic technique that is widely used in almost all areas of biomedical research. The process of molecular cloning involves several steps of manipulation of DNA. First, the vector DNA is cleaved with a restriction enzyme to create compatible ends with the foreign DNA fragment to be cloned. The vector and the DNA fragment are then joined by a DNA ligase. Finally, the ligation product is introduced into competent host *Escherichia coli*; this procedure is called transformation. The resulting plasmid vector can be amplified in *E. coli* to prepare large quantities of DNA for its subsequent applications such as transfection, gene therapy, transgenics, and knockout mice.

Detection of Nucleic Acids and Proteins

Southern Blot Hybridization

Southern blotting refers to the technique of transferring DNA fragments from an electrophoresis gel to a membrane support, and the subsequent analysis of the fragments by hybridization with a radioactively labeled probe. Southern blotting normally begins with the digestion of the DNA samples with appropriate restriction enzymes and the separation of DNA samples in an agarose gel. The DNA is then denatured and transferred onto a nitrocellulose membrane. After immobilization, the DNA can be subjected to hybridization analysis, enabling bands with sequence similarity to a radioactively labeled probe to be identified.

The development of Southern transfer and the associated hybridization techniques made it possible to obtain information about the physical organization of genes in complex genomes. Its applications include genetic fingerprinting and prenatal diagnosis of genetic diseases.

Northern Blot Hybridization

Northern blotting refers to the technique of size fractionation of RNA in a gel and the transferring of an RNA sample to a membrane support. In principle, Northern blot hybridization is similar to Southern blot hybridization (and hence its name), with the exception that RNA, not DNA, is on the membrane. The membrane is then hybridized with a labeled probe complementary to the mRNA of interest. Signals generated from detection of the membrane can be used to determine the size and abundance of the target RNA. Although RT-PCR has been used in many applications (described below), Northern analysis is the only method that provides information regarding mRNA size. Thus, Northern blot analysis is commonly used in molecular biology studies relating to gene expression.

Polymerase Chain Reaction

PCR is a method for the polymerase-directed amplification of specific DNA sequences using two oligonucleotide primers that hybridize to opposite strands and flank the region of interest in the target DNA. One cycle of PCR reaction involves template denaturation, primer annealing, and the extension of the annealed primers by DNA polymerase. Because the primer extension products synthesized in one cycle can serve as a template in the next, the number of target DNA copies nearly doubles at each cycle. Thus a repeated series of cycles result in the exponential accumulation of a specific fragment defined by the primers. The introduction of the thermostable DNA polymerase (e.g., Taq polymerase) transforms the PCR into a simple and robust reaction.

The emergence of the PCR technique has dramatically altered the approach to both fundamental and applied biologic problems. The capability of amplifying a specific DNA fragment from a gene or the whole genome greatly advances the study of the gene and its function. It is simple, yet robust, speedy, and most of all, flexible. As a recombinant DNA tool, it underlies almost all of molecular biology. This revolutionary technique enabled the modern methods for the isolation of genes, construction of a DNA vector, introduction of alterations into DNA, and quantitation of gene expression, making it a fundamental cornerstone of genetic and molecular analysis.

Antibody-based Techniques

Analyses of proteins are primarily carried out by antibody-directed immunologic techniques. For example, Western blotting, also called immunoblotting, is performed to detect protein levels in a population of cells or tissues, whereas immunoprecipitation is used to concentrate proteins from a larger pool. Using specific antibodies, microscopic analysis called immunofluorescence and immunohistochemistry is possible for the subcellular localization and expression of proteins in cells or tissues, respectively.

Immunoblotting refers to the process of identifying a protein from a mixture of proteins using specific antibody. It consists of five steps: sample preparation, electrophoresis, transfer of proteins from gel onto membrane support, immunodetection of target proteins with specific antibody, and colorimetric or

chemiluminescent visualization of the antibody-recognized protein. Immunoblotting is a powerful tool used to determine the presence and the quantity of a protein in a given cellular condition and its relative molecular weight. Immunoblotting also can be used to determine whether posttranslational modification such as phosphorylation has occurred on a protein. Importantly, through immunoblotting analysis a comparison of the protein levels and modification states in normal versus diseased tissues is possible.

Immunoprecipitation, another widely used immunochemical technique, is a method which uses antibody to enrich a protein of interest and any other proteins that are associated with it. The principle of the technique lies in the property of a strong and specific affinity between antibodies and their antigens to pull down the antibody-antigen complexes in the solution. The purified protein can then be analyzed by a number of biochemical methods. When immunoprecipitation is combined with immunoblotting, it can be used for detecting proteins in low concentrations and for analyzing protein-protein interactions or determining posttranslational modifications of proteins.

DNA Microarray

With the tens of thousands of genes present in the genome, traditional methods in molecular biology, which generally work on a one-gene-in-one-experiment basis, cannot generate the “whole” picture of genome function. To this end, DNA microarray has attracted tremendous interest among biologists and clinicians. This technology promises to monitor the whole genome on a single chip so researchers can have a better picture of the interactions among thousands of genes simultaneously.

DNA microarray, also called gene chip, DNA chip, and gene array, refers to large sets of probes of known sequences orderly arranged on a small chip, enabling many hybridization reactions to be carried out in parallel in a small device. Like Southern and Northern hybridization, the underlying principle of this technology is the remarkable ability of nucleic acids to form a duplex between two strands with complementary base sequences. DNA microarray provides a medium for matching known and unknown DNA samples based on base-pairing rules, and automating the process of identifying the unknowns. Microarrays require specialized robotics and imaging equipment that spot the samples on a glass or nylon substrate, carry out the hybridization, and analyze the data generated. The massive scale of microarray experiments requires the aid of computers to quantitate the extent of hybridization, and to allow meaningful interpretation of the extent of hybridization.

DNA microarray technology has produced many significant results in quite different areas of application. There are two major application forms for the technology: identification of sequence (gene/gene mutation) and determination of expression level (abundance) of genes. For example, analysis of genomic DNA detects amplifications and deletions found in human tumors. Differential gene expression analysis also has uncovered networks of genes differentially present in cancers that cannot be distinguished by conventional means.

Cell Manipulations

Cell culture is used in a diversity of biologic fields ranging from traditional cell biology to modern medicine. Through their ability to be maintained *in vitro*, cells can be manipulated by the introduction of genes of interest (cell transfection) and can be transferred into *in vivo* biologic receivers (cell transplantation)

to study the biologic effect of the interested genes. In transfection, the transfer of foreign macromolecules, such as DNA, into living cells provides an efficient method for studying a variety of cellular processes and functions at the molecular level. DNA transfection has become an important tool for studying the regulation and function of genes. Depending on the cell type, many ways of introducing DNA into mammalian cells have been developed. Commonly used approaches include calcium phosphate, electroporation, liposome-mediated transfection, the nonliposomal formulation, and the use of viral vectors. One application of DNA transfection is the generation of transgenic or knockout mouse models. Transfected cells also can be transplanted into host organs.

Genetic Manipulations

Understanding how genes control the growth and differentiation of the mammalian organism has been the most challenging topic of modern research. Genetically altered mice are powerful model systems in which to study the function and regulation of genes during mammalian development. A gene of interest can be introduced into the mouse (transgenic mouse) to study its effect on development or diseases. The gene function also can be studied by creating mutant mice through homologous recombination (gene knockout). As mouse models do not precisely represent human biology, genetic manipulations of human somatic or embryonic stem cells provide a great means for the understanding of the molecular networks in human cells.

Transgenic Mice

The transgenic technique has proven to be extremely important for basic investigations of gene regulation, creation of animal models of human disease, and genetic engineering of livestock. A transgenic mouse is created by the microinjection of DNA into the one-celled mouse embryo, allowing the efficient introduction of cloned genes into the developing mouse somatic tissues, and into the germline. Generation of transgenic mice generally is comprised of the following steps: (1) Designs of a transgene. A simple transgene construct consists of a protein-encoding gene and a promoter that precedes it. The most common applications for the use of transgenic mice are similar to those in the cell culture system to study the functions of proteins encoded by the transgene, and to analyze the tissue-specific and developmental-stage-specific activity of a gene promoter. (2) Production of transgenic mice. Pure DNA is microinjected into mouse embryos. Mice that develop from injected eggs are often termed “founder mice.” (3) Genotyping of transgenic mice. The screening of “founder mice” and the transgenic lines derived from the founders is accomplished by determining the integration of the injected gene into the genome. This is normally achieved by performing PCR or Southern blot analysis. Once a given founder mouse is identified to be transgenic, it will be mated to begin establishing a transgenic line. (4) Analysis of phenotype of transgenic mice. Phenotypes of transgenic mice are dictated by both the expression pattern and biologic functions of the transgene. Elucidation of the functions of the transgene-encoded protein *in vitro* often offers some clue to what the protein might do *in vivo*.

Gene Knockout in Mice

The isolation and genetic manipulation of ES cells represents one of the most important milestones for modern genetic technologies. Several unique

properties of these ES cells, such as the pluripotency to differentiate into different tissues in an embryo, make them an efficient vehicle for introducing genetic alterations into this species. Thus, this technology provides an important breakthrough, making it possible to genetically manipulate ES cells in a controlled way in the culture dish and then introduce the mutation into the germline. This not only makes mouse genetics a powerful approach for addressing important gene functions but also identifies the mouse as a great system to model human disease. Generation of gene knockout in mice includes the following steps: (1) Construction of targeting vector. Two segments of homologous sequence to a gene of interest that flank a part of the gene essential for functions (e.g., the coding region) are used as arms of the targeting vector. On the homologous regions of the gene of interest in ES cells, the positive selectable marker will replace the essential segment of the target gene, thus creating a null allele. To create a conditional knockout (i.e., gene knockout in a spatiotemporal fashion), site-specific recombinases such as the popular cre-loxP system are used. This method is markedly useful to prevent developmental compensations and to introduce null mutations in the adult mouse that would otherwise be lethal. (2) Introduction of the targeting vector into ES cells. To alter the genome of ES cells, the targeting vector DNA is then transfected into ES cells. Stable ES cells are selected in the presence of a positive selectable antibiotic drug. Before injecting the ES cells, DNA is prepared from ES colonies to screen for positive ES cells that exhibit the correct integration or homologous recombination of the targeting vector. Positive ES colonies are then expanded and used for creation of chimeras. (3) Creation of the chimera. A chimeric organism is one in which cells originate from more than one embryo. Here, chimeric mice are denoted as those that contain some tissues from the ES cells with an altered genome. When these ES cells give rise to the lineage of the germ layer, the germ cells carrying the altered genome can be passed on to the offspring, thus creating the germline transmission from ES cells. ES cells are introduced into preimplantation-stage embryos by injection of embryonic cells directly into the cavity of blastocysts. The mixture of recognizable markers (e.g., coat color) that are specific for the donor mouse and ES cells can be used to identify chimeric mice. (4) Genotyping and phenotyping of knockout animals. The next step is to analyze whether germline transmission of targeted mutation occurs in mice. DNA from a small amount of tissue from offspring of the chimera is extracted and subjected to genomic PCR or Southern blot DNA hybridization. Positive mice (i.e., those with properly integrated targeting vector into the genome) will be used for the propagation of more knockout mice for phenotype analysis. The phenotypic studies of these mice provide ample information on the functions of these genes in growth and differentiation of organs, and during development of human diseases.

RNA Interference

Although gene ablation in animal models provides an important means to understand the *in vivo* functions of genes of interest, animal models may not adequately represent human biology.

Development of RNA interference (RNAi) technology in the past few years has provided a promising approach to understanding the biologic functions of human genes in human cells. RNAi is an ancient natural mechanism by which small, double-stranded RNA (dsRNA) acts as a guide for an enzyme complex that destroys complementary RNA and downregulates gene expression in a

sequence-specific manner. There are two ways to introduce RNAi to knock down gene expression in human cells: (1) RNA transfection: siRNA can be made chemically or using an in vitro transcription method. siRNA oligos or mixtures can be transfected into cell lines. (2) DNA transfection: Expression vectors for expressing siRNA have been made using RNA polymerase III promoters. These promoters precisely transcribe a hairpin structure of dsRNA, which will be processed into siRNA in the cell. siRNA expression vectors are advantageous over siRNA oligos for the long-term silencing of target genes to allow a wide spectrum of applications in gene therapy.

There has been a fast and fruitful development of RNAi tools for in vitro and in vivo use in mammals. These novel approaches, together with future developments, will be crucial to put RNAi technology to use for effective disease therapy or to exert the power of mammalian genetics. Therefore, the applications of RNAi to human health are enormous. With the availability of the human genome sequences, RNAi approaches hold tremendous promise for unleashing the dormant potential of sequenced genomes. Practical applications of RNAi possibly will result in new therapeutic interventions. The concept of using siRNA in battling infectious diseases and carcinogenesis was proven effective. These include notable successes in blocking replication of viruses, such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). In cancers, silencing of oncogenes such as c-Myc or Ras can slow down the proliferation rate of cancer cells. Finally, siRNA also has potential applications for some dominant genetic disorders.

The 21st century, already heralded as the “century of the gene,” carries great promise for alleviating suffering from disease and improving human health. On the whole, completion of the human genome blueprint, the promise of gene therapy and RNA interference, and the existence of stem cells has captured the imagination of the public and the biomedical community for good reason. Surgeons must take the opportunity to participate together with scientists to make realistic promises and to face the new era of modern medicine.

PART II | SPECIFIC CONSIDERATIONS

This page intentionally left blank

Skin and Subcutaneous Tissue

*Scott L. Hansen, Stephen J. Mathes,
and David M. Young*

The skin is the largest and among the most complex organs of the body. Although the skin functions simply as a protective barrier to interface with our environment, its structure and physiology are complex. The skin protects against most noxious agents, such as chemicals (by the impermeability of the epidermis), solar radiation (by means of pigmentation), infectious agents (through efficient immunosurveillance), and physically deforming forces (by the durability of the dermis). Its efficient ability to conserve or disperse heat makes the skin the major organ responsible for thermoregulation. To direct all these functions, the skin has a highly specialized nervous structure. The palms and soles are particularly thick to bear weight. The fingertips have the highest density of sensory innervation and allow for intricate tasks. Even the lines of the skin, first described by Langer, are oriented perpendicularly to the long axis of muscles to allow the greatest degree of stretching and contraction without deformity.

ANATOMY AND PHYSIOLOGY

The skin is divided into three layers: the epidermis, the basement membrane, and the dermis. The epidermis is composed mainly of cells (keratinocytes), with very little extracellular matrix. The deep, mitotically active, basal cells are a single-cell layer of the least-differentiated keratinocytes. Some multiplying cells leave the basal layer and begin to travel upward. In the spinous layer, they lose the ability to undergo mitosis. These differentiated cells start to accumulate keratohyalin granules in the granular layer. Finally, in the horny layer, the keratinocytes age, the once-numerous intercellular connections disappear, and the dead cells are shed. The keratinocyte transit time is between 40 and 56 days. The internal skeleton of cells (intermediate filaments), called keratins in epithelial cells, play an important role in the function of the epidermis. Intermediate filaments provide flexible scaffolding that enables the cell to resist external stress. Different keratins are expressed at different stages of keratinocyte maturation. In the mitotically active inner layer of the epidermis, the keratinocytes mainly express keratins 5 and 14. Patients with epidermolysis bullosa simplex, a blistering disease, were found to have a point mutation in one or the other keratin gene, thus revealing the etiology of one of the more baffling skin diseases.

Melanocytes migrate to the epidermis from precursor cells in the neural crest and provide a barrier to radiation. There are 35 keratinocytes for every melanocyte. The melanocytes produce the pigment melanin from tyrosine and cysteine. The pigment is packaged in melanosomes and transported to the tips of dendritic processes and phagocytized by the keratinocyte (apocoptation), thus transferring the pigment to the keratinocyte. The melanin aggregates on the superficial side of the nucleus in an umbrella shape. The density of melanocytes is constant among individuals of different skin color. The rate of melanin production, transfer to keratinocytes, and melanosome degradation determine

the degree of skin pigmentation. Genetically activated factors, as well as ultraviolet radiation, hormones such as estrogen, adrenocorticotrophic hormone, and melanocyte-stimulating hormone, influence these activities.

The Langerhans cells migrate from the bone marrow and function as the skin's macrophages. The Langerhans cells constitutively express class II major histocompatibility antigens and have antigen-presenting capabilities. These cells play a crucial role in immunosurveillance against viral infections and neoplasms of the skin, and may initiate skin allograft rejection.

The dermis is mostly comprised of several structural proteins. Collagen constitutes 70 percent of the dry weight of dermis and is responsible for its remarkable tensile strength. Of the seven structurally distinct collagens, the skin contains mostly type I. Early fetal dermis contains mostly type III (reticulin fibers) collagen, but this remains only in the basement membrane zone and the perivascular regions in postnatal skin. Elastic fibers are highly branching proteins that are capable of being reversibly stretched to twice their resting length. This allows skin to return to its original form after stretching. Ground substance, consisting of various polysaccharide–polypeptide (glycosaminoglycans) complexes, is an amorphous material that fills the remaining spaces.

Fibroblasts are scattered throughout the dermis and are responsible for production and maintenance of the protein matrix. Recently, proteins that control the proliferation and migration of fibroblasts have been isolated. The study of fibroblast activity by these growth factor interactions is crucial to understanding wound healing and organogenesis.

The basement membrane zone of the dermoepidermal junction is a highly organized structure of proteins that anchors the epidermis to the dermis. Mechanical disruption or a genetic defect in the synthesis of this structure results in separation of the epidermis from the dermis.

The remaining structures of the skin are situated in the dermis. An intricate network of blood vessels regulates body temperature. Vertical vascular channels interconnect two horizontal plexuses, one at the dermal–subcutaneous junction and one in the papillary dermis. Glomus bodies are tortuous arteriovenous shunts that allow a tremendous increase in blood flow to the skin when open. This ability not only provides for the nutritional needs of the skin, but enables it to dissipate a vast amount of body heat when needed. Sensory innervation follows a dermatomal distribution from segments of the spinal cord. These fibers connect to corpuscular receptors (pacinian, Meissner, and Ruffini) that respond to pressure, vibration, and touch, and to “unspecialized” free nerve endings associated with Merkel cells of the basal epidermis, and to hair follicles. These nerves are stimulated by temperature, touch, pain, and itch. The skin has three main adnexal structures. The eccrine glands, which produce sweat, are located over the entire body but are concentrated on the palms, soles, axillae, and forehead. The apocrine glands are found primarily in the axillae and the anogenital region. In lower mammals, these glands produce scent hormones (pheromones).

INJURIES TO SKIN AND SUBCUTANEOUS TISSUE

Injuries that violate the continuity of the skin and subcutaneous tissue can occur as a result of trauma or from various environmental exposures. Environmental exposures that damage the skin and subcutaneous tissues include caustic substances, exposure to extreme temperatures (Chapter 7), prolonged

or excessive pressure, and exposure to radiation. Disruption of the continuity of the skin allows the entry of organisms that can lead to local or systemic infection.

Traumatic Injuries

Traumatic wounds include penetrating, blunt, and shear forces (sliding against a fixed surface), bite, and degloving injuries. Sharp lacerations, bullet wounds, "road rash" (injury from scraping against road pavement), and degloving injuries should be treated by gentle cleansing, débridement of all foreign debris and necrotic tissue, and application of a proper dressing. Dirty or infected wounds should be left open to heal by secondary intention or delayed primary closure. Clean lacerations may be closed primarily. Road rash injuries are treated as second-degree burns and degloving injuries as third-degree or full-thickness burns. The degloved skin can be placed back on the wound like a skin graft and assessed daily for survival. If the skin becomes necrotic, it is débrided and the wound is covered with split-thickness skin grafts.

Radiation Exposure

Acute radiation injuries such as those that occur in an industrial accident are devastating. The dose of radiation exposure is oftentimes lethal. In addition to the development of skin lesions (cutaneous radiation syndrome), patients suffer from gastrointestinal hemorrhage, bone marrow suppression, and multi-organ system failure. The most notable industrial radiation exposure accident occurred in 1986 at the Chernobyl nuclear power plant. Of the 237 individuals initially suspected of being exposed, 54 suffered from cutaneous radiation syndrome. The severity of symptoms ranged widely and included xerosis (dry skin), cutaneous telangiectasias and subungual splinter hemorrhages, hemangiomas and lymphangiomas, epidermal atrophy, disseminated keratoses, extensive dermal and subcutaneous fibrosis with partial ulcerations, and pigment changes (radiation lentigo). To date, no cutaneous malignancies have been noted.

Solar or ultraviolet (UV) radiation represents the most common form of radiation exposure. The ultraviolet spectrum is divided into UVA (400–315 nm), UVB (315–290 nm), and UVC (290–200 nm). Regarding skin damage and development of skin cancers, the only significant wavelengths are in the ultraviolet spectrum. The ozone layer absorbs UV wavelengths below 290 nm, thus allowing only UVA and UVB to reach the earth. UVB is responsible for the acute sunburns and for the chronic skin damage leading to malignant degeneration, although it makes up less than 5 percent of the solar UV radiation that hits the earth.

The treatment of various malignancies oftentimes includes radiation therapy. Given the basis of this therapy to act on rapidly dividing cell types, the skin and subcutaneous tissue are significantly affected. Acute radiation changes include erythema and basal epithelial cellular death. Dry desquamation may proceed to moist desquamation. With cellular repair, permanent hyperpigmentation is observed in the field of radiation. Chronic radiation changes begin at 4–6 months and are characterized by a loss of capillaries as a result of thrombosis and fibrinoid necrosis of vessel walls. This fibrosis and hypovascularity are generally progressive, which eventually may lead to ulceration because of poor tissue perfusion.

Inflammatory Diseases

Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is a relatively uncommon destructive cutaneous lesion that is associated with an underlying systemic disease including inflammatory bowel disease, rheumatoid arthritis, hematologic malignancy, and monoclonal immunoglobulin A (IgA) gammopathy. Recognition of the underlying disease is of paramount importance in the management of skin ulceration because surgical treatment without medical management is fraught with complication. The majority of patients are treated with systemic steroids and cyclosporine. Control of the inflammatory phase, local wound care and coverage with a skin graft is efficacious.

Staphylococcal Scalded Skin Syndrome and Toxic Epidermal Necrolysis

Staphylococcal scalded skin syndrome and toxic epidermal necrolysis create a similar clinical picture, which includes erythema of the skin, bullae formation, and, eventually, wide areas of skin loss. Staphylococcal scalded skin syndrome (SSSS) is caused by an exotoxin produced during a staphylococcal infection of the nasopharynx or middle ear in the pediatric population. Toxic epidermal necrolysis (TEN) is thought to be an immunologic reaction to certain drugs, such as sulfonamides, phenytoin, barbiturates, and tetracycline. Diagnosis can be made with a skin biopsy examination because SSSS produces a cleavage plane in the granular layer of the epidermis, whereas TEN occurs at the dermoepidermal junction. The injury is similar to a second-degree burn. Treatment involves fluid and electrolyte replacement and wound care as in a burn injury. Patients with less than 10 percent of epidermal detachment are classified as Stevens-Johnson syndrome, whereas those with more than 30 percent of total body surface area involvement are classified as TEN. In Stevens-Johnson syndrome, epithelial sloughing of the respiratory and alimentary tracts occurs with resultant respiratory failure and intestinal malabsorption. Patients with TEN should be treated in burn units to decrease the morbidity from the wounds. The skin slough has been successfully treated with cadaveric or porcine skin or semisynthetic biologic dressings (Biobrane). Temporary coverage with a biologic dressing allows the underlying epidermis to regenerate spontaneously. Corticosteroid therapy has not been efficacious.

BENIGN TUMORS

Cysts (Epidermal, Dermoid, Trichilemmal)

Epidermal cysts are the most common type of cutaneous cyst and can occur anywhere on the body as a single, firm nodule. Trichilemmal (pilar) cysts, the next most common, occur more often in females and usually on the scalp. When ruptured, these cysts have a characteristic strong odor. Dermoid cysts are present at birth and may result from epithelium trapped during midline closure in fetal development. Dermoid cysts are most often found in the midline of the face (e.g., on the nose or forehead) and also are common on the lateral eyebrow.

The walls of all these cysts consist of a layer of epidermis oriented with the basal layer superficial and the more mature layers deep (i.e., with the epidermis growing into the center of the cyst). The desquamated cells (keratin) collect in the center and form the creamy substance of the cyst. Histologic examination

is needed to differentiate the different types. Surgeons often refer to cutaneous cysts as sebaceous cysts because they appear to contain sebum; however, this is a misnomer because the substance is actually keratin.

Cysts usually are asymptomatic and ignored until they rupture and cause local inflammation. The area becomes infected and an abscess forms. Incision and drainage is recommended for an acutely infected cyst. After resolution of the abscess, the cyst wall must be excised or the cyst will recur. Similarly, when excising an unruptured cyst, care must be taken to remove the entire wall to prevent recurrence.

Nevi (Acquired, Congenital)

Acquired melanocytic nevi are classified as junctional, compound, or dermal, depending on the location of the nevus cells. This classification does not represent different types of nevi but rather different stages in the maturation of nevi. Initially, nevus cells accumulate in the epidermis (junctional), migrate partially into the dermis (compound), and finally rest completely in the dermis (dermal). Eventually most lesions undergo involution.

Congenital nevi are much rarer, occurring in only 1 percent of neonates. These lesions are larger and oftentimes contain hair. Histologically they appear similar to acquired nevi. Congenital giant lesions (giant hairy nevus) most often occur in a bathing trunk distribution or on the chest and back. These lesions are cosmetically unpleasant. Additionally, they may develop malignant melanoma in 1–5 percent of the cases. Excision of the nevus is the treatment of choice, but often the lesion is so large that closure of the wound with autologous skin grafts is not possible because of the lack of adequate donor sites. Serial excisions over several years with either primary closure or skin grafting and tissue expansion of the normal surrounding skin are the present modes of therapy.

Soft-Tissue Tumors (Acrochordons, Dermatofibromas, Lipomas)

Acrochordons (skin tags) are fleshy, pedunculated masses located on the axillae, trunk, and eyelids. They are composed of hyperplastic epidermis over a fibrous connective tissue stalk. These lesions are usually small and are always benign.

Dermatofibromas are usually solitary nodules measuring approximately 1–2 cm in diameter. They are found primarily on the legs and sides of the trunk. The lesions are composed of whorls of connective tissue containing fibroblasts. The mass is not encapsulated and vascularization is variable. Dermatofibromas can be diagnosed by clinical examination. When lesions enlarge to 2–3 cm, excisional biopsy is recommended to assess for malignancy. Lipomas are the most common subcutaneous neoplasm. They are found mostly on the trunk but may appear anywhere. They may sometimes grow to a large size. Microscopic examination reveals a lobulated tumor containing normal fat cells. Excision is performed for diagnosis and to restore normal skin contour.

MALIGNANT TUMORS

Epidemiology

Increased exposure to ultraviolet radiation is associated with an increased development of all three of the common skin malignancies; basal cell carcinoma, squamous cell carcinoma, and melanoma. Chemical carcinogens such as tar, arsenic, and nitrogen mustard are known carcinogens. Human papillomavirus

has been found in certain squamous cell cancers and may be linked with oncogenesis. Radiation therapy in the past for skin lesions such as acne vulgaris, when it resulted in radiation dermatitis, is associated with an increased incidence of basal and squamous cell cancers in the treated areas. Any area of skin subjected to chronic irritation, such as burn scars (Marjolin ulcers), repeated sloughing of skin from bullous diseases, and decubitus ulcers, all have an increased chance of developing squamous cell cancer.

Immunosuppressed patients receiving chemotherapy for other malignancies or immunosuppressants for organ transplants have an increased incidence of basal cell and squamous cell cancers and malignant melanoma. Acquired immune deficiency syndrome (AIDS) is associated with an increased risk of developing skin neoplasms.

Basal Cell Carcinoma

Basal cell carcinomas contain cells that resemble the basal cells of the epidermis. It is the most common type of skin cancer and is subdivided into several types by gross and histologic morphology. The nodulocystic or noduloulcerative type accounts for 70 percent of basal cell carcinomas. It is a waxy, cream-colored lesion with rolled, pearly borders. It often contains a central ulcer. When these lesions are large they are called "rodent ulcers." Pigmented basal cell carcinomas are tan to black in color and should be distinguished by biopsy examination from melanoma. Superficial basal cell cancers occur more commonly on the trunk and form a red, scaling lesion that is sometimes difficult to distinguish grossly from Bowen disease. A rare form of basal cell carcinoma is the basosquamous type, which contains elements of basal cell and squamous cell cancer. These lesions can metastasize more like a squamous cell carcinoma and should be treated aggressively. Other types include morpheaform, adenoid, and infiltrative carcinomas.

Basal cell carcinomas usually are slow growing, and patients often neglect these lesions for years. Metastasis and death from this disease are extremely rare, but these lesions can cause extensive local destruction. The majority of small (less than 2 mm), nodular lesions may be treated by dermatologists with curettage and electrodesiccation or laser vaporization. A drawback to these procedures is that no pathologic specimen is obtained to confirm the diagnosis or evaluate the tumor margins. Larger tumors, lesions that invade bone or surrounding structures, and more aggressive histologic types (morpheaform, infiltrative, and basosquamous) are best treated by surgical excision with a 2–4-mm margin of normal tissue. Histologic confirmation that the margins of resection do not contain tumor is required. Because nodular lesions are less likely to recur, the smaller margin may be used, whereas other types need a wider margin of resection.

Squamous Cell Carcinoma

Squamous cell carcinomas arise from keratinocytes of the epidermis. It is less common than basal cell carcinoma but is more devastating because it can invade surrounding tissue and metastasize more readily. In situ lesions have the eponym of Bowen disease, and in situ squamous cell carcinomas of the penis are referred to as erythroplasia of Queyrat. Contrary to previous reports, Bowen's disease is not a marker for other systemic malignancies.

Tumor thickness correlates well with its biologic behavior. Lesions that recur locally are more than 4 mm thick and lesions that metastasize are 10 mm

or more. The location of the lesion also is important. Tumors arising in burn scars (Marjolin ulcer), areas of chronic osteomyelitis, and areas of previous injury metastasize early. Lesions on the external ear frequently recur and involve regional lymph node basins early. Squamous cell cancers in areas with solar damage behave less aggressively and usually require only local excision.

Lesions should be excised with a 1-cm margin if possible, and histologic confirmation that the margins are tumor-free is mandatory. Tumor-invading bone should be excised if recurrence is to be avoided. Regional lymph node excision is indicated for clinically palpable nodes (therapeutic lymph node dissection). Lesions arising in chronic wounds behave aggressively and are more likely to spread to regional lymph nodes. For these lesions lymphadenectomy before the development of palpable nodes is indicated (prophylactic lymph node dissection). Metastatic disease is a poor prognostic sign, with only 13 percent of patients surviving after 10 years.

Alternative Therapy

Alternatives to surgical therapy for squamous and basal cell cancers consist of radiation therapy or topical 5-fluorouracil for patients unable or unwilling to undergo surgery. Radiation therapy for small and superficial lesions obtains cure rates comparable to surgical excision. Radiation damage to surrounding normal skin with inflammation and scarring can be a problem. The development of cutaneous malignancies in irradiated skin also is a serious long-term risk with this treatment modality.

For lesions on the face or near the nose or eye, resection of a wide rim of normal tissue to remove the entire tumor can cause significant functional and cosmetic problems. These lesions can be removed by Mohs micrographic surgery. Mohs fresh tissue chemosurgery technique, developed in 1932, is a method to serially excise a tumor by taking small increments of tissue until the entire tumor is removed. Each piece of tissue removed is frozen and immediately examined microscopically to determine whether the entire lesion has been resected. The advantage of the Mohs fresh tissue chemosurgery technique is that the entire margin of resection is evaluated, although with wide excision and traditional histologic examination, only selected samples of the surgical margin are examined. The major benefit of Mohs fresh tissue chemosurgery technique is the ability to remove a tumor with the least sacrifice of uninvolved tissue. This technique is effective for treating carcinomas around the eyelids and nose, where tissue loss is most conspicuous. Cure rates are comparable to those of wide excision.

Patients with basal cell carcinomas have been treated with intralesional injection of interferon. The majority of the lesions were eliminated or controlled by the injections. The major disadvantages of this treatment are the need for multiple office visits over several weeks for injections, the systemic side effects of interferon, and a potential need for surgery if the lesions do not respond to injections. Clinical trials with combinations of retinoids (vitamin A derivatives) and interferon have demonstrated good response rates in patients with advanced, inoperable squamous cell carcinomas.

Malignant Melanoma

What was a relatively rare disease 50 years ago has now become alarmingly more common. The rise in the rate of melanoma is the highest of any cancer in the United States. In 1935, the annual incidence of the disease was 1 per

100,000 people. By 1991, the incidence had risen to 12.9 per 100,000 people. The 1998 age-adjusted rate for invasive melanoma is 18.3 per 100,000 for white males and 13.0 per 100,000 for white females in the United States.

Pathogenesis

Melanoma arises from transformed melanocytes and occur anywhere that melanocytes have migrated during embryogenesis. The eye, central nervous system, gastrointestinal tract, and even the gallbladder have been reported as primary sites of the disease. More than 90 percent of melanomas are found on the skin; however, 4 percent are discovered as metastases without an identifiable primary site.

Nevi are benign melanocytic neoplasms found on the skin of most people. Once the melanocyte has transformed into the malignant phenotype, the growth of the lesion is radial in the plane of the epidermis. Even though microinvasion of the dermis can be observed during this radial growth phase, metastases do not occur. Only when the melanoma cells form nests in the dermis are metastases observed.

Types

The most common type of melanoma, representing up to 70 percent of melanomas, is the superficial spreading type. These lesions occur anywhere on the skin except the hands and feet. They are flat, commonly contain areas of regression, and measure 1–2 cm in diameter at the time of diagnosis. There is a relatively long radial growth phase before vertical growth begins. The nodular type accounts for 15–30 percent of melanomas. These lesions are darker and raised. Nodular melanoma lack radial growth peripheral to the area of vertical growth; hence, all nodular melanomas are in the vertical growth phase at the time of diagnosis. Although it is an aggressive lesion, the prognosis for a patient with a nodular-type lesion is the same as that for a patient with a superficial spreading lesion of the same depth of invasion. The lentigo maligna type, accounting for 4–15 percent of melanomas, occurs mostly on the neck, the face, and the back of the hands of older adult people. These lesions are always surrounded by dermis with heavy solar degeneration. They tend to become quite large before a diagnosis is made, but also have the best prognosis because invasive growth occurs late. Only 5–8 percent of lentigo malignas are estimated to evolve to invasive melanoma. Acral lentiginous type is the least-common subtype, representing only 2–8 percent of melanoma in whites. It occurs on the palms and soles and in the subungual regions. Although melanoma among dark-skinned people is relatively rare, the acral lentiginous type accounts for 29–72 percent of all melanomas in dark-skinned people (African Americans, Asians, and Hispanics) than in people with less-pigmented skin. Subungual lesions appear as blue-black discolorations of the posterior nail fold and are most common on the great toe or thumb. The additional presence of pigmentation in the proximal or lateral nail folds (Hutchinson sign) is diagnostic of subungual melanoma.

Prognostic Factors

The most current staging system, from the American Joint Committee on Cancer (AJCC), contains the best method of interpreting clinical information in regard to prognosis of this disease (Table 15-1).

The T classification of lesions comes from the original observation by Clark that prognosis is directly related to the level of invasion of the skin by the

melanoma. Whereas Clark used the histologic level (I, superficial to basement membrane [in situ]; II, papillary dermis; III, papillary/reticular dermal junction; IV, reticular dermis; and V, subcutaneous fat), Breslow modified the approach to obtain a more reproducible measure of invasion by the use of an ocular micrometer. The lesions were measured from the granular layer of the epidermis or the base of the ulcer to the greatest depth of the tumor (I, 0.75 mm or less; II, 0.76–1.5 mm; III, 1.51–4.0 mm; IV, 4.0 mm or more). These levels of invasion have been subsequently modified and incorporated in the AJCC staging system.

Evidence of tumor in regional lymph nodes is a poor prognostic sign. This is accounted for in the staging system by advancing any T classifications from stage I or II to stage III (Table 15-2). The 15-year survival rate drops precipitously with the presence of lymph node metastasis. The number of positive lymph nodes also is correlated with survival rates.

The presence of distant metastasis is a grave prognostic sign (stage IV). The median survival ranges from 2–7 months, depending on the number and site of metastases, but survival up to a few years has been reported.

TABLE 15-1 TNM Classification of Melanoma of the Skin

Primary tumor (T)	
T1	1.0 mm in thickness or less
T1a	Without ulceration and Clark level II/III
T1b	With ulceration or level IV/V
T2	1.01–2.0 mm in thickness
T2a	Without ulceration
T2b	With ulceration
T3	2.01–4.0 mm in thickness
T3a	Without ulceration
T3b	With ulceration
T4	4.01 mm or greater in thickness
T4a	Without ulceration
T4b	With ulceration
Nodal status (N)	
N1	1 node
N1a	Micrometastasis (as diagnoses after sentinel lymph node or lymphadenectomy)
N1b	Macrometastasis (clinically detectable, confirmed by pathology)
N2	2–3 nodes
N2a	Micrometastasis
N2b	Macrometastasis
N2c	In-transit met(s) without metastatic nodes
N3	4 or more metastatic nodes, or matted nodes, or in-transit met(s)/satellite(s) with metastatic node(s)
Metastasis (M)	
M1	Distant skin, subcutaneous or nodal metastasis, serum LDH normal
M2	Lung metastasis, normal LDH
M3	All other visceral metastasis with normal LDH or any distant mets with elevated LDH

LDH = lactic dehydrogenase.

TABLE 15-2 Stage Grouping

Stage IA	T1a	N0	M0
IB	T1b	N0	M0
	T2a	N0	M0
IIA	T2b	N0	M0
T3a	N0	M0	
IIB	T3b	N0	M0
T4a	N0	M0	
IIC	T4b	N0	M0
III	Any T	N1	M0
		N2	
		N3	
IV	Any T	Any N	Any M1

Source: From the American Joint Committee on Cancer Staging.

Other independent prognostic factors have been identified:

Anatomic location. People with lesions of the extremities have a better prognosis than people with melanomas of the head and neck or trunk (82 percent 10-year survival rate for localized disease of the extremity, compared to a 68 percent survival rate with a lesion of the face).

Ulceration. The 10-year survival rate for patients with local disease (stage I) and an ulcerated melanoma was 50 percent, compared to 78 percent for the same stage lesion without ulceration. Early studies identified that the incidence of ulceration increases with increasing thickness, from 12.5 percent in melanomas less than 0.75 mm–72.5 percent in melanomas greater than 4.0 mm.

Gender. Numerous studies demonstrate that females have an improved survival compared to males. After correcting for thickness, age, and location, females continue to have a higher survival rate than men (80 percent 10-year survival rate for women vs. 61 percent 10-year survival rate for men with stage I disease).

Histologic type. Nodular melanomas have the same prognosis as superficial spreading types when lesions are matched for depth of invasion. Lentigo maligna types, however, have a better prognosis even after correcting for thickness, and acral lentiginous lesions have a worse prognosis.

Treatment

The treatment of melanoma is primarily surgical. The indication for procedures such as lymph node dissection, sentinel lymphadenectomy, superficial parotidectomy, and resection of distant metastases have changed somewhat over time, but the only hope for cure and the best treatment for regional control and palliation remains surgery. Most cases of cutaneous melanoma are cured by excision of the primary tumor alone. Radiation therapy, regional and systemic chemotherapy, and immunotherapy are effective in a limited set of circumstances, but none are a first-line option.

All suspicious lesions should undergo biopsy. A 1-mm margin of normal skin is taken if the wound can be closed primarily. If removal of the entire lesion creates too large a defect, then an incisional biopsy of a representative part is recommended. Biopsy incisions should be made with the expectation that a

subsequent wide excision of the biopsy site may be done. Once a diagnosis of melanoma is made, the biopsy scar and any remains of the lesion need to be removed to eradicate any remaining tumor. Four randomized prospective trials suggest that lesions 1 mm or less in thickness can be treated with a 1-cm margin. For lesions 1–4-mm thick, a 2-cm margin is recommended. There is little data to support the use of margins wider than 2 cm. The surrounding tissue should be removed down to the fascia to remove all lymphatic channels. If the deep fascia is not involved by the tumor, removing it does not affect recurrence or survival rates, so the fascia is left intact. If the defect cannot be closed primarily, a skin graft or local flap is used.

All clinically positive lymph nodes should be removed by regional nodal dissection. When groin lymph nodes are removed, the deep (iliac) nodes must be removed along with the superficial (inguinal) nodes. For axillary dissections the nodes medial to the pectoralis minor muscle must also be resected. For lesions on the face, anterior scalp, and ear, a superficial parotidectomy to remove parotid nodes and a modified neck dissection is recommended. Disruption of the lymphatic outflow does cause significant problems with chronic edema, especially of the lower extremity.

Treatment of regional lymph nodes that do not obviously contain tumor in patients without evidence of metastasis (stages I and II) is determined by considering the possible benefits of the procedure as weighed against the risks. In patients with thin lesions (less than 0.75 mm), the tumor cells are still localized in the surrounding tissue, and the cure rate is excellent with wide excision of the primary lesion; therefore treatment of regional lymph nodes is not beneficial. With very thick lesions (more than 4 mm), it is highly likely that the tumor cells have already spread to the regional lymph nodes and distant sites. Removal of the lymph nodes has no effect on survival. Most of these patients die of metastatic disease before developing problems in regional nodes. Because there are significant morbid effects of lymphadenectomy, most surgeons defer the procedure until clinically evident disease appears. Approximately 40 percent of these patients eventually develop disease in the lymph nodes and require a second palliative operation. Elective lymphadenectomy is sometimes performed in these patients as a staging procedure before entry into clinical trials.

In patients with intermediate-thickness tumors (T2 and T3, 0.76–4.0 mm) and no clinical evidence of nodal or metastatic disease, the use of prophylactic dissection (elective lymph node dissection on clinically negative nodes) is controversial. Numerous retrospective studies suggested that patients with primary melanoma who underwent elective lymph node dissection had improved survival. However, prospective, randomized studies have not demonstrated that elective lymph node dissection improves survival in patients with intermediate-thickness melanomas. Careful examination of specimens in patients undergoing elective lymph node dissection have found that, in 25–50 percent of the cases, specimens contain micrometastases. Among patients who do not have an elective lymph node dissection, 20–25 percent eventually develop clinically evident disease and require lymphadenectomy. More evidence suggests that there may be improved survival with elective lymph node dissection in patients with a higher risk of developing metastasis (i.e., lesions with ulceration or those located on the trunk, head, and neck). The most compelling argument for the potential benefits of elective lymph node dissection comes from evidence in large clinical trials; patients with intermediate-thickness melanomas without elective node dissection continue

to die of the disease 10 years later, whereas patients who had an elective lymph node dissection do not. However, these differences are not statistically significant.

Sentinel lymphadenectomy for malignant melanoma is rapidly becoming the standard procedure. The sentinel node may be preoperatively located with the use of a gamma camera, or by intraoperative injection of 1 percent isosulfan blue dye into the site of the primary melanoma. These techniques enable the surgeon to identify the lymphatic drainage from the primary lesion and determine the first (sentinel) lymph node draining the tumor. The node is removed, and if micrometastases are identified in frozen-section examination, a complete lymph node dissection is performed. Whether this procedure actually improves survival in these patients awaits the results of clinical trials.

When patients develop distant metastases, surgical therapy may be indicated. Once melanoma has spread to a distant site, median survival is 7–8 months and the 5-year survival rate is less than 5 percent. Solitary lesions in the brain, gastrointestinal tract, or skin that are symptomatic should be excised when possible. Although cure is extremely rare, the degree of palliation can be high and asymptomatic survival prolonged. A decision to operate on metastatic lesions must be made after careful deliberation with the patient.

A promising area in the nonsurgical treatment of melanoma is the use of immunologic manipulation. Interferon- α (INF- α) 2b is the only Food and Drug Administration (FDA)-approved adjuvant treatment for AJCC stages IIB/III melanoma. Several randomized trials of INF- α adjuvant therapy have been conducted. In these patients, both the relapse-free interval and overall survival were improved with use of INF- α . Side effects were common and frequently severe.

Vaccines have been developed with the hope of stimulating the body's own immune system against the tumor. All treatments are currently investigational. One defined-antigen vaccine has entered clinical testing, the ganglioside GM2. Gangliosides are carbohydrate antigens found on the surface of melanomas and many other tumors.

Although initially thought to be ineffective in the treatment of melanoma, radiation therapy has been shown to be useful. High-dose-per-fraction radiation produces a better response rate than low-dose-large-fraction therapy. It has been found that postoperative radiation to the neck or axilla after radical lymph node dissections decreases regional recurrence rates in node-positive patients. Radiation therapy is the treatment of choice for patients with symptomatic multiple brain metastases. Up to 70 percent of treated patients show measurable improvement in tumor size, symptomatology, or performance status.

Hyperthermic regional perfusion of the limb with a chemotherapeutic agent (e.g., melphalan) is the treatment of choice for patients with local recurrence or in-transit lesions (local disease in lymphatics) on an extremity that is not amenable to excision. In-transit metastases develop in 5–8 percent of melanoma patients with a high-risk primary melanoma (> 1.5 mm). The goal of regional perfusion therapy is to increase the dosage of the chemotherapeutic agent to maximize tumor response while limiting systemic toxic effects. Prospective clinical trials are under way to evaluate the use of regional perfusion for melanoma of the limbs as adjuvant therapy for patients with stage I disease. Additionally, regional perfusion therapy for metastatic disease to the liver is under investigation.

OTHER MALIGNANCIES

Merkel Cell Carcinoma (Primary Neuroendocrine Carcinoma of the Skin)

Merkel cell carcinomas are of neuroepithelial differentiation. These tumors are associated with a synchronous or metachronous squamous cell carcinoma 25 percent of the time. These tumors are very aggressive, and wide local resection with 3-cm margins is recommended. Local recurrence rates are high, and distant metastases occur in one third of patients. Prophylactic regional lymph node dissection and adjuvant radiation therapy are recommended. Overall, the prognosis is worse than for malignant melanoma.

Extramammary Paget Disease

This tumor is histologically similar to the mammary type. It is a cutaneous lesion that appears as a pruritic red patch that does not resolve. Biopsy demonstrates classic Paget cells. Paget disease is thought to be a cutaneous extension of an underlying adenocarcinoma, although an associated tumor cannot always be demonstrated.

Adnexal Carcinomas

This group includes the rare-type tumors apocrine, eccrine, and sebaceous carcinomas. They are locally destructive and can cause death by distant metastasis.

Angiosarcomas

Angiosarcomas may arise spontaneously, mostly on the scalp, face, and neck. They usually appear as a bruise that spontaneously bleeds or enlarges without trauma. Tumors also may arise in areas of prior radiation therapy or in the setting of chronic lymphedema of the arm, such as after mastectomy (Stewart-Treves syndrome). The angiosarcomas that arise in these areas of chronic change occur decades later. The tumors consist of anaplastic endothelial cells surrounding vascular channels. Although total excision of early lesions can provide occasional cure, the prognosis usually is poor, with 5-year survival rates of less than 20 percent. Chemotherapy and radiation therapy are used for palliation.

Kaposi Sarcoma

Kaposi sarcoma (KS) appears as rubbery bluish nodules that occur primarily on the extremities but may appear anywhere on the skin and viscera. These lesions are usually multifocal rather than metastatic. Classic KS is seen in people of Eastern Europe or sub-Saharan Africa. The lesions are locally aggressive but undergo periods of remission. Visceral spread of the lesions is rare, but a subtype of the African variety has a predilection for spreading to lymph nodes. A different variety of KS has been described for people with AIDS or with immunosuppression from chemotherapy. In this form of the disease, the lesions spread rapidly to the nodes, and the gastrointestinal and respiratory tract often are involved. Development of AIDS-related KS may be associated with concurrent infection with a herpes-like virus.

Treatment for all types of KS consists of radiation to the lesions. Combination chemotherapy is effective in controlling the disease, although most

patients develop an opportunistic infection during or shortly after treatment. Surgical treatment is reserved for lesions that interfere with vital functions, such as bowel obstruction or airway compromise.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans consists of large nodular lesions located mainly on the trunk. They often ulcerate and become infected. With enlargement, the lesions become painful. Histologically, the lesions contain atypical spindle cells, probably of fibroblast origin, located around a core of collagen tissue. Sometimes they are mistaken for an infected keloid. Metastases are rare and surgical excision can be curative. Excision must be complete because local recurrences are common.

Fibrosarcoma

Fibrosarcomas are hard, irregular masses found in the subcutaneous fat. The fibroblasts appear markedly anaplastic with disorganized growth. If they are not excised completely, metastases usually develop. The 5-year survival rate after excision is approximately 60 percent.

Liposarcoma

Liposarcomas arise in the deep muscle planes and, rarely, from the subcutaneous tissue. They occur most commonly on the thigh. An enlarging lipoma should be excised and inspected to distinguish it from a liposarcoma. Wide excision is the treatment of choice, with radiation therapy reserved for metastatic disease.

FUTURE DEVELOPMENTS IN SKIN SURGERY

Despite three decades of effort, the major challenge in surgical therapy for diseases of the skin remains the lack of an optimum replacement for diseased or damaged tissue. Autologous skin grafts are still the best method to treat skin defects, but donor-site problems and limited availability of autologous skin remain problematic. Tissue expansion with subcutaneous balloon implants produces new epidermis; however, much of this tissue is rearrangement of the old tissue. Expansion of skin produces a limited amount of useful tissue. The future of surgical therapy for diseases of the skin lies in the development of engineered skin replacements. Current research is directed at identifying different materials and cells that can be used to replace both epidermis and dermis.

HISTORY OF MODERN BREAST CANCER SURGERY

In 1894, Halsted and Meyer established the radical mastectomy as state-of-the-art breast cancer treatment. They advocated complete dissection of axillary lymph node levels I–III and routinely resected the long thoracic nerve and the thoracodorsal neurovascular bundle with the axillary contents. In 1948, to reduce the morbidity of breast cancer surgery, Patey and Dyson of the Middlesex Hospital, London, advocated a modified radical mastectomy for the management of advanced operable breast cancer. Their technique included preservation of the pectoralis major muscle, the long thoracic nerve, and the thoracodorsal neurovascular bundle. They showed that removal of only the pectoralis minor muscle allowed adequate access to and clearance of axillary lymph node levels I–III. Subsequently, Madden advocated a modified radical mastectomy that preserved both the pectoralis major and minor muscles even though this approach prevented dissection of the apical (level III) axillary lymph nodes.

The National Surgical Adjuvant Breast and Bowel Project B-04 (NSABP B-04) conducted by Fisher and colleagues compared local and regional treatments of breast cancer. Life table estimates were obtained for 1665 women enrolled and followed for a mean of 120 months. This study randomized clinically node-negative women into three groups: (1) Halsted radical mastectomy (RM); (2) total mastectomy plus radiation therapy (TM+RT); and (3) total mastectomy (TM) alone. Clinically node-positive women were treated with RM or TM+RT. There were no differences in survival between the three groups of node-negative women or between the 2 groups of node-positive women. Correspondingly, there were no differences in survival during the first and second 5-year follow-up periods.

FUNCTIONAL ANATOMY OF THE BREAST

The breast is composed of 15–20 lobes, which are each composed of several lobules. Each lobe of the breast terminates in a major (lactiferous) duct (2–4 mm in diameter), which opens through a constricted orifice (0.4–0.7 mm in diameter) into the ampulla of the nipple. Fibrous bands of connective tissue travel through the breast (suspensory ligaments of Cooper), which insert perpendicularly into the dermis and provide structural support. The axillary tail of Spence extends laterally across the anterior axillary fold. The upper outer quadrant of the breast contains a greater volume of tissue than do the other quadrants.

Blood supply, innervation, and lymphatics. The breast receives its blood supply from (1) perforating branches of the internal mammary artery; (2) lateral branches of the posterior intercostal arteries; and (3) branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery. The veins and lymph vessels of the breast follow the course of the arteries with venous drainage being toward the axilla. The vertebral venous plexus of Batson, which invests the vertebrae and

extends from the base of the skull to the sacrum, can provide a route for breast cancer metastases to the vertebrae, skull, pelvic bones, and central nervous system.

Lateral cutaneous branches of the third through sixth intercostal nerves provide sensory innervation of the breast (lateral mammary branches) and of the anterolateral chest wall. The intercostobrachial nerve is the lateral cutaneous branch of the second intercostal nerve and may be visualized during surgical dissection of the axilla. Resection of the intercostobrachial nerve causes loss of sensation over the medial aspect of the upper arm.

The boundaries for lymph drainage of the axilla are not well demarcated, and there is considerable variation in the position of the axillary lymph nodes. The 6 axillary lymph node groups recognized by surgeons are (1) the axillary vein group (lateral); (2) the external mammary group (anterior or pectoral); (3) the scapular group (posterior or subscapular); (4) the central group; (5) the subclavicular group (apical); and (6) the interpectoral group (Rotter's).

The lymph node groups are assigned levels according to their relationship to the pectoralis minor muscle. Lymph nodes located lateral to or below the lower border of the pectoralis minor muscle are referred to as level I lymph nodes, which include the axillary vein, external mammary, and scapular groups. Lymph nodes located superficial or deep to the pectoralis minor muscle are referred to as level II lymph nodes, which include the central and interpectoral groups. Lymph nodes located medial to or above the upper border of the pectoralis minor muscle are referred to as level III lymph nodes, which make up the subclavicular group. The axillary lymph nodes usually receive more than 75 percent of the lymph drainage from the breast.

PHYSIOLOGY OF THE BREAST

Breast development and function. Breast development and function are initiated by a variety of hormonal stimuli, including estrogen, progesterone, prolactin, oxytocin, thyroid hormone, cortisol, and growth hormone. Estrogen, progesterone, and prolactin especially have profound trophic effects that are essential to normal breast development and function. Estrogen initiates ductal development, although progesterone is responsible for differentiation of epithelium and for lobular development. Prolactin is the primary hormonal stimulus for lactogenesis in late pregnancy and the postpartum period. It upregulates hormone receptors and stimulates epithelial development. Secretion of neurotrophic hormones from the hypothalamus is responsible for regulation of the secretion of the hormones that affect the breast tissues. The gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) regulate the release of estrogen and progesterone from the ovaries. In turn, the release of LH and FSH from the basophilic cells of the anterior pituitary is regulated by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Positive and negative feedback effects of circulating estrogen and progesterone regulate the secretion of LH, FSH, and GnRH.

Gynecomastia. Gynecomastia refers to an enlarged breast in the male. Physiologic gynecomastia usually occurs during three phases of life: the neonatal period, adolescence, and senescence. Common to each of these phases is an excess of circulating estrogens in relation to circulating testosterone. Neonatal gynecomastia is caused by the action of placental estrogens on neonatal breast tissues, although in adolescence, there is an excess of estradiol relative to testosterone, and with senescence, the circulating testosterone level falls,

resulting in relative hyperestrogenism. In gynecomastia, the ductal structures of the male breast enlarge, elongate, and branch with a concomitant increase in epithelium. During puberty, the condition often is unilateral and typically occurs between ages 12 and 15 years. In contrast, senescent gynecomastia usually is bilateral. In the nonobese male, breast tissue measuring at least 2 cm in diameter must be present before a diagnosis of gynecomastia is made. Dominant masses or areas of firmness, irregularity, and asymmetry suggest the possibility of a breast cancer, particularly in the older male. Mammography and ultrasonography are employed for diagnostic purposes.

INFECTIOUS AND INFLAMMATORY DISORDERS OF THE BREAST

Bacterial infection. *Staphylococcus aureus* and *Streptococcus* species are the organisms most frequently recovered from nipple discharge from an infected breast. Breast abscesses are typically seen in staphylococcal infections and present with point tenderness, erythema, and hyperthermia. These abscesses are related to lactation and occur within the first few weeks of breast-feeding. Progression of a staphylococcal infection may result in subcutaneous, subareolar, interlobular (periductal), and retromammary abscesses (unicentric or multicentric), necessitating operative drainage of fluctuant areas. Preoperative ultrasonography is effective in delineating the extent of the needed drainage procedure, which is best accomplished via circumareolar incisions or incisions paralleling Langer lines. Although staphylococcal infections tend to be more localized and may be located deep in the breast tissues, streptococcal infections usually present with diffuse superficial involvement. They are treated with local wound care, including warm compresses, and the administration of intravenous antibiotics (penicillins or cephalosporins). Breast infections may be chronic, possibly with recurrent abscess formation. In this situation, cultures are taken to identify acid-fast bacilli, anaerobic and aerobic bacteria, and fungi. Uncommon organisms may be encountered and long-term antibiotic therapy may be required.

Hidradenitis suppurativa. Hidradenitis suppurativa of the nipple-areola complex or axilla is a chronic inflammatory condition that originates within the accessory areolar glands of Montgomery or within the axillary sebaceous glands. When located in and about the nipple-areola complex, this disease may mimic other chronic inflammatory states, Paget disease of the nipple, or invasive breast cancer. Involvement of the axillary skin is often multifocal and contiguous. Antibiotic therapy with incision and drainage of fluctuant areas is appropriate treatment. Complete excision of the involved areas may be required and may necessitate coverage with advancement flaps or split-thickness skin grafts.

Mondor's disease. This variant of thrombophlebitis involves the superficial veins of the anterior chest wall and breast. In 1939, Mondor described the condition as "string phlebitis," a thrombosed vein presenting as a tender, cord-like structure. Typically, a woman presents with acute pain in the lateral aspect of the breast or the anterior chest wall. A tender, firm cord is found to follow the distribution of one of the major superficial veins. Most women have no evidence of thrombophlebitis in other anatomic sites. When the diagnosis is uncertain, or when a mass is present near the tender cord, biopsy is indicated. Therapy for Mondor disease includes the liberal use of antiinflammatory medications and warm compresses that are applied along the symptomatic vein. Restriction of

motion of the ipsilateral extremity and shoulder and brassiere support of the breast are important. The process usually resolves within 4–6 weeks. When symptoms persist or are refractory to therapy, excision of the involved vein segment is appropriate.

COMMON BENIGN DISORDERS AND DISEASES OF THE BREAST

Aberrations of normal development and involution. The basic principles underlying the aberrations of normal development and involution (ANDI) classification of benign breast conditions are (1) benign breast disorders and diseases are related to the normal processes of reproductive life and to involution; (2) there is a spectrum of breast conditions that ranges from normal to disorder to disease; and (3) the ANDI classification encompasses all aspects of the breast condition, including pathogenesis and the degree of abnormality. The horizontal component of Table 16-1 defines ANDI along a spectrum from normal, to mild abnormality (disorder), to severe abnormality (disease). The vertical component defines the period during which the condition develops.

Reproductive Years: Fibroadenomas are seen predominantly in younger women age 15–25 years. Fibroadenomas usually grow to 1 or 2 cm in diameter

TABLE 16-1 ANDI Classification of Benign Breast Disorders

	Normal →	Disorder →	Disease
Early reproductive years (age 15–25)	Lobular development	Fibroadenoma	Giant fibroadenoma
	Stromal development	Adolescent hypertrophy	Gigantomastia
	Nipple eversion	Nipple inversion	Subareolar abscess Mammary duct fistula
Later reproductive years (age 25–40)	Cyclical changes of menstruation	Cyclical mastalgia	Incapacitating mastalgia
	Epithelial hyperplasia of pregnancy	Nodularity Bloody nipple discharge	
Involution (age 35–55)	Lobular involution	Macrocysts	
	Duct involution	Sclerosing lesions	
	–Dilation	Duct ectasis	Periductal mastitis
	–Sclerosis	Nipple retraction	
	Epithelial turnover	Epithelial hyperplasia	Epithelial hyperplasia with atypia

ANDI = Aberrations of normal development and involution.

Modified with permission from Hughes LE: Aberrations of normal development and involution (ANDI): A concept of benign breast disorders based on pathogenesis. In Hughes LE, Mansel RE, Webster DJT (eds): *Benign Disorders and Diseases of the Breast: Concepts and Clinical Management*. London: WB Saunders, 2000, p 23.

and then are stable, but may grow to a larger size. Small fibroadenomas (1 cm in size or less) are considered normal, although larger fibroadenomas (up to 3 cm) are disorders and giant fibroadenomas (larger than 3 cm) are disease. Similarly, multiple fibroadenomas (more than 5 lesions in one breast) are very uncommon and are considered disease. The precise etiology of adolescent breast hypertrophy is unknown. A spectrum of changes from limited to massive stromal hyperplasia (gigantomastia) is seen. Nipple inversion is a disorder of development of the major ducts, which prevents normal protrusion of the nipple. Mammary duct fistulas arise when nipple inversion predisposes to major duct obstruction, leading to recurrent subareolar abscess and mammary duct fistula.

Later Reproductive Years: Cyclical mastalgia and nodularity are usually associated with premenstrual enlargement of the breast and are regarded as normal. Cyclical pronounced mastalgia and severe painful nodularity that persists for more than 1 week of the menstrual cycle is considered a disorder. In epithelial hyperplasia of pregnancy, papillary projections sometimes give rise to bilateral bloody nipple discharge. The term fibrocystic disease is nonspecific. Too frequently, it is used as a diagnostic term to describe symptoms, to rationalize the need for breast biopsy, and to explain biopsy results. Synonyms include fibrocystic changes, cystic mastopathy, chronic cystic disease, chronic cystic mastitis, Schimmelbusch disease, mazoplasia, Cooper disease, Reclus disease, and fibroadenomatosis. Fibrocystic disease refers to a spectrum of histopathologic changes that are best diagnosed and treated specifically.

Treatment of Selected Benign Breast Disorders and Diseases

Cysts: In practice, the first investigation of palpable breast masses is frequently needle biopsy, which allows for the early diagnosis of cysts. A 21-gauge needle attached to a 10-mL syringe is placed directly into the mass, which is fixed by fingers of the nondominant hand. The volume of a typical cyst is 5–10 mL, but it may be 75 mL or more. If the fluid that is aspirated is not bloodstained, then the cyst is aspirated to dryness, the needle is removed, and the fluid is discarded as cytologic examination of such fluid is not cost-effective. After aspiration, the breast is carefully palpated to exclude a residual mass. If one exists, ultrasound examination is performed to exclude a persistent cyst, which is reaspirated if present. If the mass is solid, a tissue specimen is obtained. When cystic fluid is bloodstained, 2 mL of fluid are taken for cytology. The mass is then imaged with ultrasound and any solid area on the cyst wall is biopsied by needle. The presence of blood usually is obvious, but in cysts with dark fluid, an occult blood test or microscopy examination will eliminate any doubt. The two cardinal rules of safe cyst aspiration are (1) the mass must disappear completely after aspiration, and (2) the fluid must not be bloodstained. If either of these conditions is not met, then ultrasound, needle biopsy, and perhaps excisional biopsy are recommended.

Fibroadenomas: Removal of all fibroadenomas has been advocated irrespective of patient age or other considerations, and solitary fibroadenomas in young women are frequently removed to alleviate patient concern. Yet most fibroadenomas are self-limiting and many go undiagnosed, so a more conservative approach is reasonable. Careful ultrasound examination with core-needle biopsy will provide for an accurate diagnosis. Subsequently, the patient is counseled concerning the biopsy results, and excision of the fibroadenoma may be avoided.

Sclerosing Disorders: The clinical significance of sclerosing adenosis lies in its mimicry of cancer. It may be confused with cancer on physical examination, by mammography, and at gross pathologic examination. Excisional biopsy and histologic examination are frequently necessary to exclude the diagnosis of cancer. The diagnostic work-up for radial scars and complex sclerosing lesions frequently involves stereoscopic biopsy. It is usually not possible to differentiate these lesions with certainty from cancer by mammography features, hence biopsy is recommended.

Periductal Mastitis: Painful and tender masses behind the nipple-areola complex are aspirated with a 21-gauge needle attached to a 10-mL syringe. Any fluid obtained is submitted for cytology and for culture using a transport medium appropriate for the detection of anaerobic organisms. Women are started on a combination of metronidazole and dicloxacillin while awaiting the results of culture. Antibiotics are then continued based on sensitivity tests. Many cases respond satisfactorily, but when there is considerable pus present, surgical treatment is recommended. A subareolar abscess usually is unilocular and often is associated with a single duct system. Preoperative ultrasound will accurately delineate its extent. The surgeon may either undertake simple drainage with a view toward formal surgery, should the problem recur, or proceed with definitive surgery. In a woman of childbearing age, simple drainage is preferred, but if there is an anaerobic infection, recurrent infection frequently develops. Recurrent abscess with fistula is a difficult problem and may be treated by fistulectomy or by major duct excision, depending on the circumstances. When a localized periareolar abscess recurs at the previous site and a fistula is present, the preferred operation is fistulectomy, which has minimal complications and a high degree of success. However, when subareolar sepsis is diffuse rather than localized to one segment or when more than one fistula is present, total duct excision is the preferred procedure. The first circumstance is seen in young women with squamous metaplasia of a single duct, although the latter circumstance is seen in older women with multiple ectatic ducts. However, age is not always a reliable guide, and fistula excision is the preferred initial procedure for localized sepsis irrespective of age. Antibiotic therapy is useful for recurrent infection after fistula excision, and a 2–4-week course is recommended prior to total duct excision.

Nipple Inversion: More women request correction of congenital nipple inversion than request correction for the nipple inversion that occurs secondary to duct ectasia. Although the results are usually satisfactory, women seeking correction for cosmetic reasons should always be made aware of the surgical complications of altered nipple sensation, nipple necrosis, and postoperative fibrosis with nipple retraction. Because nipple inversion is a result of shortening of the subareolar ducts, a complete division of these ducts is necessary for permanent correction of the disorder.

RISK FACTORS FOR BREAST CANCER

Increased exposure to estrogen is associated with an increased risk for developing breast cancer, whereas reducing exposure is thought to be protective. Correspondingly, factors that increase the number of menstrual cycles, such as early menarche, nulliparity, and late menopause, are associated with increased risk. Moderate levels of exercise and a longer lactation period, factors that decrease the total number of menstrual cycles, are protective. The terminal differentiation of breast epithelium associated with a full-term pregnancy is

also protective, so older age at first live birth is associated with an increased risk of breast cancer.

Risk assessment. The average lifetime risk of breast cancer for newborn U.S. females is 12 percent. The longer a woman lives without cancer, the lower her risk of developing breast cancer. Thus, a woman age 50 years has an 11 percent lifetime risk of developing breast cancer, and a woman age 70 years has a 7 percent lifetime risk of developing breast cancer. As risk factors for breast cancer interact, evaluating the risk conferred by combinations of risk factors is difficult. From the Breast Cancer Detection Demonstration Project, a mammography screening program conducted in the 1970s, Gail and colleagues developed the most frequently used model, which incorporates age at menarche, the number of breast biopsies, age at first live birth, and the number of first-degree relatives with breast cancer. It predicts the cumulative risk of breast cancer according to decade of life. To calculate breast cancer risk with the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories. This risk score is then compared to an adjusted population risk of breast cancer to determine a woman's individual risk. A software program incorporating the Gail model is available from the National Cancer Institute at <http://bcra.nci.nih.gov/brc>.

Risk management. Several important medical decisions may be affected by a woman's underlying risk of breast cancer. These decisions include when to use postmenopausal hormone replacement therapy; at what age to begin mammography screening; when to use tamoxifen to prevent breast cancer; and when to perform prophylactic mastectomy to prevent breast cancer. Postmenopausal hormone replacement therapy reduces the risk of coronary artery disease and osteoporosis by 50 percent, but increases the risk of breast cancer by approximately 30 percent.

Routine use of screening mammography in women age 50 years and older reduces mortality from breast cancer by 33 percent. This reduction comes without substantial risks and at an acceptable economic cost. However, the use of screening mammography is more controversial in women younger than age 50 years for several reasons: (1) breast density is greater and screening mammography is less likely to detect early breast cancer; (2) screening mammography results in more false-positive tests, resulting in unnecessary biopsies; and (3) younger women are less likely to have breast cancer so fewer young women will benefit from screening. However, on a population basis, the benefits of screening mammography in women between the ages of 40 and 49 years still appear to outweigh the risks.

Tamoxifen, a selective estrogen receptor modulator, was the first drug shown to reduce the incidence of breast cancer in healthy women. The Breast Cancer Prevention Trial (NSABP P-01) randomly assigned more than 13,000 women, with a 5-year Gail relative risk of breast cancer of 1.70 or greater, to tamoxifen or placebo. After a mean follow-up period of 4 years, tamoxifen had reduced the incidence of breast cancer by 49 percent. Tamoxifen currently is only recommended for women who have a Gail relative risk of 1.70 or greater and it is unclear whether the benefits of tamoxifen apply to women at lower risk. Additionally, deep venous thrombosis occurs 1.6 times, pulmonary emboli 3.0 times, and endometrial cancer 2.5 times as often in women taking tamoxifen. The increased risk for endometrial cancer is restricted to early stage cancers in postmenopausal women. Cataract surgery is required almost twice as often among women taking tamoxifen. Although no formal risk-benefit

analysis is currently available, the higher a woman's risk of breast cancer, the more likely it is that the reduction in the incidence of breast cancer conveyed by tamoxifen will outweigh the risk of serious side effects.

EPIDEMIOLOGY AND NATURAL HISTORY OF BREAST CANCER

Epidemiology. Breast cancer is the most common site-specific cancer in women and is the leading cause of death from cancer for women age 40–44 years. It accounts for 33 percent of all female cancers and is responsible for 20 percent of the cancer-related deaths in women. It is predicted that approximately 211,240 invasive breast cancers will be diagnosed in women in the United States in 2005 and 40,410 of those diagnosed will die from that cancer. Breast cancer was the leading cause of cancer-related mortality in women until 1985, when it was surpassed by lung cancer. In the 1970s, the probability of a woman in the United States developing breast cancer was estimated at one in 13, in 1980 it was 1:11, and in 2002 it was 1:8. Cancer registries in Connecticut and upper New York state document that the age-adjusted incidence of new breast cancer cases has steadily increased since the mid-1940s. This increase was about 1 percent per year from 1973–1980, and there was an additional increase in incidence to 4 percent between 1980 and 1987, which was characterized by frequent detection of small primary cancers. The increase in breast cancer incidence occurred primarily in women age 55 years or older and paralleled a marked increase in the percentage of older women who had mammograms. At the same time, incidence rates for regional metastatic disease dropped and breast cancer mortality declined. From 1960–1963, 5-year overall survival rates for breast cancer were 63 and 46 percent in white and African American women, respectively, although the rates for 1981–1987 were 78 and 63 percent, respectively.

Natural history. Bloom and colleagues described the natural history of breast cancer based on the records of 250 women with untreated breast cancers who were cared for on charity wards in Middlesex Hospital, London, between 1805 and 1933. The median survival of this population was 2.7 years after initial diagnosis. The 5- and 10-year survival rates for these women were 18.0 and 3.6 percent, respectively. Only 0.8 percent survived for 15 years or longer. Autopsy data confirmed that 95 percent of these women died of breast cancer, although the remaining 5 percent died of other causes. Almost 75 percent of the women developed ulceration of the breast during the course of the disease. The longest surviving patient died in the nineteenth year after diagnosis.

HISTOPATHOLOGY OF BREAST CANCER

Carcinoma in situ. Cancer cells are in situ or invasive depending on whether or not they invade through the basement membrane. Broder's original description of in situ breast cancer stressed the absence of invasion of cells into the surrounding stroma and their confinement within natural ductal and alveolar boundaries. As areas of invasion may be minute, the accurate diagnosis of in situ cancer necessitates the analysis of multiple microscopy sections to exclude invasion. In 1941, Foote and Stewart published a landmark description of lobular carcinoma in situ (LCIS), which distinguished it from ductal carcinoma in situ (DCIS). Multicentricity refers to the occurrence of a second in situ breast cancer outside the breast quadrant of the primary in situ cancer, whereas multifocality refers to the occurrence of a second in situ breast cancer within the same breast

quadrant as the primary in situ cancer. Multicentricity occurs in 60–90 percent of women with LCIS, although the rate of multicentricity for DCIS is 40–80 percent. LCIS occurs bilaterally in 50–70 percent of cases, although DCIS occurs bilaterally in 10–20 percent of cases.

Lobular Carcinoma In Situ: LCIS originates from the terminal duct lobular units and only develops in the female breast. It is characterized by distention and distortion of the terminal duct lobular units by cancer cells, which are large but maintain a normal nuclear-to-cytoplasmic ratio. The frequency of LCIS in the general population cannot be reliably determined because it usually presents as an incidental finding. The age at diagnosis is 44–47 years, which is approximately 15–25 years younger than the age at diagnosis for invasive breast cancer. LCIS has a distinct racial predilection, occurring 12 times more frequently in white women than in African American women. Invasive breast cancer develops in 25–35 percent of women with LCIS. Invasive lobular cancer may develop in either breast, regardless of which breast harbored the initial focus of LCIS, and is detected synchronously with LCIS in 5 percent of cases. In women with a history of LCIS, up to 65 percent of subsequent invasive cancers are ductal, not lobular in origin. For these reasons, LCIS is regarded as a marker of increased risk for invasive breast cancer rather than an anatomic precursor.

Ductal Carcinoma In Situ: Although DCIS is predominantly seen in the female breast, it accounts for 5 percent of male breast cancers. Published series suggest a detection frequency of 7 percent in all biopsy tissue specimens. The term intraductal carcinoma is frequently applied to DCIS, which carries a high risk for progression to an invasive cancer. Histologically, DCIS is characterized by a proliferation of the epithelium that lines the minor breast ducts. DCIS is now frequently classified based on nuclear grade and the presence of necrosis. The risk for invasive breast cancer is increased nearly 5-fold in women with DCIS. The invasive cancers are observed in the ipsilateral breast, usually in the same quadrant as the DCIS that was originally detected, suggesting that DCIS is an anatomic precursor of invasive ductal carcinoma.

Invasive breast carcinoma. Invasive breast cancers are described as lobular or ductal in origin with histologic classifications recognizing special types of ductal breast cancers (10 percent of total cases), which are defined by specific histologic features. To qualify as a special-type cancer, at least 90 percent of the cancer must contain the defining histologic features. Eighty percent of invasive breast cancers are described as invasive ductal carcinoma of no special type (NST). These cancers generally have a worse prognosis than special-type cancers. Foote and Stewart originally proposed the following classification for invasive breast cancer:

- I. Paget disease of the nipple
- II. Invasive ductal carcinoma
 - A. Adenocarcinoma with productive fibrosis (scirrhous, simplex, no special type (NST)) 80 percent
 - B. Medullary carcinoma 4 percent
 - C. Mucinous (colloid) carcinoma 2 percent
 - D. Papillary carcinoma 2 percent
 - E. Tubular carcinoma (and invasive cribriform carcinoma (ICC)) 2 percent
- III. Invasive lobular carcinoma 10 percent
- IV. Rare cancers (adenoid cystic, squamous cell, apocrine)

Paget disease of the nipple was described in 1874. It frequently presents as a chronic, eczematous eruption of the nipple, which may be subtle, but may progress to an ulcerated, weeping lesion. Paget disease usually is associated with extensive DCIS and may be associated with an invasive cancer. A palpable mass may or may not be present. Biopsy of the nipple will show a population of cells that are identical to the underlying DCIS cells (pagetoid features or pagetoid change). Pathognomonic of this cancer is the presence of large, pale, vacuolated cells (Paget cells) in the rete pegs of the epithelium. Surgical therapy for Paget disease may involve lumpectomy, mastectomy, or modified radical mastectomy, depending on the extent of involvement and the presence of invasive cancer.

Invasive ductal carcinoma of the breast with productive fibrosis (scirrhous, simplex, NST) accounts for 80 percent of breast cancers and presents with macroscopic or microscopic axillary lymph node metastases in 60 percent of cases. This cancer usually presents in perimenopausal or postmenopausal women in the fifth to sixth decades of life as a solitary, firm mass. It has poorly defined margins and its cut surfaces show a central stellate configuration with chalky white or yellow streaks extending into surrounding breast tissues. The cancer cells often are arranged in small clusters, and there is a broad spectrum of histologies with variable cellular and nuclear grades.

DIAGNOSING BREAST CANCER

In 33 percent of breast cancer cases, the woman discovers a lump in her breast. Other less frequent presenting signs and symptoms of breast cancer include (1) breast enlargement or asymmetry; (2) nipple changes, retraction, or discharge; (3) ulceration or erythema of the skin of the breast; (4) an axillary mass; and (5) musculoskeletal discomfort. However, up to 50 percent of women presenting with breast complaints have no physical signs of breast pathology. Breast pain usually is associated with benign disease.

Misdiagnosed breast cancer accounts for the greatest number of malpractice claims for errors in diagnosis and for the largest number of paid claims. Litigation often involves younger women whose physical examination and mammography may be misleading. If a young woman (age 45 years or younger) presents with a palpable breast mass and equivocal mammography finding, ultrasound examination and biopsy are used to avoid a delay in diagnosis.

Examination

Inspection: The surgeon inspects the woman's breast with her arms by her side, with her arms straight up in the air, and with her hands on her hips (with and without pectoral muscle contraction). Symmetry, size, and shape of the breast are recorded, and any evidence of edema (*peau d'orange*), nipple or skin retraction, and erythema. With the arms extended forward and in a sitting position, the woman leans forward to accentuate any skin retraction.

As part of the physical examination, the breast is carefully palpated. Examination of the patient in the supine position is best performed with a pillow supporting the ipsilateral hemithorax. The surgeon gently palpates the breast from the ipsilateral side, making certain to examine all quadrants of the breast from the sternum laterally to the latissimus dorsi muscle, and from the clavicle inferiorly to the upper rectus sheath. The surgeon performs the examination with the palmar aspects of the fingers avoiding a grasping or pinching motion. The breast may be cupped or molded in the surgeon's hands

to check for retraction. A systematic search for lymphadenopathy then is performed. By supporting the upper arm and elbow, the shoulder girdle is stabilized. Using gentle palpation, all three levels of possible axillary lymphadenopathy are assessed. Careful palpation of supraclavicular and parasternal sites also is performed. A diagram of the chest and contiguous lymph node sites is useful for recording location, size, consistency, shape, mobility, fixation, and other characteristics of any palpable breast mass or lymphadenopathy.

Imaging Techniques

Mammography: Mammography has been used in North America since the 1960s and the techniques used continue to be modified and improved to enhance image quality. Conventional mammography delivers a radiation dose of 0.1 centigray (cGy) per study. By comparison, a chest radiograph delivers 25 percent of this dose. However, there is no increased breast cancer risk associated with the radiation dose delivered with screening mammography. Screening mammography is used to detect unexpected breast cancer in asymptomatic women. In this regard, it supplements history and physical examination. With screening mammography, two views of the breast are obtained, the craniocaudal (CC) view and the mediolateral oblique (MLO) view. The MLO view images the greatest volume of breast tissue, including the upper outer quadrant and the axillary tail of Spence. Compared with the MLO view, the CC view provides better visualization of the medial aspect of the breast and permits greater breast compression. Diagnostic mammography is used to evaluate women with abnormal findings such as a breast mass or nipple discharge. In addition to the MLO and CC views, a diagnostic examination may use views that better define the nature of any abnormalities, such as the 90-degree lateral and spot compression views. The 90-degree lateral view is used along with the CC view to triangulate the exact location of an abnormality. Spot compression may be done in any projection by using a small compression device, which is placed directly over a mammography abnormality that is obscured by overlying tissues. The compression device minimizes motion artifact, improves definition, separates overlying tissues, and decreases the radiation dose needed to penetrate the breast. Magnification techniques ($\times 1.5$) often are combined with spot compression to better resolve calcifications and the margins of masses. Mammography also is used to guide interventional procedures, including needle localization and needle biopsy.

Specific mammography features that suggest a diagnosis of a breast cancer include a solid mass with or without stellate features, asymmetric thickening of breast tissues, and clustered microcalcifications. The presence of fine, stippled calcium in and around a suspicious lesion is suggestive of breast cancer and occurs in as many as 50 percent of nonpalpable cancers. These microcalcifications are an especially important sign of cancer in younger women, in whom it may be the only mammography abnormality. Current guidelines of the National Cancer Center Network (NCCN) suggest that normal-risk women age 20 years or older should have a breast exam at least every 3 years. At age 40 years, breast exams should be performed yearly along with a yearly mammogram. Prospective, randomized studies of mammography screening confirm a 40 percent reduction for stages II, III, and IV cancer in the screened population, with a 30 percent increase in overall survival.

Xeromammography: Xeromammography techniques are identical to those of mammography with the exception that the image is recorded on a xerography plate, which provides a positive rather than a negative image. Details of the entire breast and the soft tissues of the chest wall may be recorded with one exposure.

Ultrasonography: Ultrasonography is second only to mammography in frequency of use for breast imaging and is an important method of resolving equivocal mammography findings, defining cystic masses, and demonstrating the echogenic qualities of specific solid abnormalities. On ultrasound examination, breast cysts are well circumscribed, with smooth margins and an echo-free center. Benign breast masses usually show smooth contours, round or oval shapes, weak internal echoes, and well-defined anterior and posterior margins. Breast cancer characteristically has irregular walls, but may have smooth margins with acoustic enhancement. Ultrasonography is used to guide fine-needle aspiration biopsy, core-needle biopsy, and needle localization of breast lesions. It is highly reproducible and has a high patient acceptance rate, but does not reliably detect lesions that are 1 cm or less in diameter.

Breast Biopsy

Nonpalpable Lesions: Image-guided breast biopsies are frequently required to diagnose nonpalpable lesions. Ultrasound localization techniques are employed when a mass is present, although stereotactic techniques are used when no mass is present (microcalcifications only). The combination of diagnostic mammography, ultrasound or stereotactic localization, and fine-needle aspiration (FNA) biopsy is almost 100 percent accurate in the diagnosis of breast cancer. However, although FNA biopsy permits cytologic evaluation, core-needle or open biopsy also permits the analysis of breast tissue architecture and allows the pathologist to determine whether invasive cancer is present. This permits the surgeon and patient to discuss the specific management of a breast cancer before therapy begins. Core-needle biopsy is accepted as an alternative to open biopsy for nonpalpable breast lesions. The advantages of core-needle biopsy include a low complication rate, avoidance of scarring, and a lower cost.

Palpable Lesions: FNA biopsy of a palpable breast mass is performed in an outpatient setting. A 1.5-inch, 22-gauge needle attached to a 10-mL syringe is used. A syringe holder enables the surgeon performing the FNA biopsy to control the syringe and needle with one hand while positioning the breast mass with the opposite hand. After the needle is placed in the mass, suction is applied while the needle is moved back and forth within the mass. Once cellular material is seen at the hub of the needle, the suction is released and the needle is withdrawn. The cellular material is then expressed onto microscope slides. Both air-dried and 95 percent ethanol-fixed microscopy sections are prepared for analysis. When a breast mass is clinically and mammographically suspicious, the sensitivity and the specificity of FNA biopsy approaches 100 percent. Core-needle biopsy of palpable breast masses is performed using a 14-gauge needle, such as the Tru Cut needle. Automated devices also are available. Tissue specimens are placed in formalin and then processed to paraffin blocks. Although the false-negative rate for core-needle biopsy is very low, a tissue specimen that does not show breast cancer cannot conclusively rule out that diagnosis because a sampling error may have occurred.

BREAST CANCER PROGNOSIS

Breast cancer staging. The clinical stage of breast cancer is determined primarily through physical examination of the skin, breast tissue, and lymph nodes (axillary, supraclavicular, and cervical). However, clinical determination of axillary lymph node metastases has an accuracy of only 33 percent. Mammography, chest radiograph, and intraoperative findings (primary cancer size, chest wall invasion) also provide necessary staging information. Pathologic stage combines clinical stage data with findings from pathologic examination of the resected primary breast cancer and axillary lymph nodes. A frequently used staging system is the TNM (tumor, nodes, and metastasis) system. The American Joint Committee on Cancer (AJCC) has modified the TNM system for breast cancer. The single most important predictor of 10- and 20-year survival rates in breast cancer is the number of axillary lymph nodes involved with metastatic disease. Table 16-2 shows traditional prognostic and predictive biomarkers for breast cancer.

OVERVIEW OF BREAST CANCER THERAPY

In situ breast cancer (stage 0). Both LCIS and DCIS may be difficult to distinguish from atypical hyperplasia or from cancers with early invasion. Expert pathologic review is required in all cases. Bilateral mammography is performed to determine the extent of the in situ cancer and to exclude a second cancer. Because LCIS is considered a marker for increased risk rather than an inevitable precursor of invasive disease, the current treatment of LCIS is observation with or without tamoxifen. The goal of treatment is to prevent or detect at an early stage the invasive cancer that subsequently develops in 25–35 percent of these women. There is no benefit to excising LCIS, as the disease diffusely involves both breasts and the risk of invasive cancer is equal for both breasts. The use of tamoxifen as a risk-reduction strategy should be considered in women with a diagnosis of LCIS.

Women with DCIS and evidence of widespread disease (two or more quadrants) require mastectomy. For women with limited disease, lumpectomy and radiation therapy are recommended. Low-grade DCIS of the solid, cribriform, or papillary subtype, which is less than 0.5 cm in diameter, may be managed by

TABLE 16-2 Traditional Prognostic and Predictive Factors for Invasive Breast Cancer

Tumor factors	Host factors
Nodal status	Age
Tumor size	Menopausal status
Histologic/nuclear grade	Family history
Lymphatic/vascular invasion	Previous breast cancer
Pathologic stage	Immunosuppression
Hormone receptor status	Nutrition
DNA content (ploidy, S-phase Prior chemotherapy fraction)	
Extensive intraductal component	Prior radiation therapy

lumpectomy alone. For nonpalpable DCIS, needle localization techniques are used to guide the surgical resection. Specimen mammography is performed to ensure that all visible evidence of cancer is excised. Adjuvant tamoxifen therapy is considered for all DCIS patients. The gold standard against which breast conservation therapy for DCIS is evaluated is mastectomy. Women treated with mastectomy have local recurrence and mortality rates of less than 2 percent. Women treated with lumpectomy and adjuvant radiation therapy have a similar mortality rate, but the local recurrence rate increases to 9 percent. Forty-five percent of these recurrences will be invasive cancer.

Early invasive breast cancer (stage I, IIa, or IIb). NSABP B-06 compared total mastectomy to lumpectomy with or without radiation therapy in the treatment of stages I and II breast cancer. After 12- and 20-year follow-up periods, the disease-free, distant disease-free, and overall survival rates for lumpectomy with or without radiation therapy remain similar to those observed after total mastectomy. However, the incidence of ipsilateral breast cancer recurrence (in-breast recurrence) continues higher in the lumpectomy group not receiving radiation therapy (35 percent) when compared to those receiving radiation therapy (10 percent). These findings support the use of lumpectomy and radiation in the treatment of stages I and II breast cancer.

Currently, mastectomy with assessment of axillary lymph node status and breast conservation (lumpectomy with assessment of axillary lymph node status and radiation therapy) are considered equivalent treatments for stages I and II breast cancer. Axillary lymphadenopathy or metastatic disease in a sentinel axillary lymph node (see below) necessitates an axillary lymph node dissection. Breast conservation is considered for all patients because of the important cosmetic advantages. Relative contraindications to breast conservation therapy include (1) prior radiation therapy to the breast or chest wall; (2) involved surgical margins or unknown margin status following re-excision; (3) multicentric disease; and (4) scleroderma or other connective-tissue disease.

Traditionally, dissection of axillary lymph node levels I and II has been performed in early invasive breast cancer. Sentinel lymph node biopsy is now being performed by many surgeons in the elective situation to assess axillary lymph nodes status. Candidates for this procedure have clinically uninvolved axillary lymph nodes, a T1 or T2 primary breast cancer, and have not had neoadjuvant chemotherapy. If the sentinel lymph node cannot be identified or is found to harbor metastatic disease, then an axillary lymph node dissection is performed. The performance of a sentinel lymph node biopsy is not warranted when the selection of adjuvant therapy will not be affected by the status of the axillary lymph nodes, such as in some older adult patients and in those with serious comorbid conditions.

Adjuvant chemotherapy for early invasive breast cancer is considered for all node-positive cancers, all cancers that are larger than 1 cm in size, and node-negative cancers larger than 0.5 cm in size when adverse prognostic features are present. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, human epidermal growth receptor 2 (HER-2)/neu overexpression, and negative hormone receptor status. Adjuvant endocrine therapy consisting of tamoxifen or an aromatase inhibitor is considered for hormone receptor-positive women with cancers that are larger than 1 cm in size. HER-2/neu expression is determined for all newly diagnosed patients with breast cancer and may be used to provide prognostic information in patients with node-negative breast cancer, predict

the relative efficacy of various chemotherapy regimens, and predict benefit from Herceptin in women with metastatic or recurrent breast cancer.

Advanced locoregional regional breast cancer (stage IIIa or IIIb). Women with stages IIIa and IIIb breast cancer have advanced locoregional breast cancer but have no clinically detected distant metastases. In an effort to provide optimal locoregional disease-free survival, and distant disease-free survival for these women, surgery is integrated with radiation therapy and chemotherapy. Stage IIIa patients are divided into those who have operable disease and those who have inoperable disease.

Internal mammary lymph nodes. Metastatic disease to internal mammary lymph nodes may be occult, evident on chest radiograph or CT scan, or may present as a painless parasternal mass with or without skin involvement. There is no consensus regarding the need for internal mammary lymph node radiation therapy in women who are at increased risk for occult involvement (cancers involving the medial aspect of the breast, axillary lymph node involvement), but who show no signs of internal mammary lymph node involvement. Systemic chemotherapy and radiation therapy are used in the treatment of grossly involved internal mammary lymph nodes.

Distant metastases (stage IV). Treatment for stage IV breast cancer is not curative, but may prolong survival and enhance a woman's quality of life. Hormonal therapies that are associated with minimal toxicity are preferred to cytotoxic chemotherapy. Appropriate candidates for initial hormonal therapy include women with hormone receptor-positive cancers; women with bone or soft tissue metastases only; and women with limited and asymptomatic visceral metastases. Systemic chemotherapy is indicated for women with hormone receptor-negative cancers, symptomatic visceral metastases, and hormone refractory metastases. Women with stage IV breast cancer may develop anatomically localized problems, which will benefit from individualized surgical treatment, such as brain metastases; pleural effusion; pericardial effusion; biliary obstruction; ureteral obstruction; impending or existing pathologic fracture of a long bone; spinal cord compression; and painful bone or soft tissue metastases. Bisphosphonates, which may be given in addition to chemotherapy or hormone therapy, should be considered in women with bone metastases.

Locoregional recurrence. Women with locoregional recurrence of breast cancer may be separated into two groups: those having had mastectomy and those having had lumpectomy. Women with a previous mastectomy undergo surgical resection of the locoregional recurrence and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered and adjuvant radiation therapy is given if the chest wall has not previously received radiation therapy. Women with previous breast conservation undergo a mastectomy and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered.

Breast cancer prognosis. Survival rates for women diagnosed with breast cancer between 1983 and 1987 have been calculated based on Surveillance, Epidemiology, and End Results (SEER) program data. The 5-year survival rate for stage I patients is 94 percent; for stage IIa patients, 85 percent; and for stage IIb patients, 70 percent; although for stage IIIa patients the 5-year survival rate, 52 percent; for stage IIIb patients, 48 percent and for stage IV patients, 18 percent.

SURGICAL TECHNIQUES IN BREAST CANCER THERAPY

Excisional biopsy with needle localization. Excisional biopsy implies complete removal of a breast lesion with a margin of normal-appearing breast tissue. Excellent scars generally result from circumareolar incisions through which subareolar and centrally located breast lesions may be approached. Elsewhere, incisions that parallel Langer lines, which are lines of tension in the skin that are generally concentric with the nipple-areola complex, result in acceptable scars. It is important to keep biopsy incisions within the boundaries of the skin excision that may be required as part of a subsequent mastectomy. Radial incisions in the upper half of the breast are not recommended because of possible scar contracture resulting in displacement of the ipsilateral nipple-areola complex.

After excision of a suspicious breast lesion, the biopsy tissue specimen is orientated for the pathologist using sutures, clips, or dyes. Additional margins (superior, inferior, medial, lateral, superficial, and deep) may be taken from the surgical bed to confirm complete excision of the suspicious lesion. Electrocautery or absorbable ligatures are used to achieve wound hemostasis. Although approximation of the breast tissues in the excision bed is usually not necessary, cosmesis may occasionally be facilitated by approximation of the surgical defect using 3-0 absorbable sutures. A running subcuticular closure of the skin using 4-0 or 5-0 absorbable monofilament sutures is performed, followed by approximation of the skin edges with Steri-Strips. Wound drainage is avoided.

Excisional biopsy with needle localization requires a preoperative visit to the mammography suite for placement of a localization wire. The lesion to be excised is accurately localized by mammography, and the tip of a thin wire hook is positioned close to the lesion. Using the wire hook as a guide, the surgeon subsequently excises the suspicious breast lesion while removing a margin of normal-appearing breast tissue. Before the patient leaves the operating room, specimen radiography is performed to confirm complete excision of the suspicious lesion.

Sentinel lymph node biopsy. Sentinel lymph node biopsy is primarily used in women with early breast cancers (T1 and T2, N0). It also is accurate for T3 N0 cancers, but nearly 75 percent of these women will have nonpalpable axillary lymph node metastases. In women undergoing neoadjuvant chemotherapy to permit conservation surgery, sentinel lymph node biopsy may be used. Contraindications to the procedure include palpable lymphadenopathy, prior axillary surgery, chemotherapy or radiation therapy, and multifocal breast cancers.

Evidence from large prospective studies suggests that the combination of intraoperative gamma probe detection of radioactive colloid and intraoperative visualization of isosulfan blue dye (Lymphazurin) is more accurate than the use of either agent alone. Some surgeons employ preoperative lymphoscintigraphy, although it is not necessary. On the day prior to surgery, or on the morning of surgery, radioactive colloid is injected. Using a tuberculin syringe and a 25-gauge needle, 0.5 mCi of 0.2-micron technetium-99 sulfur colloid in a volume of 0.2–0.5 mL is injected (three to four separate injections) at the cancer site or subdermally. Subdermal injections are given in proximity to the cancer site or subareolar. Subsequently, in the operating room, 4 mL of isosulfan blue dye (Lymphazurin) is injected in a similar fashion, but with an additional 1 mL injected between the cancer site and the overlying skin. For nonpalpable cancers, the injection is guided by either intraoperative ultrasound

or by a localization wire that is placed preoperatively under ultrasound or stereotactic guidance. It is helpful for the radiologist to mark the skin overlying the breast cancer at the time of needle localization using an indelible marker. In women who have undergone previous excisional biopsy, the injections are made around the biopsy cavity but not into it. Women are told preoperatively that the isosulfan blue dye injection will impart a change to the color of their urine and that there is a very small risk of allergic reaction to the dye (1 in 10,000). Anaphylactic reactions have been documented. The use of radioactive colloid is safe and radiation exposure is very low.

A hand-held gamma counter is then employed transcutaneously to identify the location of the sentinel lymph node. A 3–4-cm incision is made in line with that used for an axillary dissection, which is a curved transverse incision in the lower axilla just below the hairline. After dissecting through the subcutaneous tissue and identifying the lateral border of the pectoralis muscles, the clavipectoral fascia is divided to gain exposure to the axillary contents. The gamma counter is employed to pinpoint the location of the sentinel lymph node. As the dissection continues, the signal from the probe increases in intensity as the sentinel lymph node is approached. The sentinel lymph node also is identified by visualization of isosulfan blue dye in the afferent lymph vessel and in the lymph node itself. Before removing the sentinel lymph node, a 10-second *in vivo* radioactivity count is obtained. After removal of the sentinel lymph node, a 10-second *ex vivo* radioactive count is obtained, and the lymph node is then sent to pathology for either permanent or frozen section analysis. The lowest false-negative rates for sentinel lymph node biopsy have been obtained when all blue lymph nodes and all lymph nodes with radiation counts greater than 10 percent of the 10-second *ex vivo* count of the sentinel lymph node are harvested (10 percent rule). Based on this, the gamma counter is employed before closing the axillary wound to measure residual radioactivity in the surgical bed. When necessary, a search is made for a second sentinel lymph node. This procedure is repeated until residual radioactivity in the surgical bed is less than 10 percent of the 10-second *ex vivo* count of the most radioactive sentinel lymph node.

Breast Conservation

Breast conservation involves resection of the primary breast cancer with a margin of normal-appearing breast tissue, adjuvant radiation therapy, and assessment of axillary lymph node status. Resection of the primary breast cancer is alternatively called segmental resection, lumpectomy, partial mastectomy, and tylectomy. Conservation surgery is currently the standard treatment for women with stage I or II invasive breast cancer. Women with DCIS generally require only resection of the primary cancer and adjuvant radiation therapy. When a lumpectomy is performed, a curvilinear incision lying concentric to the nipple-areola complex is made in the skin overlying the breast cancer. Skin encompassing a prior biopsy site is excised, but is not otherwise necessary. The breast cancer is removed with an envelope of normal-appearing breast tissue that is adequate to achieve at least a 1-cm cancer-free margin. Specimen orientation is performed and additional margins from the surgical bed are taken as described previously. Requests for hormone receptor status and HER-2/neu expression are conveyed to the pathologist.

After closure of the breast wound, dissection of the ipsilateral axillary lymph nodes has traditionally been completed for cancer staging and for control of

regional disease. Ten to 15 level I and level II axillary lymph nodes usually are considered adequate for staging purposes. Sentinel lymph node biopsy is now the preferred staging procedure in the clinically uninvolved axilla. When the sentinel lymph node does not contain metastatic disease, axillary lymph node dissection is avoided.

Mastectomy and axillary dissection. A skin-sparing mastectomy removes all breast tissue, the nipple-areola complex, and only 1 cm of skin around excised scars. There is a recurrence rate of less than 2 percent when skin-sparing mastectomy is used for T1–T3 cancers. A total (simple) mastectomy removes all breast tissue, the nipple-areola complex, and skin. An extended simple mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I axillary lymph nodes. A modified radical mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I and level II axillary lymph nodes. The Halstead radical mastectomy removes all breast tissue and skin, the nipple-areola complex, the pectoralis major and pectoralis minor muscles, and the level I, II, and III axillary lymph nodes. Chemotherapy, hormone therapy, and radiation therapy for breast cancer have nearly eliminated the need for the radical mastectomy.

For a variety of biologic, economic, and psychosocial reasons, some women desire mastectomy rather than breast conservation. Women who are less concerned about cosmesis may view mastectomy as the most expeditious and desirable therapeutic option because it avoids the cost and inconvenience of radiation therapy. Women whose primary breast cancers have an extensive intraductal component undergo mastectomy because of very high local failure rates in the ipsilateral breast after breast conservation. Women with large cancers that occupy the subareolar and central portions of the breast and women with multicentric primary cancers also undergo mastectomy.

Modified Radical Mastectomy: A modified radical mastectomy preserves both the pectoralis major and pectoralis minor muscles, allowing removal of level I and level II axillary lymph nodes but not the level III (apical) axillary lymph nodes. The Patey modification removes the pectoralis minor muscle and allows complete dissection of the level III axillary lymph nodes. A modified radical mastectomy permits preservation of the medial (anterior thoracic) pectoral nerve, which courses in the lateral neurovascular bundle of the axilla and usually penetrates the pectoralis minor to supply the lateral border of the pectoralis major. Anatomic boundaries of the modified radical mastectomy are the anterior margin of the latissimus dorsi muscle laterally; the midline of the sternum medially; the subclavius muscle superiorly; and the caudal extension of the breast 2–3 cm inferior to the inframammary fold inferiorly. Skin-flap thickness, which is inclusive of skin and tela subcutanea, varies with body habitus. Once the skin flaps are fully developed, the fascia of the pectoralis major muscle and the overlying breast tissue are elevated off the underlying musculature, allowing for the complete removal of the breast.

Subsequently, an axillary lymph node dissection is performed. The most lateral extent of the axillary vein is identified and the areolar tissue of the lateral axillary space is elevated as the vein is cleared on its anterior and inferior surfaces. The areolar tissues at the junction of the axillary vein with the anterior edge of the latissimus dorsi muscle, which include the lateral and subscapular lymph node groups (level I), are cleared in an inferomedial direction. Care is taken to preserve the thoracodorsal neurovascular bundle. The dissection then continues medially with clearance of the central axillary

lymph node group (level II). The long thoracic nerve of Bell is identified and preserved as it travels in the investing fascia of the serratus anterior muscle. Every effort is made to preserve this nerve because permanent disability with a winged scapula and shoulder weakness will follow denervation of the serratus anterior muscle. If there is palpable lymphadenopathy at the apex of the axilla, the tendinous portion of the pectoralis minor muscle is divided near its insertion onto the coracoid process, which allows dissection of the axillary vein medially to the costoclavicular (Halsted) ligament. Finally, the breast and axillary contents are removed from the surgical bed and are sent for pathologic assessment.

Seromas beneath the skin flaps or in the axilla represent the most frequent complication of mastectomy and axillary lymph node dissection, reportedly occurring in as many as 30 percent of cases. The use of closed-system suction drainage reduces the incidence of this complication. Catheters are retained in the wound until drainage diminishes to less than 30 mL per day. Wound infections occur infrequently after a mastectomy and the majority occur secondary to skin-flap necrosis. Culture of the infected wound for aerobic and anaerobic organisms, débridement, and antibiotics are effective management. Moderate or severe hemorrhage in the postoperative period is rare and is best managed with early wound exploration for control of hemorrhage and reestablishment of closed-system suction drainage. The incidence of functionally significant lymphedema after a modified radical mastectomy is 10 percent. Extensive axillary lymph node dissection, radiation therapy, the presence of pathologic lymph nodes, and obesity are predisposing factors. Individually fitted compressive sleeves and intermittent compression devices may be necessary.

Reconstruction of the breast and chest wall. The goals of reconstructive surgery following a mastectomy for breast cancer are wound closure and breast reconstruction, which is either immediate or delayed. For most women, wound closure after mastectomy is accomplished with simple approximation of the wound edges. However, if a more radical removal of skin and subcutaneous tissue is necessary, a skin graft provides functional coverage that will tolerate adjuvant radiation therapy. When soft-tissue defects are present that cannot be covered with a skin graft, myocutaneous flaps are employed. Breast reconstruction after prophylactic mastectomy or after mastectomy for early invasive breast cancer is performed immediately after surgery, although reconstruction following surgery for advanced breast cancer is delayed for 6 months after completion of adjuvant therapy to insure that locoregional control of disease is obtained. Many different types of myocutaneous flaps are employed for breast reconstruction, but the latissimus dorsi and the rectus abdominus myocutaneous flaps are most frequently used. The latissimus dorsi myocutaneous flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. The transverse rectus abdominis myocutaneous (TRAM) flap consists of a skin paddle based on the underlying rectus abdominis muscle, which is supplied by vessels from the deep inferior epigastric artery. The free TRAM flap uses microvascular anastomoses to establish blood supply to the flap. When the bony chest wall is involved with cancer, resection of a portion of the bony chest wall is indicated. If only one or two ribs are resected and soft-tissue coverage is provided, reconstruction of the bony defect usually is not necessary as scar tissue will stabilize the chest wall. If more than

two ribs are sacrificed, it is advisable to stabilize the chest wall with Marlex mesh, which is then covered with soft tissue by using a latissimus dorsi or TRAM flap.

NONSURGICAL BREAST CANCER THERAPIES

Radiation therapy. Radiation therapy is used for all stages of breast cancer. For women with limited DCIS (stage 0), in whom negative margins are achieved by lumpectomy or by re-excision, adjuvant radiation therapy is given to reduce the risk of local recurrence. For women with stage I, IIa, or IIb breast cancer in which negative margins are achieved by lumpectomy or by re-excision, adjuvant radiation therapy is given to reduce the risk of local recurrence. Those women treated with mastectomy who have cancer at the surgical margins are at sufficiently high risk for local recurrence to warrant the use of adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes. Women with metastatic disease involving four or more axillary lymph nodes and premenopausal women with metastatic disease involving one to three lymph nodes also are at increased risk for recurrence and are candidates for the use of chest wall and supraclavicular lymph node radiation therapy. In advanced locoregional breast cancer (stage IIIa or IIIb), women are at high risk for recurrent disease following surgical therapy and adjuvant radiation therapy is employed to reduce the recurrence rate.

Chemotherapy

Adjuvant Chemotherapy: Adjuvant chemotherapy is of minimal benefit to node-negative women with cancers 0.5 cm or less in size and is not recommended. Node-negative women with cancers 0.6–1.0 cm are divided into those with a low risk of recurrence and those with unfavorable prognostic features that portend a higher risk of recurrence and a need for adjuvant chemotherapy. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, HER-2/neu overexpression, and negative hormone receptor status. Adjuvant chemotherapy is recommended for these women when unfavorable prognostic features are present.

For women with hormone receptor-negative cancers that are larger than 1 cm in size, adjuvant chemotherapy is appropriate. However, node-negative women with hormone receptor-positive cancers that are 1–3 cm in size are candidates for tamoxifen with or without chemotherapy. For special-type cancers (tubular, mucinous, medullary, etc.), adjuvant chemotherapy or tamoxifen for cancers smaller than 3 cm in size is controversial. For node-positive women or women with a special-type cancer that is larger than 3 cm in size, the use of chemotherapy with or without tamoxifen is appropriate. Current treatment recommendations for operable stage IIIa breast cancer are a modified radical mastectomy followed by adjuvant chemotherapy with a doxorubicin-containing regimen followed by adjuvant radiation therapy. These recommendations are based in part on the results of NSABP B-15. In this study, node-positive women with tamoxifen-nonresponsive cancers who were age 59 years or younger were randomized to 2 months of therapy with Adriamycin and cyclophosphamide versus 6 months of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF). There was no difference in relapse-free survival or overall survival rates and women preferred the shorter regimen.

Neoadjuvant Chemotherapy: NSABP B-18 evaluated the role of neoadjuvant chemotherapy in women with operable stage III breast cancer. Women entered into this study were randomized to surgery followed by chemotherapy or neoadjuvant chemotherapy followed by surgery. There was no difference in the 5-year disease-free survival rate, but after neoadjuvant chemotherapy there was an increase in the number of lumpectomies performed. It was suggested that neoadjuvant chemotherapy be considered for the initial management of breast cancers judged too large for initial lumpectomy. Current recommendations for operable advanced locoregional breast cancer are neoadjuvant chemotherapy with an Adriamycin-containing regimen, followed by mastectomy or lumpectomy with axillary lymph node dissection if necessary, followed by adjuvant chemotherapy, followed by adjuvant radiation therapy. For inoperable stage IIIa and for stage IIIb breast cancer, neoadjuvant chemotherapy is used to decrease the locoregional cancer burden. This may then permit subsequent modified radical or radical mastectomy, which is followed by adjuvant chemotherapy and adjuvant radiation therapy.

Chemotherapy for Distant Metastases: For women with stage IV breast cancer, an antiestrogen (usually tamoxifen) is the preferred therapy. However, women with hormone receptor-negative cancers with symptomatic visceral metastasis or with hormone refractory cancer may receive systemic chemotherapy. Pamidronate may be given to women with osteolytic bone metastases in addition to hormonal therapy or chemotherapy. Women with metastatic breast cancer may also be enrolled into clinical trials of high-dose chemotherapy with bone marrow or peripheral blood stem cell transplantation. No survival benefit for transplantation therapy has yet been shown.

Antiestrogen therapy. An overview analysis by the Early Breast Cancer Trialists' Collaborative Group showed that adjuvant therapy with tamoxifen produced a 25 percent reduction in the annual risk of breast cancer recurrence and a 7 percent reduction in annual breast cancer mortality. The analysis also showed a 39 percent reduction in the risk of cancer in the contralateral breast. The major advantage of tamoxifen over chemotherapy is the absence of severe toxicity. Bone pain, hot flashes, nausea, vomiting, and fluid retention may occur. Thrombotic events occur in less than 3 percent of treated women. Cataract surgery is more frequently performed in patients receiving tamoxifen. A rare long-term risk of tamoxifen use is endometrial cancer. Tamoxifen therapy usually is discontinued after 5 years.

Node-negative women with hormone receptor-positive breast cancers that are 1–3 cm in size are candidates for adjuvant tamoxifen with or without chemotherapy. For node-positive women and for all women with a cancer that is more than 3 cm in size, the use of tamoxifen in addition to adjuvant chemotherapy is appropriate. For women with stage IV breast cancer, an antiestrogen (usually tamoxifen), is the preferred initial therapy. For women with prior antiestrogen exposure, recommended second-line hormonal therapies include aromatase inhibitors in postmenopausal women and progestins, androgens, high-dose estrogen or oophorectomy (medical, surgical or radioablative) in premenopausal women. Women who respond to hormonal therapy with either shrinkage of their breast cancer or with long-term stabilization of disease receive additional hormonal therapy at the time of progression. Women with hormone receptor-negative cancers, with symptomatic visceral metastasis, or with hormone refractory disease receive systemic chemotherapy rather than hormone therapy.

Aromatase Inhibitors: In 2001, an analysis of the “Arimedex, Tamoxifen, Alone or in Combination (ATAC) Trial,” showed that in postmenopausal women with estrogen receptor (ER) and/or progesterone receptor (PR) positive cancers, Anastrozole was superior to Tamoxifen for both 1) disease-free survival and 2) reduction of new primary cancers in the contralateral breast. Follow-up studies are ongoing.

Anti-HER-2/neu antibody therapy. The determination of HER-2/neu expression for all newly diagnosed patients with breast cancer is now recommended. It is used for prognostic purposes in node-negative patients; to assist in the selection of adjuvant chemotherapy because response rates appear to be better with Adriamycin-based adjuvant chemotherapy in patients with cancer that overexpress HER-2/neu; and baseline information for when the patient develops recurrent disease that may benefit from anti-HER-2/neu therapy (trastuzumab, Herceptin). Patients with cancers that overexpress HER-2/neu may benefit if trastuzumab is added to paclitaxel chemotherapy. Considerable cardiotoxicity may develop if trastuzumab is added to Adriamycin-based chemotherapy.

SPECIAL CLINICAL SITUATIONS

Nipple Discharge

Unilateral Nipple Discharge: Nipple discharge is suggestive of cancer if it is spontaneous, unilateral, localized to a single duct, occurs in women age 40 years or older, is bloody, or is associated with a mass. A trigger point on the breast may be present where pressure induces discharge from a single duct. In this circumstance, mammography is indicated. A ductogram is also useful and consists of the cannulation of a single duct with a small nylon catheter or needle and the injection of 1.0 mL of water-soluble contrast solution. Nipple discharge associated with a cancer is clear, bloody, or serous. Testing for the presence of hemoglobin is helpful, but hemoglobin may also be detected when only an intraductal papilloma or duct ectasia is present. Definitive diagnosis depends on excisional biopsy of the offending duct and any mass lesion. A 3.0 lacrimal duct probe is used to identify the duct that requires excision. Needle localization biopsy is performed when the questionable mass lies more than 3.0 cm from the nipple.

Bilateral Nipple Discharge: Nipple discharge is suggestive of a benign condition if it is bilateral and multiductal in origin, occurs in women age 39 years or younger, or is milky or blue green in color. Prolactin-secreting pituitary adenomas are responsible for bilateral nipple discharge in less than 2 percent of cases. If serum prolactin levels are repeatedly elevated, plain x-rays of the sella turcica are indicated and thin-section computed tomography (CT) scan is required. Optical nerve compression, visual field loss, and infertility are associated with large pituitary adenomas.

Axillary lymph node metastases with unknown primary cancer. A woman who presents with an axillary lymph node metastasis that is consistent with a breast cancer metastasis has a 90 percent probability of harboring an occult breast cancer. However, axillary lymphadenopathy is the initial presenting sign in only 1 percent of breast cancer patients. Fine-needle biopsy and/or open biopsy of an enlarged axillary lymph node is performed when metastatic disease cannot be excluded. When metastatic cancer is found, immunohistochemical analysis may classify the cancer as epithelial, melanocytic, or lymphoid in origin. The presence of hormone receptors suggests a breast cancer, but is not diagnostic. The search for a primary cancer

includes careful examination of the thyroid, breast, and pelvis, including the rectum. Routine radiologic and laboratory studies include chest radiograph, liver function studies, and mammography. Chest, abdominal, and pelvic CT scans may be helpful. Positron emission tomography (PET) scans are also being employed. Suspicious mammography findings necessitate breast biopsy. When a breast cancer is found, treatment consists of an axillary lymph node dissection with a mastectomy or with whole-breast radiation therapy. Consideration is given to adjuvant chemotherapy and tamoxifen.

Breast cancer during pregnancy. Breast cancer occurs in 1 of every 3000 pregnant women and axillary lymph node metastases are present in up to 75 percent of these women. The average age of the pregnant woman with breast cancer is 34 years. Less than 25 percent of the breast nodules developing during pregnancy and lactation will be cancerous. Ultrasonography and needle biopsy are used in the diagnosis of these nodules. Open biopsy may be required. Mammography is rarely indicated because of its decreased sensitivity during pregnancy and lactation and because of the risk of radiation injury to the fetus. Approximately 30 percent of the benign conditions encountered will be unique to pregnancy and lactation (galactoceles, lobular hyperplasia, lactating adenoma and mastitis or abscess). Once a breast cancer is diagnosed, complete blood count (CBC), chest radiograph (with shielding of the abdomen), and liver function studies are performed.

Because of the deleterious effects of radiation therapy on the fetus, a modified radical mastectomy is the surgical procedure of choice during the first and second trimesters of pregnancy, even though there is an increased risk of spontaneous abortion following first trimester anesthesia. During the third trimester, lumpectomy with axillary node dissection is considered if adjuvant radiation therapy is deferred until after delivery. Lactation is suppressed. Chemotherapy administered during the first trimester carries a risk of spontaneous abortion and a 12 percent risk of birth defects. There is no evidence of teratogenicity resulting from administration of chemotherapeutic agents in the second and third trimesters. Pregnant women with breast cancer present at a later stage of disease because breast tissue changes that occur in the hormone-rich environment of pregnancy obscure early cancers. However, pregnant women with breast cancer have a prognosis, stage by stage, that is similar to that of nonpregnant women with breast cancer.

Male breast cancer. Less than 1 percent of all breast cancers occur in men. The incidence appears to be highest among North Americans and the British, in whom breast cancer constitutes as much as 1.5 percent of all male cancers. Jewish and African American males have the highest incidence. Male breast cancer is preceded by gynecomastia in 20 percent of men. It is associated with radiation exposure, estrogen therapy, testicular feminizing syndromes, and with Klinefelter syndrome (XXY). Breast cancer is rarely seen in young males and has a peak incidence in the sixth decade of life. A firm, nontender mass in the male breast requires investigation. Skin or chest wall fixation is particularly worrisome.

DCIS makes up less than 15 percent of male breast cancer, although infiltrating ductal carcinoma makes up more than 85 percent. Special-type cancers, including infiltrating lobular carcinoma, have only occasionally been reported. Male breast cancer is staged in an identical fashion to female breast cancer, and, stage by stage, men with breast cancer have the same survival rate as women. Overall, men do worse because of the advanced stage of their

cancer (stage III or IV) at the time of diagnosis. The treatment of male breast cancer is surgical, with the most common procedure being a modified radical mastectomy. Adjuvant radiation therapy is appropriate in cases in which there is a high risk for local recurrence. Eighty percent of male breast cancers are hormone receptor-positive, and adjuvant tamoxifen is considered. Systemic chemotherapy is considered for men with hormone receptor-negative cancers and for men whose cancers relapse after tamoxifen therapy.

Phyllodes tumors. The nomenclature, presentation, and diagnosis of phyllodes tumors (including cystosarcoma phyllodes) have posed many problems for surgeons. These tumors are classified as benign, borderline, or malignant. Borderline tumors have a greater potential for local recurrence. Mammography evidence of calcifications and morphologic evidence of necrosis do not distinguish between benign, borderline, and malignant phyllodes tumors. Consequently, it is difficult to differentiate benign phyllodes tumors from the malignant variant and from fibroadenomas. Phyllodes tumors are usually sharply demarcated from the surrounding breast tissue, which is compressed and distorted. Connective tissue composes the bulk of these tumors, which have mixed gelatinous, solid, and cystic areas. Cystic areas represent sites of infarction and necrosis. These gross alterations give the gross cut tumor surface its classical leaf-like (phyllodes) appearance. The stroma of a phyllodes tumor generally has greater cellular activity than that of a fibroadenoma.

Most malignant phyllodes tumors contain liposarcomatous or rhabdomyosarcomatous elements rather than fibrosarcomatous elements. Evaluation of the number of mitoses and the presence or absence of invasive foci at the tumor margins may help to identify a malignant tumor. Small phyllodes tumors are excised with a 1-cm margin of normal-appearing breast tissue. When the diagnosis of a phyllodes tumor with suspicious malignant elements is made, re-excision of the biopsy site to insure complete excision of the tumor with a 1-cm margin of normal-appearing breast tissue is indicated. Large phyllodes tumors may require mastectomy. Axillary dissection is not recommended as axillary lymph node metastases rarely occur.

Inflammatory breast carcinoma. Inflammatory breast carcinoma (stage IIb) accounts for less than 3 percent of breast cancers. This cancer is characterized by the skin changes of brawny induration, erythema with a raised edge, and edema (peau d'orange). Permeation of the dermal lymph vessels by cancer cells is seen in skin biopsies. There may be an associated breast mass. The clinical differentiation of inflammatory breast cancer may be extremely difficult, especially when a locally advanced scirrhous carcinoma invades dermal lymph vessels skin to produce peau d'orange and lymphangitis. Inflammatory breast cancer may also be mistaken for a bacterial infection of the breast. More than 75 percent of women afflicted with inflammatory breast cancer present with palpable axillary lymphadenopathy and frequently also have distant metastases. A report of the SEER program found distant metastases at diagnosis in 25 percent of white women with inflammatory breast carcinoma.

Surgery alone and surgery with adjuvant radiation therapy have produced disappointing results in women with inflammatory breast cancer. However, neoadjuvant chemotherapy with an Adriamycin-containing regimen may effect dramatic regressions in up to 75 percent of cases. In this setting, mastectomy, modified radical mastectomy, or radical mastectomy is performed to remove residual cancer from the chest wall and axilla. Adjuvant chemotherapy is then given. Finally, the chest wall and the supraclavicular, internal mammary, and

axillary lymph node basins receive adjuvant radiation therapy. This multimodal approach results in 5-year survival rates that approach 30 percent.

Disorders of the Head and Neck

*Richard O. Wein, Rakesh K. Chandra, and
Randal S. Weber*

The head and neck is a complex anatomical region in which different pathologies may affect an individual's ability to see, smell, hear, speak, obtain nutrition and hydration, or breathe. A multidisciplinary approach to many of the disorders in this region is essential in an attempt to achieve the best functional results with care. This chapter is intended to review many of the common diagnoses encountered in the field of Otolaryngology-Head and Neck Surgery. The goal of this chapter is to provide an overview that the clinician could use as a foundation for understanding head and neck diseases. As is the case with every field of surgery, care for patients with disorders of the head and neck is constantly changing as issues of quality of life and the economics of medicine continue to evolve.

BENIGN CONDITIONS OF THE HEAD AND NECK

Ear Infections

Infections may involve the external, middle, and/or internal ear. In each of these scenarios, the infection may follow an acute or chronic course and may be associated with both otologic and intracranial complications. Note that typical pathogens of common head and neck infections are listed in Table 17-1.

Otitis externa (OE) typically refers to infection of the skin of the external auditory canal. Acute OE is commonly known as "swimmer's ear," as moisture that persists within the canal after swimming often initiates the process. This leads to skin maceration, itching, and erosion of the skin/cerumen barrier with microbial proliferation and tissue cellulitis. Infected, desquamated debris accumulates within the canal. In the chronic inflammatory stage of the infection, the pain subsides but profound itching occurs for prolonged periods with gradual thickening of the external canal skin. Standard treatment requires removal of debris under otomicroscopy and application of appropriate topical antimicrobials. Systemic antibiotics are reserved for those with severe infections, diabetics, and immunosuppressed patients. Diabetic, older adult, and immune deficient patients are susceptible to a condition called malignant OE, a fulminant necrotizing infection of the otologic soft tissues combined with osteomyelitis of the temporal bone and possible cranial neuropathies may be observed. The classic physical finding is granulation tissue along the floor of the external auditory canal. These patients require intravenous anti-Pseudomonas therapy and possibly surgical débridement.

Otitis media (OM), in its acute phase, typically implies a bacterial infection of the middle ear. This diagnosis accounts for 25 percent of all antibiotic prescriptions and is the most common bacterial infection of childhood. Most cases occur before age 2 years and are secondary to immaturity of the eustachian tube. Contributing factors include upper respiratory viral infection and day care attendance, and craniofacial conditions affecting eustachian tube function, such as cleft palate. Day care attendance has been further correlated with antibiotic resistant infecting organisms.

TABLE 17-1 Microbiology of Common Otolaryngologic Infections

Condition	Microbiology
OE and Malignant OE	<i>Pseudomonas aeruginosa</i> , fungi (aspergillus most common)
Acute OM	Pneumococcus, <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i>
Chronic OM	Bacteria of acute OM plus <i>Staphylococcus aureus</i> and epidermidis, other Streptococci. May be polymicrobial. Exact role of bacteria unclear
AS	Bacteria seen in acute OM plus viruses that cause URI
CS	Same as bacteria, of chronic OM. Some forms may also represent immune response to fungi.
Pharyngitis	Viruses of URI, <i>Streptococcus pyogenes</i> , Pneumococcus, group C and G streptococci, <i>Corynebacterium diphtheriae</i> , <i>Bordatella pertussis</i> , syphilis, <i>Neisseria gonorrhea</i> , Candida, EBV (mononucleosis), HPV, CMV, HSV, HIV

AS = acute sinusitis; CMV = cytomegalovirus; CS = coronary sinus; EBV = Epstein-Barr virus; HIV = human immunodeficiency virus; HPV = human papilloma virus; HSV = herpes simplex virus; OE = otitis externa; OM = otitis media; URI = upper respiratory infection.

Classification of the infection as acute is based on the duration of the process being less than 3 weeks. In this phase, otalgia and fever are the most common symptoms, and physical exam reveals a bulging, opaque tympanic membrane. If the process lasts 3–8 weeks, it is called subacute. Chronic OM, lasting more than 8 weeks, usually results from an unresolved acute OM. Twenty percent of patients demonstrate a persistent middle ear effusion 8 weeks after resolution of the acute phase.

Rather than a purely infectious process, however, it represents chronic inflammation and hypersecretion by the middle ear mucosa associated with eustachian tube dysfunction, viruses, allergy, ciliary dysfunction, and other factors. Physical exam reveals a retracted tympanic membrane that may exhibit an opaque character, bubbles, or an air-fluid level.

Treatment for uncomplicated OM is appropriate oral antibiotic therapy. OM following a chronic or recurrent acute pattern is frequently treated with myringotomy and tube placement to remove the effusion and ventilate the middle ear.

Tympanic membrane perforation during acute OM frequently results in resolution of severe pain and provides for drainage of purulent fluid and middle ear ventilation. These perforations usually heal spontaneously after the infection has resolved. Chronic OM, however, may be associated with nonhealing tympanic membrane perforations and persistent otorrhea. This requires surgical closure (tympanoplasty) after medical treatment (topical and/or oral antibiotics) for any residual acute infection. Chronic inflammation also may be associated with erosion of the ossicular chain and/or cholesteatoma, which is an expansile destructive epidermoid cyst of the middle ear and/or mastoid. Chronic OM also may be associated with chronic mastoiditis, which along with cholesteatoma, are indications for mastoidectomy.

Complications of OM may be grouped into two categories: intratemporal (otologic) and intracranial. Intratemporal complications include acute

coalescent mastoiditis, petrositis, facial nerve paralysis, and labyrinthitis. In acute coalescing mastoiditis, destruction of the bony lamellae by an acute purulent process results in severe pain, fever, and swelling behind the ear. These diagnoses are confirmed by computed tomography (CT) scan. Facial nerve paralysis also may occur secondary to an acute inflammatory process in the middle ear or mastoid. Intratemporal complications are managed by myringotomy tube placement and appropriate intravenous (IV) antibiotics. Urgent mastoidectomy may also be necessary. Labyrinthitis refers to inflammation of the inner ear. Most cases are idiopathic or are secondary to viral infections of the endolymphatic space, but this may be bacterial (suppurative) when it complicates OM. The patient experiences vertigo with sensorineural hearing loss, and symptoms may smolder over several weeks. Acute suppurative labyrinthitis may hallmark impending meningitis and must be treated rapidly. The goal of management of inner ear infection that occurs secondary to middle ear infection is to “sterilize” the middle ear space with antibiotics and the placement of a myringotomy tube.

Meningitis is the most common intracranial complication. Otologic meningitis in children is most commonly associated with a *Haemophilus influenzae* type B infection. Other intracranial complications include epidural abscess, subdural abscess, brain abscess, otitic hydrocephalus (pseudotumor), and sigmoid sinus thrombophlebitis. The otogenic source must be urgently treated with antibiotics and myringotomy tube placement. Mastoidectomy and neurosurgical consultation may be necessary.

Bell palsy, or idiopathic facial paralysis, may be considered within the spectrum of otologic disease given the facial nerve's course through the temporal bone. This entity is the most common etiology of facial nerve paralysis and is clinically distinct from that occurring as a complication of OM in that the otologic exam is normal. Historically, Bell palsy was synonymous with “idiopathic” facial paralysis. It is now accepted, however, that the majority of these cases represent a viral neuropathy caused by herpes simplex. Treatment includes oral steroids plus antiviral therapy. Complete recovery is the norm, but does not occur universally, and selected cases may benefit from surgical decompression of the nerve within its bony canal. Varicella zoster virus may also cause facial nerve paralysis when the virus reactivates from dormancy in the nerve. This condition, known as Ramsey-Hunt syndrome, is characterized by severe otalgia followed by the eruption of vesicles of the external ear. Treatment is similar to Bell palsy, but full recovery is only seen in approximately two-thirds of cases.

Sinus Inflammatory Disease

Sinusitis is a clinical diagnosis based on patient signs and symptoms. The Task Force on Rhinosinusitis has established criteria to define “a history consistent with sinusitis.” To qualify for the diagnosis, the patient must exhibit at least two major factors or one major and two minor factors. Major factors include congestion, nasal drainage, smell loss, and facial pressure, although minor factors include nonspecific symptoms such as headache, tooth pain, bad breath, and otalgia. The classification of sinusitis as acute, subacute, or chronic is based on the time course over which those criteria have been met. If signs and symptoms are present for 7–10 days but less than 4 weeks, the process is designated acute sinusitis (AS). Sub-AS has been present for 4–12 weeks, and chronic sinusitis (CS) is diagnosed when the patient has had signs and symptoms for at least 12 weeks. In the setting of the appropriate clinical signs/symptoms, the

diagnosis may be confirmed by CT, which can demonstrate mucosal thickening and/or sinus opacification. The diagnosis should be established by history and endoscopy, rather than CT alone.

AS typically follows a viral upper respiratory infection (URI) whereby sinonasal mucosal inflammation results in closure of the sinus ostium. This results in stasis of secretions, tissue hypoxia, and ciliary dysfunction. These conditions promote bacterial proliferation and acute inflammation. The mainstay of treatment is oral antibiotics empirically directed toward the three most common organisms. Other treatments include topical and systemic decongestants, nasal saline spray, topical nasal steroids, and oral steroids in selected cases. In the acute setting, surgery is reserved for complications or pending complications, which may include extension to the eye (orbital cellulitis or abscess) or the intracranial space (meningitis, intracranial abscess). Strictly speaking, the viral URI induces acute sinus inflammation. As an effort to exclude common colds from receiving antibiotic therapy, the criteria for AS stipulate that symptoms be present for at least 7–10 days, by which time the common cold should be in a resolution phase.

CS represents a heterogeneous group of patients with multifactorial etiologies contributing to ostial obstruction, ciliary dysfunction, and inflammation. Components of genetic predisposition, allergy, anatomic obstruction, bacterial, fungal, and environmental factors play varying roles, depending on the individual patient. As of yet, no immunologic “final common pathway” has been defined, but the clinical picture is well described. CS also may be associated with nasal polyps, which are manifestations of longstanding mucosal inflammatory disease. Polyps themselves may block sinus outflow, further exacerbating microbial proliferation. Nasal endoscopy is a critical element of the diagnosis of CS. Anatomic abnormalities, such as septal deviation, nasal polyps, and purulence may be observed. Pus found on endoscopic exam is diagnostic alone. This may be cultured, and subsequent antibiotic therapy can be directed accordingly. The spectrum of bacteria found in CS is variable, and antibiotic resistance is rising. Medical management of CS includes a prolonged course of oral antibiotics (>3 weeks), oral steroids, and nasal irrigations with saline or antibiotic solutions. Underlying allergic disease is managed with antihistamines and possible allergy immunotherapy. Those failing medical management are candidates for elective endoscopic sinus surgery, in which the goals are to enlarge the natural sinus ostia and to remove chronically infected bone to promote both ventilation and drainage of the sinus cavities.

The role of fungi in sinusitis is an area of active investigation. Fungal sinusitis may take on both noninvasive and invasive forms. The former category includes fungal ball (“mycetoma”) and allergic fungal sinusitis, both of which occur in immunocompetent patients. Fungal ball usually consists of *Aspergillus* and is associated with only scant inflammatory changes. In contrast allergic fungal sinusitis involves brisk chronic hypersensitivity reactions to fungal antigens within the nose and sinuses. The exact immunologic mechanisms involved are a matter of debate. Endoscopic evaluation reveals florid polyposis and inspissated mucin containing fungal debris and products of eosinophil breakdown. The implicated organisms are usually those of the *Dematiaceae* family, but *Aspergillus* species also are seen. These conditions are treated surgically, but systemic steroids and topical (and occasionally systemic) antifungals also are indicated in allergic fungal sinusitis. Rarely, immunocompetent patients also may develop an indolent form of invasive fungal sinusitis, but more commonly,

invasive fungal sinusitis affects immunocompromised patients, diabetics, or the very older adult. Fungal invasion of the microvasculature causes ischemic necrosis and black, necrotic escharation of the sinonasal mucosa. *Aspergillus* and fungi of the *Mucorales* family are often implicated with the latter more common in diabetics. Treatment requires aggressive surgical débridement and IV antifungals, but the prognosis is nonetheless dismal.

Pharyngeal and Adenotonsillar Disease

Infectious pharyngitis, in the vast majority of cases, is viral rather than bacterial in origin. Most cases resolve, without complication, from supportive care and possibly antibiotics. Patients with tonsillitis present with sore throat, dysphagia, and fever. Tonsillar exudates and cervical adenitis may be seen when the etiology is bacterial. If adenoiditis is present, the symptoms may be similar to those of sinusitis, but visual evaluation of the adenoid, at least in children, requires endoscopy and/or imaging (lateral neck soft tissue radiograph). Tonsillitis and adenoiditis may follow acute, recurrent acute, and chronic temporal patterns. It should be noted, however, that clinical diagnosis is often inaccurate to determine whether the process is bacterially induced and thus requires antibiotics. When a bacterial cause is suspected, antibiotics should be initiated to cover the usual organisms, particularly group A beta hemolytic streptococci (*Streptococcus pyogenes*). Currently, rapid antigen assays for group A streptococci are available with sensitivity and specificity of approximately 85 and 90 percent, respectively. Complications of *Streptococcus pyogenes* pharyngitis may be systemic, including rheumatic fever (3 percent), poststreptococcal glomerulonephritis, and scarlet fever. Locoregional complications of include peritonsillar abscess, and rarely, deep neck space abscess. These conditions require surgical incision and drainage. Peritonsillar abscess may be drained transorally, and some report that needle aspiration without incision is sufficient. Deep neck space abscess, which more commonly is odontogenic in origin, usually requires external incision and drainage.

Obstructive adenotonsillar hyperplasia may present with nasal obstruction, rhinorrhea, voice changes, dysphagia, and sleep disordered breathing or obstructive sleep apnea, depending on the particular foci of lymphoid tissue involved. Adenotonsillar hypertrophy may be associated with sleep disorders, which exist on a continuum from simple snoring to upper airway resistance syndrome (UARS) to obstructive sleep apnea (OSA). UARS and OSA are associated with excessive daytime somnolence and frequent sleep arousals. Polysomnography to quantify the number of apneas, hypopneas, and oxygen desaturations can be used to grade the severity.

Tonsillectomy and adenoidectomy are indicated for chronic or recurrent acute infection and for obstructive hypertrophy. Multiple techniques have been described including electrocautery, sharp dissection, laser, and radiofrequency ablation. There is no consensus regarding the best method. In cases of chronic or recurrent infection, surgery is considered only after failure of medical therapy. Patients with recurrent peritonsillar abscess should undergo tonsillectomy when the acute inflammatory changes have resolved. Selected cases, however, require tonsillectomy in the acute setting for the management of severe inflammation, systemic toxicity, or impending airway compromise. Adenoidectomy may benefit selected children with chronic or recurrent OM to lower the bacterial burden and to decompress the eustachian tube. The primary complications of adenotonsillectomy include bleeding (3–5 percent),

airway obstruction, velopharyngeal insufficiency, pharyngeal stenosis, death, and readmission for dehydration secondary to postoperative dysphagia.

In addition to adenotonsillectomy, surgery for sleep-disordered breathing may include uvulopalatopharyngoplasty, tongue base reduction, tongue advancement, hyoid suspension, and a variety of maxillomandibular advancement procedures, depending on the sites of airway collapse. Adults with significant nasal obstruction may benefit from septoplasty or sinus surgery. Patients with severe OSA with unfavorable anatomy or comorbid pulmonary disease may require tracheotomy. Prior to surgery, these patients should be given a trial of nocturnal continuous positive airway pressure (CPAP).

Benign Conditions of the Larynx

Disorders of voice may affect a wide array of patients with respect to age, gender, and socioeconomic status. The principal symptom of these disorders, at least when a mass lesion is present, is hoarseness. Other vocal manifestations include hypophonia or aphonia, breathiness, and pitch breaks. Benign laryngeal disorders also may be associated with airway obstruction, dysphagia, and reflux. Smoking also may be a risk factor for benign disease, but this element of the history should raise the index of suspicion for malignancy.

Recurrent respiratory papillomatosis (RRP) reflects involvement of human papilloma virus (HPV) within the mucosal epithelium of the upper aerodigestive tract. The larynx is the most frequently involved site, and subtypes 6 and 11 are the most often implicated. The disorder typically presents in the early childhood, secondary to viral acquisition during vaginal delivery. Many cases resolve after puberty, but the disorder may progress into adulthood. The diagnosis can be established with office endoscopy. Currently, there is no "cure" for RRP. The treatment involves operative microlaryngoscopy with excision or laser ablation, and the natural history is eventual recurrence. Multiple procedures are typically required over the patient's lifetime.

Laryngeal granulomas typically occur in the posterior larynx on the arytenoid mucosa and develop secondary to multiple factors including reflux, voice abuse, chronic throat clearing, endotracheal intubation, and vocal fold paralysis. Effective management requires identification of the underlying cause(s). Patients report pain (often with swallowing) more commonly than vocal changes. In addition to fiberoptic laryngoscopy, workup may include voice analysis, laryngeal electromyography (EMG), and pH probe testing.

Edema in the superficial lamina propria of the vocal cord (VC) is known as polypoid corditis, polypoid laryngitis, polypoid degeneration of the VC, or Reinke edema. The superficial lamina propria just underlies the vibratory epithelial surface. Edema (usually bilateral) is thought to arise from injury to the capillaries that exist in this layer, with subsequent extravasation of fluid. Patients report progressive development of a rough, low-pitched voice. Females more commonly present for medical attention. The etiology is also multifactorial, and may involve smoking, laryngopharyngeal reflux, hypothyroidism, and vocal hyperfunction. Most of these patients are heavy smokers.

Focal, unilateral hemorrhagic VC polyps are more common in men. These occur secondary to capillary rupture within the mucosa by shearing forces during voice abuse. Use of anticoagulant or antiplatelet drugs may be a risk factor.

Cysts may occur under the laryngeal mucosa, particularly in regions containing mucous-secreting glands, such as the supraglottic larynx. Occasionally they derive from minor salivary glands, and congenital cysts may persist as

remnants of the branchial arch. Cysts of the VC may be difficult to distinguish from vocal polyps, and video stroboscopic laryngoscopy may be necessary to help establish the diagnosis. Although benign VC lesions may be treated via microsurgical laryngoscopic techniques, first-line modalities that may be employed include voice rest, voice retraining, and antireflux therapy. When maximal reflux therapy has failed, fundoplication may be indicated.

Leukoplakia of the vocal fold represents a white patch (which cannot be wiped off) on the mucosal surface, usually on the superior surface of the true VC. Rather than a diagnosis *per se*, the term describes a clinical finding. The significance of leukoplakia is that it may represent squamous hyperplasia, dysplasia, and/or carcinoma. Lesions exhibiting hyperplasia have a 1–3 percent risk of progression to malignancy, although that risk is 10–30 percent for dysplastic lesions. Ulceration, erythroplasia, or a history of smoking/alcohol abuse suggests possible malignancy, and excision is indicated. In the absence of risk factors, conservative measures are employed for 1 month. Any lesions that progress, persist, or recur should be considered for excision.

VC paralysis is most commonly iatrogenic in origin, following surgery to the thyroid, parathyroid, carotid, or cardiothoracic structures. This may also be secondary to malignant processes in the lungs, thoracic cavity, skull base, or neck. In the pediatric population, up to one fourth of cases may be neurologic, with Arnold-Chiari malformation being the most common. Overall, the left VC is more commonly involved secondary to course of the left recurrent laryngeal nerve into the thoracic cavity. The cause remains idiopathic in up to 20 percent of adults and 35 percent of children. These cases should prompt an imaging work-up to examine the skull base to the aortic arch on the left and from skull base to the subclavian on the right to rule out neoplasms of the lung, thyroid, or esophagus. Adults typically present with hoarseness, and the voice may be breathy if the contralateral VC has not compensated to close the glottic valve, in which case aspiration also is possible. Children may have a weak cry. Flexible fiberoptic laryngoscopy usually confirms the diagnosis, but laryngeal EMG may be necessary. In bilateral VC paralysis, the cords often are paralyzed in a paramedian position, creating airway compromise that necessitates tracheotomy. Treatment of unilateral VC paralysis includes speech therapy, and some patients do well with this modality alone. Medialization of the paralyzed vocal fold is performed to provide a surface on which the contralateral normal fold may make contact. This can be accomplished via injection or implantation of a variety of autologous (fat, collagen) or alloplastic (hydroxylapatite, silicone, Gore-Tex) compounds. Autologous materials are preferred. This technique also is useful for VC atrophy, which may occur with aging.

Trauma of the Head and Neck

Management of soft tissue trauma in the head and neck has several salient features. Wound closure must be understood in the context of the cosmetic and functional anatomic landmarks of the head and neck. Management of injuries to the eyelid requires identification of the orbicularis oculi, which is closed in a separate layer. The gray line must be carefully approximated to avoid lid notching or height mismatch. Management of lip injuries follows the same principle. The orbicularis oris must be closed, and the vermilion border carefully approximated. Injuries involving one fourth of the width of the eyelid or one-third the width of the lip may be closed primarily. Otherwise, flap or grafting procedures may be required. With laceration of the auricle, key

structures like the helical rim and antihelix must be carefully aligned with care to assure cartilage is covered. Cartilage has no intrinsic blood supply and thus is susceptible to ischemic necrosis following trauma. Thus auricular hematomas must be drained promptly, with placement of a bolster as a pressure dressing. Similarly, nasal septal hematomas require early drainage. The surgeon must avoid the temptation to perform aggressive débridement of facial soft tissues as many soft tissue components that appear devitalized will indeed survive secondary to healthy blood supply in this region.

Soft tissue injuries occurring in the midface may involve distal facial nerve branches. Those injured anterior to a vertical line dropped from the lateral canthus do not require repair secondary to collateral innervation in the anterior midface. Posterior to this line, the nerve should be repaired microscopically using 8-0–10-0 monofilament suture to approximate the epineurium. If neural segments are missing, cable grafting is performed using either the greater auricular (provides 7–8 cm) or sural nerve (up to 30 cm). Injuries to the buccal branch should alert the examiner to a possible parotid duct injury, which lies on a line drawn from the tragus to the midline upper lip. The duct should be repaired over a 22G stent or marsupialized into the oral cavity.

The mandible is the most commonly fractured facial bone. Fractures most often involve the angle, body, or condyle, and 2 or more sites are typically involved. Fractures are described as either favorable or unfavorable depending in whether or not the masticatory musculature tends to pull the fracture into reduction or distraction. The fracture is usually evaluated radiographically using a Panorex, but specialized plain film views and occasionally CT scan are necessary in selected cases. Classical management of mandible fractures dictated closed reduction and a 6-week period of intermaxillary fixation (IMF), with arch bars applied via circumdental wiring. Currently, arch bars and IMF are performed to establish occlusion. The fracture is then exposed and reduced, using transoral approaches where possible. Rigid fixation is then accomplished by the application of plates and screws. IMF has been associated with gingival and dental disease, and significant weight loss and malnutrition during the fixation period. Malocclusion is a longer-term complication. Edentulous patients may require refashioning of their dentures once healing is complete.

Classical signs of midface fractures in general include subconjunctival hemorrhage, malocclusion, midface numbness or hypesthesia (maxillary division of the trigeminal nerve), facial ecchymoses/hematoma, ocular signs/symptoms, and mobility of the maxillary complex. These fractures are classically described in three patterns: LeForte I, II, and III. Type I crosses the alveolus, type II passes obliquely through the maxillary sinus, and type III reflects craniofacial disjunction. Realistically, midface fractures comprise combinations of these three types. Zygoma fractures may involve the malar area and/or arch and may be associated with an orbital blowout fracture. Blowout may result in enophthalmos or entrapment of the inferior oblique muscle with diplopia on upward gaze. Fractures of the midface, zygoma, and orbital floor are best evaluated using CT scan, and repair requires a combination of transoral and external approaches to achieve at least two points of fixation for each fractured segment. Blowout fractures demonstrating significant entrapment or enophthalmos are treated by orbital exploration and reinforcement of the floor with mesh or bone grafting.

Temporal bone fractures occur in approximately one-fifth of skull fractures and blunt trauma is usually implicated. Fractures are divided into two patterns, longitudinal and transverse, but in practice, most are oblique. By classical

descriptions, longitudinal fractures comprise 80 percent and are associated with lateral skull trauma. Signs and symptoms include conductive hearing loss, ossicular injury, bloody otorrhea, and labyrinthine concussion. The facial nerve is injured in approximately 20 percent of cases. In contrast, the transverse pattern comprises only 20 percent of temporal bone fractures and occurs secondary to fronto-occipital trauma. The facial nerve is injured in 50 percent of cases. Transverse injuries frequently involve the otic capsule to cause sensorineural hearing loss and loss of vestibular function. Hemotympanum may be observed. A cerebrospinal fluid (CSF) leak must be suspected in temporal bone trauma. This resolves with conservative measures in most cases. The most significant consideration in the management of temporal bone injuries is the status of the facial nerve. Delayed or partial paralysis will almost always resolve with conservative management. Patients with immediate complete paralysis or with unfavorable electrophysiologic testing should be considered for surgical decompression when medically stable. It is of paramount importance to protect the eye in patients with facial nerve paralysis of any etiology, as absence of an intact blink reflex will predispose to corneal drying and abrasion. This requires the placement of artificial tears throughout the day, with lubricant ointment, eye taping, and/or a humidity chamber at night.

TUMORS OF THE HEAD AND NECK

When a discussion of neoplasms of the upper aerodigestive tract is initiated frequently the conversation focuses on squamous cell carcinoma. This is justifiable because the majority of malignancies of this region are represented by this pathology. The evaluation of local, regional, and distant spread of tumor and the selection of treatment protocols vary for each site within the head and neck.

Etiology and Epidemiology

Abuse of tobacco and alcohol are the most common preventable risk factors associated with the development of head and neck cancers. Individuals who both smoke (2 packs per day) and drink (4 units of alcohol per day) had an odds ratio of 35 for the development of a carcinoma compared to controls. Users of smokeless tobacco have a four times increased risk of oral cavity carcinoma when compared to nonusers.

Tobacco is the leading preventable cause of death in the United States and is responsible for 1 out of every 5 deaths. Recent trends have demonstrated an increase in the use of tobacco products by women and the long-term affects have yet to be realized. The evidence supporting the need for head and neck cancer patients to pursue smoking cessation after treatment is compelling. Forty-percent of patients that continue to smoke after treatment went on to recur or develop a second head and neck malignancy. Induction of specific p53 mutations within upper aerodigestive tract tumors have been noted in patients with histories of tobacco and alcohol use.

In India and Southeast Asia the product of the *Areca catechu* tree, known as a betel nut, is chewed in a habitual manner in combination with lime and cured tobacco as a mixture known as a quid. The long-term use of the betel nut quid is destructive to oral mucosa and is highly carcinogenic.

Environmental ultraviolet light exposure has been associated with the development of lip cancer. The projection of the lower lip, as it relates to this solar exposure, has been used to explain why the majority of squamous cell carcinomas arise along the vermilion border of the lower lip.

TABLE 17-2 TNM Staging for Oral Cavity Carcinoma**Primary tumor**

TX	Unable to assess primary tumor
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor is <2 cm in greatest dimension
T2	Tumor >2 cm and <4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension
T4 (lip)	Primary tumor invading cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (e.g., nose or chin)
T4a (oral)	Tumor invades adjacent structures (e.g., cortical bone, into deep tongue musculature, maxillary sinus) or skin of face
T4b (oral)	Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery

Regional lymphadenopathy

NX	Unable to assess regional lymph nodes
N0	No evidence of regional metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2a	Metastasis in single ipsilateral lymph node, >3 cm and <6 cm
N2b	Metastasis in multiple ipsilateral lymph nodes, all nodes <6 cm
N2c	Metastasis in bilateral or contralateral lymph nodes, all nodes <6 cm
N3	Metastasis in a lymph node >6 cm in greatest dimension

Distant metastases

MX	Unable to assess for distant metastases
M0	No distant metastases
M1	Distant metastases

TMN staging

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1-3	N1	M0
Stage IVa	T4a	N0	M0
	T4a	N1	M0

Staging

Staging for upper aerodigestive tract malignancies is defined by the American Joint Committee on Cancer (AJCC) and follows TNM (primary Tumor, regional Nodal metastases, distant Metastasis) staging format. The T staging criteria for each site varies depending on the relevant anatomy. Table 17-2 demonstrates TNM staging for oral cavity lesions.

UPPER AERODIGESTIVE TRACT

Lip

The majority of lip malignancies present on the lower lip (88–98 percent), followed by the upper lip (2–7 percent) and oral commissure (1 percent). The histology of lip cancers is predominantly squamous cell carcinoma, however, other tumors such as keratoacanthoma, verrucous carcinoma, basal cell carcinoma, malignant melanoma, minor salivary gland malignancies and tumors of mesenchymal origin (e.g., malignant fibrous histiocytoma) also may present in this location. Basal cell carcinoma presents disproportionately more frequently on the upper lip than lower.

Clinical findings in lip cancer include an ulcerated lesion on the vermilion or cutaneous surface or, less commonly, on the mucosal surface. A nodular or sclerotic lesion may be palpable within the deeper tissues. The presence of paresthesias in the area adjacent to the lesion may indicate mental nerve involvement.

Small primary lesions may be treated with surgery or radiation with equal success and acceptable cosmetic results. However, surgical excision with histologic confirmation of tumor-free margins is the preferred modality. The overall 5-year cure rate of lip cancer approximates 90 percent and drops to 50 percent in the presence of neck metastases. Postoperative radiation is administered to the primary site and neck for patients with close or positive margins, lymph node metastases, or perineural invasion.

The reconstruction of lip defects after tumor excision requires innovative techniques to provide oral competence, maintenance of dynamic function, and acceptable cosmesis. The typical lip length is 6–7 cm. Resection with primary closure is possible with a defect of up to one-third of the lip. When the resection includes one third to one half of the lip, techniques such as Burrow triangles in combination with advancement flaps or an Abbe-Estlander flap can be considered. For larger defects of up to 75 percent, the Karapandzic flap uses a sensate, neuromuscular flap that includes the remaining orbicularis oris muscle, conserving its blood supply from branches of the labial artery. Microstoma is a potential complication with these types of lip reconstruction. For very large defects, Webster or Bernard types of repair using lateral nasolabial flaps with buccal advancement have been described as well.

Oral Cavity

The oral cavity is composed of several sites with different anatomic relationships. The majority of tumors in the oral cavity are squamous cell carcinomas (>90 percent). Each site is briefly reviewed with emphasis placed on anatomy, diagnosis, and treatment options.

Oral Tongue

The oral tongue is a muscular structure with overlying nonkeratinizing squamous epithelium. The posterior limit of the oral tongue is the circumvallate

papillae, whereas its ventral portion is contiguous with the anterior floor of mouth. Tumors of the tongue begin in the stratified epithelium of the surface and eventually invade into the deeper muscular structures. The presentation is commonly an ulcerated or exophytic mass. The lingual nerve and the hypoglossal nerve may be invaded directly by tumors. Their involvement produces the clinical findings of loss of sensation of the dorsal tongue surface, deviation on tongue protrusion, fasciculations, and atrophy.

Surgical treatment of small (T1–T2) primary tumors is wide local excision with either primary closure or healing by secondary intention. A partial glossectomy, which removes a significant portion of the lateral oral tongue, permits reasonably effective postoperative function. Resection of larger tumors of the tongue that invade deeply can result in significant functional impairment in speech and swallowing function. The use of soft pliable fasciocutaneous free flaps can provide intraoral bulk and preservation of tongue mobility. Treatment of the regional lymphatics is typically performed with the modality used to address the primary site, which most frequently is via modified radical or selective neck dissection. Depth of invasion of the primary tumor can direct the need for elective lymph node dissection with early stage lesions.

Floor of Mouth

The floor of mouth is the mucosally covered semilunar area that extends from the anterior tonsillar pillar posteriorly to the frenulum anteriorly and from the inner surface of the mandible to the ventral surface of the oral tongue. The ostia of the submandibular and sublingual glands are contained in the anterior floor of mouth.

Anterior or lateral extension of tumor to the mandibular periosteum is of primary importance in preoperative treatment planning for these lesions. Deep invasion into the intrinsic musculature of the tongue causes fixation and mandates a partial glossectomy in conjunction with resection of the floor of mouth. Lesions in the anterior floor of mouth may directly invade the sublingual gland or submandibular duct and require resection of either of these glands in continuity with the primary lesion.

The resection of large tumors of the floor of mouth may require a lip-splitting incision and usually require immediate reconstruction. The goals are to obtain watertight closure to avoid a salivary fistula and to avoid tongue tethering to maximize mobility. For small mucosal lesions, wide local excision can be followed by placement of a split-thickness skin graft over the muscular bed. Larger defects that require marginal or segmental mandibulectomy require complex reconstruction with a fasciocutaneous or a vascularized bone flap.

Alveolus/Gingiva

The alveolar mucosa overlies the bone of the mandible and maxilla. It extends from the gingivobuccal sulcus to the mucosa of the floor of mouth and hard palate. Because of the tight attachment of the alveolar mucosa to the mandibular and maxillary periosteum, treatment of lesions of the alveolar mucosa frequently require resection of the underlying bone.

Marginal resection of the mandible can be performed for tumors of the alveolar surface that are associated with minimal bone invasion. Access for such a procedure can be performed using an anterior mandibulotomy, however, use of transoral and pull-through procedures are preferred if a coronal or sagittal marginal mandibulotomy is performed. For more extensive tumors that invade into the medullary cavity, segmental mandibulectomy is necessary.

Preoperative radiographic evaluation of the mandible plays an important role in determining the type of bone resection required. Sectional CT scanning with bone settings is the optimum modality for imaging subtle cortical invasion.

Retromolar Trigone

The retromolar trigone is represented by tissue posterior to inferior alveolar ridge and ascends over the inner surface of the ramus of the mandible. Similar to alveolar lesions, early involvement of the mandible is common because of the lack of intervening soft tissue in the region. Presentation of trismus may indicate muscle of mastication involvement and potential spread to the skull base. Resection of retromolar trigone tumors usually requires a marginal or segmental mandibulectomy with a soft tissue and/or osseous reconstruction. Ipsilateral elective and therapeutic neck dissection is performed because of the risk of metastasis to the regional lymphatics.

Buccal Mucosa

The buccal mucosa includes all of the mucosal lining from the inner surface of the lips to the line of attachment of mucosa of the alveolar ridges and pterygo-mandibular raphe. Tumors in this area have a propensity to spread locally and to metastasize to regional lymphatics. Local intraoral spread may necessitate resection of the alveolar ridge of the mandible or maxilla. Lymphatic drainage is to the facial and the submandibular nodes (Level I). Small lesions can be excised surgically, but more advanced tumors require combined surgery and postoperative radiation. Deep invasion into the cheek may require through-and-through resection. Ideal reconstruction to provide both internal and external lining is best accomplished with a folded fasciocutaneous free flap.

Palate

The hard palate extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone. Inflammatory lesions arising on the palate may mimic malignancy and can be differentiated by biopsy. Necrotizing sialometaplasia appears on the palate as a butterfly shaped ulcer and mimics carcinoma. Treatment is symptomatic and biopsy confirms its benign nature.

Squamous cell carcinoma and minor salivary gland tumors are the most common malignancies of the palate. Minor salivary gland tumors tend to arise at the junction of the hard and soft palate.

Squamous carcinoma of the hard palate is treated surgically. Adjuvant radiation is indicated for advanced staged tumors. Because the periosteum of the palate bones acts as a barrier to spread, mucosal excision may be adequate for very superficial lesions. Involvement of the periosteum requires removal of a portion of the bony palate. Partial or subtotal maxillectomy is required for larger lesions or those involving the maxillary antrum. Malignancies may extend along the greater palatine nerve making biopsy important for identifying neurotropic spread. Through-and-through defects of the palate require a dental prosthesis for rehabilitation of swallowing and speech.

Oropharynx

The oropharynx extends from the soft palate to the superior surface of the hyoid bone (or floor of the vallecula) and includes the base of tongue, the inferior surface of the soft palate and uvula, the anterior and posterior tonsillar pillars, the pharyngeal tonsils, and the lateral and posterior pharyngeal walls.

The histology of the majority of tumors in this region is squamous cell carcinoma. Although less common, minor salivary gland tumors may present as submucosal masses in the tongue base and palate. The palatine and lingual tonsils of Waldeyer ring may be the presenting site of a lymphoma noted as an asymmetrically enlarged tonsil or tongue base mass.

Oropharyngeal cancer usually presents as an ulcerated, exophytic mass. Tumor fetor from tumor necrosis is common. A muffled or “hot potato” voice is seen with large tongue base tumors. Dysphagia and weight loss are common symptoms. Referred otalgia, mediated by the tympanic branches of CN IX and CN X, is a common complaint. The incidence of regional metastases from cancers of the tongue base and other oropharyngeal sites is high. Consequently, a neck metastasis is a frequent presenting sign.

The treatment goals for patients with oropharyngeal cancer include maximizing survival and preserving function. Management of squamous cancers of this region includes surgery alone, primary radiation alone, surgery with postoperative radiation, and combined chemotherapy with radiation therapy. Many tumors of the oropharynx are poorly differentiated squamous cell carcinoma and tend to be radiosensitive. Early stage lesions, T1 and T2, may be eradicated with radiation alone or combination chemoradiation.

Tumors of the soft palate and tonsil extending to the tongue base are associated with poorer survival. Extensive oropharyngeal cancers that are infiltrative usually are managed with surgical resection and postoperative radiotherapy. Lesions that involve the mandible or its periosteum require composite resections, such as the classic jaw-neck resection or “commando” procedure. Tongue base involvement requires at least partial glossectomy, with the possibility of total glossectomy for lesions crossing the midline. Preservation of the larynx after total glossectomy is associated with the risk of postoperative aspiration and dysphagia.

Hypopharynx and Cervical Esophagus

The hypopharynx extends from the vallecula to the lower border of the cricoid cartilage and includes the pyriform sinuses, the lateral and posterior pharyngeal walls, and the postcricoid region. Squamous cancers of the hypopharynx frequently present at an advanced stage. Clinical findings are similar to those of lower oropharyngeal lesions and include a neck mass, muffled or hoarse voice, referred otalgia, dysphagia, and weight loss. A common symptom is dysphagia, starting with solids and progressing to liquids, leaving patients malnourished and catabolic at the time of presentation. Invasion of the larynx by direct extension can result in vocal cord paresis or paralysis and potential airway compromise.

Routine office examination should include flexible fiberoptic laryngoscopy to properly assess the extent of tumor. Barium swallow can provide information regarding postcricoid and upper esophageal extension, potential multifocality within the esophagus, and document the presence of aspiration. CT or magnetic resonance imaging (MRI) should be obtained through the neck and upper chest to assess for invasion of the laryngeal framework and to identify for regional metastases with special attention given to the paratracheal and upper mediastinal nodes.

Tumors of the hypopharynx and cervical esophagus are associated with poorer survival than other sites in the head and neck because of advanced primary stage and lymph node metastasis at presentation. Definitive radiation

therapy is effective for smaller T1–T2 tumors. Surgery with postoperative radiation therapy has been shown to improve locoregional control compared to single modality therapy in the treatment of advanced stage tumors. Surgical salvage after radiation failure has a success rate of less than 50 percent and can be associated with significant wound-healing complications. Because the majority of patients with tumors of the hypopharynx present with large lesions and significant submucosal spread, total laryngectomy often is required to achieve adequate margins.

When laryngopharyngectomy is performed for hypopharyngeal tumors the surgical defect is preferentially repaired by primary closure when possible. Generally, 4 cm or more of pharyngeal mucosa is necessary for primary closure to provide an adequate lumen for swallowing and to minimize the risk of stricture formation. Larger surgical defects require closure with the aid of pedicled myocutaneous flaps or microvascular reconstruction with radial forearm or jejunal free flap. When total laryngopharyngoesophagectomy is necessary, gastric pull-up reconstruction is performed.

Organ preservation for hypopharyngeal cancer using a platinum-based chemotherapy with radiation has resulted in a laryngeal preservation rate of 30 percent. Diminished locoregional control rates have been observed when compared to surgery and postoperative radiation. No decrease was noted in the rate distant metastases.

For the most part, cervical esophageal cancer is managed surgically. Preservation of the larynx has been described if the cricopharyngeus muscle is not involved. Unfortunately, this is not often the case and many patients with cervical esophageal cancer require a laryngectomy. Total esophagectomy is performed because of the tendency for multiple primary tumors and skip lesions seen with esophageal cancers. Recently, chemotherapy and external beam radiotherapy with and without surgery have been advocated.

Despite aggressive treatment strategies, 5-year survival for cervical esophageal cancer is less than 20 percent. Because of the presence of paratracheal lymphatic disease, surgical treatment for tumors of this area must include paratracheal lymph node dissection in addition to treatment of the lateral cervical lymphatics.

Larynx

Laryngeal carcinoma is a diagnosis typically entertained in individuals with prominent smoking histories and the complaint of a prolonged hoarse voice. The larynx is composed of three regions: the supraglottis, the glottis, and the subglottis.

The supraglottis includes the epiglottis, aryepiglottic folds, arytenoids, and ventricular bands (false vocal folds). The inferior boundary of the supraglottis is a horizontal plane passing through the lateral margin of the ventricle. The glottis is composed of the true vocal cords (superior and inferior surfaces) and includes the anterior and posterior commissures. The subglottis extends from the inferior surface of the glottis to the lower margin of the cricoid cartilage.

The normal functions of the larynx are airway patency, protection of the tracheobronchial tree during swallowing, and phonation. Patients with tumors of the supraglottic larynx may present with symptoms of chronic sore throat, dysphonia ("hot potato" voice), dysphagia, or a neck mass secondary to regional metastasis. Referred otalgia or odynophagia is encountered with advanced supraglottic cancers. Large bulky tumors of the supraglottis may result in

airway compromise. In contrast to most supraglottic lesions, hoarseness is an early symptom in patients with tumors of the glottis. Airway obstruction from a glottic tumor is usually a late symptom and is the result of tumor bulk or impaired vocal cord mobility. Decreased vocal cord mobility may be caused by direct laryngeal muscle invasion or involvement of the recurrent laryngeal nerve. Superficial tumors that are bulky may appear to cause cord fixation through mass effect. Subglottic cancers are relatively uncommon and typically present with laryngeal paralysis (usually unilateral), stridor, and/or pain.

The staging classification for squamous cancers of the larynx includes assessment of vocal cord mobility and the sites of tumor extension. Accurate clinical staging of laryngeal tumors requires fiberoptic endoscopy in the office and direct laryngoscopy of the larynx under general anesthesia. Direct laryngoscopy, used to assess the extent of local spread, may be combined with esophagoscopy or bronchoscopy to adequately stage the primary tumor and to exclude the presence of a synchronous lesion.

Radiographic imaging by CT or MRI provides important staging information and is crucial for identifying cartilage erosion or invasion and extension into the preepiglottic and paraglottic spaces.

For severe dysplasia or carcinoma in situ of the vocal cord, stripping of the surface mucosa has been shown to be an effective treatment. Multiple procedures may be necessary to control the disease and to prevent progression to an invasive cancer. Close follow-up examinations and smoking cessation are mandatory adjuncts of therapy. For early tumors of the glottis and the supraglottis, radiation therapy is equally as effective in controlling disease as surgery. The critical factors in determining the appropriate treatment modality are the patient's wishes to preserve voice, comorbid conditions (chronic obstructive pulmonary disease, cardiovascular and renal disease), and tumor stage. Voice preservation and maintenance of quality of life are key issues and significantly impact therapeutic decisions. The use of radiation therapy for early stage disease of the glottis and supraglottis provides excellent disease control with reasonable if not excellent preservation of vocal quality. Partial laryngectomy for small glottic cancers provides excellent tumor control, but with some degree of voice impairment. For supraglottic cancers without arytenoid or vocal cord extension, standard supraglottic laryngectomy results in excellent disease control with good voice function. For advanced tumors with extension beyond the endolarynx or with cartilage destruction, total laryngectomy followed by postoperative radiation is still considered the standard of care. In this setting, pharyngeal reconstruction by means of a pectoralis major flap or free flap reconstruction is occasionally required.

Subglottic tumors are rare, constituting only 1 percent of laryngeal tumors, and are best treated by total laryngectomy. Because these tumors present with adenopathy in 40 percent of cases, special attention must be given to the treatment of paratracheal lymph nodes and removal of one or both lobes of the thyroid.

The approach to the treatment for patients with advanced tumors of the larynx and hypopharynx continues to evolve over time. Sequential and concomitant chemotherapy and radiation trials have demonstrated the feasibility of these approaches for organ preservation. The recently completed RTOG 91-11 trial for laryngeal preservation demonstrated a higher laryngeal preservation rate among patients receiving concomitant chemotherapy and radiotherapy as opposed to radiation alone or sequential chemotherapy followed by radiation therapy. A randomized laryngeal preservation trial of neoadjuvant induction

chemotherapy followed by radiation therapy has yielded survival rates similar to those of laryngectomy with the benefit of preservation of the larynx in 65 percent of patients. Surgical salvage is available in cases of treatment failure or recurrent disease. The results of this study indicate that although overall survival rates are similar, patients who underwent total laryngectomy had better locoregional control, whereas those treated with chemotherapy and radiation therapy had lower rates of distant metastases.

Unknown Primary

When patients present with cervical nodal metastases without clinical or radiologic evidence of an upper aerodigestive tract primary tumor, they are referred to as having an unknown or occult primary. Given the difficulty in examining regions such as the base of tongue, crevices within the tonsillar fossa, and the nasopharynx, examination under anesthesia with directed tissue biopsies have been advocated. Ipsilateral tonsillectomy, direct laryngoscopy with base of tongue and piriform biopsies, examination of the nasopharynx, and bimanual examination can allow for identification of a primary site in a portion of patients. In those individuals in which a primary site cannot be ascertained, empiric treatment of the mucosal sources of the upper aerodigestive tract at risk and the cervical lymphatics with radiation therapy is performed.

NOSE AND PARANASAL SINUSES

As discussed previously, the nose and paranasal sinuses are the site of a great deal of infectious and inflammatory pathology. The diagnosis of tumors within this region is frequently made after a patient has been unsuccessfully treated for recurrent sinusitis and undergoes diagnostic imaging. Symptoms associated with sinonasal tumors are subtle and insidious. They include chronic nasal obstruction, facial pain, headache, epistaxis, and facial numbness. As such, tumors of the paranasal sinuses frequently present at an advanced stage. Orbital invasion can result in proptosis, diplopia, epiphora, and visual loss. Paresthesia within the distribution of CN V2 is suggestive of pterygopalatine fossa or skull base invasion and is generally a poor prognostic factor. Maxillary sinus tumors can present with loose dentition indicating erosion of the alveolar and palatal bones.

A variety of benign tumors arise in the nasal cavity and paranasal sinuses and include inverted papillomas, hemangiomas, hemangiopericytoma, angiofibroma, minor salivary tumors, and benign fibrous histiocytoma. Fibro-osseous and osseous lesions, such as fibrous dysplasia, ossifying fibroma, osteoma, and myxomas, also can arise in this region.

Malignant tumors of the sinuses are predominantly squamous cell carcinomas. Sinonasal undifferentiated carcinoma (SNUC), adenocarcinoma, mucosal melanoma, lymphoma, and olfactory neuroblastoma are some of the malignancies that have been described. Metastases from the kidney, breast, lung, and thyroid may also present as an intranasal mass.

The diagnosis of intranasal tumors is made with the assistance of a headlight and nasal speculum or nasal endoscope. The site of origin, involved bony structures, and the presence of pulsations or hypervascularity should be assessed. For paranasal sinus tumors MRI and CT scanning often are complimentary studies in determining orbital and intracranial invasion.

The standard treatment for most malignant tumors of the paranasal sinuses is surgical resection with postoperative adjuvant radiation therapy. The extent of

surgery is determined by the preoperative evaluation of disease spread. Tumors arising along the medial wall of the maxillary sinus may be treated by means of a medial maxillectomy. The treatment of advanced tumors of the paranasal sinuses frequently involves a multispecialty approach including the head and neck surgeon, neurosurgeon, prosthodontist, ophthalmologist, and reconstructive surgeon. When craniofacial resection is necessary for intracranial spread, cerebrospinal fluid decompression is performed through a lumbar drain.

NASOPHARYNX AND MEDIAN SKULL BASE

The nasopharynx extends in a plane superior to the hard plate from the choana, of the posterior nasal cavity, to the posterior pharyngeal wall. It includes the fossa of Rosenmüller, the eustachian tube orifices (torus tubarius) and the site of the adenoid pad. Tumors arising in the nasopharynx are usually of squamous cell origin and range from lymphoepithelioma to well-differentiated carcinoma. However, the differential diagnosis for nasopharyngeal tumors is broad and also includes lymphoma, chordoma, nasopharyngeal cysts, angiofibroma, minor salivary gland tumors, paraganglioma, rhabdomyosarcoma, extramedullary plasmacytoma, and neuroblastoma.

Risk factors for nasopharyngeal carcinoma include area of habitation, ethnicity, environment, and tobacco use. There is a high incidence of nasopharyngeal cancer in southern China, Africa, Alaska, and in Greenland Eskimos. A strong correlation exists between nasopharyngeal cancer and the presence of Epstein-Barr virus (EBV) infection, such that EBV titers may be used as a means to follow a patient's response to treatment.

The symptoms associated with presentation of nasopharyngeal tumors include nasal obstruction, posterior (Level V) neck mass, epistaxis, headache, serous otitis media with hearing loss, and otalgia. Cranial nerve involvement is indicative of skull base extension and advanced disease.

Examination of the nasopharynx is facilitated by the use of the flexible or rigid fiberoptic endoscope. Evaluation with imaging studies is important for staging and treatment planning. CT with contrast is best for determining bone destruction, and MRI is important for determining intracranial and soft tissue extension. The status of the cavernous sinus and optic chiasm should also be evaluated when reviewing imaging to determine the potential for treatment related morbidities.

For squamous cell carcinoma and undifferentiated nasopharyngeal carcinoma, the standard treatment is a combination of chemotherapy and radiation therapy. Combination therapy has been shown to produce superior rates over radiation alone for nasopharyngeal carcinoma. Surgical treatment for nasopharyngeal carcinoma is rarely feasible, but may occasionally be considered as salvage therapy for patients with localized recurrences.

EAR AND TEMPORAL BONE

Tumors of the ear and temporal bone are uncommon and account for less than 1 percent of all head and neck malignancies. Primary sites can include the external ear (pinna), external auditory canal (EAC), middle ear, mastoid, or petrous portion of the temporal bone. The most common site is the EAC and the most common histology is squamous cell carcinoma. Minor salivary gland tumors, including adenoid cystic carcinoma and adenocarcinoma, may also present in this region. The pinna, because of its exposure to ultraviolet light, is a site for basal cell and squamous cell carcinoma to arise. In the

middle ear, squamous cell carcinoma related to the presence of chronic otitis media is a typical feature. In the pediatric population, tumors of the temporal bone are most commonly soft tissue sarcomas. For advanced stage tumors with extensive temporal bone extension, the complex anatomy of the temporal bone makes removal of tumors with functional preservation challenging.

The diagnosis of tumors of the ear and temporal bone is frequently delayed because the initial presentation of these patients appears consistent with benign infectious disease. When patients fail to improve with conservative care and symptoms evolve to include a facial nerve paralysis or worsening hearing loss, the need for imaging and biopsy are considered. Granulation tissue in the external auditory canal or middle ear should always be biopsied in patients with atypical presentations or histories consistent with chronic otologic disease. The complexity of the temporal bone anatomy makes the use of imaging studies of paramount importance in the diagnosis, staging, and treatment of tumors of the temporal bone. Temporal bone CT scans (thin cuts with axial and coronal planes), MRI imaging, and angiography can allow for assessment of tumor extension of the skull base and involvement of the carotid.

Small skin cancers on the helix of the ear can be readily treated with simple excision and primary closure. Mohs microsurgery with frozen section margin control may also be used for cancer of the external ear. In lesions that are recurrent or invade the underlying perichondrium and cartilage, rapid spread through tissue planes can occur. Tumors may extend from the cartilaginous external canal to the bony canal and invade the parotid, temporomandibular joint, and the skull base. For extensive pinna-based lesions more radical procedures, such as auriculectomy, may be required in combination with additional procedures. Radiation therapy is combined with surgery for advanced skin cancer or in the context of positive margins or perineural spread.

The optimal treatment for tumors of the middle ear and bony external canal is en bloc resection followed by radiation therapy. Management of the regional lymphatics is determined by the site and stage of the tumor at presentation.

NECK

The diagnostic evaluation of a neck mass requires a planned approach that does not compromise the effectiveness of future treatment options. A neck mass in a 50-year-old smoker/drinker with a synchronous oral ulcer is different than a cystic neck mass in an 18-year-old that enlarges with an upper respiratory infection. As with all diagnoses, a complete history with full head and neck exam, including flexible laryngoscopy, are the core to this work-up. The differential diagnosis of a neck mass is dependent on its location and the patient's age. In children, most neck masses are inflammatory or congenital. However, in the adult population a neck mass greater than 2 cm in diameter has a greater than 80 percent probability of being malignant. Once the physician has developed a differential diagnosis, interventions to confirm or dispute diagnoses are initiated. Fine needle aspiration, with or without the assistance of ultrasound or CT guidance, can provide a valuable tool for early treatment planning that provides less oncologic disruption to a tissue mass than an open biopsy. The use of CT scanning and/or MRI imaging is dictated by the patient's presentation. Imaging allows the physician the ability to evaluate the anatomic relationships of the mass to the surrounding neck, and as such, sharpen the differential. A cystic lesion may represent benign pathology such a branchial cleft cyst, however, it may also represent a regional metastasis of a tonsil/base

of tongue squamous cell carcinoma or a papillary thyroid carcinoma. In this circumstance, evaluation of these potential primary sites, in addition to the characteristics of the neck mass, can alter the planned operative intervention such that a “lumpectomy” can be spared with the need for definitive surgery in a previously operated field.

Patterns of Lymph Node Metastasis

The regional lymphatic drainage of the neck is divided into seven levels. The levels allow for a standardized format for radiologists, surgeons, pathologists, and radiation oncologists to communicate concerning specific sites within the neck and does not represent regions isolated by fascial planes. The levels are defined as the following:

- Level I – the submental and submandibular nodes
 - Level Ia – the submental nodes; medial to the anterior belly of the digastric muscle bilaterally, symphysis of mandible superiorly, and hyoid inferiorly
 - Level Ib – the submandibular nodes and gland; posterior to the anterior belly of digastric, anterior to the posterior belly of digastric and inferior to the body of the mandible
- Level II – upper jugular chain nodes
 - Level IIa – jugulodigastric nodes; deep to sternocleidomastoid (SCM), anterior to the posterior border of the muscle, posterior to the posterior aspect of the posterior belly of digastric, superior to the level of the hyoid, inferior to spinal accessory nerve (CN XI)
 - Level IIb – submuscular recess; superior to spinal accessory nerve to the level of the skull base
- Level III – middle jugular chain nodes; inferior to the hyoid, superior to the level of the hyoid, deep to SCM from posterior border of the muscle to the strap muscles medially
- Level IV – lower jugular chain nodes; inferior to the level of the cricoid, superior to the clavicle, deep to SCM from posterior border of the muscle to the strap muscles medially
- Level V – posterior triangle nodes
 - Level Va – lateral to the posterior aspect of the SCM, inferior and medial to splenius capitis and trapezius, superior to the spinal accessory nerve
 - Level Vb – lateral to the posterior aspect of SCM, medial to trapezius, inferior to the spinal accessory nerve, superior to the clavicle
- Level VI – anterior compartment nodes; inferior to the hyoid, superior to suprasternal notch, medial to the lateral extent of the strap muscles bilaterally
- Level VII – paratracheal nodes; inferior to the suprasternal notch in the upper mediastinum.

Patterns of spread from primary tumor sites in the head and neck to cervical lymphatics are well described. The location and incidence of metastasis vary according to the primary site. Primary tumors within the oral cavity and lip metastasize to the nodes in Levels I, II, and III. The occurrence of skip metastases with oral tongue lesions makes possible the involvement of nodes in Level III or IV without involvement of higher echelon nodes. Tumors arising in the oropharynx, hypopharynx, and larynx most commonly spread to the lymph nodes in Levels II, III, and IV. Isolated Level V nodes are uncommon with oral cavity, pharyngeal and laryngeal primaries, however, Level V adenopathy may be seen with concomitant involvement of higher echelon

nodes. Malignancies of the nasopharynx and thyroid commonly spread to posterior lymph nodes in addition to the jugular chain nodes. Retropharyngeal nodes are sites for metastasis from tumors of the nasopharynx, soft palate, and lateral and posterior walls of the oropharynx and hypopharynx. Tumors of the hypopharynx, cervical esophagus, and thyroid frequently involve the paratracheal nodal compartment and may extend to the lymphatics in the upper mediastinum (Level VII). The Delphian node, a pretracheal lymph node, may become involved by advanced tumors of the glottis with subglottic spread.

Selective neck dissection options have become increasingly popular given the benefits of improved shoulder function and cosmetic impact on neck contour when compared to modified radical neck dissection (MRND). The principle behind preservation of certain nodal groups is that specific primary sites preferentially drain their lymphatics in a predictable pattern, as mentioned previously. Types of selective neck dissections include the supraomohyoid neck dissection, the lateral neck dissection, and the posterolateral neck dissection. The supraomohyoid dissection, typically used with oral cavity primaries, removes lymph nodes in levels I–III. The lateral neck dissection, frequently used for laryngeal malignancies, removes those nodes in levels II–IV. The posterolateral neck dissection, used with thyroid cancer, removes the lymphatics in levels II–V. In the clinically negative neck (N0), if the risk for occult metastasis is greater than 20 percent, an elective treatment of the nodes at risk is advocated. This may be in the form of elective neck irradiation or elective neck dissection, typically using a selective neck dissection option.

For clinically N+ necks, frequently the surgical treatment of choice is the MRND or radical neck dissection (RND). Selective neck dissection (SND) options have been advocated by some authors for treatment of limited N1 disease, however, do not have a role in the treatment of advanced N-stage disease. When negative prognostic factors such as extracapsular spread, perineural invasion, vascular invasion, and the presence of multiple positive node surgical management of the neck alone is not adequate. Adjuvant radiation therapy is indicated in these cases.

Benign Neck Masses

A number of benign masses of the neck occur that require surgical management. Many of these masses are seen in the pediatric population. The differential diagnosis includes thyroglossal duct cyst, branchial cleft cyst, lymphangioma (cystic hygroma), hemangioma, and dermoid cyst.

Thyroglossal duct cysts represent the vestigial remainder of the tract of the descending thyroid gland from the foramen cecum, at the tongue base, into the lower anterior neck during fetal development. They present as a midline or paramedian cystic mass adjacent to the hyoid bone. After an upper respiratory infection, the cyst may enlarge or even suppurate. Surgical management of a thyroglossal duct cyst requires removal of the cyst, the tract, and the central portion of the hyoid bone (Sistrunk procedure), and a portion of the tongue base up to the foramen cecum.

Congenital branchial cleft remnants are derived from the branchial cleft apparatus that persists after fetal development. There are several types, numbered according to their corresponding embryologic branchial cleft. First branchial cleft cysts and sinuses are associated intimately with the external auditory canal and the parotid gland. Second and third branchial cleft cysts are found along the anterior border of the sternocleidomastoid muscle and can produce drainage

via a sinus tract to the neck skin. Secondary infections can occur, producing enlargement, cellulitis, and neck abscess that requires operative drainage. The removal of branchial cleft cysts and fistula requires removal of the fistula tract to the point of origin to decrease the risk of recurrence. The second branchial cleft remnant tract courses between the internal and external carotid arteries and proceeds into the tonsillar fossa. The third branchial cleft remnant courses posterior to the common carotid artery, ending in the pyriform sinus region. Surgical excision is preferred to establish the definitive diagnosis of a branchial cleft cyst and avoid nontreatment of a masquerading head and neck regional metastasis. Cystic metastasis from squamous cell carcinoma of the tonsil or tongue base to a cervical lymph node can be confused for a branchial cleft cyst in an otherwise asymptomatic patient. Dermoid cysts tend to present as midline masses and represent trapped epithelium originating from the timing embryonic closure of the midline.

Lymphatic malformations such as lymphangiomas and cystic hygromas can be difficult management problems. They typically present as mobile, fluid-filled masses with either firm or doughy consistency. Because of their predisposition to track extensively into the surrounding soft tissues, complete removal to these lesions often is difficult. Recurrence and regrowth occur with incomplete removal, and cosmetic deformity or nerve damage can result when extensive surgical dissection is performed for large lesions. In newborns and infants, there is higher associated morbidity when cystic hygromas and lymphangiomas become massive, require tracheostomy, and involve the deep neck and mediastinum.

SALIVARY GLAND TUMORS OF THE HEAD AND NECK

Tumors of the salivary gland are relatively uncommon and represent less than 2 percent of all head and neck neoplasms. The major salivary glands are the parotid, submandibular, and sublingual glands. Minor salivary glands are found throughout the submucosa of the upper aerodigestive tract with the highest density found within palate. Eighty-five percent of salivary gland neoplasms arise in the parotid gland. The majority of these neoplasms are benign with the most common histology being pleomorphic adenoma (benign mixed tumor). In contrast, approximately 50 percent of tumors arising in the submandibular and sublingual glands are malignant. Tumors arising from minor salivary gland tissue carry an even higher risk for malignancy (75 percent).

Salivary gland tumors are usually slow growing and well-circumscribed. Patients with a mass and findings of rapid growth, pain, paresthesias, and facial weakness are at increased risk of harboring a malignancy. The facial nerve, which separates the superficial and deep lobes of the parotid, may be directly involved by tumors in 10–15 percent of patients. Additional findings ominous for malignancy include skin invasion and fixation to the mastoid tip. Trismus suggests invasion of the masseter or pterygoid muscles.

Submandibular and sublingual gland tumors present as a neck mass or floor of mouth swelling, respectively. Malignant tumors of the sublingual or submandibular gland may invade the lingual or hypoglossal nerves, causing paresthesias or paralysis. Bimanual examination is important for determining the size of the tumor and possible fixation to the mandible or involvement of the tongue.

Minor salivary gland tumors present as painless submucosal masses and most frequently are seen at the junction of the hard and soft palate, but can occur

throughout the upper aerodigestive tract. Minor salivary gland tumors arising in the prestyloid parapharyngeal space may produce medial displacement of the lateral oropharyngeal wall and tonsil.

Benign and malignant tumors of the salivary glands are divided into epithelial, nonepithelial, and metastatic neoplasms. Benign epithelial tumors include pleomorphic adenoma (80 percent), monomorphic adenoma, Warthin tumor, oncocytoma, or sebaceous neoplasms. Nonepithelial benign lesions include hemangioma, neural sheath tumors, and lipoma. Treatment of benign neoplasms is surgical excision of the affected gland or, in the case of the parotid, excision of the superficial lobe with facial nerve dissection and preservation. The minimal surgical procedure for neoplasms of the parotid is superficial parotidectomy with preservation of the facial nerve. "Shelling out" of the tumor mass is not recommended because of the risk of incomplete excision and tumor spillage.

Tumor spillage of a pleomorphic adenoma during removal can lead to recurrences and should be avoided.

The primary treatment of salivary malignancies is surgical excision. In this setting, basic surgical principles include the en bloc removal of the involved gland with preservation of all nerves unless invaded directly by tumor. For parotid tumors that arise in the lateral lobe, superficial parotidectomy with preservation of CN VII is indicated. If the tumor extends into the deep lobe of the parotid, a total parotidectomy with nerve preservation is performed. Although malignant tumors may abut the facial nerve, if a plane of dissection can be developed without leaving gross tumor, it is preferable to preserve the nerve. If the nerve is encased by tumor and preservation would mean leaving gross residual disease, the nerve is sacrificed. Sacrifice of the facial nerve and temporal bone resection are a component of the surgical removal of advanced tumors with direct extension into the facial nerve or temporal bone. Radiation therapy is used as adjuvant treatment in the postoperative setting for specific indications.

The removal of submandibular malignancies includes en bloc resection of the gland and submental and submandibular lymph nodes. Radical resection is indicated with tumors that invade the mandible, tongue or floor of mouth. Therapeutic removal of the regional lymphatics is indicated for clinical adenopathy or when the risk of regional metastasis exceeds 20 percent based on tumor characteristics.

Postoperative radiation treatment plays an important role in the treatment of salivary malignancies. The presence of extraglandular disease, perineural invasion, direct invasion of regional structures, regional metastasis, and high-grade histology are all indications for radiation treatment.

RECONSTRUCTION IN HEAD AND NECK SURGERY

Defects of soft tissue and bony anatomy of the head and neck can occur after oncologic resection. Tumor surgery frequently necessitates removal of structures related to speech and swallowing. Loss of sensation and motor function can produce dysphagia through impairment of food bolus formation, manipulation, and propulsion. Cosmetic deformities that result from surgery also can significantly impact the quality of life of cancer survivors.

Basic principles of reconstruction typically include attempting to replace resected tissue components (bone, skin, soft tissue) with like tissue. The head and neck reconstructive surgeon must take into consideration a patient's preoperative comorbidities and anatomy when constructing a care plan.

A stepladder analogy has been used to describe the escalation in complexity of reconstructive options in the repair of head and neck defects. It is important to remember that the most complex is not always the most appropriate. Progression for closure by secondary intention, primary closure, skin grafts, local flaps, regional flaps, and free-tissue transfer flaps (free flaps) run the gamut of options available. The most appropriate reconstructive technique used is based on the medical condition of the patient, the location and size of the defect to be repaired, and the functional impairment associated with the defect.

Skin Grafts

Split- and full-thickness skin grafts are used in the head and neck for a variety of defects. Following oral cavity resections, split-thickness grafts can provide adequate reconstruction of the mucosal surface if an adequate soft tissue bed is available to support the blood supply needed for survival. These grafts incorporate into the recipient site at around 5 days and do not provide replacement of absent soft tissue, but are expeditious for covering mucosal defects and provide for ease of monitoring for recurrences of the primary tumor. Full-thickness grafts are used on the face when local rotational flaps are not available. These grafts have far less contracture than split-thickness grafts and also can provide a good color match for the defect area. Grafts can be harvested from the postauricular or supraclavicular areas to maximize the match of skin characteristics.

Local Flaps

Local flaps encompass a large number of mainly random pattern flaps used to reconstruct defects in adjacent areas. It is beyond the scope of this chapter to enumerate all of these flaps, but they should be designed according to the relaxed skin tension lines of the face and neck skin. These lines are tension lines inherent in the facial regions and caused in part by the insertions of muscles of facial animation. Incisions paralleling the relaxed skin tension lines that respect the aesthetic subunits of the face heal with the least amount of tension and camouflage into a more appealing result. Poorly designed incisions or flaps result in widened scars and distortion of important aesthetic units. Flaps have many different configurations and sizes, with the most common being the rotation and transposition flaps.

Regional Flaps

Regional flaps are those that are available as pedicled transfer of soft tissue or bone from areas adjacent to the defect. These flaps have an axial blood supply that traverses the flap longitudinally from proximal to distal between the fascia and subcutaneous tissue. Single-stage reconstruction is possible and harvest can occur simultaneously with the resection of primary disease, thus decreasing operative time.

The deltopectoral fasciocutaneous flap is a medially based flap from the anterior chest wall reliant on the perforators of the internal mammary artery. The flap provides a fair color match for surface defects. Its pliability permits folding, making it useful for reconstruction of pharyngoesophageal defects. Use of the flap requires a second stage for inseting approximately 2 weeks after the original procedure.

The pectoralis myocutaneous flap is based on the pectoral branch of the thoracoacromial artery (medial) and the lateral thoracic artery (lateral). The

latter vessel may be sacrificed to increase the arc of rotation. This flap includes the pectoralis major muscle, either alone or with overlying anterior chest skin. The pectoralis myocutaneous flap has enjoyed tremendous popularity because of its ease of harvest, the ability to tailor its thickness to the defect, and minimal donor site morbidity. It can be used for many reconstructive needs in the oropharynx, oral cavity, and the hypopharynx and can be tubed in some cases to replace cervical esophageal defects. Bulk associated with this flap may make certain applications less practical and this problem is exacerbated in obese patients. The arc of rotation limits the superior extent of this flap to the zygomatic arch externally and the superior pole of the tonsil internally. It should be remembered that the least reliable portion of this flap is that portion furthest from the blood supply: the skin. When portions of the flap are extended into regions beyond the underlying muscle, relying on random blood supply, healing at the primary site may be adversely affected. For patients that require expeditious recovery to initiate postoperative radiation therapy this can be a significant problem. This flap is still frequently used but has been replaced in many instances by free-tissue transfer for oral cavity and oropharyngeal defects because of its greater reliability and pliability.

Free-Tissue Transfer

Free-tissue transfer with microvascular anastomosis (free flaps) affords the reconstructive surgeon unparalleled ability to replace tissue loss with tissues of similar characteristics. There are a number of donor sites available for various types of flaps, including osteomyocutaneous, myocutaneous, fasciocutaneous, fascial, and myoosseous flaps. The flaps most popular in head and neck reconstructive armamentarium are those with ease of harvesting from a standpoint of patient positioning and those that allow for a two-teamed approach for simultaneous flap harvesting and oncologic resection.

The radial forearm fasciocutaneous flap is a hardy flap with constant vascular anatomy and a potentially long vascular pedicle, allowing for ease of inseting and choice in anastomotic vascular recipient sites. It is pliable and can be reinnervated as a sensate flap, making it ideal for repair of oral cavity and oropharyngeal defects. It can be tubed to repair hypopharyngeal and upper esophageal defects.

The lateral thigh flap, based on perforators of the profunda femoris artery, provides relatively pliable tissue that can be tubed and is used to reconstruct similar defects as that of the radial forearm flap, and pharyngoesophageal defects extending from the thoracic inlet to the nasopharynx.

The fibular osteocutaneous or osteomyocutaneous flap allows for one-stage reconstruction of resected mandible. In the adult, 25 cm of bone can be harvested, and a cuff of soleus and flexor hallucis longus muscles can be included for additional soft tissue bulk. The pedicle length can be extended by harvesting a long segment of bone; the donor site defect is well tolerated as long as approximately 6 cm of bone is retained proximally and distally for knee and ankle stability.

Iliac crest osteocutaneous flaps are frequently used for mandible defects involving the angle; the natural shape of this donor site bone is similar to the mandibular angle and eliminates the need for shaping of the bone flap prior to inseting into the defect.

Large soft tissue defects can result from trauma, excision of skull base tumors, and tumors involving large segments of skin. Furthermore, after

extensive skull base resections in the anterior and lateral skull base, the need for separation of the oropharyngeal and sinonasal tracts from the dura requires soft tissue interposition between the dura and the contaminated upper aerodigestive tract. The rectus abdominis myocutaneous flap provides a large amount of soft tissue and is ideal for closure of wounds of the lateral skull base and dura.

For reconstruction of defects of the hypopharynx and cervical esophagus, both free flaps and regional pedicled flaps are available. The free transfer of a jejunal segment can be performed based on branches of the superior mesenteric artery. Other free flaps used in this area include fasciocutaneous flaps, such as tubed radial forearm, lateral thigh, and lateral arm flap. The gastric pull-up is a regional flap that also is in use for reconstruction of cervical esophageal defects. The stomach is mobilized and pedicled on the right gastric and gastroepiploic vessels into the defect via tunneling through the anterior mediastinum.

TRACHEOSTOMY

Tracheostomy is indicated in the management of patients who require prolonged intubation, assisted ventilation, pulmonary toilet, and in those patients with neurologic deficits that impair protective airway reflexes. Its use in head and neck surgery often is for the temporary management of the airway in the perioperative period. After surgical resection of oral cavity and oropharyngeal cancers, bleeding into the sublingual and submaxillary soft tissue spaces may result in airway compromise, and elective tracheostomy is indicated to prevent loss of the airway.

The avoidance of prolonged orotracheal and nasotracheal intubation decreases the risk of laryngeal damage and subglottic stenosis, facilitates oral and pulmonary toilet, and decreases patient discomfort. When the tracheostomy is no longer needed, the tube is removed and prompt closure of the opening usually occurs. Complications of tracheostomy include pneumothorax or pneumomediastinum, recurrent laryngeal nerve injury, formation of granulation tissue, tracheal stenosis, wound infection with large vessel erosion, and failure to close after decannulation. The use of cricothyroidotomy as an alternative to tracheostomy for patients who require prolonged intubation has been associated with a higher incidence of vocal cord dysfunction and subglottic stenosis. When cricothyroidotomy is used in the setting of establishing an emergency airway, conversion to a standard tracheostomy should be considered if decannulation is not anticipated within 5–7 days.

Placement of a tracheostomy does not obligate a patient to loss of speech. When a large cuffed tracheostomy tube is in place, expecting a patient to be capable of normal speech is impractical. However, after a patient is downsized to an uncuffed tracheostomy tube, intermittent finger occlusion or Passy-Muir valve placement will allow a patient to communicate while still using the tracheostomy to bypass the upper airway for inhalation. When a patient no longer has the original indication for the tracheostomy (secretion management, need for ventilatory support, upper airway edema) and can tolerate capping of the trach tube for greater than 24 h, decannulation is considered safe. If an upper airway mass or tissue reconstruction was the indication for the tracheostomy, predecannulation flexible laryngoscopic examination of the airway is recommended.

LUNG

Anatomy

Lymphatic Drainage

Lymph nodes draining the lungs are divided into two groups according to the tumor-node-metastasis (TNM) staging system for lung cancer: the pulmonary lymph nodes, N1, and the mediastinal nodes, N2.

Thoracic Surgical Approaches

Mediastinoscopy is used for diagnostic assessment of mediastinal lymphadenopathy and staging of lung cancer and is performed through 2–3-cm suprasternal notch incision. Blunt dissection along the anterior trachea is performed to the level of the carina. The mediastinoscope is inserted, and anatomic definition of the trachea, carina, and lateral aspect of both proximal main bronchi is achieved with blunt dissection using a long suction catheter. Long biopsy forceps can be inserted through the scope for sampling. The standard staging procedure for lung cancer includes biopsies of the paratracheal (stations 4R and 4L) and subcarinal lymph nodes (station 7).

In patients with left upper lobe tumors, lymph node spread is often to the regional aortopulmonary and preaortic lymph nodes (station 5 and 6). These nodes can be sampled via a modified Chamberlain procedure through a 4–5-cm incision over the left second costal cartilage, which on occasion is excised. This approach also may be used to biopsy anterior masses.

The posterolateral thoracotomy incision is the most common incision for the majority of pulmonary resections, esophageal operations, and for access to the posterior mediastinum and vertebral column. The skin incision typically starts at the anterior axillary line just below the nipple level and extends posteriorly below the tip of the scapula. The latissimus dorsi is divided and the serratus anterior is retracted. Typically the fifth interspace is entered and a rib spreader is used to separate the rib space.

The anterolateral thoracotomy has traditionally been used in trauma victims. This approach allows quick entry into the chest with the patient supine. In the face of hemodynamic instability, this approach is better than the lateral decubitus position, and gives the anesthesiologist control over the patient's cardiopulmonary system and resuscitation efforts. The incision is submammary, beginning at the sternal border overlying the fourth intercostal space and extending to the midaxillary line. Should more exposure be necessary, the sternum can be transected and the incision carried to the contralateral thoracic cavity ("clamshell" thoracotomy). A bilateral anterior thoracotomy incision with transection of the sternum ("clamshell" thoracotomy) is a standard operative approach to the heart and mediastinum in certain elective circumstances such as double-lung transplantation. A median sternotomy also can be added to an anterior thoracotomy ("trap-door" thoracotomy) for access to mediastinal structures.

The median sternotomy incision allows exposure of anterior mediastinal structures and is principally used for cardiac operations and for anterior and middle mediastinal tumors. Either pleural cavity may be entered, and if indicated, formal pulmonary resection can be performed. Sternotomy is associated with less pain and less compromise of pulmonary function than a lateral thoracotomy.

Video-Assisted Thoracoscopic Surgery

Video-assisted thoracoscopic surgery (VATS) is a common approach to the diagnosis and treatment of pleural effusions, recurrent pneumothoraces, lung biopsies, lobectomy, resection of bronchogenic and mediastinal cysts, esophageal myotomy, and intrathoracic esophageal mobilization for esophagectomy. VATS is performed via two to four incisions measuring 0.5–1.2 cm in length to allow insertion of the thoracoscope and instruments. The incision location varies according to the procedure. Formal VATS lobectomy for cancer is now accepted as equivalent to the open procedure for lung cancer. It is performed with a 6-cm access incision without rib spreading and two to three additional 1-cm ports. The specimen is removed via the access incision. Endoscopic staplers are used to divide the major vascular structures and bronchus.

Postoperatively, the pleural cavity typically is drained with a chest tube(s). Each chest tube is brought out through a separate stab incision in the chest wall below the level of the thoracotomy, or through a VATS port site. If the pleura has not been violated and no drainage is expected (i.e., after VATS sympathectomies), no chest tube is necessary. The lung is then ventilated and placed under positive pressure ventilation to assist with reexpansion of atelectatic segments.

Postoperative Care

Chest Tube Management

Pleural tubes are left for two reasons: to drain fluid, thereby preventing pleural fluid accumulation, and to evacuate air if an air leak is present. The volume of drainage over 24 h predicting safe chest tube removal is unknown. The ability of the pleural lymphatics to absorb fluid is substantial. It can be as high as 0.40 mL/kg per hour in a healthy individual, resulting in absorption of up to 500 mL of fluid over 24 h. The capacity of the pleural space to manage and absorb fluid is high if the pleural lining and lymphatics are healthy.

A drainage volume of 150 mL or less over 24 h has been thought necessary to safely remove a chest tube. Recently, it has been shown that pleural tubes can be removed after VATS lobectomy with 24-hour drainage volumes as high as 400 mL, without subsequent development of pleural effusions. Currently, it is the practice of these authors to remove chest tubes with 24-h outputs of 400 mL or less after lobectomy or lesser pulmonary resections.

If the pleural space is altered (e.g., malignant pleural effusion, pleural space infections or inflammation, and pleurodesis), strict adherence to a volume requirement before tube removal is appropriate (typically 100–150 mL over 24 h). Such circumstances alter normal pleural fluid dynamics.

The use of suction and the management of air leaks vary. Suction levels of 20 cm H₂O have been routinely used after pulmonary surgery in an effort to eradicate residual air spaces and to control postoperative parenchymal air leaks. Recently it has been shown that the routine use of a water seal (with

the patient off suction) actually promotes more rapid healing of parenchymal air leaks. The main guidelines for the use of a water seal are the degree of air leakage and the degree of expansion of the remaining lung. If the leak is significant enough to induce atelectasis or collapse during use of water seal (off suction), suction should be used to achieve lung reexpansion.

It is important to remember the process of assessing an air leak. The chest tube and its attached tubing should be examined and the lack of kinks or external mechanical obstruction (e.g., patient lying on the tube) verified. The patient is asked to voluntarily cough. During the cough, the water seal chamber is observed. If bubbles pass through the water seal chamber, an air leak is presumed. Occasionally, if the chest tube is not secured snugly at the skin surface, air can entrain around the tube into the patient with respiration; thus an air leak will be present, although not emanating from the lung itself. During the voluntary cough, the fluid level in the water seal chamber should move up and down with the cough and with deep respiration, reflecting the pleural pressure changes occurring with these maneuvers. A stationary fluid level implies a mechanical blockage, either because of external tube compression or a clot or debris within the tube.

Pain Control

Good pain control permits the patient to actively participate in breathing maneuvers designed to clear and manage secretions, and promotes ambulation and a feeling of well being. The two most common techniques of pain management are epidural and intravenous. To maximize efficacy, epidural catheters should be inserted at about the T6 level, roughly at the level of the scapular tip. Lower placement risks inadequate pain control and higher placement may provoke hand and arm numbness. Typically, combinations of fentanyl at 0.3 $\mu\text{g/mL}$, combined with either bupivacaine (0.125 percent) or ropivacaine (0.1 percent) are used. Ropivacaine has less cardiotoxicity than bupivacaine; thus in the case of inadvertent intravenous injection, the potential for refractory complete heart block that is seen with bupivacaine is significantly less.

When properly placed, a well-managed epidural can provide outstanding pain control without significant systemic sedation. Urinary retention is a frequent side effect, particularly in males who require an indwelling urinary catheter. Additionally, the use of local anesthetics may cause sympathetic outflow blockade, leading to vasodilation and hypotension often requiring intravenous vasoconstrictors (an alpha agonist such as phenylephrine) and/or fluid administration. In such circumstances, fluid administration for hypotension may be undesirable in pulmonary surgery patients, particularly after pneumonectomy.

Alternatively, intravenous narcotics via patient-controlled analgesia can be used, often in conjunction with ketorolac. Titration of basal and intermittent dosing is often necessary to balance the degree of pain relief with the degree of sedation. Oversedated, narcotized patients are as ominous as patients without adequate pain control, because of the significant risk of secretion retention and development of atelectasis or pneumonia. Proper pain control with intravenous narcotics is a balance of pain relief and sedation. An alternative to epidural is the intraoperatively placed intercostal nerve catheter. A recent randomized trial demonstrated that a catheter placed along the intercostal nerves with infusion of local anesthetic yielded equivalent pain control to epidural catheter in a postthoracotomy study.

Respiratory Care

The best respiratory care is an effective cough to clear secretions. The process ideally begins preoperatively, with clear instructions on using pillows (or other support techniques) over the wound and then applying pressure. Postoperatively, proper pain control is essential, without oversedation. Adjunctive respiratory care techniques (e.g., intermittent positive pressure breathing and incentive spirometry) has been shown to be of limited benefit, consistent with our impression that respiratory care is best accomplished by a dedicated team and educated patients.

In patients whose pulmonary function preoperatively is significantly impaired, generating an effective cough postoperatively may be nearly impossible. Here routine nasotracheal suctioning can be employed, but is uncomfortable for the patient. A better alternative is placement at the time of surgery of a percutaneous transtracheal suction catheter which is comfortable and allows suctioning.

Postoperative Complications

Postpneumonectomy pulmonary edema occurs in 1–5 percent of patients undergoing pneumonectomy, with a higher incidence after right pneumonectomy. Clinically, symptoms of respiratory distress manifest hours to days after surgery. Radiographically, diffuse interstitial infiltration or frank alveolar edema is seen. The syndrome reportedly has a nearly 100 percent mortality rate despite aggressive therapy. Treatment consists of ventilatory support, fluid restriction, and diuretics.

Postoperative air leak and bronchopleural fistula are two different problems, but distinguishing the two may be difficult. Postoperative air leaks are common after pulmonary resection. They occur more often and last longer in patients with emphysematous changes because the fibrotic changes and destroyed blood supply impairs healing of surface injuries. Prolonged air leaks—those lasting over 7 days—may be treated by diminishing or discontinuing suction (if used), by continuing chest drainage, or by instilling a pleurodesis agent, usually talcum powder.

If the leak is moderate to large and if a bronchopleural fistula from the resected bronchial stump is possible, flexible bronchoscopy is performed. Management options include continued prolonged chest tube drainage; reoperation and reclosure (with stump reinforcement with intercostals or a serratus muscle pedicle flap); or, for fistulas less than 4 mm, bronchoscopic fibrin glue application. Patients often have concomitant empyemas and open drainage may be necessary.

Solitary Pulmonary Nodule

A solitary pulmonary nodule or “coin lesion” is typically recognized as a single, well-circumscribed, spherical lesion less than 3 cm in diameter and completely surrounded by normal lung parenchyma. About 150,000 solitary nodules are found incidentally each year. The clinical significance of such a lesion depends on whether or not it represents a malignancy.

Differential Diagnosis

In nonselected patient populations, a new solitary pulmonary nodule has a 20–40 percent likelihood of being malignant, with the risk approximating 50 percent or higher for smokers. The remaining causes of pulmonary nodules

are numerous benign conditions. Infectious granulomas arising from a variety of organisms account for 70–80 percent of this type of solitary nodule; hamartomas are the next most common single cause, accounting for about 10 percent. The initial assessment of a pulmonary nodule should proceed from a clinical history and physical examination. Risk factors for malignancy include a history of smoking, prior neoplastic disease, hemoptysis, and age over 35 years.

Imaging

Chest thin-section computed tomography (CT) scan is critical in characterizing nodule location, size, margin morphology, calcification pattern, and growth rate. Lesions larger than 3 cm are regarded as masses and are more likely malignant. Irregular, lobulated, or spiculated edges strongly suggest malignancy. The corona radiata sign (consisting of fine linear strands extending 4–5 mm outward and appearing spiculated on radiographs) is highly cancer-specific.

Calcification within a nodule suggests a benign lesion. Four patterns of benign calcification are common: diffuse, solid, central, and laminated or “popcorn.” Granulomatous infections such as tuberculosis can demonstrate the first three patterns, whereas the popcorn pattern is most common in hamartomas.

Calcification that is stippled, amorphous, or eccentric is usually associated with cancer. Characteristically neoplasms grow, and several studies have confirmed that lung cancers have volume-doubling times from 20–400 days. Lesions with shorter doubling times are likely because of infection, as longer doubling times suggest benign tumors. Traditionally, 2-year size stability per chest radiography has been considered a sign of a benign tumor. This long-held notion has been challenged by recent investigations, which demonstrated only a 65 percent positive predictive value for chest radiographs. Thus size stability of a pulmonary mass on chest films is a relatively unreliable benign indicator that must be interpreted with caution.

PET is used to help differentiate benign from malignant nodules. One meta-analysis estimated its sensitivity for identifying neoplasms as 97 percent and its specificity as 78 percent. False-negative results can occur (especially in patients who have bronchoalveolar carcinomas, carcinoids, and tumors less than 1 cm in diameter), and false-positive results (because of confusion with other infectious or inflammatory processes).

Biopsy versus Resection

Only a biopsy can definitively diagnose a pulmonary nodule. Bronchoscopy has a 20–80 percent sensitivity for detecting a neoplastic process within a solitary pulmonary nodule, depending on the nodule size, its proximity to the bronchial tree, and the prevalence of cancer in the population being sampled. Transthoracic fine-needle aspiration (FNA) biopsy can accurately identify the status of peripheral pulmonary lesions in up to 95 percent of patients; the false-negative rate ranges from 3–29 percent.

VATS is often used for excising and diagnosing indeterminate pulmonary nodules. Lesions most suitable for VATS are those that are located in the outer one third of the lung and those that are less than 3 cm in diameter. Certain principles must be followed when excising potentially malignant lesions via VATS. The nodule must not be directly manipulated with instruments, the visceral pleura overlying the nodule must not be violated, and the excised nodule must be extracted from the chest within a bag to prevent seeding of the chest wall.

TABLE 18-1 Cumulative Percentage of Survival by Stage After Treatment for Lung Cancer

Pathologic stage	Time after treatment	
	24 Months	60 Months
pT1N0M0 (<i>n</i> = 511)	86 percent	67 percent
pT2N0M0 (<i>n</i> = 549)	76 percent	57 percent
pT1N1M0 (<i>n</i> = 76)	70 percent	55 percent
pT2N1M0 (<i>n</i> = 288)	56 percent	39 percent
pT3N0M0 (<i>n</i> = 87)	55 percent	38 percent

Lung Neoplasms

Lung cancer is the leading cancer killer in the United States accounting for 30 percent of all cancer deaths—more than cancers of the breast, prostate, and ovary combined. It is the third most frequently diagnosed cancer in the United States, behind prostate cancer in men and breast cancer in women. Most patients are diagnosed at an advanced stage of disease, so therapy is rarely curative. The overall 5-year survival for all patients with lung cancer is 15 percent, making lung cancer the most lethal of the leading four cancers (Table 18-1).

Epidemiology

Cigarette smoking is the primary cause of lung cancer. Two lung cancer cell types, squamous cell carcinoma and small cell carcinoma, are extraordinarily rare in the absence of cigarette smoking. The risk of developing lung cancer escalates with the number of cigarettes smoked, the number of years smoked, and the use of unfiltered cigarettes. Conversely, the risk of lung cancer declines with smoking cessation. Only 15 percent of lung cancers are not related to smoking, and the majority of these are adenocarcinomas.

Lung Cancer Histology

The term bronchial carcinoma is synonymous with lung cancer in general. Both terms refer to any epithelial carcinoma occurring in the bronchopulmonary tree. Lung cancer is broadly divided into two main groups based primarily on light microscopic observations: non–small-cell lung carcinoma and neuroendocrine tumors (typical carcinoid, atypical carcinoid, large-cell neuroendocrine carcinoma, and small-cell carcinoma).

Non–small-cell lung carcinoma. The term non–small-cell lung carcinoma (NSCLC) is used to distinguish a group of tumors from small-cell carcinoma. Tumors in the NSCLC group include squamous cell carcinoma, adenocarcinoma (including bronchoalveolar carcinoma), and large-cell carcinoma. Although they differ in appearance histologically, their clinical behavior and treatment is similar. As such, they are usefully thought of as a uniform group. However, each type has unique features that affect their clinical presentation and findings.

Squamous cell carcinoma. Squamous cell carcinoma accounts for 30–40 percent of lung cancers. It is the cancer most frequently found in men and is highly correlated with cigarette smoking. Importantly, squamous cell carcinoma is primarily located centrally and arises in the major bronchi, often causing the typical symptoms of centrally located tumors, such as hemoptysis, bronchial obstruction with atelectasis, dyspnea, and pneumonia. Central

necrosis is frequent and may lead to the radiographic findings of a cavity (possibly with an air-fluid level). Such cavities may become infected, with resultant abscess formation.

Adenocarcinoma. The incidence of adenocarcinoma has increased over the last several decades, and it now accounts for 25–40 percent of all lung cancers. It occurs with equal frequency in males and females. In contradistinction to squamous cell carcinoma, adenocarcinoma is most often a peripherally based tumor, thus it is frequently discovered incidentally on routine chest radiographs. Symptoms of chest wall invasion or malignant pleural effusions dominate.

Bronchoalveolar carcinoma. Bronchoalveolar carcinoma (BAC) is a relatively unusual (5 percent of all lung cancers) subtype of adenocarcinoma that has a unique growth pattern that differs from adenocarcinoma. Rather than invading and destroying contiguous lung parenchyma, tumor cells multiply and fill the alveolar spaces. To be classified as a pure BAC, no evidence of destruction of surrounding lung parenchyma should be seen. Because of their growth within alveoli, BAC tumor cells from one site can aerogenously seed other parts of the same lobe or lung, or the contralateral lung. This growth pattern and tendency to seed can produce three radiographic presentations: a single nodule, multiple nodules (in single or multiple lobes), or a diffuse form with an appearance mimicking that of a lobar pneumonia. Because tumor cells fill the alveolar spaces and envelop small airways rather than destroying them, air bronchograms can be seen, unlike with other carcinomas.

Large-cell carcinoma. Large-cell carcinoma accounts for 10–20 percent of lung cancers and may be located centrally or peripherally.

Neuroendocrine neoplasms. Recently, neuroendocrine lung tumors have been reclassified into neuroendocrine hyperplasia and three separate grades of neuroendocrine carcinoma (NEC). Listed below is the grading system now applied to NEC (left column), with the previously used common name (right column):

Grade I NEC	Classic or typical carcinoid
Grade II NEC	Atypical carcinoid
Grade III NEC	Large-cell type or small-cell type

Grade I NEC (classic or typical carcinoid) is a low-grade NEC. An epithelial tumor, it arises primarily in the central airways, although 20 percent of the time it occurs peripherally. It occurs primarily in younger patients. Because of the central location, it classically presents with hemoptysis, with or without airway obstruction and pneumonia. These tumors are very vascular which can predispose to life-threatening hemorrhage with even simple bronchoscopic biopsy maneuvers. Regional lymph node metastases are seen in 15 percent of patients, but rarely spread systemically or cause death.

Grade II NEC (atypical carcinoid) describes a group of tumors with a degree of aggressive clinical behavior. Unlike Grade I NEC, these tumors are etiologically linked to cigarette smoking and are more likely to be peripherally located. These tumors have a much higher malignant potential. Lymph node metastases are found in 30–50 percent of patients. At the time of their diagnosis, 25 percent of patients already have remote metastases.

Grade III NEC large-cell type tumors occur primarily in heavy smokers. These tumors tend to occur in the middle to peripheral lung fields. Their neuroendocrine nature is revealed by positive immunohistochemical staining for at least one neuroendocrine marker. Grade III NEC small-cell type (small-cell lung carcinoma [SCLC]) is the most malignant NEC, and accounts for 25 percent of all lung cancers. These tumors are centrally located and consist of smaller cells with a diameter of 10–20 μm that have little cytoplasm and very dark nuclei. They also have a high mitotic rate and areas of extensive necrosis. Multiple mitoses are easily seen. Importantly, very small bronchoscopic biopsies can distinguish NSCLC from SCLC, but crush artifact may make NSCLC appear similar to SCLC. These tumors are the leading producer of paraneoplastic syndromes.

Clinical Presentation

Lung cancer displays one of the most diverse presentation patterns of all human maladies. The wide variety of symptoms and signs is related to (1) histologic features, which often help determine the anatomic site of origin in the lung; (2) the specific tumor location in the lung and its relationship to surrounding structures; (3) biologic features, and the production of a variety of paraneoplastic syndromes; and (4) the presence or absence of metastatic disease.

Tumor Histology

Squamous cell and small-cell carcinomas frequently arise in centrally located main, lobar, and first segmental bronchi. Symptoms of airway irritation or obstruction are common, and include cough, hemoptysis, wheezing (because of high-grade airway obstruction), dyspnea (because of bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis).

In contrast, adenocarcinomas are often located peripherally and are often discovered incidentally as an asymptomatic lesion on chest radiograph. When symptoms occur, they are because of pleural or chest wall invasion (pleuritic or chest wall pain) or pleural seeding with malignant pleural effusion. Bronchoalveolar carcinoma (a variant of adenocarcinoma) may present as a solitary nodule, as multifocal nodules, or as a diffuse infiltrate mimicking an infectious pneumonia (pneumonic form).

Tumor Location

Symptoms related to the local intrathoracic effect of the primary tumor can be conveniently divided into two groups: pulmonary and nonpulmonary thoracic.

Pulmonary symptoms. Pulmonary symptoms result from the direct effect of the tumor on the bronchus or lung tissue. Symptoms (in order of frequency) include cough (secondary to irritation or compression of a bronchus), dyspnea (usually because of central airway obstruction or compression, with or without atelectasis), wheezing (with narrowing of a central airway of greater than 50 percent), hemoptysis (typically, blood streaking of mucus that rarely is massive, and indicates a central airway location), pneumonia (usually because of airway obstruction by the tumor), and lung abscess (because of necrosis and cavitation, with subsequent infection).

Nonpulmonary thoracic symptoms. Nonpulmonary thoracic symptoms result from invasion of the primary tumor directly into a contiguous structure (e.g., chest wall, diaphragm, pericardium, phrenic nerve, recurrent laryngeal

nerve, superior vena cava, and esophagus), or from mechanical compression of a structure (e.g., esophagus or superior vena cava) by enlarged tumor-bearing lymph nodes.

Peripherally located tumors (often adenocarcinomas) extending through the visceral pleura lead to irritation or growth into the parietal pleura, and potentially to continued growth into the chest wall structures. Three types of symptoms, depending on the extent of chest wall involvement, are possible: (1) pleuritic pain, from noninvasive contact of the parietal pleura with inflammatory irritation and from direct parietal pleural invasion, (2) localized chest wall pain, with deeper invasion and involvement of the rib and/or intercostal muscles, and (3) radicular pain, from involvement of the intercostal nerve(s).

Superior sulcus tumors (usually adenocarcinomas), may produce the Pancoast syndrome. Depending on the exact tumor location, symptoms can include apical chest wall and/or shoulder pain (from involvement of the first rib and chest wall), Horner syndrome (unilateral enophthalmos, ptosis, miosis, and facial anhidrosis from invasion of the stellate sympathetic ganglion), and radicular arm pain (from invasion of T1, and occasionally C8, brachial plexus nerve roots).

Invasion of the primary tumor into the mediastinum may lead to involvement of the phrenic or recurrent laryngeal nerves. Direct invasion of the phrenic nerve occurs with tumors of the medial surface of the lung, or with anterior hilar tumors. Symptoms may include shoulder pain (referred), hiccups, and dyspnea with exertion because of diaphragm paralysis. Radiographically, the diagnosis is suggested by unilateral diaphragm elevation on chest radiograph, and can be confirmed by fluoroscopic examination of the diaphragm with breathing and sniffing (the “sniff” test).

Recurrent laryngeal nerve (RLN) involvement most commonly occurs on the left side, given the hilar location of the left RLN as it passes under the aortic arch. Paralysis may occur from invasion of the vagus nerve above the aortic arch by a medially based left upper lobe (LUL) tumor, from invasion of the RLN directly by a hilar tumor, or from invasion by hilar or aortopulmonary lymph nodes involved with metastatic tumor. Symptoms include voice change, often referred to as hoarseness, but more typically a loss of tone associated with a breathy quality, and coughing, particularly when drinking liquids.

Superior vena cava (SVC) syndrome most frequently occurs with small-cell carcinoma, with bulky enlargement of involved mediastinal lymph nodes and compression of the SVC. Symptoms include variable degrees of swelling of the head, neck, and arms; headache; and conjunctival edema.

Direct invasion of a vertebral body produces symptoms of back pain, which is often localized and severe. If the neural foramina are involved, radicular pain may also be present.

Tumor Biology

Lung cancers, both non-small-cell and small-cell, are capable of producing a variety of paraneoplastic syndromes, most often from tumor production and release of biologically active materials systemically. The majority of such syndromes are caused by small-cell carcinomas, including many endocrinopathies. Paraneoplastic syndromes may produce symptoms even before symptoms are produced by the primary tumor, thereby leading to early diagnosis. Their presence does not influence resectability or the potential to successfully treat the tumor. Symptoms of the syndrome often will abate with successful treatment, and recurrence may be heralded by recurrent paraneoplastic symptoms.

One of the more common paraneoplastic syndromes in patients with SCLC is hypertrophic pulmonary osteoarthropathy (HPO). Clinically, the syndrome is characterized by tenderness and swelling of the ankles, feet, forearms, and hands. It is because of periostitis of the fibula, tibia, radius, metacarpals, and metatarsals.

Hypercalcemia occurs in up to 10 percent of patients with lung cancer and is most often because of metastatic disease. However, 15 percent of cases are because of secretion of ectopic parathyroid hormone–related peptide, most often with squamous cell carcinoma. A diagnosis of ectopic parathyroid hormone secretion can be made by measuring elevated serum levels of parathyroid hormone; however, the clinician must also rule out concurrent metastatic bone disease by a bone scan. Symptoms of hypercalcemia include lethargy, depressed level of consciousness, nausea, vomiting, and dehydration. Most patients have resectable tumors, and following complete resection the calcium level will normalize. Endocrinopathies are caused by the release of hormones or hormone analogues into the systemic circulation. Most occur with SCLCs.

Metastatic Symptoms

Metastases occur most commonly in the central nervous system (CNS), vertebral bodies, bones, liver, adrenal glands, lungs, and skin and soft tissues. At diagnosis, 10 percent of patients with lung cancer have CNS metastases; another 10–15 percent will develop CNS metastases. Symptoms are often focal and include headache, nausea and vomiting, seizures, hemiplegia, and speech difficulty.

Nonspecific Symptoms

Lung cancer often produces a variety of nonspecific symptoms such as anorexia, weight loss, fatigue, and malaise. The cause of these symptoms is often unclear, but should raise concern about possible metastatic disease.

Diagnosis, Evaluation, and Staging

In a patient with either a histologically confirmed lung cancer or a pulmonary lesion suspected to be a lung cancer, assessment encompasses three areas: the primary tumor, presence of metastatic disease, and functional status (the patient's ability to tolerate a pulmonary resection).

Assessment of the primary tumor. Assessment includes questions regarding the presence or absence of pulmonary, nonpulmonary, thoracic, and paraneoplastic symptoms. Patients often have already undergone a chest radiograph or CT scan before their initial visit with the surgeon; the location of the tumor can then help direct the history.

A routine chest CT should include intravenous contrast for delineation of mediastinal lymph nodes relative to normal mediastinal structures. Chest CT allows assessment of the primary tumor and its relationship to surrounding and contiguous structures and may demonstrate invasion of contiguous structures. Thoracotomy should not be denied because of presumptive evidence of invasion of the chest wall, vertebral body, or mediastinal structures; proof of invasion may require thoracoscopy or even thoracotomy. Magnetic resonance imaging (MRI), because of its excellent imaging of vascular structures, may be of value primarily to define a tumor's relationship to a major vessel.

Tissue diagnosis of the primary tumor can be obtained through bronchoscopy or needle biopsy. Bronchoscopy is particularly useful for centrally

located tumors with a higher probability of being visualized and biopsied and may discover additional unsuspected endobronchial lesions. Diagnostic tissue from bronchoscopy can be obtained by one of four methods: (1) brushings and washings for cytology, (2) direct forceps biopsy of a visualized lesion, (3) FNA with a Wang needle of an externally compressing lesion without visualized endobronchial tumor, and (4) transbronchial biopsy with the use of forceps guided to the lesion by fluoroscopy.

Transthoracic needle aspiration is ideally suited for peripheral lesions not easily accessible by bronchoscopy. Using image guidance (fluoroscopy or CT), either an FNA or core-needle biopsy is performed. The primary complication is pneumothorax (in up to 50 percent of patients) usually is minor and requires no treatment. Three biopsy results are possible: malignant, a specific benign process, or indeterminate. The overall false-negative rate is 20–30 percent, therefore unless a specific benign diagnosis (such as granulomatous inflammation or hamartoma) is made, malignancy is not ruled out and further efforts at diagnosis are warranted.

A thoracotomy occasionally is necessary to diagnose and stage a primary tumor. Although this occurs in fewer than 5 percent of patients, two circumstances may require such an approach: (1) a deep-seated lesion that yielded an indeterminate needle biopsy result or that could not be biopsied for technical reasons, or (2) inability to determine invasion of a mediastinal structure by any method short of palpation. In the circumstance of a deep-seated lesion without a diagnosis, FNA, a Tru-Cut biopsy, or preferably an excisional biopsy, can be performed with frozen-section analysis. If the biopsy result is indeterminate, a lobectomy may instead be necessary. When a pneumonectomy is required, a tissue diagnosis of cancer must be made before excision.

Assessment of metastatic disease. Distant metastases are found in about 40 percent of patients with newly diagnosed lung cancer. As with the primary tumor, assessment for the presence of metastatic disease should begin with the history and physical examination, focusing on the presence or absence of new bone pain, neurologic symptoms, and new skin lesions. Additionally, constitutional symptoms (e.g., anorexia, malaise, and unintentional weight loss of greater than 5 percent of body weight) suggest either a large tumor burden or the presence of metastases. Physical examination should focus on the patient's overall appearance, noting any evidence of weight loss with muscle wasting. The appearance of cervical and supraclavicular lymph nodes and that of the oropharynx should also be examined for tobacco-associated tumors. Routine laboratory studies include serum glutamic oxaloacetic transaminase and alkaline phosphatase and serum calcium (to detect bone metastases or the ectopic parathyroid syndrome). Elevation of either hepatic enzymes or serum calcium levels typically occurs with extensive metastases.

Mediastinal lymph nodes. Chest CT is the most effective noninvasive method available to assess the mediastinal and hilar nodes for enlargement. However, a positive CT result (i.e., nodal diameter more than 1.0 cm) predicts actual metastatic involvement in only about 70 percent of patients. Thus, up to 30 percent of such nodes are enlarged from inflammation because of atelectasis or pneumonia secondary to the tumor. Therefore, no patient should be denied an attempt at curative resection just because of a positive CT result for mediastinal lymph node enlargement. Any CT finding of metastatic nodal involvement must be confirmed histologically.

Positron emission tomography (PET) scanning for metastatic disease is now routine and allows whole body imaging permitting simultaneous evaluation of the primary lung lesion, mediastinal lymph nodes, and distant organs.

Cervical mediastinoscopy is commonly employed to evaluate mediastinal lymph nodes. It has several advantages over other techniques of mediastinal lymph node staging. It can provide a tissue diagnosis, allows sampling of all paratracheal and subcarinal lymph nodes, and permits visual determination of the presence of extracapsular extension of nodal metastasis. An absolute indication for mediastinoscopy is mediastinal lymph node enlargement greater than 1.0 cm by CT scan. When the size of mediastinal lymph nodes is normal, mediastinoscopy is generally recommended for centrally located tumors, for T2 and T3 primary tumors, and occasionally for T1 adenocarcinomas.

Pleural effusion. The presence of pleural effusion on a CT scan (or chest radiograph) is not synonymous with a malignant effusion. Malignant pleural effusion can only be diagnosed by finding malignant cells in a sample of pleural fluid examined microscopically. Pleural effusion is often secondary to the atelectasis or consolidation seen with central tumors. However, pleural effusion associated with a peripherally based tumor, particularly one that abuts the visceral or parietal pleural surface, does have a higher probability of being malignant. Regardless, no pleural effusion should be assumed to be malignant.

Distant metastases. Until recently, detection of distant metastases outside the thorax was performed with a combination of chest CT scan and multiorgan scanning (e.g., brain CT or MRI, abdominal CT, and bone scan). Chest CT scans always include the upper abdomen and allow visualization of the liver and adrenal glands. Routine preoperative multiorgan scanning is not recommended for patients with a negative clinical evaluation and clinical stage I disease. However, it is recommended for patients with regionally advanced (clinical stage II, IIIA, and IIIB) disease. Any patient, regardless of clinical stage who has a positive clinical evaluation should also undergo radiographic evaluation for metastatic disease.

PET scanning has supplanted multiorgan scanning in the search for distant metastases to the liver, adrenal glands, and bones. Currently, chest CT and PET are routine in the evaluation of patients with lung cancer. Brain MRI should be performed when the suspicion or risk of brain metastases is increased. Several reports show that PET scanning appears to detect an additional 10–15 percent of distant metastases not detected by routine chest or abdominal CT and bone scans.

Assessment of functional status. For patients with a potentially resectable primary tumor, their functional status and ability to tolerate either lobectomy or pneumonectomy needs to be carefully assessed. The surgeon should first estimate the likelihood of pneumonectomy, lobectomy, or possibly sleeve resection, given the CT scan results. A sequential process of evaluation then unfolds.

A patient's history is the most important tool for gauging risk. It must be emphasized that numbers alone (e.g., forced expiratory volume in 1 second [FEV-1] and carbon monoxide diffusion capacity [DLCO]) do not supplant the clinician's assessment. The clinical assessment entails the observation of the patient's general vigor and attitude.

When obtaining the patient's history, specific questions should be routinely asked that help determine the amount of lung that the patient will likely tolerate

having resected. Can the patient walk on a flat surface indefinitely, without oxygen and without having to stop and rest secondary to dyspnea? If so, the patient will be very likely to tolerate thoracotomy and lobectomy. Can the patient walk up two flights of stairs (up two standard levels), without having to stop and rest secondary to dyspnea? If so, the patient will likely tolerate pneumonectomy. Finally, nearly all patients, except those with CO₂ retention on arterial blood gas analysis, will be able to tolerate periods of single-lung ventilation and wedge resection.

Other pertinent elements of the history are current smoking status and sputum production. Current smokers have a significantly increased risk of postoperative complications. To diminish the risk significantly requires cessation of smoking at least 8 weeks preoperatively, a requirement that is often not feasible in a cancer patient. Nevertheless, efforts to abstain should be encouraged, ideally for 2 weeks before surgery. Sputum culture, antibiotic administration, and bronchodilators may be warranted preoperatively.

Pulmonary function studies are routinely performed when any resection greater than a wedge resection will be performed. The two most valuable measurements are FEV-1 and DLco. General guidelines for the use of FEV-1 in assessing the patient's ability to tolerate pulmonary resection are as follows: greater than 2.0 L can tolerate pneumonectomy, and greater than 1.2 L can tolerate lobectomy. It must be emphasized that these are guidelines only. It is also important to note that the raw value is often imprecise because normal values are reported as "percent predicted" based on corrections made for age, height, and gender. For example, a raw FEV-1 value of 1.3 L in a 62-year-old, 6-foot 3-inch male has a percent predicted value of 30 percent (because the normal expected value is 4.31 L); in a 62-year-old, 5-foot 2-inch female, the predicted value is 59 percent (normal expected value 2.21 L). The male patient is at high risk for lobectomy, although the female could potentially tolerate pneumonectomy.

The percent predicted value of both FEV-1 and DLco correlates with the risk of development of complications postoperatively, particularly pulmonary complications. Patients with predicted values of less than 50 percent show a significant increase in complication rates, with the risk of complications increasing in a stepwise fashion for each 10 percent decline.

Quantitative perfusion scanning is used in select circumstances to help estimate the functional contribution of a lobe or whole lung. Such perfusion scanning is most useful when the impact of a tumor on pulmonary physiology is difficult to discern. With complete collapse of a lobe or whole lung, the impact is apparent, and perfusion scanning is usually unnecessary. However, with centrally located tumors associated with partial obstruction of a lobar or main bronchus or of the pulmonary artery, perfusion scanning may be valuable in predicting the postoperative result of resection. Exercise testing that yields maximal oxygen consumption (VO₂max) has emerged as a valuable decision-making technique for patients with abnormal FEV-1 and DLco. In these circumstances, and in other situations in which decision making is difficult, the VO₂max should be measured. Values of less than 10 mL/kg per min generally prohibit any major pulmonary resection, although those greater than 15 mL/kg per min generally indicate the patient's potential ability to tolerate pneumonectomy.

The risk assessment of a patient is an amalgam of clinical judgment and data. Commonly, there are gray areas in which data such as that described above can provide more accurate assessment of the risk. This risk must be

integrated with the experienced clinician's sense of the patient, and with the patient's attitude toward the disease and toward life.

Lung Cancer Staging

The staging of any tumor is an attempt to measure or estimate the extent of disease present and in turn use that information to help determine the patient's prognosis. The staging of solid epithelial tumors is based on the tumor-node-metastasis (TNM) staging system. The "T" status provides information about the primary tumor itself, such as its size and relationship to surrounding structures; the "N" status provides information about regional lymph nodes; and the "M" status provides information about the presence or absence of metastatic disease. Table 18-2 lists the TNM descriptors that have been developed for use in NSCLC.

The designation of lymph nodes as N1, N2, or N3 requires familiarity with the mediastinal lymph node map, which places lymph nodes in stations defined by clearly delineated anatomic boundaries. A tumor in a given patient is typically classified into a clinical stage and a pathologic stage. The clinical stage (cTNM) is derived from an assessment of all data short of surgical resection of the primary tumor and lymph nodes. Thus clinical staging information would include the history and physical examination, radiographic test results, and diagnostic biopsy information. A therapeutic plan is then generated based on the clinical stage. After surgical resection of the tumor and lymph nodes, a postoperative pathologic stage (pTNM) is determined, providing further prognostic information.

Treatment

Early stage disease. Early stage disease is typically defined as stages I and II. In this group are T1 and T2 tumors (with or without local N1 nodal involvement), and T3 tumors (without N1 nodal involvement). This group represents a small proportion of the total number of patients diagnosed with lung cancer each year (about 15 percent of 150,000 patients).

The current standard of treatment is surgical resection, accomplished by lobectomy or pneumonectomy, depending on the tumor location. Despite the term "early stage," surgery as a single treatment modality remains disappointing. After surgical resection of postoperative pathologic stage IA disease, 5-year survival is only 67 percent as reported by Mountain in 1997. The figures decline with higher stages. The overall 5-year survival rate for stage I disease as a group is about 65 percent; for stage II disease it is about 41 percent.

Appropriate surgical procedures for patients with early stage disease include lobectomy, sleeve lobectomy, and occasionally pneumonectomy with mediastinal lymph node dissection or sampling. Sleeve resection is performed for tumors located at airway bifurcations when an acceptable length bronchial margin cannot be obtained by standard lobectomy. Pneumonectomy is rarely performed; it is indicated primarily for larger central tumors involving the distal main stem bronchus when a bronchial sleeve resection is not possible, and when resection of involved N1 lymph nodes cannot be achieved short of pneumonectomy. The latter circumstance occurs with bulky adenopathy or with extracapsular nodal spread.

Pancoast tumor (apical tumor) resection should always be preceded by mediastinoscopy. In general, the treatment of these tumors has evolved to a multimodal approach in which radiation plays a constant role. Typically, an induction radiation dose of 30–35 Gy is administered to enhance the probability of

TABLE 18-2 American Joint Committee on Cancer Staging System for Lung Cancer

		Stage	TNM
		IA	T1N0M0
		IB	T2N0M0
		IIA	T1N1M0
		IIB	T2N1M0 T3N0M0
		IIIA	T3N1M0 T1–3N2M0
		IIIB	T4 Any N M0 Any T N3 M0
		IV	Any T Any N M1
TNM Definitions			
T	TX	Positive malignant cell, but primary tumor not visualized by imaging or bronchoscopy	
	T0	No evidence of primary tumor	
	Tis	Carcinoma in situ	
	T1	Tumor \leq 3 cm, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus	
	T2	Tumor with any of the following features of size or extent: <ul style="list-style-type: none"> • > 3 cm in greatest dimension • > Involves main bronchus, \geq 2 cm distal to the carina • > Invades the visceral pleura • > Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung 	
	T3	Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus < 2 cm distal to the carina, but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung	
	T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural or pericardial effusion, or with satellite tumor nodule(s) within the ipsilateral primary-tumor lobe of the lung	
N	NX	Regional lymph nodes cannot be assessed	
	N0	No regional lymph node metastasis	
	N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and intrapulmonary nodes involved by direct extension of the primary tumor	
	N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)	
	N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)	

TABLE 18-2 (Continued)

M	MX	Presence of distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis present (including metastatic tumor nodule[s] in the ipsilateral nonprimary tumor lobe[s] of the lung)
Summary of Staging Definitions		
Occult stage		Microscopically identified cancer cells in lung secretions on multiple occasions (or multiple daily collections); no discernible primary cancer in the lung
Stage 0		Carcinoma in situ
Stage IA		Tumor surrounded by lung or visceral pleura \leq 3 cm arising more than 2 cm distal to the carina (T1 N0)
Stage IB		Tumor surrounded by lung $>$ 3 cm, or tumor of any size with visceral pleura involved arising more than 2 cm distal to the carina (T2 N0)
Stage IIA		Tumor \leq 3 cm not extended to adjacent organs, with ipsilateral peribronchial and hilar lymph node involvement (T1 N1)
Stage IIB		Tumor $>$ 3 cm not extended to adjacent organs, with ipsilateral peribronchial and hilar lymph node involvement (T2 N1) Tumor invading chest wall, pleura, or pericardium but not involving carina, nodes negative (T3 N0)
Stage IIIA		Tumor invading chest wall, pleura, or pericardium and nodes in hilum or ipsilateral mediastinum (T3, N1–2) or tumor of any size invading ipsilateral mediastinal or subcarinal nodes (T1–3, N2)
Stage IIIB		Direct extension to adjacent organs (esophagus, aorta, heart, cava, diaphragm, or spine); satellite nodule same lobe, or any tumor associated with contralateral mediastinal or supraclavicular lymph-node involvement (T4 or N3)
Stage IV		Separate nodule in different lobes or any tumor with distant metastases (M1)

complete resection, followed by surgery 4–5 weeks later. With this approach, 5-year survival rates of 35 percent have been achieved. Surgical excision usually includes a portion of the lower trunk of the brachial plexus, the stellate ganglion, and the chest wall, along with lobectomy.

With chest wall involvement, en bloc chest wall resection, along with lobectomy, is performed, with or without chest wall reconstruction. For small rib resections or those posterior to the scapula, chest wall reconstruction is usually unnecessary. Larger defects (two rib segments or more) are usually reconstructed with Gore-Tex to provide chest wall contour and stability.

If a patient is deemed medically unfit for major pulmonary resection because of inadequate pulmonary reserve or other medical conditions, then options include limited surgical resection or radiotherapy. Limited resection, defined as segmentectomy or wedge resection, can only be applied to more peripheral T1 or T2 tumors. Moreover, limited resection is associated with an increased rate of local recurrence and a decreased long-term survival rate,

probably because of incomplete resection of occult intrapulmonary lymphatic tumor spread. Alternatively, definitive radiotherapy consisting of a total dose of 60–65 Gy has resulted in a 5-year survival rate of about 30 percent for patients with stage I disease.

The role of chemotherapy in early stage NSCLC is evolving. Postoperative adjuvant chemotherapy previously was of no benefit in multiple prospective randomized trials; however, newer, more effective agents have been of benefit, although the final results of current trials are pending.

Locoregional advanced disease. Surgical resection as sole therapy has a limited role in stage III disease. T3N1 tumors can be treated with surgery alone and have a 5-year survival rate of approximately 25 percent. Patients with N2 disease are a heterogeneous group. Patients with clinically evident N2 disease (i.e., bulky adenopathy present on CT scan or mediastinoscopy, with lymph nodes often replaced by tumor) have a 5-year survival rate of 5–10 percent with surgery alone. In contrast, patients with microscopic N2 disease discovered incidentally in one lymph node station after surgical resection have a 5-year survival rate that may be as high as 30 percent. Surgery generally does not play a role in the care of patients with N3 disease (IIIB); however, it is occasionally appropriate in select patients with a T4 primary tumor (superior vena caval, carinal, or vertebral body involvement) and no N2 or N3 disease. Survival rates remain low for these patients.

Definitive radiotherapy as a single modality can cure patients with N2 or N3 disease, albeit in less than 10 percent. Recent improvement has been seen with three-dimensional conformal radiotherapy and altered fractionation. Such poor results are reflective of the facts that radiotherapy is a locoregional treatment, and that most stage III patients die of systemic disease. Therefore, definitive treatment of stage III disease (when surgery is not felt to be feasible at any time) is usually a combination of chemotherapy and radiation.

Small-cell lung carcinoma. Small-cell lung carcinoma (SCLC) accounts for about 20 percent of primary lung cancers and is not generally treated surgically. These aggressive neoplasms have early widespread metastases. Histologically, they can be difficult to distinguish from lymphoproliferative lesions and atypical carcinoid tumors. Therefore a definitive diagnosis must be established with adequate tissue samples.

Unlike NSCLC, clinical staging of SCLC is broadly defined by the presence of local or distant disease. Patients present without evidence of distant metastatic disease, but often have bulky locoregional disease, termed “limited” SCLC. Most often, the primary tumor is large and associated with bulky mediastinal adenopathy, which may lead to obstruction of the superior vena cava. The other clinical stage, disseminated, usually presents with widely disseminated metastatic disease. Patients in either stage are treated primarily with chemotherapy and radiation.

Metastatic lesions to the lung. Surgical resection of pulmonary metastases has a role in properly selected patients. General principles of selection include the following: (1) the primary tumor must already be controlled; (2) the patient must be able to tolerate general anesthesia, potential single-lung ventilation, and the planned pulmonary resection; (3) the metastases must be completely resectable according to CT imaging; (4) there must be no evidence of extrapulmonary tumor burden; and (5) alternative superior therapy must be unavailable.

The technical aim of pulmonary metastasis resections is complete resection of all macroscopic tumor. Additionally, any adjacent structure involved should be resected en bloc (i.e., chest wall, diaphragm, and pericardium). Multiple lesions and/or hilar lesions may require lobectomy. Pneumonectomy is rarely justified or employed. In general the best prognosis is seen with germ-cell tumors, osteosarcomas, a disease-free interval over 36 months, and a single metastasis.

Pulmonary Infections

Lung Abscess

A lung abscess is a localized area of pulmonary parenchymal necrosis caused by an infectious organism; tissue destruction results in a solitary or dominant cavity measuring at least 2 cm in diameter. Based on this lung abscesses are classified as primary or secondary. A primary lung abscess occurs, for example, in immunocompromised patients (as a result of malignancy, chemotherapy, or an organ transplant, etc.), in patients as a result of highly virulent organisms inciting a necrotizing pulmonary infection, or in patients who have a predisposition to aspirate oropharyngeal or gastrointestinal secretions. A secondary lung abscess occurs in patients with an underlying condition such as a partial bronchial obstruction, a lung infarct, or adjacent suppurative infections (subphrenic or hepatic abscesses).

Microbiology. In community-acquired pneumonia, the causative bacteria are predominantly gram-positive; in hospital-acquired pneumonia, 60–70 percent of the organisms are gram-negative. Gram-negative bacteria associated with nosocomial pneumonia include *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Proteus* species, *Pseudomonas aeruginosa*, *Escherichia coli*, *Enterobacter cloacae*, and *Eikenella corrodens*. Normal oropharyngeal secretions contain many more *Streptococcus* species and more anaerobes (about 108 organisms/mL) than aerobes (about 107 organisms/mL). Overall, at least 50 percent of these infections are caused by purely anaerobic bacteria, 25 percent are caused by mixed aerobes and anaerobes, and 25 percent or fewer are caused by aerobes only.

Clinical features and diagnosis. Typical symptoms include productive cough, fever, chills, leukocytosis ($> 15,000$ cells/mm³), weight loss, fatigue, malaise, pleuritic chest pain, and dyspnea. Lung abscesses may also present in a more indolent fashion, with weeks to months of cough, malaise, weight loss, low-grade fever, night sweats, leukocytosis, and anemia. After aspiration pneumonia, 1–2 weeks typically elapse before cavitation occurs; 40–75 percent of such patients produce a putrid, foul-smelling sputum. Severe complications such as massive hemoptysis, endobronchial spread to other portions of the lungs, rupture into the pleural space and development of pyopneumothorax, or septic shock and respiratory failure are rare in the modern antibiotic era. The mortality rate is about 5–10 percent, except in the presence of immunosuppression, in which rates range from 9–28 percent.

Chest radiograph shows a density or mass with a relatively thin-walled cavity and air-fluid level, indicating a communication with the tracheobronchial tree. CT scan is useful to clarify the diagnosis when the radiograph is equivocal, to help rule out endobronchial obstruction, and to look for an associated mass or other pathologic anomalies. A cavitating lung carcinoma is frequently mistaken for a lung abscess.

Bronchoscopy is essential to rule out endobronchial obstruction, which is usually because of tumor or foreign body, and to obtain uncontaminated cultures by bronchoalveolar lavage. Cultures can also be obtained by percutaneous, transthoracic FNA under ultrasound or CT guidance.

Management. Systemic antibiotics are the mainstay of therapy. For community-acquired infections secondary to aspiration, likely pathogens are oropharyngeal streptococci and anaerobes. Penicillin G, ampicillin, or amoxicillin are the main therapeutic agents, but a β -lactamase inhibitor or metronidazole should be added to cover the increasing prevalence of gram-negative anaerobes that produce β -lactamase. Clindamycin is also a primary therapeutic agent. For hospital-acquired infections, *Staphylococcus aureus* and aerobic gram-negative bacilli are common organisms of the oropharyngeal flora. Piperacillin or ticarcillin with a β -lactamase inhibitor (or equivalent alternatives) provide better coverage of likely pathogens. The duration of antimicrobial therapy is variable: 1–2 weeks for simple aspiration pneumonia and 3–12 weeks for necrotizing pneumonia and lung abscess.

Surgical drainage of lung abscesses is uncommon because drainage usually occurs spontaneously via the tracheobronchial tree. Indications for intervention include failure of medical therapy; an abscess under tension; an abscess increasing in size during appropriate treatment; contralateral lung contamination; an abscess larger than 4–6 cm in diameter; necrotizing infection with multiple abscesses, hemoptysis, abscess rupture, or pyopneumothorax; and inability to exclude a cavitating carcinoma. External drainage may be accomplished with tube thoracostomy, percutaneous drainage, or surgical cavernostomy. Surgical resection is required in fewer than 10 percent of lung abscess patients.

Mycobacterial Infections

Microbiology. *Mycobacterium tuberculosis* is the highly virulent bacillus of this species that produces invasive infection among humans, principally pulmonary tuberculosis. Because of improper application of antimycobacterial drugs and multifactorial interactions, MDRTB organisms have emerged that are defined by their resistance to two or more first-line antimycobacterial drugs. Approximately 10 percent of new tuberculosis cases, and as many as 40 percent of recurrent cases, are attributed to MDRTB organisms. The more important NTM organisms include *M. kansasii*, *M. avium*, and *M. intracellulare* complex (MAC), and *M. fortuitum*. The highest incidence of *M. kansasii* infection is in midwestern U.S. cities among middle-aged males from good socioeconomic surroundings. MAC organisms are important infections in older adult and immunocompromised patient groups. *M. fortuitum* infections are common complications of underlying severe debilitating disease. None of these organisms are as contagious as *M. tuberculosis*.

Pathogenesis and pathology. The main route of transmission is via airborne inhalation of viable mycobacteria. Three stages of primary infection have been described. In the first stage, alveolar macrophages ingest the bacilli. In the second stage, from days –21, the bacteria continue to multiply in macrophages. The patient is often asymptomatic. The third stage is characterized by the onset of cell-mediated immunity (CD4 + helper T cells) and delayed-type hypersensitivity. Activated macrophages acquire an increased capacity for bacterial killing. Macrophage death increases, resulting in the formation of a granuloma, the characteristic lesion found on pathologic examination.

Clinical presentation and diagnosis. About 80–90 percent of tuberculosis patients present with clinical disease in the lungs. In 85–90 percent of these patients, involution and healing occur, leading to a dormant phase that may last a lifetime. The only evidence of tuberculosis infection may be a positive skin reaction to tuberculin challenge or a Ghon complex observed on chest radiograph. Within the first 2 years of primary infection, reactivation may occur in up to 10–15 percent of infected patients. In 80 percent, reactivation occurs in the lungs; other reactivation sites include the lymph nodes, pleura, and the musculoskeletal system.

After primary infection, pulmonary tuberculosis is frequently asymptomatic. Systemic symptoms of low-grade fever, malaise, and weight loss are subtle and may go unnoticed. A productive cough may develop, usually after tubercle cavitation. Hemoptysis often develops from complications of disease such as bronchiectasis or erosion into vascular malformations associated with cavitation. Extrapulmonary involvement is because of hematogenous or lymphatic spread from pulmonary lesions. Virtually any organ can become infected, giving rise to the protean manifestations of tuberculosis. Of note to the thoracic surgeon, the pleura, chest wall, and mediastinal organs may all be involved. More than one third of immunocompromised patients have disseminated disease, with hepatomegaly, diarrhea, splenomegaly, and abdominal pain.

The definitive diagnosis of tuberculosis requires identification of the mycobacterium in a patient's bodily fluids or involved tissues. Skin testing using purified protein derivative is important for epidemiologic purposes, and can help exclude infection in uncomplicated cases. For pulmonary tuberculosis, sputum examination is inexpensive and has a high diagnostic yield. Bronchoscopy with alveolar lavage has high diagnostic accuracy. Chest CT scan can delineate the extent of parenchymal disease.

Management. Medical therapy is the primary treatment of pulmonary tuberculosis and is often initiated before a mycobacterial pathogen is definitively identified. Combinations of two or more drugs are routinely used to minimize resistance, which inevitably develops with only single-agent therapy. First-line drugs include isonicotinic acid hydrazine (isoniazid; INH), ethambutol, rifampin, and pyrazinamide. Second-line drugs include cycloserine, ethionamide, kanamycin, ciprofloxacin, and amikacin, among others.

The initial therapy for patients with active pulmonary tuberculosis consists of various drug regimens lasting from 6–9 months. Bacterial sensitivity profiles help to tailor drug therapy. In the case of MDRTB organisms, four or more antimycobacterial drugs are often used, generally for 18–24 months. Rifampin and INH augmented with one or more second-line drugs are most commonly used to treat NTM infections. Generally, therapy lasts about 18 months. The overall response rate is unsatisfactory in 20–30 percent of patients with *M. kansasii* infection, although most such patients do not require surgical intervention. In contrast, pulmonary MAC infections respond poorly, even to combinations of four or more drugs, thus most such patients become surgical candidates. Overall, sputum conversion is achieved in only 50–80 percent of NTM infections, and relapses occur in up to 20 percent of patients.

In the United States, surgical intervention for MDRTB is necessary when lung tissue has been destroyed and with persistent thick-walled cavitation. Indications for surgery are: (1) complications of previous surgery for tuberculosis; (2) failure of optimum medical therapy (e.g., progressive disease, lung gangrene, intracavitary aspergillosis superinfection); (3) biopsy for definitive

diagnosis; (4) complications of pulmonary scarring (e.g., massive hemoptysis, cavernomas, bronchiectasis, or bronchostenosis); (5) extrapulmonary thoracic involvement; (6) pleural tuberculosis; and (7) NTM infections. The goal of surgery generally is removal of all gross disease with preservation of uninvolved lung tissue. Scattered nodular disease may be left, given its low mycobacterial burden. Antimycobacterial medications are given preoperatively (for about 3 months) and postoperatively for 12–24 months. Overall, 90 percent of patients are cured with appropriate medical and surgical therapy.

Pulmonary Mycoses

Mycotic lung infections can often mimic bronchial carcinoma or tuberculosis. Most fungal infections occur as opportunistic. Examples include *Aspergillus*, *Cryptococcus*, *Candida*, and *Mucor*. However, some fungi are primary or true pathogens including *Histoplasma*, *Coccidioides*, and *Blastomyces*.

Fungal infections are definitively diagnosed by directly identifying the organism in body exudates or tissues, preferably grown in culture. Serologic testing to identify mycotic-specific antibodies may be useful.

Aspergillosis. Three species of *Aspergillus* most commonly cause clinical disease: *A. fumigatus*, *A. flavus*, and *A. niger*. *Aspergillus* is a saprophytic, filamentous fungus with septate hyphae. Spores (2.5–3 μm in diameter) are inhaled and then reach the distal bronchi and alveoli. Three syndromes may occur: *Aspergillus* hypersensitivity lung disease, aspergilloma, or invasive pulmonary aspergillosis. Overlap occurs between these syndromes, depending on the patient's immune status. Hypersensitivity leads to cough, fever, infiltrates, eosinophilia, and elevation of immunoglobulin (Ig)E antibodies to *Aspergillus*.

Aspergilloma (fungal ball) results from colonization of preexisting cavities. Fungal balls are the most common presentation of (noninvasive) pulmonary aspergillosis. Clinical features vary from asymptomatic, to hemoptysis (sometimes life threatening), to a chronic process of productive cough, clubbing, malaise, and weight loss. Chest radiograph can show a crescentic radiolucency above a rounded radiopaque lesion (Monod sign). Asymptomatic aspergilloma do not require treatment. For mild, non-life-threatening hemoptysis, initial treatment is medical management with Amphotericin B. Indications for surgery include recurrent or massive hemoptysis, chronic cough with systemic symptoms, progressive infiltrate around the mycetoma, and a pulmonary mass of unknown cause. The postresectional residual space in the thorax should be obliterated. Techniques to do so include pleural tent, pneumoperitoneum, decortication, muscle flap, omental transposition, and thoracoplasty.

Invasive pulmonary aspergillosis usually affects immunocompromised patients and is an invasive and often necrotizing bronchopneumonia. Presentation is fever unresponsive to antibiotic therapy in the setting of neutropenia. A chest CT scan shows infiltrate and consolidation and occasional characteristic signs (e.g., halo sign and cavitary lesions). Empiric antifungal therapy (using amphotericin B) should be started in these high-risk patients. The mortality rate is high, from 90 percent in bone marrow transplantation and up to 40 percent in kidney transplantation. Surgical removal of the infectious nidus is advocated by some groups because medical treatment has such poor outcomes.

Cryptococcosis. *Cryptococcus* are present in soil and dust contaminated by pigeon droppings. When inhaled, a nonfatal pulmonary and central nervous system infection may occur. *Cryptococcosis* is the fourth most common

opportunistic infection in patients with HIV infection, affecting 6–10 percent of that population. Four pathologic patterns are seen: granulomas; granulomatous pneumonia; diffuse alveolar or interstitial involvement; and proliferation of fungi in alveoli and lung vasculature. Symptoms and radiographic findings are nonspecific. *Cryptococcus* may be isolated from sputum, bronchial washings, percutaneous needle aspiration of the lung, or cerebrospinal fluid. Multiple antifungal agents are effective against *C. neoformans*, including amphotericin B and the azoles.

Candidiasis. *Candida* organisms are oval, budding cells (with or without mycelial elements) that colonize the oropharynx of many healthy individuals and are common hospital and laboratory contaminants. Usually, *Candida albicans* causes disease in the oral or bronchial mucosa, among other anatomic sites. Other potentially pathogenic *Candida* species include *C. tropicalis*, *C. glabrata*, and *C. krusei*.

Candida infections are no longer confined to immunocompromised patients, but now affect those who are critically ill, are taking multiple antibiotics long-term, have indwelling vascular catheters (or urinary catheters), sustain recurrent gastrointestinal perforations, or have burn wounds. With respect to the thorax, such patients commonly have candidal pneumonia, pulmonary abscess, esophagitis, and mediastinitis. Amphotericin B, often in combination with 5-fluorocytosine, is a proven therapeutic treatment for *Candida* tissue infections.

Primary fungal pathogens. Histoplasmosis primarily affects the respiratory system after spore inhalation. It is the most common of all fungal pulmonary infections. In the United States this disease is endemic in the Midwest and Mississippi River Valley, where about 500,000 new cases arise each year. Active, symptomatic disease is uncommon. Acute forms present as primary or disseminated pulmonary histoplasmosis; chronic forms present as pulmonary granulomas (histoplasmoses), chronic cavitary histoplasmosis, mediastinal granulomas, fibrosing mediastinitis, or broncholithiasis. In immunocompromised patients, the infection may become systemic and more virulent. Diagnosis is by fungal smear, culture, direct biopsy of infected tissues, or serologic testing.

Acute pulmonary histoplasmosis commonly presents with fever, chills, headache, chest pain, and nonproductive cough. Chest radiographs may be normal or may show mediastinal lymphadenopathy and patchy parenchymal infiltrates. Most patients improve in a few weeks and do not require antifungal therapy. Amphotericin B is the treatment of choice if moderate symptoms persist for 2–4 weeks; if the illness is extensive, including dyspnea and hypoxia; and if patients are immunosuppressed.

With healing the infiltrate will consolidate into a solitary nodule (histoplasmosis). This condition is asymptomatic and usually is seen incidentally on radiographs as a coin-shaped lesion with central calcification.

When lymph nodes and pulmonary granulomas calcify over time, pressure atrophy on the bronchial wall may result in erosion and migration of the granulomatous mass into the bronchus, causing broncholithiasis. Typical symptoms include cough, hemoptysis, and dyspnea. Life-threatening complications include massive hemoptysis or bronchoesophageal fistula. Treatment is surgical removal of the bronchial mass repair of associated complications.

Coccidioides immitis is an endemic fungus found in soil and dust of the southwestern United States. Acute pulmonary coccidioidomycosis occurs in

about 40 percent of people who inhale spores. Symptoms consist of fever, sweating, anorexia, weakness, arthralgia, cough, sputum, and chest pain. When symptoms and radiographic findings persist for more than 6–8 weeks, the disease is considered to be persistent coccidioidal pneumonia. Immunocompromised patients are susceptible to disseminated coccidioidomycosis, which carries a mortality rate over 40 percent. Treatment is with itraconazole and fluconazole for mild to moderate disease and amphotericin B for disseminated disease and immunocompromised patients. Surgical resection is considered if cavities persist for more than 2 years; are larger than 2 cm in diameter; rapidly enlarge, rupture, are thick-walled; or are associated with severe or recurrent hemoptysis.

Blastomyces dermatitidis is a round, single-budding yeast with a characteristic thick, refractile cell wall. It primarily infects the lungs of people who inhale contaminated soil that has been disturbed. *B. dermatitidis* has a worldwide distribution; in the United States it is endemic in the central states. Symptoms include cough, sputum production, fever, weight loss, and hemoptysis. In acute disease, consolidation is seen on radiographs; in chronic disease, fibronodular lesions (with or without cavitation) similar to tuberculosis are noted. Oral itraconazole for 6 months is the treatment of choice. Amphotericin B is warranted for patients with cavitory blastomycosis, disseminated disease, or extensive lung involvement and immunocompromised patients. After adequate drug therapy, surgical resection of cavitory lesions is considered because viable organisms can persist.

Antifungals. Amphotericin B has been the mainstay for systemic fungal infections. A lipophilic organic compound leads to binding ergosterol in the fungal cell membrane with disruption and ion leakage. Nephrotoxicity limits its applicability. Three lipid-based formulations of amphotericin B have shown decreased nephrotoxicity and higher drug-dose delivery but higher costs and limited data concerning better efficacy have tempered widespread adoption. The azoles include miconazole, ketoconazole, fluconazole, and itraconazole. This drug class inhibits cytochrome P450, interfering with fungal cell membrane synthesis.

Massive Hemoptysis

Massive hemoptysis is generally defined as expectoration of over 600 mL of blood within a 24-hour period. It is a medical emergency associated with a mortality rate of 30–50 percent. One should be aware, however, that the volume of hemoptysis that is life-threatening is highly dependent on the individual's respiratory status.

Anatomy

Most cases of massive hemoptysis involve bleeding from the bronchial artery circulation or from the pulmonary circulation pathologically exposed to the high pressures of the bronchial circulation. In many cases of hemoptysis, particularly those because of inflammatory disorders, the bronchial arterial tree becomes hyperplastic and tortuous. The systemic pressures within these arteries, combined with a disease process within the airway and erosion, lead to bleeding.

Causes

Most common causes of massive hemoptysis are secondary to inflammation. Chronic inflammatory disorders (i.e., bronchiectasis, cystic fibrosis, tuberculosis) lead to localized bronchial arterial proliferation, and with erosion, bleeding of these hypervascular areas occurs.

Tuberculosis can cause hemoptysis by erosion of a broncholith (a calcified tuberculous lymph node) into a vessel, or when a tuberculous cavity is present, by erosion of a blood vessel within the cavity. Within such cavities, aneurysms of the pulmonary artery (referred to as Rasmussen aneurysm) can erode with subsequent massive bleeding.

Hemoptysis because of lung cancer usually is mild, resulting in blood-streaked sputum. When massive, bleeding hemoptysis usually is because of malignant invasion of pulmonary artery vessels by large central tumors and is often a terminal event.

Management

Treatment involves a multidisciplinary team of intensive care physicians, interventional radiologists, and thoracic surgeons. Treatment priorities are: (1) respiratory stabilization and prevention of asphyxiation, (2) localize the bleeding site, (3) stop the hemorrhage, (4) determine the cause, and (5) definitively prevent recurrence. The clinically pragmatic definition of massive hemoptysis is a degree of bleeding that threatens respiratory stability. Therefore clinical judgment of the risk of respiratory compromise is the first step in evaluating a patient. Two scenarios are possible: (1) bleeding is significant and persistent, but its rate allows a rapid but sequential diagnostic and therapeutic approach, and (2) bleeding is so rapid that emergency airway control and therapy are necessary.

Scenario 1: significant, persistent, but nonmassive bleeding. Although bleeding is brisk in scenario 1, the patient may be able to maintain clearance of the blood and secretions with his or her own respiratory reflexes. Immediate measures are admission to an intensive care unit, strict bedrest, Trendelenburg positioning with the affected side down (if known), administration of humidified oxygen, monitoring of oxygen saturation and arterial blood gases, and insertion of large-bore intravenous catheters. Strict bedrest with sedation may lead to slowing or cessation of bleeding, and the judicious use of intravenous narcotics or other relaxants to mildly sedate the patient and diminish some of the reflexive airway activity often is necessary. Also recommended are administration of aerosolized adrenaline, intravenous antibiotic therapy if needed, and correction of abnormal blood coagulation study results. Finally, unless contraindicated, intravenous vasopressin (20 U over 15 min, followed by an infusion of 0.2 U/min) can be given.

A chest radiograph may reveal a localized lesion but the effects of blood soiling of other areas of the lungs may predominate, obscuring the area of pathology. Chest CT scan provides more detail and is nearly always performed if the patient is stable.

Some clinicians argue that rigid bronchoscopy should always be performed. However, if clinically stable and the ongoing bleeding is not imminently threatening, flexible bronchoscopy is appropriate. It allows diagnosis of airway abnormalities and will usually permit localization of the bleeding site to either a lobe or even a segment.

Because most cases of massive hemoptysis arise from the bronchial arterial tree selective bronchial arteriography and embolization is next. Prearteriogram bronchoscopy is extremely useful to direct the angiographer. However, if bronchoscopy fails to localize the bleeding site, then bilateral bronchial arteriograms can be performed. Typically, the abnormal vascularity is visualized, rather than extravasation of the contrast dye.

Embolization will acutely arrest the bleeding in 80–90 percent of patients. However, 30–60 percent of patients will have recurrences. Therefore, embolization should be viewed as an immediate but likely temporizing measure to acutely control bleeding. Subsequently, definitive treatment of the underlying pathologic process is appropriate. If bleeding persists after embolization, a pulmonary artery source should be suspected and a pulmonary angiogram performed.

If respiratory compromise is impending, orotracheal intubation should be performed. After intubation, flexible bronchoscopy should be performed to clear blood and secretions and to attempt localization of the bleeding site. Depending on the possible causes of the bleeding, bronchial artery embolization or (if appropriate) surgery can be considered.

Scenario 2: significant, persistent, and massive bleeding. Life-threatening bleeding requires emergency airway control and preparation for potential surgery. Such patients are best cared for in an operating room equipped with rigid bronchoscopy. Immediate orotracheal intubation may be necessary to gain control of ventilation and suctioning. However, rapid transport to the operating room with rigid bronchoscopy should be facilitated. Rigid bronchoscopy allows adequate suctioning of bleeding with visualization of the bleeding site; the nonbleeding side can be cannulated with the rigid scope and the patient ventilated. After stabilization, ice-saline lavage of the bleeding site can then be performed (up to 1 L in 50-mL aliquots); bleeding stops in up to 90 percent of patients.

Alternatively, blockade of the main stem bronchus of the affected side can be accomplished with a double-lumen endotracheal tube, with a bronchial blocker, or by intubation of the nonaffected side by an uncut standard endotracheal tube. Placement of a double-lumen endotracheal tube is challenging in these circumstances, given the bleeding and secretions. Proper placement and suctioning may be difficult, and attempts could compromise the patient's ventilation. The best option is to place a bronchial blocker in the affected bronchus with inflation. The blocker is left in place for 24 h and the area is reexamined bronchoscopically. After this 24-h period, bronchial artery embolization can be performed.

Surgical intervention. In most patients, bleeding can be stopped, recovery can occur, and plans to definitively treat the underlying cause can be made. In scenario 1 (significant, persistent, but nonmassive bleeding), the patient may undergo further evaluation as an inpatient or outpatient. A chest CT scan and pulmonary function studies should be obtained preoperatively. In scenario 2 (patients with significant, persistent, and massive bleeding), surgery, if appropriate, usually will be performed during the same hospitalization as the rigid bronchoscopy or main stem bronchus blockade. In less than 10 percent of patients, emergency surgery will be necessary, delayed only by efforts to localize the bleeding site by rigid bronchoscopy.

Surgical treatment is individualized according to the source of bleeding and the patient's medical condition, prognosis, and pulmonary reserve. General

indications for urgent surgery include (1) presence of a fungus ball, (2) a lung abscess, (3) significant cavitary disease, or (4) failure to control the bleeding.

Spontaneous Pneumothorax

Spontaneous pneumothorax is most commonly because of rupture of an apical subpleural bleb which occurs most frequently in young postadolescent males with a tall thin body habitus. Treatment is generally chest tube insertion with water seal. If a leak is present and it persists for greater than 3 days, thoracoscopic management (i.e., bleb resection with pleurodesis by talc or pleural abrasion) is performed. Recurrences or complete lung collapse with the first episode are generally indications for thoracoscopic intervention.

Other causes of spontaneous pneumothorax are emphysema (rupture of a bleb or bulla), cystic fibrosis, acquired immune deficiency syndrome [AIDS], metastatic cancer (especially sarcoma), asthma, lung abscess, and occasionally lung cancer. Management of pneumothorax in these circumstances is often tied to therapy of the specific disease process and may involve tumor resection, thoracoscopic pleurectomy, or talc pleurodesis.

CHEST WALL

Chest Wall Mass

Clinical Approach

All chest wall tumors should be considered malignant until proven otherwise. Patients with either a benign or malignant chest wall tumor typically present with a slowly enlarging palpable mass (50–70 percent), chest wall pain (25–50 percent), or both.

Pain is typically localized to the area of the tumor, and although more often present (and more intense) with malignant tumors, it also can be present in one-third of benign tumors. With Ewing sarcoma, fever and malaise may also be present. Age can provide guidance regarding the possibility of malignancy. Patients with benign chest wall tumors are on average 26 years old; the average age for patients with malignant tumors is 40 years old. Overall, the probability of a chest wall tumor being malignant is 50–80 percent.

Evaluation and Management

Radiography. Chest radiograph may reveal evidence of rib destruction and calcification within the lesion. CT scan is routinely performed done to evaluate the primary lesion and to determine its relationship to contiguous structures and to search for pulmonary metastases. Contiguous involvement of underlying lung or other soft tissues or the presence of pulmonary metastases does not preclude successful surgery.

MRI is valuable for evaluating tumors contiguous to or near neurovascular structures or spine and can potentially enhance the ability to distinguish benign from malignant sarcomas.

Biopsy. Inappropriate or misguided attempts at tissue diagnosis through casual open biopsy techniques have the potential (if the lesion is a sarcoma) to seed surrounding tissues and contiguous body cavities (e.g., the pleural space) with tumor cells, potentially compromising local tumor control and patient survival. Accurately typing chest wall sarcomas has a profound impact on their management.

Tissue diagnosis can be made by one of three methods: a needle biopsy (typically CT-guided, FNA or a core biopsy), incisional biopsy, or excisional biopsy.

An excisional biopsy should be done when the initial radiographic diagnosis indicates that it is a benign lesion, or when the lesion has the classic appearance of a chondrosarcoma (in which case definitive surgical resection can be undertaken). Any lesion less than 2.0 cm can be excised as long as the resulting wound is small enough to close primarily. When the diagnosis cannot be made by radiographic evaluation, a needle biopsy (FNA or core) should be done. Needle biopsy has the advantage of avoiding wound and body cavity contamination (a potential complication with an incisional biopsy).

If a needle biopsy is nondiagnostic, an incisional biopsy may be performed, with caveats. When performing an incisional biopsy, the skin incision must be placed directly over the mass and oriented to allow subsequent excision of the scar. Development of skin flaps must be avoided, and in general no drains are used. A drain may be placed if a hematoma is likely to develop, as this can potentially limit soft tissue contamination by tumor cells. Subsequently, if definitive surgical resection is undertaken, the entire area of the biopsy (including skin) must be excised en bloc with the tumor.

CHEST WALL NEOPLASMS

Benign

Chondroma. Chondromas are one of the more common benign tumors of the chest wall. They are primarily seen in children and young adults and occur at the costochondral junction anteriorly. Clinically, a painless mass is present. Chondromas may grow to huge sizes if left untreated. Treatment is surgical resection with a 2-cm margin. One must be certain, however, that the lesion is not a well-differentiated chondrosarcoma. In this case, a wider 4-cm margin is required to prevent local recurrence. Therefore, large chondromas should be treated surgically as low-grade chondrosarcomas.

Osteochondroma. Osteochondromas are the most common benign bone tumor and are often detected as incidental radiographic findings. Most are solitary; however, patients with multiple osteochondromas have a higher incidence of malignancy.

Osteochondromas occur in the first two decades of life and they arise at or near the growth plate of bones. The lesions are benign during youth or adolescence. Osteochondromas that enlarge after completion of skeletal growth have the potential to develop into chondrosarcomas.

Desmoid tumors. Desmoid tumors are unusual soft tissue neoplasms that arise from fascial or musculoaponeurotic structures. Some authorities consider desmoid tumors to be a form of fibrosarcoma. Clinically, patients are usually in the third to fourth decade, and have pain, a fixed chest wall mass, or both. No radiographic findings are typical. Histologic diagnosis may not be possible by a needle biopsy because of low cellularity. An open incisional biopsy for lesions over 3–4 cm often is necessary, following the caveats listed above.

Desmoid tumors do not metastasize, but they have a significant propensity to recur locally, with local recurrence rates as high as 5–50 percent, sometimes despite complete initial resection with histologically negative margins. Such

locally aggressive behavior is secondary to microscopic tumor infiltration of muscle and surrounding soft tissues.

Surgery consists of wide local excision with a margin of 2–4 cm, and with intraoperative assessment of resection margins by frozen section. Survival after wide local excision with negative margins is 90 percent at 10 years.

Primary Malignant Chest Wall Tumors

Sarcomas can be divided into two broad groups by potential chemotherapeutic responsiveness. Preoperative (neoadjuvant) chemotherapy offers the ability to (1) assess tumor chemosensitivity by the degree of tumor size reduction and microscopic necrosis, (2) determine which chemotherapeutic agents the tumor is sensitive to, and (3) lessen the extent of surgical resection by reducing tumor size. Patients whose tumors are responsive to preoperative chemotherapy (as judged by the reduction in the size of the primary tumor and/or by the degree of necrosis seen histologically following resection) have a much better prognosis than those with a poor response.

Given the tumor's potential response to chemotherapy or the presence of metastatic disease, the initial treatment is either (1) preoperative chemotherapy (for patients with osteosarcoma, rhabdomyosarcoma, primitive neuroectodermal tumor [PNET], or Ewingsarcoma) followed by surgery and postoperative chemotherapy, (2) primary surgical resection and reconstruction (for patients with nonmetastatic malignant fibrous histiocytoma, fibrosarcoma, liposarcoma, or synovial sarcoma), or (3) neoadjuvant chemotherapy followed by surgical resection if indicated in patients presenting with metastatic soft tissue sarcomas.

Malignant Chest Wall Bone Tumors

Chondrosarcoma. Chondrosarcomas are the most common primary chest wall malignancy. As with chondromas, they usually arise anteriorly from the costochondral arches. These slowly enlarging, often painful masses of the anterior chest wall can reach massive proportions. CT scan shows a radiolucent lesion often with stippled calcifications pathognomonic for chondrosarcomas.

Most chondrosarcomas are slow growing, low-grade tumors. For this reason, any lesion in the anterior chest wall likely to be a chondroma or a low-grade chondrosarcoma should be treated with wide (4-cm) resection. Chondrosarcomas are not sensitive to chemotherapy or radiation therapy. Prognosis is determined by tumor grade and extent of resection.

Osteosarcoma. Osteosarcomas are the most common bone malignancy, but they are an uncommon malignancy of the chest wall, representing only 10 percent of all malignant chest wall tumors. They present as rapidly enlarging, painful masses. Although they primarily occur in young adults, osteosarcomas can occur in patients older than the age of 40 years, sometimes in association with previous radiation, Paget disease, or chemotherapy.

As with chondrosarcomas, careful CT assessment of the pulmonary parenchyma for metastasis is necessary. Osteosarcomas have a propensity to spread to the lungs and up to one third of patients present with metastatic disease.

Osteosarcomas are potentially sensitive to chemotherapy. Currently, preoperative chemotherapy before surgical resection is common. After chemotherapy, complete resection is performed with wide (4-cm) margins, followed by

reconstruction. In patients presenting with lung metastases that are potentially amenable to surgical resection, induction chemotherapy may be given, followed by surgical resection of the primary tumor and of the pulmonary metastases. Following surgical treatment of known disease, additional maintenance chemotherapy is usually recommended.

Other Tumors

Ewing's Sarcoma

Ewing sarcomas occur in adolescents and young adults who present with progressive chest wall pain, but without the presence of a mass. Systemic symptoms of malaise and fever often are present with elevation of the erythrocyte sedimentation rate and white blood cell count.

Radiographically, the characteristic onion peel appearance is produced by multiple layers of periosteum in the bone formation. The diagnosis can be made by a percutaneous needle biopsy or an incisional biopsy.

These tumors have a strong propensity to spread to the lungs and skeleton. Their aggressive behavior produces patient survival rates of only 50 percent or less at 3 years. Increasing tumor size is associated with decreasing survival. Treatment has improved significantly, now consisting of multiagent chemotherapy, radiation therapy, and surgery.

Malignant Chest Soft Tissue Sarcomas

Soft tissue sarcomas of the chest wall are uncommon and include fibrosarcomas, liposarcomas, malignant fibrous histiocytomas (MFHs), rhabdomyosarcomas, angiosarcomas, and other extremely rare lesions. With the exception of rhabdomyosarcomas, the primary treatment of these lesions is wide surgical resection with 4-cm margins and reconstruction. Rhabdomyosarcomas are sensitive to chemotherapy and are often treated with preoperative chemotherapy. As with all sarcomas, soft tissue sarcomas of the chest wall have a propensity to spread to the lungs. The prognosis of such tumors heavily depends on their grade and stage.

Chest Wall Reconstruction

The principles of surgery for any malignant chest wall tumor are to strategically plan the anatomy of resection and to carefully assess what structures will need to be sacrificed to obtain a 4-cm margin. Prosthetic reconstruction is usually with 2-mm Gore-Tex, and with appropriate soft-tissue coverage to obtain good coverage of a potentially large defect and to achieve an acceptable cosmetic result.

The extent of resection depends on the tumor's location and on any involvement of contiguous structures. Laterally based lesions often require simple wide excision, with resection of any contiguously involved lung, pleura, muscle, or skin. Anteriorly based lesions contiguous with the sternum require partial sternectomy. Primary malignant tumors of the sternum may require complete sternectomy. Posterior lesions involving the rib heads over their articulations with the vertebral bodies may, depending on the extent of rib involvement, require partial en bloc vertebrectomy.

Reconstruction of the chest wall can always be accomplished with the use of 2-mm Gore-Tex, attached to the surrounding bony structures with stout sutures

of Gore-Tex or polypropylene. Gore-Tex is impervious to fluid, thus preventing pleural fluid from entering the chest wall; it is firm and provides excellent rigidity and stability when secured taut to the surrounding bony structures; and it provides a good platform for myocutaneous flap reconstruction.

Tissue coverage, except for smaller lesions, invariably involves the use of myocutaneous flaps using the latissimus dorsi, serratus anterior, rectus abdominis, or pectoralis major muscles.

MEDIASTINUM

General Concepts

Anatomy and Pathologic Entities

The mediastinum, the central part of the thoracic cavity, can be divided into three compartments for classification of anatomic components and disease processes: the anterior, middle, and posterior mediastinum. The anterior mediastinum lies between the sternum and the anterior surface of the heart and great vessels. The middle mediastinum is located between the great vessels and the trachea. Posterior to this is the posterior mediastinum.

The anterior compartment includes the thymus gland or its remnant, the internal mammary artery and vein, lymph nodes, and fat. The middle mediastinum contains the pericardium and its contents, the ascending and transverse aorta, the superior and inferior venae cavae, the brachiocephalic artery and vein, the phrenic nerves, the upper vagus nerve trunks, the trachea, the main bronchi and their associated lymph nodes, and the central portions of the pulmonary arteries and veins. The posterior mediastinum contains the descending aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and lymph nodes.

History and Physical Examination

The type of mediastinal pathology encountered varies significantly by age of the patient. In adults, the most common tumors include neurogenic tumors of the posterior compartment, benign cysts occurring in any compartment, and thymomas of the anterior mediastinum. In children, neurogenic tumors of the posterior mediastinum are also common; lymphoma is the second most common mediastinal tumor, usually located in the anterior or middle mediastinum; and thymoma is rare. In both age groups, about 25 percent of mediastinal tumors are malignant.

Up to two thirds of mediastinal tumors in adults are incidental findings radiologic studies ordered for other problems. Benign masses are even more likely to be asymptomatic. Local symptoms usually arise from larger, bulky tumors, expanding cysts, and teratomas which can cause compression of mediastinal structures, in particular the trachea, leading to cough, dyspnea on exertion, or stridor. Chest pain or dyspnea may be reported secondary to associated pleural effusions, cardiac tamponade, or phrenic nerve involvement.

The history and physical examination in conjunction with the imaging findings may suggest a specific diagnosis. The association of a mediastinal mass, enlarged lymph nodes, and a constitutional symptom such as night sweats or weight loss suggests a lymphoma. An anterior mediastinal mass in the setting of a history of fluctuating weakness and early fatigue or ptosis suggests a thymoma and myasthenia gravis.

Diagnostic Evaluation

Imaging and Serum Markers

Discovery of a mediastinal mass on chest radiograph is followed by contrast-enhanced CT scan. MRI often is performed for posterior mediastinal masses to delineate the relationship of the mass to the spinal column and to assess the possibility of neural foraminal invasion.

The use of serum markers to evaluate a mediastinal mass is important in the diagnosis and therapeutic monitoring of patients with mediastinal germ cell tumors. For example, seminomatous and nonseminomatous germ cell tumors can frequently be diagnosed and often distinguished from one another by the levels of alpha-fetoprotein (AFP) and human chorionic gonadotropin (hCG). In over 90 percent of nonseminomatous germ cell tumors, either the AFP or the hCG level will be elevated. Results are close to 100 percent specific if the level of either AFP or hCG is greater than 500 ng/mL. Some centers institute chemotherapy based on this result alone, without a biopsy. In contrast, the AFP level is always normal in patients with mediastinal seminomas; only 10 percent will have an elevated hCG, which is usually less than 100 ng/mL.

Diagnostic Nonsurgical Biopsies of the Mediastinum

The indications and decision-making steps for performing a diagnostic biopsy of a mediastinal mass remain somewhat controversial. In some patients, given noninvasive imaging results and the history, surgical removal may be the obvious choice; preoperative biopsy may be unnecessary and even hazardous. In other patients whose primary treatment is likely to be nonsurgical, a biopsy is essential.

Percutaneous biopsy may be technically difficult because of the overlying bony thoracic cavity and the proximity to lung tissue, the heart, and great vessels. FNA biopsy minimizes some of these potential hazards and may be effective in diagnosing mediastinal thyroid tissue, cancers, carcinomas, seminomas, inflammatory processes, and cysts. Other noncarcinomatous malignancies such as lymphoproliferative disorders, thymomas, and benign tumors may require larger pieces of tissue. Such biopsies may be obtained by a core-needle technique or by surgically performed open biopsy. In general, if the clinical and radiographic features suggest a lymphoproliferative lesionsurgical biopsy is indicated because a larger volume of tissue is often required to both diagnose and type the lymphoma. However, if a nonlymphoproliferative diagnosis was suggested, FNA has a high yield and is recommended.

If an anterior mediastinal mass appears localized and consistent with a thymoma, surgical resection is performed. Surgical resection without biopsies for most localized tumors of the posterior mediastinum suspected to be neurogenic in origin also appropriate.

Surgical Biopsies and Resection of Mediastinal Masses

For mediastinal tumors not amenable to CT-guided needle biopsy or needle biopsy has not yielded sufficient tissue for diagnosis, surgical biopsy is indicated. Masses in the paratracheal region are easily biopsied by mediastinoscopy. For tumors of the anterior or posterior mediastinum, a left or right VATS approach often allows safe and adequate surgical biopsies. In some patients, an anterior mediastinotomy (i.e., Chamberlain procedure) may be ideal

for an anterior tumor or a tumor with significant parasternal extension. Before a surgical biopsy is pursued, a discussion should be held with the pathologist regarding routine histologic assessment, special stains and markers, and requirements for lymphoma work-up.

The gold standard for the resection of most anterior and middle mediastinal masses is through a median sternotomy or lateral thoracotomy. In some cases, a lateral thoracotomy with sternal extension (hemi-clamshell) provides excellent exposure for extensive mediastinal tumors that have a lateral component. Alternatively, a right or left VATS approach can be used for resection of the thymus gland and for resection of small (1–2 cm) encapsulated thymomas. Most would agree that if a larger anterior mediastinal tumor is seen or malignancy is suspected, a median sternotomy with a more radical resection should be performed.

Neoplasms

Thymus

Thymic Tumors

Thymoma. Thymoma is the most frequently encountered neoplasm of the anterior mediastinum in adults (seen most frequently between 40 and 60 years of age). They are rare in children. Most thymomas are asymptomatic. However, between 10 and 50 percent have symptoms suggestive of myasthenia gravis or have circulating antibodies to acetylcholine receptor. However, less than 10 percent of patients with myasthenia gravis are found to have a thymoma on CT. Thymectomy leads to improvement or resolution of symptoms of myasthenia gravis in only about 25 percent of patients with thymomas. In contrast, in patients with myasthenia gravis and no thymoma, thymectomy results are superior: up to 50 percent of patients have a complete remission and 90 percent improve. In 5 percent of patients with thymomas, other paraneoplastic syndromes, including red cell aplasia, hypogammaglobulinemia, systemic lupus erythematosus, Cushing syndrome, or syndrome of inappropriate antidiuretic hormone (SIADH) may be present. Large thymic tumors may present with symptoms related to a mass effect, which may include cough, chest pain, dyspnea, or superior vena cava syndrome.

The diagnosis may be suspected based on CT scan and history, but imaging alone is not diagnostic. CT-guided FNA biopsy has a diagnostic sensitivity of 85 percent and a specificity of 95 percent in specialized centers. Cytokeratin is the marker that best distinguishes thymomas from lymphomas. In most patients, the distinction between lymphomas and thymomas can be made on CT scan, because most lymphomas have marked lymphadenopathy and thymomas most frequently appear as a solitary encapsulated mass.

The most commonly accepted staging system for thymomas is that of Masaoka. It is based on the presence or absence of gross or microscopic invasion of the capsule and of surrounding structures, and on the presence or absence of metastases.

The definitive treatment for thymomas is complete surgical removal for all resectable tumors; local recurrence rates and survival vary according to stage. Resection is generally accomplished by median sternotomy with extension to hemi-clamshell in more advanced cases. Even advanced tumors with local invasion of resectable structures such as the pericardium, superior vena cava, or innominate vessels should be considered for resection with reconstruction.

Currently, chemotherapy is being offered preoperatively and postoperatively to select patients with advanced stage thymomas.

Common Adult Neurogenic Tumors

Nerve sheath tumors. Nerve sheath tumors account for 20 percent of all mediastinal tumors. More than 95 percent of nerve sheath tumors are benign neurilemmomas or neurofibromas. Malignant neurosarcomas are much less common.

Neurilemoma. Neurilemmomas, also called schwannomas, arise from Schwann cells in intercostal nerves. They are firm, well-encapsulated, and generally benign. If routine CT scan suggests extension of a neurilemoma into the intervertebral foramen, MRI is suggested to evaluate the extent of this “dumbbell” configuration. Such a configuration may lead to cord compression and paralysis, and requires a more complex surgical approach. It is recommended that most nerve sheath tumors be resected. Traditionally, this has been performed by open thoracotomy but more recently, a VATS approach has been established as safe and effective for simple operations. It is reasonable to follow small, asymptomatic paravertebral tumors in older patients or in patients at high risk for surgery.

In children, ganglioneuroblastomas or neuroblastomas are more common; therefore all neurogenic tumors should be completely resected.

Neurofibroma. Neurofibromas have components of both nerve sheaths and nerve cells and account for up to 25 percent of nerve sheath tumors. Up to 40 percent of patients with mediastinal fibromas have generalized neurofibromatosis (von Recklinghausen’s disease). About 70 percent of neurofibromas are benign. Malignant degeneration to a neurofibrosarcoma may occur in 25–30 percent of patients.

Neurofibrosarcomas carry a poor prognosis because of rapid growth and aggressive local invasion along nerve bundles. Complete surgical resection is the mainstay of treatment.

Ganglion cell tumors. Ganglion cell tumors arise from the sympathetic chain or from the adrenal medulla and include ganglioneuromas, ganglioneuroblastomas, and neuroblastomas.

Lymphoma

Overall, lymphomas are the most common malignancy of the mediastinum. In about 50 percent of patients who have both Hodgkin and non-Hodgkin lymphoma, the mediastinum may be the primary site. The anterior compartment is most commonly involved, with occasional involvement of the middle compartment and hilar nodes. The posterior compartment is rarely involved. Chemotherapy and/or radiation results in a cure rate of up to 90 percent for patients with early stage Hodgkin disease, and up to 60 percent with more advanced stages.

Mediastinal Germ Cell Tumors

Germ cell tumors are uncommon neoplasms, with only about 7000 diagnosed each year. However, they are the most common malignancy in young men between age 15 and 35 years. Most germ cell tumors are gonadal in origin. Those with the mediastinum as the primary site are rare, constituting less than 5 percent of all germ cell tumors, and less than 1 percent of all mediastinal

tumors (usually occurring in the anterior compartment). If a malignant mediastinal germ cell tumor is found, it is important to exclude a gonadal primary tumor. Primary mediastinal germ cell tumors (including teratomas, seminomas, and nonseminomatous malignant germ cell tumors) are a heterogeneous group of benign and malignant neoplasms thought to originate from primitive pluripotent germ cells “misplaced” in the mediastinum during embryonic development.

About one-third of all primary mediastinal germ cell tumors are seminomatous. Two thirds are nonseminomatous tumors or teratomas. Treatment and prognosis vary considerably within these two groups. FNA biopsy alone may be diagnostic for seminomas, usually with normal serum markers, including hCG and AFP. In 10 percent of seminomas, hCG levels may be slightly elevated. FNA findings, along with high hCG and AFP levels, can accurately diagnose nonseminomatous tumors. If the diagnosis remains uncertain after assessment of FNA findings and serum marker levels, then core-needle biopsies or surgical biopsies may be required. An anterior mediastinotomy (Chamberlain procedure) or a thoracoscopy is the most frequent diagnostic surgical approach.

Teratoma. Teratomas are the most common type of mediastinal germ cell tumors, accounting for 60–70 percent of mediastinal germ cell tumors. They contain two or three embryonic layers that may include teeth, skin, hair (ectodermal), cartilage and bone (mesodermal), or bronchial, intestinal, or pancreatic tissue (endodermal). Therapy for mature, benign teratomas is surgical resection, which confers an excellent prognosis.

Seminoma. Most patients with seminomas have advanced disease at the time of diagnosis and present with symptoms of local compression, including superior vena caval syndrome, dyspnea, or chest discomfort. With advanced disease, the preferred treatment is combination cisplatin-based chemotherapy regimens with bleomycin and either etoposide or vinblastine. Complete responses have been reported in over 75 percent of patients treated with these regimens. Surgical resection may be curative for small asymptomatic seminomas that are found incidentally with screening CT scans. Surgical resection of residual masses after chemotherapy may be indicated.

Nonseminomatous germ cell tumors. Nonseminomatous germ cell tumors include embryonal cell carcinomas, choriocarcinomas, endodermal sinus tumors, and mixed types. They are often bulky, irregular tumors of the anterior mediastinum with areas of low attenuation on CT scan because of necrosis, hemorrhage, or cyst formation. Frequently, adjacent structures have been involved, with metastases to regional lymph nodes, pleura, and lungs. Lactate dehydrogenase (LDH), AFP, and hCG levels are frequently elevated. Chemotherapy is the preferred treatment and includes combination therapy with cisplatin, bleomycin, and etoposide. With this regimen, survival at 2 years is 67 percent and at 5 years is 60 percent. Surgical resection of residual masses is indicated, as it may guide further therapy. Up to 20 percent of residual masses contain additional tumors; in another 40 percent, mature teratomas; and the remaining 40 percent, fibrotic tissue.

Mediastinitis

Acute Mediastinitis

Acute mediastinitis is a fulminant infectious process that spreads along the fascial planes of the mediastinum. Infections originate most commonly from esophageal perforations, sternal infections, and oropharyngeal or neck infections, but a number of less common etiologic factors can lead to this deadly process. As infections from any of these sources enter the mediastinum, spread may be rapid along the continuous fascial planes connecting the cervical and mediastinal compartments. Clinical signs and symptoms include fever, chest pain, dysphagia, respiratory distress, and cervical and upper thoracic subcutaneous crepitus. In severe cases, the clinical course can rapidly deteriorate to florid sepsis, hemodynamic instability, and death. Thus, a high index of suspicion is required in the context of any infection with access to the mediastinal compartments.

A chest CT scan can be particularly helpful in determining the extent of spread and the best approach to surgical drainage. Acute mediastinitis is a true surgical emergency and treatment must be instituted immediately and must be aimed at correcting the primary problem, such as the esophageal perforation or oropharyngeal abscess. Another major concern is débridement and drainage of the spreading infectious process within the mediastinum, neck, pleura, and other tissue planes. Antibiotics, fluid resuscitation, and other supportive measures are important, but surgical correction of the problem at its source and open débridement of infected areas are critical measures. Surgical débridement may need to be repeated, and other planes and cavities explored depending on the patient's clinical status. Persistent sepsis or collections on CT scan may require further radical surgical débridement.

Chronic Mediastinitis

Sclerosing or fibrosing mediastinitis is a result of chronic inflammation of the mediastinum, most frequently as a result of granulomatous infections such as histoplasmosis or tuberculosis. The process begins in lymph nodes and continues as a chronic, low-grade inflammation leading to fibrosis and scarring. In many patients, the clinical manifestations are silent. However, if the fibrosis is progressive and severe, it may lead to encasement of the mediastinal structures, causing entrapment and compression of the low-pressure veins (including the superior vena cava and innominate and azygos veins). This fibrotic process can compromise other structures such as the esophagus and pulmonary arteries. There is no definitive treatment. Surgery is indicated only for diagnosis or in specific patients to relieve airway or esophageal obstruction or to achieve vascular reconstruction.

DISEASES OF THE PLEURA AND PLEURAL SPACE

Pleural Effusion

Pleural effusion refers to any significant collection of fluid within the pleural space. Normally, there is an ongoing balance between the lubricating fluid flowing into the pleural space and its continuous absorption. Between 5 and 10 L of fluid normally enters the pleural space daily by filtration through microvessels supplying the parietal pleura. The net balance of pressures in these capillaries leads to fluid flow from the parietal pleural surface into the

pleural space, and the net balance of forces in the pulmonary circulation leads to absorption through the visceral pleura. Normally, 15–20 mL of pleural fluid is present at any given time. Any disturbance in these forces can lead to imbalance and accumulation of pleural fluid. Common pathologic conditions in North America that lead to pleural effusion include congestive heart failure, bacterial pneumonia, malignancy, and pulmonary emboli.

Diagnostic Work-Up

The initial evaluation of a pleural effusion is guided by the history and physical examination. Bilateral pleural effusions are because of congestive heart failure in over 80 percent of patients.

The presence of a unilateral effusion in a patient with cough, fever, leukocytosis, and unilateral infiltrate is likely to be a parapneumonic process. If the effusion is small and the patient responds to antibiotics, a diagnostic thoracentesis may be unnecessary. However, a patient who has an obvious pneumonia and a large pleural effusion that is purulent and foul-smelling has an empyema. Aggressive drainage with chest tubes is required, possibly with surgical intervention. Outside of the setting of congestive heart failure or small effusions associated with an improving pneumonia, most patients with pleural effusions of unknown cause should undergo thoracentesis.

A general classification of pleural fluid collections into transudates and exudates is helpful in understanding the various causes. Transudates are protein-poor ultrafiltrates of plasma that occur because of alterations in the systemic hydrostatic pressures or colloid osmotic pressures (for example, with congestive heart failure or cirrhosis). On gross visual inspection, a transudative effusion is generally clear or straw-colored. Exudates are protein-rich pleural fluid collections that generally occur because of inflammation or invasion of the pleura by tumors. Grossly, they are often turbid, bloody, or purulent. Grossly bloody effusions in the absence of trauma are frequently malignant, but may also occur in the setting of a pulmonary embolism or pneumonia. Several criteria have been traditionally used to differentiate transudates from exudates. An effusion is considered exudative if the pleural fluid to serum ratio of protein is greater than 0.5 and the LDH ratio is greater than 0.6 or the absolute pleural LDH level is greater than two-thirds of the normal upper limit for serum. If these criteria suggest a transudate, the patient should be carefully evaluated for congestive heart failure, cirrhosis, or conditions associated with transudates.

If an exudative effusion is suggested, further diagnostic studies may be helpful. If total and differential cell counts reveal a predominance of neutrophils (> 50 percent of cells), the effusion is likely to be associated with an acute inflammatory process (such as a parapneumonic effusion or empyema, pulmonary embolus, or pancreatitis). A predominance of mononuclear cells suggests a more chronic inflammatory process (such as cancer or tuberculosis). Gram's stains and cultures should be obtained, if possible with inoculation into culture bottles at the bedside. Pleural fluid glucose levels are frequently decreased (< 60 mg/dL) with complex parapneumonic effusions or malignant effusions.

Cytologic testing should be done on exudative effusions to rule out an associated malignancy. Cytologic diagnosis is accurate in diagnosing over 70 percent of malignant effusions associated with adenocarcinomas, but is less sensitive for mesotheliomas (< 10 percent), squamous cell carcinomas (20 percent), or lymphomas (25–50 percent). If the diagnosis remains uncertain

after drainage and fluid analysis, thoracoscopy and direct biopsies are indicated. Tuberculous effusions can now be diagnosed accurately by increased levels of pleural fluid adenosine deaminase (above 40 U per L). Pulmonary embolism should be suspected in a patient with a pleural effusion occurring in association with pleuritic chest pain, hemoptysis, or dyspnea out of proportion to the size of the effusion. These effusions may be transudative, but if an associated infarct near the pleural surface occurs, an exudate may be seen. If a pulmonary embolism is suspected in a postoperative patient, most clinicians would obtain a spiral CT scan.

Malignant Pleural Effusion

Malignant pleural effusions may occur in association with a variety of malignancies, most commonly lung cancer, breast cancer, and lymphomas, depending on the patient's age and gender. Malignant effusions are exudative and often tinged with blood. An effusion in the setting of a malignancy means a more advanced stage; it generally indicates an unresectable tumor, with a mean survival of 3–11 months. Occasionally, benign pleural effusions may be associated with a bronchogenic NSCLC, and surgical resection may still be indicated if the cytology of the effusions is negative for malignancy. An important issue is the size of the effusion and the degree of dyspnea that results. Symptomatic, moderate to large effusions should be drained by chest tube, pigtail catheter, or VATS, followed by instillation of a sclerosing agent. Before sclerosing the pleural cavity, whether by chest tube or VATS, the lung should be nearly fully expanded. Poor expansion of the lung (because of entrapment by tumor or adhesions) generally predicts a poor result. The choice of sclerosant includes talc, bleomycin, or doxycycline. Success rates of controlling the effusion range from 60–90 percent, depending on the exact scope of the clinical study, the degree of lung expansion after the pleural fluid is drained, and the care with which the outcomes were reported.

Empyema

Thoracic empyema is defined by a purulent pleural effusion. The most common causes are parapneumonic, but postsurgical or posttraumatic empyema is also common. Grossly purulent, foul-smelling pleural fluid makes the diagnosis of empyema obvious on visual examination at the bedside. Diagnosis is confirmed by a combination of clinical scenario with positive pleural fluid cultures.

Pathophysiology

The spectrum of organisms involved in the development of a parapneumonic empyema is changing. Pneumococci and staphylococci continue to be the most common, but gram-negative aerobic bacteria and anaerobes are becoming more prevalent. Cases involving mycobacteria or fungi are rare. Multiple organisms may be found in up to 50 percent of patients, but cultures may be sterile if antibiotics were initiated before the culture or if the culture process was not efficient. Therefore, it is imperative that the choice of antibiotics be guided by the clinical scenario and not just the organisms found on culture. Broad spectrum coverage may be still required even when cultures have failed to grow out an organism or if a single organism is grown when the clinical picture is more consistent with a multiorganism process. Common gram-negative organisms include *Escherichia coli*, *Klebsiella*, *Pseudomonas*, and *Enterobacteriaceae*. Anaerobic organisms may be fastidious and difficult to document

by culture and are associated with periodontal diseases, aspiration syndromes, alcoholism, general anesthesia, drug abuse, or other functional associations with gastroesophageal reflux.

The route of organism entry into the pleural cavity may be by contiguous spread from pneumonia, lung abscess, liver abscess, or another infectious process with contact with the pleural space. Organisms may also enter the pleural cavity by direct contamination from thoracentesis, thoracic surgical procedures, esophageal injuries, or trauma.

In the early stage of an empyema the effusion is watery and free-flowing in the pleural cavity. Thoracentesis at this stage yields fluid with a pH typically above 7.3, a glucose level greater than 60 mg/dL, and a low LDH level (< 500 U/L). At this stage, the decision to use antibiotics alone or perform a repeat thoracentesis, chest tube drainage, thoracoscopy, or open thoracotomy depends on the amount of pleural fluid, its consistency, the clinical status of the patient, the degree of expansion of the lung after drainage, and the presence of loculated fluid in the pleural space (versus free-flowing purulent fluid). If relatively thin, purulent pleural fluid is diagnosed early in the setting of a pneumonic process, the fluid often can be completely drained with simple large-bore thoracentesis. If complete lung expansion is obtained and the pneumonic process is responding to antibiotics, no further drainage may be necessary. Pleural fluid with a pH lower than 7.2 and with a low glucose level means that a more aggressive approach to drainage should be pursued.

The pleural fluid may become thick and loculated over the course of hours to days, and may be associated with fibrinous adhesions (the fibrinopurulent stage). At this stage, chest tube insertion with closed-system drainage or drainage with thoracoscopy may be necessary to remove the fluid and adhesions and to allow complete lung expansion. Further progression of the inflammatory process leads to the formation of a pleural peel, which may be flimsy and easy to remove early on. However, as the process progresses, a thick pleural rind may develop, leaving a trapped lung; complete lung decortication by thoracotomy would then be necessary, or in some patients, thoracoscopy.

Management

If there is a residual space, persistent pleural infection is likely to occur. A persistent pleural space may be secondary to contracted, but intact, underlying lung; or it may be secondary to surgical lung resection. If the space is small and well-drained by a chest tube, a conservative approach may be possible. This requires leaving the chest tubes in place and attached to closed-system drainage until symphysis of the visceral and parietal surfaces takes place. At this point, the chest tubes can be removed from suction; if the residual pleural space remains stable, the tubes can be cut and advanced out of the chest over the course of several weeks. If the patient is stable, tube removal can frequently be done in the outpatient setting, guided by the degree of drainage and the size of the residual space visualized on serial CT scans. Larger spaces may require open thoracotomy and decortication in an attempt to reexpand the lung to fill this residual space. If reexpansion has failed or appears too high risk, then open drainage, rib resection, and prolonged packing may be required, with delayed closure with muscle flaps or thoracoplasty. Most chronic pleural space problems can be avoided by early specialized thoracic surgical consultation and complete drainage of empyemas, allowing space obliteration by the reinflated lung.

Chylothorax

Chylothorax develops most commonly after surgical trauma to the thoracic duct or a major branch, but may be also associated with a number of other conditions. It is generally unilateral; for example, it may occur on the right after esophagectomy in which the duct is most frequently injured during dissection of the distal esophagus. The esophagus comes into close proximity to the thoracic duct as it enters the chest from its origin in the abdomen at the cisterna chyli. If the mediastinal pleura is disrupted on both sides, bilateral chylothoraces may occur. Left-sided chylothoraces may develop after a left-sided neck dissection, especially in the region of the confluence of the subclavian and internal jugular veins. It may be seen in association with a variety of benign and malignant diseases that generally involve the lymphatic system of the mediastinum or neck.

Pathophysiology

Most commonly, the thoracic duct originates in the abdomen from the cisterna chyli, which is located in the midline, near the level of the second lumbar vertebra. From this origin, the thoracic duct ascends into the chest through the aortic hiatus at the level of T10 to T12, and courses just to the right of the aorta. As the thoracic duct courses cephalad above the diaphragm, it most commonly remains in the right chest, lying just behind the esophagus, between the aorta and azygos vein. At about the level of the fifth or sixth thoracic vertebra, it crosses behind the aorta and the aortic arch into the left posterior mediastinum. From this location, it again courses superiorly, staying near the esophagus and mediastinal pleura as it exits the thoracic inlet. As it exits the thoracic inlet, it passes just to the left, just behind the carotid sheath and anterior to the inferior thyroid and vertebral bodies. Just medial to the anterior scalene muscle, it courses inferiorly and drains into the union of the internal jugular and subclavian veins.

The treatment plan for any chylothorax depends on its cause, the amount of drainage, and the clinical status of the patient. In general, most patients are treated with a short period of chest tube drainage, nothing by mouth (NPO) orders, total parenteral nutrition (TPN), and observation. Chest cavity drainage must be adequate to allow complete lung expansion. Somatostatin has been advocated by some authors, with variable results. If significant chyle drainage (> 500 mL per day in an adult, > 100 mL in an infant) continues despite TPN and good lung expansion, early surgical ligation of the duct is recommended.

Chylothoraces because of malignant conditions often respond to radiation and/or chemotherapy, so less commonly require surgical ligation. Untreated chylothoraces are associated with significant nutritional and immunologic depletion that leads to significant mortality. Before the introduction of surgical ligation of the thoracic duct, the mortality rate from chylothorax exceeded 50 percent. With the availability of TPN for nutritional supplementation and surgical ligation for persistent leaks, the mortality rate of chylothorax is less than 10 percent.

Tumors of the Pleura

Malignant Mesothelioma

Malignant mesothelioma is the most common pleural tumor, with an annual incidence in the United States of 3000 cases. Asbestos exposure is the only

known risk factor; it can be established in over 50 percent of patients. Malignant mesotheliomas have a male predominance of 2:1, and are most common after the age of 40.

Clinical presentation. Most patients present with dyspnea and chest pain. Over 90 percent have a pleural effusion. Thoracentesis is diagnostic in less than 10 percent of patients. Frequently, a thoracoscopy or open pleural biopsy with special stains is required to differentiate mesotheliomas from adenocarcinomas. Once the diagnosis is confirmed, cell types can be distinguished (e.g., epithelial, sarcomatous, and mixed). Epithelial types are associated with a more favorable prognosis, and in some patients long-term survival may be seen with no treatment. Sarcomatous and mixed tumors share a more aggressive course.

Surgical Management

Surgical options include palliative pleurectomy or talc pleurodesis with improved local control and a modest improvement in short-term survival. More radical surgical approaches (such as extrapleural pneumonectomy followed by adjuvant chemotherapy and radiation) have an increased morbidity rate; moreover, the mortality rate exceeds 10 percent in all but the most experienced centers.

In the modern era, the goal in most cases of congenital heart disease (CHD) is early definitive repair. Therefore, a more clinically relevant classification scheme divides particular defects into three categories based on the feasibility of achieving this goal: (1) defects that have no reasonable palliation and for which repair is the only option; (2) defects for which repair is not possible and for which palliation is the only option; and (3) defects that can either be repaired or palliated in infancy. It bears mentioning that all defects in the second category are those in which the appropriate anatomic components either are not present, as in hypoplastic left-heart syndrome, or cannot be created from existing structures.

DEFECTS IN WHICH REPAIR IS THE ONLY OR BEST OPTION

Atrial Septal Defect

An atrial septal defect (ASD) is defined as an opening in the interatrial septum that enables the mixing of blood from the systemic venous and pulmonary venous circulations.

Anatomy

ASDs can be classified into three different types: (1) sinus venosus defects, comprising approximately 5–10 percent of all ASDs; (2) ostium primum defects, which are more correctly described as partial atrioventricular canal defects; and (3) ostium secundum defects, which are the most prevalent subtype, comprising 80 percent of all ASDs.

Pathophysiology

ASDs result in an increase in pulmonary blood flow secondary to left-to-right shunting through the defect. The direction of the intracardiac shunt is predominantly determined by the compliance of the respective ventricles. In utero, the distensibility, or compliance, of the right and left ventricles is equal, but postnatally the left ventricle (LV) becomes less compliant than the right ventricle (RV).

A minority of patients with ASDs develop progressive pulmonary vascular changes as a result of chronic overcirculation. The increased pulmonary vascular resistance in these patients leads to an equalization of left and right ventricular pressures, and their ratio of pulmonary (Q_p) to systemic flow (Q_s), $Q_p:Q_s$, will approach 1. This does not mean, however, that there is no intracardiac shunting, only that the ratio between the left-to-right component and the right-to-left component is equal.

The ability of the right ventricle to recover normal function is related to the duration of chronic overload, because those undergoing ASD closure before age 10 years have a better likelihood of achieving normal RV function in the postoperative period.

The physiology of sinus venosus ASDs is similar to that discussed above except that these are frequently accompanied by anomalous pulmonary venous

drainage. This often results in significant hemodynamic derangements that accelerate the clinical course of these infants.

The same increase in symptoms is true for those with ostium primum defects because the associated mitral insufficiency from the “cleft” mitral valve can lead to more atrial volume load and increased atrial level shunting.

Diagnosis

Patients with ASDs may present with few physical findings. Auscultation may reveal prominence of the first heart sound with fixed splitting of the second heart sound. This results from the relatively fixed left-to-right shunt throughout all phases of the cardiac cycle. A diastolic flow murmur indicating increased flow across the tricuspid valve may be discerned, and, frequently, an ejection flow murmur can be heard across the pulmonary valve. A right ventricular heave and increased intensity of the pulmonary component of the second heart sound indicate pulmonary hypertension and possible unreparability.

Chest radiographs in the patient with an ASD may show evidence of increased pulmonary vascularity, with prominent hilar markings and cardiomegaly. The electrocardiogram (ECG) shows right axis deviation with an incomplete bundle-branch block. When right bundle-branch block is associated with a leftward or superior axis, an AV canal defect should be strongly suspected.

Diagnosis is clarified by two-dimensional echocardiography, and use of color-flow mapping facilitates an understanding of the physiologic derangements created by the defects. Echocardiography also enables the clinician to estimate the amount of intracardiac shunting, can demonstrate the degree of mitral regurgitation in patients with ostium primum defects, and with the addition of microcavitation, can assist in the detection of sinus venosus defects.

The advent of two-dimensional echocardiography with color-flow Doppler has largely obviated the need for cardiac catheterization because the exact nature of the ASD can be precisely defined by echo alone. However, in cases in which the patient is older than age 40 years, catheterization can quantify the degree of pulmonary hypertension present, because those with a pulmonary vascular resistance (PVR) greater than 12 U/mL are considered inoperable. Cardiac catheterization also can be useful in that it provides data that enable the calculation of Qp and Qs so that the magnitude of the intracardiac shunt can be determined. The ratio (Qp:Qs) can then be used to determine whether closure is indicated in equivocal cases, because a Qp:Qs greater than 1.5:1 is generally accepted as the threshold for surgical intervention. Finally, in patients older than age 40 years, cardiac catheterization can be important to disclose the presence of coronary artery disease.

In general, ASDs are closed when patients are between 4 and 5 years of age. Children of this size can usually be operated on without the use of blood transfusion and generally have excellent outcomes. Patients who are symptomatic may require repair earlier, even in infancy. Some surgeons, however, advocate routine repair in infants and children, as even smaller defects are associated with the risk of paradoxical embolism, particularly during pregnancy. In a recent review by Reddy and colleagues, 116 neonates weighing less than 2500 g who underwent repair of simple and complex cardiac defects with the use of cardiopulmonary bypass were found to have no intracerebral hemorrhages, no long-term neurologic sequelae, and a low operative-mortality rate (10 percent). These results correlated with the length of cardiopulmonary bypass and the complexity of repair. These investigators also found an 80 percent

actuarial survival at 1 year and, more importantly, that growth following complete repair was equivalent to weight-matched neonates free from cardiac defects.

Treatment

ASDs can be repaired in a facile manner using standard cardiopulmonary bypass (CPB) techniques through a midline sternotomy approach. The details of the repair itself are generally straightforward. An oblique atriotomy is made, the position of the coronary sinus and all systemic and pulmonary veins are determined, and the rim of the defect is completely visualized. Closure of ostium secundum defects is accomplished either by direct suture or by insertion of a patch. The decision of whether patch closure is necessary can be determined by the size and shape of the defect and by the quality of the edges.

Sinus venosus ASDs associated with partial anomalous pulmonary venous connection are repaired by inserting a patch, with redirection of the pulmonary veins behind the patch to the left atrium. Care must be taken with this approach to avoid obstruction of the pulmonary veins or the superior vena cava, although usually the superior vena cava is dilated and provides ample room for patch insertion.

These operative strategies have been well established, with a low complication rate and a mortality rate approaching zero. As such, attention has shifted to improving the cosmetic result and minimizing hospital stay and convalescence. Multiple new strategies have been described to achieve these aims, including the right submammary incision with anterior thoracotomy, limited bilateral submammary incision with partial sternal split, transxiphoid window, and limited midline incision with partial sternal split. Some centers use video-assisted thoracic surgery (VATS) in the submammary and transxiphoid approaches to facilitate closure within a constricted operative field. The morbidity and mortality of all of these approaches are comparable to those of the traditional median sternotomy; however, each has technical drawbacks. The main concern is that operative precision be maintained with limited exposure. Luo and associates recently described a prospective randomized study comparing ministernotomy (division of the upper sternum for aortic and pulmonary lesions, and the lower sternum for septal lesions) to full sternotomy in 100 consecutive patients undergoing repair of septal lesions. The patients in the ministernotomy group had longer procedure times (by 15–20 min), less bleeding, and shorter hospital stays. These results have been echoed by other investigators from Boston who maintain that ministernotomy provides a cosmetically acceptable scar without compromising aortic cannulation or limiting the exposure of crucial mediastinal structures. This approach also can be easily extended to a full sternotomy should difficulty or unexpected anomalies be encountered.

First performed in 1976, transcatheter closure of ASDs with the use of various occlusion devices is gaining widespread acceptance. Certain types of ASDs, including patent foramen ovale, secundum defects, and some fenestrated secundum defects, are amenable to device closure. Complications reported to occur with transcatheter closure include air embolism (1–3 percent); thromboembolism from the device (1–2 percent); disturbed atrioventricular valve function (1–2 percent); systemic/pulmonary venous obstruction (1 percent); perforation of the atrium or aorta with hemopericardium (1–2 percent); atrial arrhythmias (1–3 percent); and malpositioning/embolization of the device requiring intervention (2–15 percent). Thus, although percutaneous approaches are cosmetic and often translate into shorter periods of convalescence,

their attendant risks are considerable, especially because their use may not result in complete closure of the septal defect.

Results

Surgical repair of ASDs should be associated with a mortality rate near zero. Early repairs in neonates weighing less than 1000 g have been increasingly reported with excellent results. Uncommonly, atrial arrhythmias or significant left atrial hypertension may occur soon after repair. The latter is caused by the noncompliant small, left atrial chamber and generally resolves rapidly.

AORTIC STENOSIS

Anatomy and Classification

The spectrum of aortic valve abnormality represents the most common form of CHD, with the great majority of patients being asymptomatic until midlife. Obstruction of the left ventricular outflow tract (LVOT) occurs at multiple levels: subvalvular, valvular, and supra-ventricular. The critically stenotic aortic valve in the neonate or infant is commonly unicommissural or bicommissural, with thickened, dysmorphic, and myxomatous leaflet tissue and a reduced cross-sectional area at the valve level. Associated left-sided lesions are often present. Endocardial fibroelastosis also is common among infants with critical aortic stenosis (AS). In this condition, the LV is largely nonfunctional, and these patients are not candidates for simple valve replacement or repair, because the LV is incapable of supporting the systemic circulation. Often, the LV is markedly hypertrophic with a reduced cavity size, but on rare occasion, a dilated LV, reminiscent of overt heart failure, is encountered.

Pathophysiology

The unique intracardiac and extracardiac shunts present in fetal life allow even neonates with critical aortic stenosis (AS) to survive. In utero, left ventricular hypertrophy and ischemia cause left atrial hypertension, which reduces the right-to-left flow across the foramen ovale. In severe cases, a reversal of flow may occur, causing right ventricular volume loading. The RV then provides the entire systemic output via the patent ductus arteriosus. Although cardiac output is maintained, the LV suffers continued damage as the intracavitary pressure precludes adequate coronary perfusion, resulting in LV infarction and subendocardial fibroelastosis. The presentation of the neonate with critical AS is then determined by both the degree of left ventricular dysfunction and on the completeness of the transition from a parallel circulation to an in-series circulation on closure of the foramen ovale and the ductus arteriosus. Those infants with mild-to-moderate AS in which LV function is preserved are asymptomatic at birth. The only abnormalities may be a systolic ejection murmur and ECG evidence of left ventricular hypertrophy. However, those neonates with severe AS and compromised LV function are unable to provide adequate cardiac output at birth, and will present in circulatory collapse once the ductus closes, with dyspnea, tachypnea, irritability, narrowed pulse pressure, oliguria, and profound metabolic acidosis. If ductal patency is maintained, systemic perfusion will be provided by the RV via ductal flow, and cyanosis may be the only finding.

Diagnosis

Neonates and infants with severe valvular AS may have a relatively nonspecific history of irritability and failure to thrive. Angina, if present, is usually

manifested by episodic, inconsolable crying that coincides with feeding. As discussed previously, evidence of poor peripheral perfusion, such as extreme pallor, indicates severe LVOT obstruction. Differential cyanosis is an uncommon finding, but is present when enough antegrade flow occurs only to maintain normal upper body perfusion, although a large patent ductus arteriosus produces blue discoloration of the abdomen and legs.

Physical findings include a systolic ejection murmur, although a quiet murmur may paradoxically indicate a more severe condition with reduced cardiac output. A systolic click correlates with a valvular etiology of obstruction. As LV dysfunction progresses, evidence of congestive heart failure occurs.

The chest radiograph is variable, but may show dilatation of the aortic root, and the ECG often demonstrates LV hypertrophy. Echocardiography with Doppler flow is extremely useful in establishing the diagnosis, and quantifying the transvalvular gradient. Furthermore, echocardiography can facilitate evaluation for the several associated defects that can be present in critical neonatal AS, including mitral stenosis, LV hypoplasia, LV endocardial fibroelastosis, subaortic stenosis, VSD, or coarctation. The presence of any or several of these defects has important implications related to treatment options for these patients. Although cardiac catheterization is not routinely performed for diagnostic purposes, it can be invaluable as part of the treatment algorithm if the lesion is amenable to balloon valvotomy.

Treatment

The infant with severe AS may require urgent intervention. Preoperative stabilization, however, has dramatically altered the clinical algorithm and outcomes for this patient population. The preoperative strategy begins with endotracheal intubation and inotropic support. Prostaglandin infusion is initiated to maintain ductal patency, and confirmatory studies are performed prior to operative intervention.

Therapy is generally indicated in the presence of a transvalvular gradient of 50 mm Hg with associated symptoms including syncope, congestive heart failure (CHF), or angina, or if a gradient of 50–75 mmHg exists with concomitant ECG evidence of LV strain or ischemia. In the critically ill neonate, there may be little gradient across the aortic valve because of poor LV function. These patients depend on patency of the ductus arteriosus to provide systemic perfusion from the RV, and all ductal-dependent patients with critical AS require treatment. However, the decision regarding treatment options must be based on a complete understanding of associated defects. For example, in the presence of a hypoplastic LV (left ventricular) end-diastolic volume $< 20 \text{ mL/m}^2$, isolated aortic valvotomy should not be performed because studies have demonstrated high mortality in this population following isolated valvotomy.

Relief of valvular AS in infants and children can be accomplished with standard techniques of CPB and direct exposure to the aortic valve. A transverse incision is made in the ascending aorta above the sinus of Valsalva, extending close to, but not into, the noncoronary sinus. Exposure is attained with placement of a retractor into the right coronary sinus. After inspection of the valve, the chosen commissure is incised to within 1–2 mm of the aortic wall.

Balloon valvotomy performed in the cath lab has gained widespread acceptance as the procedure of choice for reduction of transvalvular gradients in symptomatic infants and children. This procedure is an ideal palliative option because mortality from surgical valvotomy can be high because of the

critical nature of these patients' condition. Furthermore, balloon valvotomy provides relief of the valvular gradient by opening the valve leaflets without the trauma created by open surgery, and allows future surgical intervention to be performed on an unscarred chest. In general, most surgical groups have abandoned open surgical valvotomy and favor catheter-based balloon valvotomy. The decision regarding the most appropriate method to use depends on several crucial factors including the available medical expertise, the patient's overall status and hemodynamics, and the presence of associated cardiac defects requiring repair. Although recent evidence is emerging to the contrary, simple valvotomy, whether performed percutaneously or open, is generally considered a palliative procedure. The goal is to relieve LVOT obstruction without producing clinically significant regurgitation, to allow sufficient annular growth for eventual aortic valve replacement. The majority of survivors of valvotomy performed during infancy will require further intervention on the aortic valve in 10 years.

Valvotomy may result in aortic insufficiency. Eventually, the combination of aortic stenosis and/or insufficiency may result in the need for an aortic valve replacement. Neonates with severely hypoplastic LVs or significant LV endocardial fibroelastosis may not be candidates for two-ventricle repair and are treated the same as infants with the hypoplastic left-heart syndrome (HLHS), which is discussed later (see Hypoplastic Left-Heart Syndrome below).

Many surgeons previously avoided aortic valve replacement for aortic stenosis in early childhood because the more commonly used mechanical valves would be outgrown and require replacement later, and the obligatory anticoagulation for mechanical valves resulted in a substantial risk for complications. Additionally, mechanical valves had an important incidence of bacterial endocarditis or perivalvular leak requiring re-intervention.

The use of allografts and the advent of the Ross procedure have largely obviated these issues and made early definitive correction of critical AS a viable option. Donald Ross first described transposition of the pulmonary valve into the aortic position with allograft reconstruction of the pulmonary outflow tract in 1967, in which a normal trileaflet semilunar valve made of a patient's native tissue was used to replace the damaged aortic valve. Since then, the Ross procedure has become the optimal choice for aortic valve replacement in children, because it has improved durability and can be performed with acceptable morbidity and mortality rates. Lupinetti and Jones compared allograft aortic valve replacement with the Ross procedure and found a more significant transvalvular gradient reduction and regression of left ventricular hypertrophy in those patients who underwent the Ross procedure. In some cases, the pulmonary valve may not be usable because of associated defects or congenital absence. These children are not candidates for the Ross procedure and are now most frequently treated with cryopreserved allografts (cadaveric human aortic valves). At times, there may be a size discrepancy between the RVOT and the LVOT, especially in cases of severe critical AS in infancy. For these cases, the pulmonary autograft is placed in a manner that also provides enlargement of the aortic annulus (Ross/Konno).

Subvalvular AS occurs beneath the aortic valve and may be classified as discrete or tunnel-like (diffuse). A thin, fibromuscular diaphragm immediately proximal to the aortic valve characterizes discrete subaortic stenosis. This diaphragm typically extends for 180 degrees or more in a crescentic or circular fashion, often attaching to the mitral valve and the interventricular septum. The aortic valve itself is usually normal in this condition, although the turbulence

imparted by the subvalvular stenosis may affect leaflet morphology and valve competence.

Diffuse subvalvular AS results in a long, tunnel-like obstruction that may extend to the left ventricular apex. In some individuals, there may be difficulty in distinguishing between hypertrophic cardiomyopathy and diffuse subaortic stenosis. Operation for subvalvular AS is indicated with a gradient exceeding 30 mmHg or when symptoms indicating LVOT obstruction are present. Some surgeons advocate repair in all cases of discrete AS, because it entails only simple membrane excision, to avoid aortic insufficiency, which often occurs with this lesion. Diffuse AS oftentimes requires aortoventriculoplasty as previously described. Results are generally excellent, with operative mortality less than 5 percent.

Supravalvular AS occurs more rarely, and also can be classified into a discrete type, which produces an hourglass deformity of the aorta, and a diffuse form that can involve the entire arch and brachiocephalic arteries. The aortic valve leaflets are usually normal, but in some cases, the leaflets may adhere to the supravalvular stenosis, thereby narrowing the sinuses of Valsalva in diastole and restricting coronary artery perfusion. Additionally, accelerated intimal hyperplastic changes in the coronary arteries can be demonstrated in these patients because the proximal position of the coronary arteries subjects them to abnormally high perfusion pressures.

The signs and symptoms of supravalvular AS are similar to other forms of LVOT obstruction. An asymptomatic murmur is the presenting manifestation in approximately half these patients. Syncope, poor exercise tolerance, and angina may all occur with nearly equal frequency. Occasionally, supravalvular AS is associated with Williams syndrome, a constellation of elfin facies, mental retardation, and hypercalcemia. Following routine evaluation, cardiac catheterization should be performed to delineate coronary anatomy, and to delineate the degree of obstruction. A gradient of 50 mmHg or greater is an indication for operation. However, the clinician must be cognizant of any coexistent lesions, most commonly pulmonic stenosis, which may add complexity to the repair.

The localized form of supravalvular AS is treated by creating an inverted Y-shaped aortotomy across the area of stenosis, straddling the right coronary artery. The obstructing shelf is then excised and a pantaloon-shaped patch is used to close the incision.

The diffuse form of supravalvular stenosis is more variable, and the particular operative approach must be tailored to each specific patient's anatomy. In general, either an aortic endarterectomy with patch augmentation can be performed, or if the narrowing extends past the aorta arch, a prosthetic graft can be placed between the ascending and descending aorta. Operative results for discrete supravalvular AS are generally good, with a hospital mortality of less than 1 percent and an actuarial survival rate exceeding 90 percent at 20 years. In contrast, however, the diffuse form is more hazardous to repair, and carried a mortality of 15 percent in a recent series.

Patent Ductus Arteriosus

Anatomy

The ductus arteriosus is derived from the sixth aortic arch and normally extends from the main or left pulmonary artery to the upper descending thoracic aorta, distal to the left subclavian artery.

Delayed closure of the ductus is termed prolonged patency, whereas failure of closure causes persistent patency, which may occur as an isolated lesion or in association with more complex congenital heart defects. In many of these infants with more complex congenital heart defects, either pulmonary or systemic perfusion may depend on ductal flow, and these infants may decompensate if exogenous PGE is not administered to maintain ductal patency.

Natural History

The incidence of patent ductus arteriosus (PDA) is approximately 1 in every 2000 births; however, it increases dramatically with increasing prematurity. In some series, PDAs have been noted in 75 percent of infants of 28–30 weeks gestation. Persistent patency occurs more commonly in females, with a 2:1 ratio.

PDA is not a benign entity, although prolonged survival has been reported. The estimated death rate for infants with isolated, untreated PDA is approximately 30 percent. The leading cause of death is congestive heart failure, with respiratory infection as a secondary cause. Endocarditis is more likely to occur with a small ductus and is rarely fatal if aggressive antibiotic therapy is initiated early.

Clinical Manifestations and Diagnosis

After birth, in an otherwise normal cardiovascular system, a PDA results in a left-to-right shunt that depends on both the size of the ductal lumen and its total length. As the pulmonary vascular resistance falls 16–18 weeks postnatally, the shunt will increase, and its flow will ultimately be determined by the relative resistances of the pulmonary and systemic circulations.

The hemodynamic consequences of an unrestrictive ductal shunt are left ventricular volume overload with increased left atrial and pulmonary artery pressures, and right ventricular strain from the augmented afterload. These changes result in increased sympathetic discharge, tachycardia, tachypnea, and ventricular hypertrophy. The diastolic shunt results in lower aortic diastolic pressure and increases the potential for myocardial ischemia and underperfusion of other systemic organs, although the increased pulmonary flow leads to increased work of breathing and decreased gas exchange. Unrestrictive ductal flow may lead to pulmonary hypertension within the first year of life. These changes will be significantly attenuated if the size of the ductus is only moderate, and completely absent if the ductus is small.

Physical examination of the afflicted infant will reveal evidence of a hyperdynamic circulation with a widened pulse pressure and a hyperactive precordium. Auscultation demonstrates a systolic or continuous murmur, often termed a machinery murmur. Cyanosis is not present in uncomplicated isolated PDA.

The chest radiograph may reveal increased pulmonary vascularity or cardiomegaly, and the ECG may show LV strain, left atrial enlargement, and possibly RV hypertrophy. Echocardiogram with color mapping reliably demonstrates the patency of the ductus and estimates the shunt size. Cardiac catheterization is necessary only when pulmonary hypertension is suspected.

Therapy

The presence of a persistent PDA is sufficient indication for closure because of the increased mortality and risk of endocarditis. In older patients with

pulmonary hypertension, closure may not improve symptoms and is associated with much higher mortality.

In premature infants, aggressive intervention with indomethacin to achieve early closure of the PDA is beneficial. Term infants, however, are generally unresponsive to pharmacologic therapy with indomethacin, so mechanical closure must be undertaken once the diagnosis is established. This can be accomplished either surgically or with catheter-based therapy. Currently, transluminal placement of various occlusive devices, such as the Rashkind double-umbrella device or embolization with Gianturco coils, are in widespread use. However, there are a number of complications inherent with the use of percutaneous devices, such as thromboembolism, endocarditis, incomplete occlusion, vascular injury, and hemorrhage secondary to perforation. Additionally, these techniques may not be applicable in very young infants, as the peripheral vessels do not provide adequate access for the delivery devices.

Video-assisted thoracoscopic occlusion, using metal clips, also has been described, although it offers few advantages over the standard surgical approach. Preterm newborns and children, however, may do well with the thoracoscopic technique, although older patients (older than age 5 years) and those with smaller ducts (< 3 mm) do well with coil occlusion. In fact, Moore and colleagues recently concluded from their series that coil occlusion is the procedure of choice for ducts smaller than 4 mm. Complete closure rates using catheter-based techniques have steadily improved. Comparative studies of cost and outcome between open surgery and transcatheter duct closure, however, have shown no overwhelming choice between the two modalities. Burke prospectively reviewed coil occlusion and VATS at Miami Children's Hospital, and found both options to be effective and less morbid than traditional thoracotomy.

Standard surgical approach involves triple ligation of the ductus with permanent suture through either a left anterior or a posterior thoracotomy. Occasionally, a short, broad ductus, in which the dimension of its width approaches that of its length, will be encountered. In this case, division between vascular clamps with oversewing of both ends is advisable. In extreme cases, the use of CPB to decompress the large ductus during ligation is an option.

Outcomes

In premature infants, the surgical mortality is very low, although the overall hospital death rate is significant as a consequence of other complications of prematurity. In older infants and children, mortality is less than 1 percent. Bleeding, chylothorax, vocal cord paralysis, and the need for reoperation occur infrequently. With the advent of muscle-sparing thoracotomy, the risk of subsequent arm dysfunction or breast abnormalities is virtually eliminated.

Aortic Coarctation

Anatomy

Coarctation of the aorta (COA) is defined as a luminal narrowing in the aorta that causes an obstruction to blood flow. This narrowing is most commonly located distal to the left subclavian artery. Extensive collateral circulation develops, predominantly involving the intercostals and mammary arteries as a direct result of aortic flow obstruction. This translates into the well-known

finding of “rib-notching” on chest radiograph, and a prominent pulsation underneath the ribs.

Other associated anomalies, such as ventricular septal defect, patent ductus arteriosus, and atrial septal defect, may be seen with COA, but the most common is that of a bicuspid aortic valve, which can be demonstrated in 25–42 percent of cases.

Pathophysiology

Infants with COA develop symptoms consistent with left ventricular out-flow obstruction, including pulmonary overcirculation and, later, biventricular failure. Additionally, proximal systemic hypertension develops as a result of mechanical obstruction to ventricular ejection, and hypoperfusion-induced activation of the renin–angiotensin–aldosterone system. Interestingly, hypertension is often persistent after surgical correction despite complete amelioration of the mechanical obstruction and pressure gradient. It has been shown that early surgical correction may prevent the development of long-term hypertension, which undoubtedly contributes to many of the adverse sequelae of COA, including the development of circle of Willis aneurysms, aortic dissection and rupture, and an increased incidence of coronary arteriopathy with resulting myocardial infarction.

Diagnosis

COA is likely to become symptomatic either in the newborn period if other anomalies are present or in the late adolescent period with the onset of left ventricular failure.

Physical examination will demonstrate a hyperdynamic precordium with a harsh murmur localized to the left chest and back. Femoral pulses will be dramatically decreased when compared to upper extremity pulses, and differential cyanosis may be apparent until ductal closure.

Echocardiography will reliably demonstrate the narrowed aortic segment, and define the pressure gradient across the stenotic segment. Additionally, detailed information regarding other associated anomalies can be gleaned. Aortography is reserved for those cases in which the echocardiographic findings are equivocal.

Therapy

The routine management of hemodynamically significant COA in all age groups has traditionally been surgical. The most common technique in current use is resection with end-to-end anastomosis or extended end-to-end anastomosis, taking care to remove all residual ductal tissue. The subclavian flap aortoplasty is another frequently used repair. In this method, the left subclavian artery is transected and brought down over the coarcted segment as a vascularized patch. The main benefit of these techniques is that they do not involve the use of prosthetic materials.

However, end-to-end anastomosis may not be feasible when there is a long segment of coarctation, because sufficient mobilization of the aorta above and below the lesion may not be possible. In this instance, prosthetic materials, such as a patch aortoplasty, in which a prosthetic patch is used to enlarge the coarcted segment, or an interposition tube graft must be employed.

The most common complications after COA repair are late restenosis and aneurysm formation at the repair site. Aneurysm formation is particularly common after patch aortoplasty when using Dacron material. In a large

series of 891 patients, aneurysms occurred in 5.4 percent of the total, with 89 percent occurring in the group who received Dacron-patch aortoplasty, compared to 8 percent in those who received resection with primary end-to-end anastomosis. A further complication, although uncommon, is lower-body paralysis resulting from ischemic spinal cord injury during the repair. This unfortunate outcome complicates 0.5 percent of all surgical repairs, but its incidence can be lessened with the use of some form of distal perfusion, preferably left-heart bypass with the use of femoral arterial or distal thoracic aorta for arterial inflow and the femoral vein or left atrium for venous return.

Although operative repair is still the gold standard, treatment of COA by catheter-based intervention has become more widespread. Both balloon dilatation and primary stent implantation have been used successfully. The most extensive study of the results of balloon angioplasty reported on 970 procedures: 422 native and 548 recurrent COAs. Mean gradient reduction was 74 ± 24 percent for native and 70 ± 31 percent for recurrent COA. This demonstrated that catheter-based therapy could produce equally effective results both in recurrent and in primary COA, a finding with far-reaching implications in the new paradigm of multidisciplinary treatment algorithms for CHD. In the valvuloplasty and angioplasty of congenital anomalies (VACA) report, higher preangioplasty gradient, earlier procedure date, older patient age, and the presence of recurrent COA were independent risk factors for suboptimal procedural outcome.

The gradient after balloon dilatation in most series is generally acceptable. However, there is a significant minority (0–26 percent) for whom the procedural outcome is suboptimal, with a postprocedure gradient of 20 mmHg or greater. These patients may be ideal candidates for primary stent placement. Restenosis is much less common in children, presumably reflecting the influence of vessel wall scarring and growth in the pediatric age group.

Deaths from the procedure also are infrequent (less than 1 percent of cases), and the main major complication is aneurysm formation, which occurs in 7 percent of patients. With stent implantation, many authors have demonstrated improved resolution of stenosis compared with balloon dilatation alone, yet the long-term complications on vessel wall compliance remain largely unknown because only mid-term data are widely available.

In summary, children younger than age 6 months with native COA should be treated with surgical repair, although those requiring intervention at later ages may be ideal candidates for balloon dilatation or primary stent implantation. Additionally, catheter-based therapy should be employed for those cases of restenosis following either surgical or primary endovascular management.

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC) occurs in 1–2 percent of all cardiac malformations and is characterized by abnormal drainage of the pulmonary veins into the right heart, whether through connections into the right atrium or into its tributaries. Accordingly, the only mechanism by which oxygenated blood can return to the left heart is through an ASD, which is almost uniformly present with TAPVC.

Unique to this lesion is the absence of a definitive form of palliation. Thus, TAPVC represents one of the only true surgical emergencies across the entire spectrum of congenital heart surgery.

Anatomy and Embryology

The lungs develop from an outpouching of the foregut, and their venous plexus arises as part of the splanchnic venous system. TAPVC arises when the pulmonary vein evagination from the posterior surface of the left atrium fails to fuse with the pulmonary venous plexus surrounding the lung buds. In place of the usual connection to the left atrium, at least one connection of the pulmonary plexus to the splanchnic plexus persists. Accordingly, the pulmonary veins drain to the heart through a systemic vein.

Darling and colleagues classified TAPVC according to the site or level of connection of the pulmonary veins to the systemic venous system: type I (45 percent), anomalous connection at the supracardiac level; type II (25 percent), anomalous connection at the cardiac level; type III (25 percent), anomalous connection at the infracardiac level; and type IV (5 percent), anomalous connection at multiple levels. Within each category, further subdivisions can be implemented, depending on whether pulmonary venous obstruction exists. Obstruction to pulmonary venous drainage is a powerful predictor of adverse natural outcome and occurs most frequently with the infracardiac type, especially when the pattern of infracardiac connection prevents the ductus venosus from bypassing the liver.

Pathophysiology and Diagnosis

Because both pulmonary and systemic venous blood return to the right atrium in all forms of TAPVC, a right-to-left intracardiac shunt must be present in order for the afflicted infant to survive. This invariably occurs via a nonrestrictive patent foramen ovale. Because of this obligatory mixing, cyanosis is usually present, and its degree depends on the ratio of pulmonary to systemic blood flow. Decreased pulmonary blood flow is a consequence of pulmonary venous obstruction, the presence of which is unlikely if the right ventricular pressure is less than 85 percent of systemic pressure.

The child with TAPVC may present with severe cyanosis and respiratory distress necessitating urgent surgical intervention if a severe degree of pulmonary venous obstruction is present. However, in cases in which there is no obstructive component, the clinical picture is usually one of pulmonary overcirculation, hepatomegaly, tachycardia, and tachypnea with feeding. In a child with serious obstruction, arterial blood gas analysis reveals severe hypoxemia (P_{O_2} less than 20 mmHg), with metabolic acidosis.

Chest radiography will show normal heart size with generalized pulmonary edema. Two-dimensional echocardiography is very useful in establishing the diagnosis, and also can assess ventricular septal position, which may be leftward secondary to small left ventricular volumes, and estimate the right ventricular pressure based on the height of the tricuspid regurgitant jet. Echocardiography can usually identify the pulmonary venous connections (types I–IV), and it is rarely necessary to perform other diagnostic tests.

Cardiac catheterization is not recommended in these patients because the osmotic load from the intravenous contrast can exacerbate the degree of pulmonary edema. When cardiac catheterization is performed, equalization of oxygen saturations in all four heart chambers is a hallmark finding in this

disease because the mixed blood returned to the right atrium gets distributed throughout the heart.

Therapy

Operative correction of TAPVC requires anastomosis of the common pulmonary venous channel to the left atrium, obliteration of the anomalous venous connection, and closure of the atrial septal defect.

All types of TAPVC are approached through a median sternotomy, and most surgeons use deep hypothermic circulatory arrest to achieve an accurate and widely patent anastomosis. The technique for supracardiac TAPVC includes early division of the vertical vein, retraction of the aorta and the superior vena cava laterally to expose the posterior aspect of the left atrium and the pulmonary venous confluence, and a side-to-side anastomosis between a long, horizontal biatrial incision and a longitudinal incision within the pulmonary venous confluence. The ASD can then be closed with an autologous pericardial patch.

In patients with TAPVC to the coronary sinus without obstruction, a simple unroofing of the coronary sinus can be performed through a single right atriotomy. If pulmonary venous obstruction is present, the repair should include generous resection of roof of the coronary sinus.

Repair of infracardiac TAPVC entails ligation of the vertical vein at the diaphragm, followed by construction of a proximal, patent longitudinal venotomy. This repair is usually performed by "rolling" the heart toward the left, thus exposing the left atrium where it usually overlies the descending vertical vein.

The perioperative care of these infants is crucial because episodes of pulmonary hypertension can occur within the first 48 h, which contribute significantly to mortality following repair. Muscle relaxants and narcotics should be administered during this period to maintain a constant state of anesthesia. Arterial P_{CO_2} should be maintained at 30 mmHg with use of a volume ventilator and the FiO_2 should be increased to keep the pulmonary arterial pressure at less than two-thirds of the systemic pressure.

Results

Results of TAPVC in infancy have markedly improved in recent years, with an operative mortality of 5 percent or less in some series. This improvement is probably multifactorial, mainly as a consequence of early noninvasive diagnosis and aggressive perioperative management. The routine use of echocardiography; improvements in myocardial protection with specific attention to the right ventricle; creation of a large, tension-free anastomosis with maximal use of the venous confluence and atrial tissue; careful geometric alignment of the pulmonary venous sinus with the body of the left atrium avoiding tension and rotation of the pulmonary veins; and prevention of pulmonary hypertensive events have likely played a major role in reducing operative mortality. Risk factors such as venous obstruction at presentation, urgency of operative repair, and infradiaphragmatic anatomic type are no longer correlated with early mortality.

The most significant postoperative complication of TAPVC repair is pulmonary venous obstruction, which occurs 9–11 percent of the time, regardless of the surgical technique employed. Mortality varies between 30 and 45 percent and alternative catheter interventions do not offer definitive solutions. Recurrent pulmonary venous obstruction can be localized at the site of the

pulmonary venous anastomosis (extrinsic), which can usually be cured with patch enlargement or balloon dilatation, or it may be secondary to endocardial thickening of the pulmonary venous ostia frequently resulting in diffuse pulmonary venous sclerosis (intrinsic), which carries a 66 percent mortality rate because few good solutions exist. More commonly, postrepair left ventricular dysfunction can occur as the noncompliant left ventricle suddenly is required to handle an increased volume load from redirected pulmonary venous return. This can manifest as an increase in pulmonary artery pressure but is distinguishable from primary pulmonary hypertension (another possible postoperative complication following repair of TAPVC) from the elevated left atrial pressure found in LV dysfunction along with echocardiographic evidence of poor LV contractility. In pulmonary hypertension, the left atrial (LA) pressure may be low, the LV may appear “underfilled” (by echocardiography), and the RV may appear dilated. In either case, postoperative support for a few days with extracorporeal membrane oxygenation (ECMO) may be life-saving, and TAPVC should be repaired in centers that have this capacity.

Some investigators have speculated that preoperative pulmonary venous obstruction is associated with increased medial thickness within the pulmonary vasculature, which may predispose these infants to intrinsic pulmonary venous stenosis despite adequate pulmonary venous decompression. Another complication following repair of TAPVC is the development of atrial arrhythmias secondary to altered atrial geometry and left atrial enlargement procedures. These arrhythmias may be asymptomatic, and certain surgeons therefore advocate routine long-term follow-up with 24-h ECG monitoring to facilitate their detection and treatment.

DEFECTS REQUIRING PALLIATION

Hypoplastic Left-Heart Syndrome (HLHS)

Hypoplastic Left-Heart Syndrome (HLHS) comprises a wide spectrum of cardiac malformations, including hypoplasia or atresia of the aortic and mitral valves and hypoplasia of the left ventricle and ascending aorta. HLHS has a reported prevalence of 0.2 per 1000 live births and occurs twice as often in boys as in girls. Left untreated, HLHS is invariably fatal and is responsible for 25 percent of early cardiac deaths in neonates. However, the recent evolution of palliative surgical procedures has dramatically improved the outlook for patients with HLHS, and an improved understanding of anatomic and physiologic alterations have spurred advances in parallel arenas such as intrauterine diagnosis and fetal intervention, echocardiographic imaging, and neonatal critical care.

Anatomy

As implied by its name, HLHS involves varying degrees of underdevelopment of left-sided structures, including the left ventricle and the aortic and mitral valves. Thus, HLHS can be classified into four anatomic subtypes based on the valvular morphology: (1) aortic and mitral stenosis; (2) aortic and mitral atresia; (3) aortic atresia and mitral stenosis; and (4) aortic stenosis and mitral atresia. Aortic atresia tends to be associated with more-severe degrees of hypoplasia of the ascending aorta than does aortic stenosis.

Even in cases without frank aortic atresia, however, the aortic arch is generally hypoplastic and, in severe cases, may even be interrupted. There is an associated coarctation shelf in 80 percent of patients with HLHS, and the

ductus itself is usually quite large, as is the main pulmonary artery. The segmental pulmonary arteries, however, are small, secondary to reduced intrauterine pulmonary blood flow, which is itself a consequence of the left-sided outflow obstruction. The left atrial cavity is generally smaller than normal, and is accentuated because of the leftward displacement of the septum primum. There is almost always an interatrial communication via the foramen ovale, which can be large, but more commonly restricts right-to-left flow. In rare cases, there is no atrial-level communication, which can be lethal for these infants because there is no way for pulmonary venous return to cross over to the right ventricle.

Associated defects can occur with HLHS, and many of them have importance with respect to operative repair. For example, if a ventricular septal defect is present, the left ventricle can retain its normal size during development even in the presence of mitral atresia. This is because a right-to-left shunt through the defect impels growth of the left ventricle. This introduces the feasibility of biventricular repair for this subset of patients.

Although HLHS undoubtedly results from a complex interplay of developmental errors in the early stages of cardiogenesis, many investigators have hypothesized that the altered blood flow is responsible for the structural underdevelopment that characterizes HLHS. In other words, if the stimulus for normal development of the ascending aorta from the primordial aortic sac is high-pressure systemic blood flow from the left ventricle through the aortic valve, then an atretic or stenotic aortic valve, which impedes flow and leads to only low-pressure diastolic retrograde flow via the ductus, will change the developmental signals and result in hypoplasia of the downstream structures. Normal growth and development of the left ventricle and mitral valve can be secondarily affected, resulting in hypoplasia or atresia of these structures.

Pathophysiology and Diagnosis

Neonates with severe HLHS receive all pulmonary, systemic, and coronary blood flow from the right ventricle. Generally, a child with HLHS will present with respiratory distress within the first day of life, and mild cyanosis may be noted. These infants must be rapidly triaged to a tertiary center, and echocardiography should be performed to confirm the diagnosis. Prostaglandin E1 must be administered to maintain ductal patency, and the ventilatory settings adjusted to avoid excessive oxygenation and increase carbon dioxide tension. These maneuvers will maintain pulmonary vascular resistance and promote improved systemic perfusion. Cardiac catheterization should generally be avoided because it is not usually helpful and might result in injury to the ductus and compromised renal function secondary to the osmotic dye load.

Treatment

In 1983, Norwood and colleagues described a two-stage palliative surgical procedure for relief of HLHS that was later modified to the currently used three-stage method of palliation. Stage 1 palliation, also known as the modified Norwood procedure, bypasses the left ventricle by creating a single outflow vessel, the neo-aorta, which arises from the right ventricle.

The current technique of arch reconstruction involves completion of a connection between the pulmonary root, the native ascending aorta, and a piece of pulmonary homograft used to augment the diminutive native aorta. There are several modifications of this anastomosis, most notably the

Damus-Kaye-Stansel (DKS) anastomosis, which involves dividing both the aorta and the pulmonary artery at the sinotubular junction. The proximal aorta is anastomosed to the proximal pulmonary artery creating a “double-barreled” outlet from the heart. This outlet is anastomosed to the distal aorta, which can be augmented with homograft material if there is an associated coarctation. At the completion of arch reconstruction, a 3.5- or 4-mm shunt is placed from the innominate artery to the right pulmonary artery. The interatrial septum is then widely excised, thereby creating a large interatrial communication and preventing pulmonary venous hypertension.

The DKS connection, as described above, might avoid postoperative distortion of the tripartite connection in the neo-aorta, and thus decrease the risk of coronary insufficiency. It can be used when the aorta is 4 mm or larger. Unfortunately, in many infants with HLHS; especially if there is aortic atresia; the aorta is diminutive and often less than 2 mm in diameter.

Following stage 1 palliation, the second surgical procedure is the creation of a bidirectional cavopulmonary shunt, generally at 3–6 months of life when the pulmonary vascular resistance has decreased to normal levels. This is the first step in separating the pulmonary and systemic circulations, and it decreases the volume load on the single ventricle. The existing innominate artery-to-pulmonary shunt (or RV-pulmonary shunt) is eliminated during the same operation.

The third stage of surgical palliation, known as the modified Fontan procedure, completes the separation of the systemic and pulmonary circulations and is performed between 18 months and 3 years of age, or when the patient has outgrown the capacity to perfuse the systemic circulation with adequately oxygenated blood and becomes progressively cyanotic. This has traditionally required a lateral tunnel within the right atrium to direct blood from the inferior vena cava to the pulmonary artery, allowing further relief of the volume load on the right ventricle, and providing increased pulmonary blood flow to alleviate cyanosis. More recently, many favor using an extracardiac conduit (e.g., 20-mm tube graft) to connect the inferior vena cava to the pulmonary artery.

Not all patients with HLHS require this three-stage palliative repair. Some infants afflicted with a milder form of HLHS, recently described as hypoplastic left-heart complex (HLHC), have aortic or mitral hypoplasia without intrinsic valve stenosis and antegrade flow in the ascending aorta. In this group, a two-ventricle repair can be achieved with reasonable outcome.

Transplantation can be used as a first-line therapy or when anatomic or physiologic considerations exist that preclude a favorable outcome with palliative repair. Significant tricuspid regurgitation, intractable pulmonary artery hypertension, or progressive right ventricular failure, are cases in which cardiac replacement may be advantageous. The local probability of organ availability should be considered prior to electing transplantation, as 24 percent of infants died awaiting transplantation in the largest series to date.

Results

Outcomes for HLHS are still significantly worse than those for other complex cardiac defects. However, with improvements in perioperative care and modifications in surgical technique, the survival following the Norwood procedure now exceeds 80 percent in experienced centers. The outcome for low-birth-weight infants has improved, but low weight still remains a major predictor of adverse survival, especially when accompanied by additional

cardiac defects, such as systemic outflow obstruction, or extracardiac anomalies.

DEFECTS THAT MAY BE PALLIATED OR REPAIRED

Transposition of the Great Arteries

Anatomy

Complete transposition is characterized by connection of the atria to their appropriate ventricles with inappropriate ventriculoarterial connections. Thus, the aorta arises anteriorly from the right ventricle, although the pulmonary artery arises posteriorly from the left ventricle. Van Praagh and coworkers introduced the term D-transposition of the great arteries (D-TGA) to describe this defect, although L-TGA describes a form of corrected transposition in which there is concomitant atrioventricular discordance.

D-TGA requires an obligatory intracardiac mixing of blood, which usually occurs at both the atrial and the ventricular levels or via a patent ductus.

Pathophysiology

D-TGA results in parallel pulmonary and systemic circulations, with patient survival dependent on intracardiac mixing of blood. Postnatally, the left ventricle does not hypertrophy because it is not subjected to systemic afterload. The lack of normal extrauterine left ventricular maturation has important implications for the timing of surgical repair because the LV must be converted to the systemic ventricle early enough to allow adaptation, usually within a few weeks after birth.

Clinical Manifestations and Diagnosis

Infants with D-TGA and an IVS are usually cyanotic at birth, with an arterial Po_2 between 25 and 40 mm Hg. If ductal patency is not maintained, deterioration will be rapid with ensuing metabolic acidosis and death. Conversely, those infants with a coexisting VSD may be only mildly hypoxemic and may come to medical attention after 2–3 weeks, when the falling PVR leads to symptoms of CHF.

The ECG will reveal right ventricular hypertrophy, and the chest radiograph will reveal the classic egg-shaped configuration. Definitive diagnosis is made by echocardiography, which reliably demonstrates ventriculoarterial discordance and any associated lesions. Cardiac catheterization is rarely necessary, except in those infants requiring surgery after the neonatal period to assess the suitability of the LV to support the systemic circulation. Limited catheterization, however, is useful for performance of atrial septostomy in those neonates with inadequate intracardiac mixing.

Surgical Repair

Blalock and Hanlon introduced the first operative intervention for D-TGA with the creation of an atrial septectomy to enhance intracardiac mixing. This initial procedure was feasible in the precardiopulmonary bypass era, but carried a high mortality rate. Later, Rashkind and Causo developed a catheter-based balloon septostomy, which largely obviated the need for open septectomy.

These early palliative maneuvers, however, met with limited success, and it was not until the late 1950s, when Senning and Mustard developed the first

“atrial repair,” that outcomes improved. The Senning operation consisted of rerouting venous flow at the atrial level by incising and realigning the atrial septum over the pulmonary veins and using the right atrial free wall to create a pulmonary venous baffle.

Although the Mustard repair was similar, it made use of either autologous pericardium or synthetic material to create the interatrial baffle. These atrial switch procedures resulted in a physiologic correction, but not an anatomic one, as the systemic circulation is still based on the right ventricle. Still, survival rose to 95 percent in most centers by using an early balloon septostomy followed by an atrial switch procedure at 3–8 months of age.

Despite the improved early survival rates, long-term problems, such as superior vena cava or pulmonary venous obstruction, baffle leak, arrhythmias, tricuspid valve regurgitation, and right ventricular failure, prompted the development of the arterial switch procedure by Jatene in 1975. The arterial switch procedure involves the division of the aorta and the pulmonary artery, posterior translocation of the aorta (LeCompte maneuver), mobilization of the coronary arteries, placement of a pantaloon-shaped pericardial patch, and proper alignment of the coronary arteries on the neo-aorta.

The most important consideration is the timing of surgical repair, because arterial switch should be performed within 2 weeks after birth, before the left ventricle loses its ability to pump against systemic afterload. In patients presenting later than 2 weeks, the left ventricle can be retrained with preliminary pulmonary artery banding and aortopulmonary shunt followed by definitive repair. Alternatively, the unprepared left ventricle can be supported following arterial switch with a mechanical assist device for a few days although it recovers ability to manage systemic pressures. Echocardiography can be used to assess left ventricular performance and guide operative planning in these circumstances.

For patients with D-TGA, IVS, and VSD the arterial switch operation provides excellent long-term results with a mortality rate of less than 5 percent. Operative risk is increased when unfavorable coronary anatomic configurations are present, or when augmentation of the aortic arch is required. The most common complication is supravalvular pulmonary stenosis, occurring 10 percent of the time, which may require reoperation.

Results of the Rastelli operation have improved substantially, with an early mortality rate of 5 percent in a recent review. Late mortality rate results were less favorable because conduit failure requiring reoperation, pacemaker insertion, or relief of left ventricular outflow obstruction were frequent.

Tetralogy of Fallot

Anatomy

The four features of tetralogy of Fallot (TOF) are (1) malalignment ventricular septal defect, (2) dextroposition of the aorta, (3) right ventricular outflow tract obstruction, and (4) right ventricular hypertrophy. This combination of defects arises as a result of underdevelopment and anteroleftward malalignment of the infundibular septum.

Anomalous coronary artery patterns, related to either origin or distribution, have been described in TOF. However, the most surgically important coronary anomaly occurs when the left anterior descending artery arises as a branch of the right coronary artery. This occurs in approximately 3 percent of cases of

TOF and may preclude placement of a transannular patch, as the left anterior descending coronary artery crosses the RVOT at varying distances from the pulmonary valve annulus.

Coexisting lesions are uncommon in TOF, but the most frequently associated lesions are atrial septal defect, patent ductus arteriosus, complete atrioventricular septal defect, and multiple VSDs.

Pathophysiology and Clinical Presentation

The initial presentation of a child afflicted with TOF depends on the degree of RVOT obstruction. Those children with cyanosis at birth usually have severe pulmonary annular hypoplasia with concomitant hypoplasia of the peripheral pulmonary arteries. Most children, however, present with mild cyanosis at birth, which then progresses as the right ventricular hypertrophy further compromises the RVOT. Cyanosis usually becomes significant within the first 6–12 months of life, and the child may develop characteristic “tet” spells, which are periods of extreme hypoxemia. These spells are characterized by decreased pulmonary blood flow and an increase in aortic flow. They can be triggered by any stimulus that decreases systemic vascular resistance, such as fever or vigorous physical activity. Cyanotic spells increase in severity and frequency as the child grows, and older patients with uncorrected TOF may often squat, which increases peripheral vascular resistance and relieves the cyanosis.

Physical examination in the older patient with TOF may demonstrate clubbing, polycythemia, or brain abscesses. Chest radiography will demonstrate a boot-shaped heart, and ECG will show the normal pattern of right ventricular hypertrophy. Echocardiography confirms the diagnosis because it demonstrates the position and nature of the VSD, defines the character of the RVOT obstruction, and often visualizes the branch pulmonary arteries and the proximal coronary arteries. Cardiac catheterization is rarely necessary and is actually risky in TOF because it can create spasm of the RVOT muscle and result in a hypercyanotic episode (tet spell). Occasionally, aortography is necessary to delineate the coronary artery anatomy.

Treatment

The optimal age and surgical approach of repair of TOF have been debated for several decades. Currently, most centers favor primary elective repair in infancy, as contemporary perioperative techniques have improved outcomes substantially in this population. Additionally, definitive repair protects the heart and other organs from the pathophysiology inherent in the defect, and its palliated state.

However, systemic-to-pulmonary shunts, generally a B-T shunt, may still be preferred with an unstable neonate younger than 6 months of age, when an extracardiac conduit is required because of an anomalous left anterior descending coronary artery, or when pulmonary atresia, significant branch pulmonary artery hypoplasia, or severe noncardiac anomalies coexist with TOF.

Traditionally, TOF was repaired through a right ventriculotomy, providing excellent exposure for closure of the VSD and relief of the RVOT obstruction, but concerns that the resultant scar would significantly impair right ventricular function or lead to lethal arrhythmias led to the development of a transatrial approach. Transatrial repair, except in cases when the presence of diffuse RVOT hypoplasia requires insertion of a transannular patch, is now being increasingly

advocated by many, although its superiority has not been conclusively demonstrated.

Results

Operative mortality for primary repair of TOF in infancy is less than 5 percent in most series. Previously reported risk factors such as transannular patch insertion or younger age at time of repair have been eliminated secondary to improved intraoperative and postoperative care.

A major complication of repaired TOF is the development of pulmonary insufficiency, which subjects the RV to the adverse effects of acute and chronic volume overload. This is especially problematic if residual lesions such as a VSD or peripheral pulmonary stenosis exists. When significant deterioration of ventricular function occurs, insertion of a pulmonary valve may be required, although this is rarely necessary in infants.

Ventricular Septal Defect

Anatomy

VSD refers to a hole between the left and right ventricles. These defects are common, comprising 20–30 percent of all cases of congenital heart disease, and may occur as an isolated lesion or as part of a more complex malformation. VSDs vary in size from 3–4 mm to more than 3 cm, and are classified into four types based on their location in the ventricular septum: perimembranous, atrioventricular canal, outlet or supracristal, and muscular.

Perimembranous VSDs are the most common type requiring surgical intervention, comprising approximately 80 percent of cases. These defects involve the membranous septum and include the malalignment defects seen in tetralogy of Fallot. In rare instances, the anterior and septal leaflets of the tricuspid valve adhere to the edges of the perimembranous defect, forming a channel between the left ventricle and the right atrium. These defects result in a large left-to-right shunt owing to the large pressure differential between the two chambers.

Atrioventricular canal defects, also known as inlet defects, occur when part or all of the septum of the AV canal is absent. The VSD lies beneath the tricuspid valve and is limited upstream by the tricuspid annulus, without intervening muscle.

The supracristal or outlet VSD results from a defect within the conal septum. Characteristically, these defects are limited upstream by the pulmonary valve and are otherwise surrounded by the muscle of the infundibular septum.

Muscular VSDs are the most common type, and may lie in four locations: anterior, midventricular, posterior, or apical. These are surrounded by muscle, and can occur anywhere along the trabecular portion of the septum. The rare “Swiss-cheese” type of muscular VSD consists of multiple communications between the right and left ventricles, complicating operative repair.

Pathophysiology and Clinical Presentation

The size of the VSD determines the initial pathophysiology of the disease. Large VSDs are classified as nonrestrictive, and are at least equal in diameter to the aortic annulus. These defects allow free flow of blood from the left ventricle to the right ventricle, elevating right ventricular pressures to the same level as systemic pressure. Consequently, Qp:Qs is inversely dependent on the ratio of pulmonary vascular resistance to systemic vascular resistance.

Nonrestrictive VSDs produce a large increase in pulmonary blood flow, and the afflicted infant will present with symptoms of congestive heart failure. However, if untreated, these defects will cause pulmonary hypertension with a corresponding increase in pulmonary vascular resistance. This will lead to a reversal of flow (a right-to-left shunt), which is known as Eisenmenger's syndrome.

Small restrictive VSDs offer significant resistance to the passage of blood across the defect, and therefore right ventricular pressure is either normal or only minimally elevated and Qp:Qs rarely exceeds 1.5. These defects are generally asymptomatic because there are few physiologic consequences. However, there is a long-term risk of endocarditis, because endocardial damage from the jet of blood through the defect may serve as a possible nidus for colonization.

Diagnosis

The child with a large VSD will present with severe congestive heart failure and frequent respiratory tract infections. Those children with Eisenmenger syndrome may be deceptively asymptomatic until frank cyanosis develops.

The chest radiograph will show cardiomegaly and pulmonary overcirculation and the ECG will show signs of left ventricular or biventricular hypertrophy. Echocardiography provides definitive diagnosis, and can estimate the degree of shunting and pulmonary arterial pressures. Cardiac catheterization has largely been supplanted by echocardiography, except in older children in which measurement of pulmonary resistance is necessary prior to recommending closure of the defect.

Treatment

VSDs may close or narrow spontaneously, and the probability of closure is inversely related to the age at which the defect is observed. Thus, infants at 1 month of age have an 80 percent incidence of spontaneous closure, whereas a child at 12 months of age has only a 25 percent chance of closure. This has an important impact on operative decision making, because a small or moderate-size VSD may be observed for a period of time in the absence of symptoms. Large defects and those in severely symptomatic neonates should be repaired during infancy to relieve symptoms and because irreversible changes in pulmonary vascular resistance may develop during the first year of life.

Repair of isolated VSDs requires the use of cardiopulmonary bypass with moderate hypothermia and cardioplegic arrest. The right atrial approach is preferable for most defects, except apical muscular defects, which often require a left ventriculotomy for adequate exposure. Supracristal defects may alternatively be exposed via a longitudinal incision in the pulmonary artery a transverse incision in the right ventricle below the pulmonary valve. Regardless of the type of defect present, a right atrial approach can be used initially to inspect the anatomy, as this may be abandoned should it offer inadequate exposure for repair. After careful inspection of the heart for any associated malformations, a patch repair is employed, taking care to avoid the conduction system. Routine use of intraoperative transesophageal echocardiography should be used to assess for any residual defects.

Successful percutaneous device closure of VSDs using the Amplatzer muscular VSD was recently described. The device has demonstrated a 100 percent closure rate in a small series of patients with isolated or residual VSDs, or as a collaborative treatment strategy for the VSD component in more complex congenital lesions. Proponents of device closure argue that their use

can decrease the complexity of surgical repair, avoid reoperation for a small residual lesion, or avoid the need for a ventriculotomy.

Multiple or “Swiss-cheese” VSDs represent a special case, and many cannot be repaired during infancy. In those patients in whom definitive VSD closure cannot be accomplished, temporary placement of a pulmonary artery band can be employed to control pulmonary flow. This allows time for spontaneous closure of many of the smaller defects, thus simplifying surgical repair.

Some centers, however, have advocated early definitive repair of the Swiss-cheese septum, by using oversize patches, fibrin glue, and combined intraoperative device closure, and techniques to complete the repair transatrially. At the UCSF, 69 percent of patients with multiple VSDs underwent single-stage correction, and the repaired group had improved outcome as compared to the palliated group.

Results

Even in very small infants, closure of VSDs can be safely performed with hospital mortality near 0 percent. The main risk factor remains the presence of other associated lesions, especially when present in symptomatic neonates with large VSDs.

Clinical Evaluation

The importance of the history and physical examination when evaluating a patient with acquired heart disease for potential surgery cannot be overemphasized. It is imperative that the surgeon be well aware of the functional status of the patient and the clinical relevance of each symptom because operative decisions depend on the accurate assessment of the significance of a particular pathologic finding. Associated risk factors and coexisting conditions must be identified, as they significantly influence a patient's operative risk for cardiac or noncardiac surgery.

Symptoms

The classic symptoms of heart disease are fatigue, angina, dyspnea, edema, cough or hemoptysis, palpitations, and syncope as outlined by Braunwald. An important feature of cardiac disease is that myocardial function or coronary blood supply that may be adequate at rest may become inadequate with exercise or exertion. Thus chest pain or dyspnea that occurs primarily during exertion is frequently cardiac in origin, although symptoms that occur at rest often are not.

In addition to evaluating the patient's primary symptoms, the history should include a family history, past medical history (prior surgery or myocardial infarction [MI], concomitant hypertension, diabetes, and other associated diseases), personal habits (smoking, alcohol or drug use), functional capacity, and a detailed review of systems.

Easy fatigability is a frequent but nonspecific symptom of cardiac disease that can arise from many causes. In some patients, easy fatigability reflects a generalized decrease in cardiac output or low-grade heart failure. The significance of subjective easy fatigability is vague and nonspecific.

Angina pectoris is the hallmark of myocardial ischemia secondary to coronary artery disease, although a variety of other conditions can produce chest pain. Classic angina is precordial pain described as squeezing, heavy, or burning in nature, lasting from 2–10 min. Angina usually is provoked by exercise, emotion, sexual activity, or eating, and is relieved by rest or nitroglycerin. Angina is present in its classic form in 75 percent of patients with coronary disease, although atypical symptoms occur in 25 percent of patients and more frequently in women. A small but significant number of patients have "silent" ischemia, most typically occurring in diabetics. Angina also is a classic symptom of aortic stenosis.

Noncardiac causes of chest pain that may be confused with angina include gastroesophageal reflux disease, musculoskeletal pain, peptic ulcer disease, costochondritis, biliary tract disease, pleuritis, pulmonary embolus, pulmonary hypertension, pericarditis, and aortic dissection. Dyspnea appears as an early sign in patients with mitral stenosis because of restriction of flow from the left atrium into the left ventricle. However, with other forms of heart disease dyspnea is a late sign, as it develops only after the left ventricle has failed and

the end-diastolic pressure rises significantly. Dyspnea associated with mitral insufficiency, aortic valve disease, or coronary disease represents relatively advanced pathophysiology.

A number of other respiratory symptoms represent different degrees of pulmonary congestion. These include orthopnea, paroxysmal nocturnal dyspnea, cough, hemoptysis, and pulmonary edema. Occasionally dyspnea represents an “angina equivalent,” occurring secondary to ischemia-related left ventricular dysfunction. This finding is more common in women and in diabetic patients.

Left-sided heart failure may result in fluid retention and pulmonary congestion, subsequently leading to pulmonary hypertension and progressive right-sided heart failure. A history of exertional dyspnea with associated edema is frequently because of heart failure.

Palpitations are secondary to rapid, forceful, ectopic, or irregular heartbeats. These should not be ignored, as occasionally they represent significant or potentially life-threatening arrhythmias. The underlying cardiac arrhythmia may range from premature atrial or ventricular contractions to atrial fibrillation, atrial flutter, paroxysmal atrial or junctional tachycardia, or sustained ventricular tachycardia.

Atrial fibrillation is one of the most common causes of palpitations. It is a common arrhythmia in patients with mitral stenosis, and results from left atrial hypertrophy that evolves from sustained elevation in left atrial pressure. Palpitations caused by a slow heart rate are frequently because of complete or intermittent atrioventricular nodal block.

Severe, life-threatening forms of ventricular tachycardia or ventricular fibrillation may occur in any patient with ischemic disease, either from ongoing ischemia or from prior infarction and myocardial scarring.

Syncope, or sudden loss of consciousness, is usually a result of sudden decreased perfusion of the brain. The differential diagnosis includes: (1) third-degree heart block with bradycardia or asystole, (2) malignant ventricular tachyarrhythmias or ventricular fibrillation, (3) aortic stenosis, (4) hypertrophic cardiomyopathy, (5) carotid artery disease, (6) seizure disorders, and (7) vasovagal reaction. Many of these conditions can result in sudden death.

Functional Disability and Angina

An important part of the history is the assessment of the patient's overall cardiac functional disability, which is a good approximation of the severity of the patient's underlying disease. The New York Heart Association (NYHA) has developed a classification of patients with heart disease based on symptoms and functional disability (Table 20-1). A different grading system for patients with ischemic disease, developed by the Canadian Cardiovascular Society (CCS), is used to assess the severity of angina (Table 20-2).

Cardiac Risk Assessment in General Surgery Patients

Cardiac risk stratification for patients undergoing noncardiac surgery is an important part of the preoperative evaluation of the general surgery patient. The joint American College of Cardiology/American Heart Association (ACC/AHA) task force, chaired by Eagle, recently reported guidelines and recommendations. In general, the preoperative cardiovascular evaluation involves an assessment of clinical markers, the patient's underlying functional capacity, and various surgery-specific risk factors.

TABLE 20-1 New York Heart Association Functional Classification

Class I: Patients with cardiac disease but without resulting limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or angina pain.

Class II: Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina pain.

Class III: Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.

Class IV: Patients with cardiac disease resulting in an inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

Based on the clinical markers, the functional class of the patient, and the proposed surgical procedure, the patient is assigned a high, intermediate, or low cardiac risk, and then managed appropriately. In patients who are considered high cardiac risk because of clinical markers or by virtue of noninvasive testing, coronary angiography may be recommended prior to surgery. Because of the common atherosclerotic etiology and the close association between clinically relevant coronary artery disease and peripheral vascular disease, patients undergoing major vascular surgery should be screened closely. Any significant underlying coronary disease should be aggressively treated, either with intensive perioperative management or with coronary revascularization prior to surgery, using standard indications.

Diagnostic Studies

Electrocardiogram and Chest Radiograph

The electrocardiogram (ECG) and the chest radiograph are the two classic diagnostic studies. The electrocardiogram is used to detect rhythm disturbances, heart block, atrial or ventricular hypertrophy, ventricular strain, myocardial ischemia, and MI. The chest radiograph is excellent for determining cardiac enlargement and pulmonary congestion, and for assessing associated pulmonary pathology.

TABLE 20-2 Canadian Cardiovascular Society

Class I: Ordinary physical activity, such as walking or climbing stairs, does not cause angina. Angina may occur with strenuous, rapid, or prolonged exertion at work or recreation.

Class II: There is slight limitation of ordinary activity. Angina may occur with walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals or in the cold, in the wind, or under emotional stress, or walking more than two blocks on the level, or climbing more than one flight of stairs under normal conditions at a normal pace.

Class III: There is marked limitation of ordinary physical activity. Angina may occur after walking one or more blocks on the level or climbing one flight of stairs under normal conditions at a normal pace.

Class IV: There is inability to carry on any physical activity without discomfort; angina may be present at rest.

Echocardiography

Echocardiography has become the most widely used cardiac diagnostic study. It incorporates the use of ultrasound and reflected acoustic waves for cardiac imaging. Intracardiac pressures, valvular insufficiency, and transvalvular gradients can be estimated from Doppler measurements. Transthoracic echocardiography has become an excellent noninvasive screening test for evaluating cardiac size and wall motion and for assessing valvular pathology.

Transesophageal echocardiography (TEE), which is done by placement of the two-dimensional transducer in a flexible endoscope is particularly useful in evaluation of the left atrium, the mitral valve, and the aortic arch. TEE studies are used when more precise imaging is required or when the diagnosis is uncertain after the transthoracic study. Dobutamine stress echocardiography has evolved as an important noninvasive provocative study and is used to assess cardiac wall motion in response to inotropic stimulation.

Radionuclide Studies

Currently the most widely used myocardial perfusion screening study is the thallium scan, which uses the nucleide thallium-201. Initial uptake of thallium-201 into myocardial cells is dependent on myocardial perfusion, although delayed uptake depends on myocardial viability. Thus, reversible defects occur in underperfused, ischemic, but viable zones, although fixed defects occur in areas of infarction.

The exercise thallium test is widely used to identify inducible areas of ischemia and is 95 percent sensitive in detecting multivessel coronary disease. This is the best overall test to detect myocardial ischemia, but it requires the patient to exercise on the treadmill. The dipyridamole thallium study is a provocative study using intravenous dipyridamole, which induces vasodilation and consequently unmasks myocardial ischemia in response to stress. This is the most widely used provocative study for risk stratification for patients who cannot exercise. Global myocardial function frequently is evaluated by the gated blood pool scan (equilibrium radionuclide angiocardiology) using technetium-99m (99mTc). This study can detect areas of hypokinesis and measure left ventricular ejection fraction, end-systolic volume, and end-diastolic volume. An exercise-gated blood pool scan is an excellent method for assessing a patient's global cardiac response to stress.

Positron Emission Tomography Scan

The positron emission tomography (PET) scan is a special radionuclide imaging technique used to assess myocardial viability in underperfused areas of the heart. PET allows the noninvasive functional assessment of perfusion, substrate metabolism, and cardiac innervation in vivo. The PET scan may be most useful in determining whether an area of apparently infarcted myocardium may in fact be hibernating and capable of responding to revascularization.

Magnetic Resonance Imaging Viability Studies

Magnetic resonance imaging (MRI) may be used to delineate the transmural extent of MI and to distinguish between reversible and irreversible myocardial ischemic injury.

Cardiac Catheterization

The cardiac catheterization study remains an important part of cardiac diagnosis. Complete cardiac catheterization includes the measurement of intracardiac

pressures, cardiac output, localization of intracardiac shunts, determination of internal cardiac anatomy, ventricular wall motion by cineradiography, and determination of coronary anatomy by coronary angiography. During cardiac catheterization the cardiac output can be calculated using the Fick oxygen method, in which cardiac index (l/min per square meter) = oxygen consumption (mL/min per square meter)/arteriovenous oxygen content difference (mL/min).

The area of a cardiac valve can be determined from measured cardiac output and intracardiac pressures using Gorlin formula. This formula relates the valve area to the flow across the valve divided by the square root of the transvalvular pressure gradient. The significance of valvular stenosis should be based on the calculated valve area (the normal mitral valve area is 4 to 6 cm² and the normal aortic valve area is 2.5–3.5 cm² in adults).

Coronary angiography is currently the primary diagnostic procedure for determining the degree of coronary artery disease. The left coronary system supplies the major portion of the left ventricular myocardium, through the left main, left anterior descending, and circumflex coronary arteries. The right coronary artery supplies the right ventricle, and the posterior descending artery supplies the inferior wall of the left ventricle. The atrioventricular (AV) nodal artery arises from the right coronary artery in 80–85 percent of patients, termed right dominant circulation. In 15–20 percent of cases the circumflex branch of the left coronary system supplies the posterior descending branch and the AV nodal artery, termed left dominant, although 5 percent are codominant.

Computed Tomography Coronary Angiography

Technologic advances in computed tomography (CT) now allow less invasive imaging of the coronary anatomy. Newer rapid CT coronary angiography has been shown to be extremely sensitive in detecting coronary stenoses, comparable to traditional angiography in some recent studies.

Extracorporeal Perfusion

The pioneering imagination and efforts of Gibbon were largely responsible for the development of extracorporeal circulation (cardiopulmonary bypass [CPB] with pump-oxygenators). Subsequently, bubble oxygenators were developed, using a blood-gas interface, although membrane oxygenators now widely used use a blood-membrane-gas interface for oxygenation and gas exchange. In addition to the oxygenator, the initial heart-lung machine used a simple roller pump, developed by DeBakey, for perfusion. A variety of other pumps have subsequently been used, such as the centrifugal pump, which minimizes trauma to blood elements.

Technique

Heparin is given to elevate the activated clotting time (ACT) above 500 seconds starting with a heparin dose of 3–4 mg/kg. At New York University (NYU), a centrifugal pump is used for arterial perfusion, in combination with vacuum-assisted venous drainage and a membrane oxygenator. Venous blood was traditionally drained by gravity through large cannulae, but more recently vacuum-assisted venous drainage has been used. Flow rates during extracorporeal perfusion depend on the body oxygen consumption requirements of the patient, which vary based on the patient's body temperature. Normothermic perfusion is done at a flow rate of about 2.5–3.5 L/min per square

meter, which is the normal cardiac index. Because hypothermia decreases the metabolic rate (approximately 50 percent for each 7°C [44.6°F]), flow rates can be diminished as the patient is cooled. Oxygen flow through the oxygenator is adjusted to produce an arterial oxygen tension above 150 mm Hg. Systemic temperature is controlled with a heat exchanger in the circuit; the temperature is usually lowered to 25–32°C (77–89.6°F), although colder temperatures are necessary for more complex procedures. Spilled intracardiac blood is aspirated with a suction apparatus, filtered, and returned to the oxygenator. A cell-saving device is routinely used to aspirate spilled blood before and after bypass.

Once the operation is completed and the patient is systemically rewarmed to normothermic levels, perfusion is slowed and then stopped. Prior to discontinuing bypass, the surgeon checks the ECG, potassium level, hematocrit, and hemostasis of the suture lines. Both visual inspection and TEE are used to assess myocardial contractility. As the perfusion flow rate is slowed, the patient's blood is returned from the pump to the patient, restoring normal intracardiac pressures. After discontinuing bypass, heparin is neutralized with protamine, which is given to achieve the baseline ACT.

Systemic Response

Significant changes in bodily functions occur during extracorporeal perfusion. These changes mainly involve platelet dysfunction and a generalized systemic inflammatory response syndrome (SIRS), because of the activation of complement and other acute phase inflammatory components by extracorporeal circuits. Aprotinin and steroids may attenuate the inflammatory response to bypass, although aprotinin and ϵ -aminocaproic acid diminish coagulopathy. Zero-balance ultrafiltration (Z-BUF) is a method of ultrafiltration during CPB. This technique removes significant amounts of inflammatory mediators associated with CPB, and potentially attenuates the adverse effects of bypass although maintaining the patient's volume status.

Myocardial Protection

The development of a myocardial protective solution (cardioplegia) to induce asystolic cardiac arrest and protect the heart muscle during cardiac surgery was a major advance. The primary theory is that when infused through the coronary circulation, cold, high-potassium cardioplegic solution produces diastolic arrest, slowing the metabolic rate and protecting the heart from ischemia. The arrested heart allows the surgeon to work precisely on the heart in a bloodless field.

CORONARY ARTERY DISEASE

History

Starting in the late 1930s, different investigators attempted to increase the blood supply to the ischemic heart by developing collateral circulation with vascular adhesions. In 1946, Vineberg developed implantation of the internal mammary artery into a tunnel in the myocardium. Coronary artery endarterectomy for coronary revascularization was attempted by Longmire. Late results were poor, however, because of progressive restenosis and occlusion. Shortly thereafter, CPB was used to facilitate coronary revascularization.

The development of the coronary artery bypass operation in the 1960s was a dramatic medical milestone. In the United States, the principal credit belongs to Favaloro and Effler from the Cleveland Clinic, who did the first series of

coronary bypass grafts beginning in 1967, using CPB and saphenous vein grafts, launching the modern era of coronary bypass surgery. An additional breakthrough came in 1968 when Green and colleagues performed the first left internal mammary artery to left anterior descending artery bypass.

Etiology and Pathogenesis

The etiology of coronary artery disease is atherosclerosis. The disease is multifactorial, with the primary risk factors being hyperlipidemia, smoking, diabetes, hypertension, obesity, sedentary lifestyle, and male gender. Newly identified risk factors include elevated levels of C-reactive protein, lipoprotein (a), and homocysteine. Atherosclerosis is the leading cause of death in the Western world, and acute MI alone accounts for 25 percent of the deaths in the United States each year.

Among the three major coronary arteries, the proximal anterior descending artery frequently is stenosed or occluded, with the distal half of the artery remaining patent. The right coronary artery often is stenotic or occluded throughout its course, but the posterior descending and left atrioventricular groove branches almost always are patent. The circumflex artery often is diseased proximally, but one or more distal marginal branches usually are patent.

Clinical Manifestations

Myocardial ischemia from coronary artery disease may result in angina pectoris, MI, congestive heart failure, or cardiac arrhythmias and sudden death. Angina is the most frequent symptom, but MI may appear without prior warning. Congestive heart failure usually results as a sequela of MI, with significant muscular injury resulting in ischemic myopathy.

Angina pectoris, the most common manifestation, manifests by periodic chest discomfort, usually substernal, and typically appearing with exertion. Establishing a diagnosis of myocardial ischemia in these patients is difficult and perhaps impossible without provocative diagnostic studies. The differential diagnosis in patients with atypical symptoms includes aortic stenosis, hypertrophic cardiomyopathy, musculoskeletal disorders, pulmonary disease, gastritis or peptic ulcer disease, gastroesophageal reflux, and anxiety.

Myocardial infarction is the most common serious complication of coronary artery disease, with 900,000 occurring in the United States annually. Modern therapy, which involves early reperfusion with either thrombolytic therapy or emergent angioplasty, has lowered the mortality to less than 5 percent. MI may result in acute pump failure and cardiogenic shock, or in mechanical rupture of infarcted zones of the heart.

Preoperative Evaluation

A complete history and physical examination should be performed in every patient with suspected coronary artery disease, along with a chest radiograph, ECG, and baseline echocardiogram. In patients with atypical symptoms, provocative stress tests, such as adenosine thallium or dobutamine echocardiography, may also be beneficial in deciding if cardiac catheterization is indicated. Cardiac catheterization remains the gold standard of evaluation, as it outlines the location and severity of the coronary disease and accurately assesses cardiac function. "Angiographically significant" coronary stenosis is

considered to be present when the diameter is reduced by more than 50 percent, corresponding to a reduction in cross-sectional area greater than 75 percent.

Ventricular function is expressed as the left ventricular ejection fraction, with 0.55–0.70 considered as normal, 0.40–0.55 as mildly depressed, less than 0.40 as moderately depressed, and below 0.25 as severely depressed. The left ventricular ejection fraction is used to determine operative risk and the long-term prognosis.

Studies such as the PET scan, thallium scan, dobutamine echocardiogram, or MRI viability scan may be used to determine myocardial viability and the reversibility of ischemia in areas of the heart that might benefit from revascularization.

Coronary Artery Bypass Grafting

Indications

Coronary artery bypass grafting (CABG) may be indicated in patients with chronic angina, unstable angina, or postinfarction angina, and in asymptomatic patients or patients with atypical symptoms who have easily provoked ischemia during stress testing.

Chronic angina. In some patients with chronic angina, CABG is associated with improved survival and improved complication-free survival when compared to medical management. In general, patients with more severe angina (Canadian Cardiovascular Society (CCS) class III or IV symptoms) are most likely to benefit from bypass. For patients with less severe angina (CCS class I or II), other factors, such as the anatomic distribution of disease (left main disease or triple-vessel disease versus single-vessel disease) and the degree of left ventricular dysfunction, are used to determine which patients will most benefit from operative revascularization.

Unstable angina. Unstable angina exists when angina is persistent or rapidly progressive despite optimal medical therapy. Patients with unstable angina should be promptly hospitalized for intensive medical therapy and undergo prompt cardiac catheterization. Most patients with unstable angina will require urgent revascularization with either percutaneous coronary intervention (PCI) or coronary bypass grafting.

Acute myocardial infarction. CABG generally does not have a primary role in the treatment of uncomplicated acute MI, as PCI or thrombolysis is the preferred method of emergent revascularization in these patients. However, patients with subendocardial MI and underlying left main disease or postinfarction angina and multivessel involvement may require surgery.

The primary indication for surgery after acute transmural MI is in patients who develop late complications, such as postinfarction ventricular septal defect, papillary muscle rupture with mitral insufficiency, or left ventricular rupture. Postinfarction ventricular septal defect (VSD) typically occurs 4–5 days after MI, in approximately 1 percent of patients. These patients usually present with congestive heart failure and pulmonary edema, and a new systolic murmur. Once recognized, patients with postinfarction VSD should have an intraaortic balloon pump placed and undergo emergent repair. Papillary muscle rupture with acute mitral insufficiency also typically presents 4–5 days postinfarction and prompt valve repair or replacement offers the only meaningful chance for survival. Operative risk is 10–20 percent. Left ventricular free wall rupture

presents with cardiogenic shock, often with acute tamponade. Emergent surgery has a success rate of approximately 50 percent.

Percutaneous Coronary Intervention Versus Coronary Artery Bypass Grafting

PCI, or angioplasty, has significantly changed the treatment of patients with coronary artery disease. The indications for PCI have continually expanded as the technology has advanced. Most recently, stents coated with pharmacologic agents (such as paclitaxel or sirolimus) aimed at reducing in-stent restenosis have been introduced. A number of large, randomized studies have compared outcomes of patients with coronary disease treated with PCI and CABG. These studies have attempted to identify the optimal therapy for patients with coronary disease, based on their anatomy and risk stratification.

Results demonstrate that with appropriate patient selection both procedures are safe and effective, with little difference in mortality. PCI is associated with less short-term morbidity, decreased cost, and shorter hospital stay, but requires more late reinterventions. CABG provides more complete relief of angina, requires fewer reinterventions, and is more durable. CABG appears to offer a survival advantage in diabetic patients with multivessel disease.

Operative Techniques and Results

Conventional coronary artery bypass grafting. Conventional CABG is performed through a median sternotomy incision using cardiopulmonary bypass for extracorporeal perfusion and cold cardioplegia for intraoperative myocardial protection of the heart.

In the vast majority of patients the left internal mammary artery (IMA) is used as the primary conduit for bypassing the left anterior descending artery. The left IMA has a 10-year patency rate of approximately 95 percent when used as an in situ graft to the left anterior descending artery. The excellent results obtained with in situ left IMA grafts prompted other centers to use the right IMA in coronary revascularization. The right IMA can be used to provide a second arterial conduit as either an in situ or a free graft. Even when the IMA is used as a "free" graft, patency rates are approximately 70–80 percent at 10 years.

Saphenous vein grafts, which were initially the primary conduits used for CABG, continue to be used widely, usually for grafting secondary targets on the side and back of the heart. Once CPB has been established and the heart arrested, a small arteriotomy is performed in the coronary artery, and the distal anastomosis is performed between the saphenous vein and the coronary artery. The proximal anastomosis then connects each vein graft to the ascending aorta. The 10-year patency of saphenous vein grafts is approximately 65 percent.

Surgeons have explored the use of other arterial conduits. The most widely used has been the radial artery graft. Other alternative arterial grafts include the right gastroepiploic artery and the inferior epigastric artery. Reports are mixed regarding late patency rates, however. Although the expanded use of arterial grafts is appealing, improved patency of alternative arterial conduits compared to vein grafts has yet to be verified.

Results. The operative mortality for coronary artery bypass is 1–3 percent, depending on the number of risk factors present. Both the Society of Thoracic Surgeons (STS) and New York State have established large databases to establish risk factors and report outcomes. Variables that have been identified as influencing operative risk according to STS risk modeling include: female

gender, age, race, body surface area, NYHA class IV status, low ejection fraction, hypertension, peripheral vascular disease, prior stroke, diabetes, renal failure, chronic obstructive pulmonary disease, immunosuppressive therapy, prior cardiac surgery, recent MI, urgent or emergent presentation, cardiogenic shock, left main disease, and concomitant valvular disease. Late results demonstrate that relief of angina is striking after CABG. Angina is completely relieved or markedly decreased in over 98 percent of patients, and recurrent angina is rare in the first 5–7 years. Reintervention is required in less than 10 percent of patients within 5 years.

Late survival is similarly excellent after CABG, with a 5-year survival of over 90 percent and a 10-year survival of 75–90 percent, depending on the number of comorbidities present. Late survival is influenced by age, diabetes, left ventricular function, NYHA class, congestive heart failure, associated valvular insufficiency, completeness of revascularization, and nonuse of an IMA graft. Intense medical therapy for control of diabetes, hypercholesterolemia, and hypertension, and cessation of smoking significantly improves late survival.

Off-pump coronary artery bypass. One of the most significant developments in cardiac surgery in the last 15–20 years has been the introduction of off-pump coronary artery bypass (OPCAB). The main concept driving this approach is the elimination of the deleterious consequences of cardiopulmonary bypass. During OPCAB surgery the coronary artery is temporarily snared or occluded to provide a relatively bloodless field for the creation of the anastomosis.

Results. The OPCAB technique has been extensively studied and results compared to conventional surgery. Initial attention was given to assessing the accuracy of graft placement with the OPCAB approach, which required grafting onto the beating heart. Results were equivalent to those published for conventional CABG. A prospective randomized comparison between OPCAB and conventional CABG, reported by Puskas, demonstrated equivalent operative mortality and risk of stroke in each group, but less myocardial injury, fewer blood transfusions, earlier postoperative extubation, and earlier hospital discharge in OPCAB patients.

A study performed at NYU in high-risk patients with severe atheromatous aortic arch disease who required CABG compared outcomes in 245 OPCAB patients with outcomes in 245 conventional patients. In this high-risk patient population OPCAB was associated with a decreased risk of death (6.5 vs. 11.4 percent), stroke (1.6 vs. 5.7 percent), and all perioperative complications.

Minimally invasive direct coronary artery bypass. An even less invasive off-pump approach for CABG, termed minimally invasive direct coronary artery bypass (MIDCAB), uses a small left anterior minithoracotomy incision to perform bypass grafting on the beating heart, without cardiopulmonary bypass. The technique uses a mechanical stabilizer to isolate the coronary artery and facilitate the anastomosis and an in situ left IMA graft. The technique is mainly useful in performing bypass to the anterior wall of the heart, primarily to the left anterior descending artery or to the diagonal branches.

Results. The operative mortality for MIDCAB has been less than 2 percent, and the patency rate of the IMA graft has been approximately 98 percent. MIDCAB patients have less pain and blood loss, fewer perioperative complications, and a shorter recovery time than conventional CABG patients.

New Developments

Total endoscopic coronary artery bypass. Minimal access coronary artery bypass performed using endoscopic instrumentation is facilitated with the latest generation of surgical robotic technology. Total endoscopic coronary artery bypass (TECAB) has been reported on both the arrested and beating heart. Robotic instrumentation also has been described to perform internal mammary artery harvests as part of the MIDCAB technique.

Transmyocardial laser revascularization. Transmyocardial laser revascularization (TMR) uses a high-powered carbon dioxide laser or holmium:yttrium-aluminum-garnet laser to drill multiple holes (1 cm^2) through the myocardium into the ventricular cavity. The procedure is performed on the beating heart with the laser pulses gated to the R wave on the ECG. The TMR procedure has been used primarily for patients with refractory angina who are unsuitable candidates for standard CABG because of poor distal coronary artery anatomy. The mechanism of benefit of TMR remains uncertain. The most likely possibility is that TMR works by stimulating angiogenesis in the area of injury. Despite subjective reports of improvement, however, the results of objective cardiac perfusion measurements after TMR have been inconclusive.

Facilitated anastomotic devices. Significant technologic progress has led to the development of devices that mechanically construct proximal and distal vascular anastomoses, without the need for sutures or knot tying. The goals for these devices are to provide safe, rapid, and reproducible anastomoses; reduce operative time; limit anastomotic variability between surgeons; and improve graft patency.

VENTRICULAR ANEURYSMS**Pathophysiology**

Approximately 5–10 percent of transmural myocardial infarctions result in left ventricular aneurysms, which develop 4–8 weeks following a transmural infarct as necrotic myocardium is replaced by fibrous tissue.

The classic aneurysm is an avascular thin scar, 4–6-mm thick, which bulges outward when the remaining left ventricular muscle contracts in systole. Left ventricular aneurysms generally do not rupture, but manifest clinically as progressive heart failure, often with associated malignant ventricular arrhythmias. Over 80 percent of aneurysms are in the anteroapical portion of the left ventricle, resulting from occlusion of the left anterior descending coronary artery. Posterior ventricular aneurysms are less common (15–20 percent) and lateral wall aneurysms are rare.

Diagnostic Evaluation

The diagnostic workup generally begins with echocardiography to assess wall motion in the various zones of the heart, to determine left ventricular end-systolic and end-diastolic size, and to assess for any associated mitral valve insufficiency. Cardiac MRI may also be useful. Cardiac catheterization is performed preoperatively to assess for the severity of coronary artery disease, and to determine the anatomic extent of the aneurysm and the areas of myocardium that still have good function. Workup of arrhythmias may include electrophysiologic studies.

Operative Treatment

Operative treatment requires excision or exclusion of the aneurysm and bypass grafting of diseased coronary arteries. The classic repair was performed by excision of the aneurysm and linear closure of the ventricle. However, this technique had a geometrically deforming effect on the remaining left ventricle, and did not address aneurysmal deformity of the septum. Therefore, a more physiologic technique of intracavitary endoventricular patch reconstruction, or left ventricular restoration, was proposed by Jatene, Cooley, and Dor. Endoventricular patch reconstruction involves placement of a Dacron patch to obliterate the aneurysmal ventricle and septum. This repair remodels the ventricular cavity and obliterates the septal component of the aneurysm.

Results

Doss and colleagues compared the long-term results of linear closure and endoventricular patch reconstruction with 8 years follow up. The left ventricular ejection fraction increased significantly in patients who underwent endoventricular reconstruction, but decreased in those who underwent linear closure. The operative mortality was 1.9 percent, with an 8-year survival of 85.6 percent. In general, the published data suggest better results with the endoventricular patch reconstruction technique.

ISCHEMIC CARDIOMYOPATHY

Patients with ischemic cardiomyopathy and heart failure are being evaluated and treated by surgeons with increasing frequency, as surgical options for the failing heart have expanded considerably over the last 10–20 years. Anatomically, ischemic cardiomyopathy results from multiple myocardial infarctions, which produce extensive myocardial scarring with decreased left ventricular systolic function. These patients may have a definable left ventricular aneurysm, but more commonly have diffuse myocardial scarring with large, nonfunctioning, akinetic zones of the heart.

Ventricular Restoration Surgery

Left ventricular surgical restoration for ischemic cardiomyopathy is performed similarly to the endoventricular patch reconstruction described above for repair of anteroapical left ventricular aneurysms. The goal of ventricular restoration is to restore the normal left ventricular size and shape, thus improving the efficiency of left ventricular ejection.

Results

A large international study (reconstructive endoventricular surgery returning torsion original radius elliptical shape to the LV (RESTORE)) investigated outcomes after surgical anterior ventricular endocardial restoration (SAVER). They found an overall hospital mortality of 6.6 percent, with an increase in ejection fraction from 29.7–40 percent and a 3-year survival rate approaching 90 percent.

MECHANICAL CIRCULATORY SUPPORT AND MYOCARDIAL REGENERATION

IntraAortic Balloon Pump

The intraaortic balloon pump (IABP) is the most common and effective technique for assisted circulation. The most frequent indications for use of IABP

are to provide hemodynamic support during or after cardiac catheterization, cardiogenic shock, weaning from cardiopulmonary bypass, and for preoperative use in high-risk patients and refractory unstable angina. A balloon catheter is inserted through the femoral artery and advanced into the thoracic aorta. With electronic synchronization, the balloon is inflated during diastole and deflated during systole. Coronary blood flow is increased by improved diastolic perfusion, and afterload is reduced. The cardiac index typically improves after insertion, and the preload decreases.

Limb ischemia on the side of insertion is the most serious complication, and the extremity must be examined frequently for viability. Studies have shown major IABP complications (limb ischemia, bleeding, balloon leakage, or death directly because of IABP insertion) occur in 2.6 percent of cases.

Ventricular Assist Devices

Mechanical circulatory support systems (ventricular assist devices; VADs) are designed for temporary assisted circulation (“bridge to recovery”), for long-term treatment (“bridge to transplantation”), or as a permanent substitute for the heart (“artificial heart” or “destination therapy”). Temporary assisted circulation is a valuable clinical modality in the treatment of transient cardiac injury. The most common indication for temporary assisted circulation is cardiac failure after cardiac surgery. Inflow for these devices is through either the left atrium or the apex of the left ventricle, and outflow is into the aorta. External pulsatile assist devices deliver blood flow in synchrony with the native heart and are used for short-term support after cardiac surgery or as a long-term bridge to cardiac transplantation.

A definitive solution for heart failure may be a permanent artificial heart. Total cardiac replacement with an artificial heart, however, is still in the experimental arena. Long-term risks include thromboembolic complications, the risk of infection, and trauma to blood elements.

VALVULAR HEART DISEASE

General Principles

According to the STS database, valve operations accounted for 14.0 percent of all classified procedures performed in 1996. By 2002, that percentage had increased by 45 percent of all classified procedures. Although CABG volume declined by 15.3 percent between 1996 and 1999, aortic valve replacements increased by 11.7 percent and mitral valve operations increased by 58 percent during the same period.

Valvular heart disease can result in a pressure load (valvular stenosis), a volume load (valvular insufficiency), or both (mixed stenosis and insufficiency). Demonstration of a decreased ejection fraction at rest (or a rise in the end-systolic volume by echocardiography) or a fall in the ejection fraction during exercise are probably the best signs that the systolic function of the heart is beginning to deteriorate and that surgery should be performed promptly.

Postoperative cardiac function generally returns to normal if the operation is performed at an early phase of ventricular dysfunction. Even with impaired left ventricular function, NYHA class IV disability, and pulmonary hypertension, patients with valvular heart disease are rarely inoperable. Except in the rare case of advanced cardiomyopathy combined with other systemic disease, surgery

should not be denied to patients. The typical valve-related complications from valvular surgery include thromboembolic events, anticoagulant-related hemorrhage, prosthetic valve failure, endocarditis, prosthetic paravalvular leakage, and failure of valve repair.

Surgical Options

Two basic types of prosthetic valves are available: mechanical valves and tissue valves (xenografts). Valve replacement, in particular aortic valve replacement, also can be performed using human homografts or autografts. Finally, valve repair is increasingly an option, as opposed to valve replacement. The recommendations for valve repair or replacement, type of prosthesis, and operative approach are based on multiple factors, such as the patient's age, lifestyle, associated medical conditions, access to follow-up health care, desire for future pregnancy, and experience of the surgeon.

Mechanical prostheses are highly durable but require permanent anticoagulation therapy to minimize the risk of valve thrombosis and thromboembolic complications. Lifelong anticoagulation therapy carries the risk of hemorrhagic complications and may dictate lifestyle changes.

Tissue valves are more natural and less thrombogenic, and therefore generally do not require anticoagulation therapy. Consequently, tissue valves have lower risks of thromboembolic and anticoagulant-related complications, with the total yearly risk of all valve-related complications being considerably less than with mechanical valves. Unfortunately, tissue valves are more prone to structural failure because of late calcification of the xenograft tissue. However, it is anticipated that it may take 15–20 years before structural failure will occur in these prostheses.

For aortic valve replacement, a mechanical prosthesis, a newer-generation tissue valve (either stented or nonstented), a homograft, or a pulmonary autograft (Ross procedure) may be recommended. Some type of tissue valve usually is recommended for patients older than 65 years of age because anticoagulation therapy may be hazardous and valve durability is better in older patients.

Although valve repair can be performed in the vast majority of patients with mitral insufficiency, valve replacement may still be required in certain patients, and in the vast majority with rheumatic disease and valvular stenosis. When valve replacement is necessary, a tissue valve is an appropriate choice in women planning pregnancy or in patients over 60–65 years of age. A mechanical prosthesis is recommended for younger patients, especially if the patient is in atrial fibrillation, because anticoagulation therapy is already required in this group.

Mechanical Valves

A common mechanical valve used in the United States is the St. Jude Medical bileaflet prosthesis. Mechanical (disk) valves have excellent flow characteristics, acceptable low risk of late valve-related complications, and an extremely low risk of mechanical valve failure. With proper anticoagulation and keeping the international normalized ratio (INR) at 2–3 times the normal for mechanical aortic valves and 2.5–3.5 times the normal for mechanical mitral valves, the incidence of thromboembolism is approximately 1–2 percent per patient per year, and the risk of anticoagulant-related hemorrhage is 0.5–2 percent per patient per year.

Tissue Valves

Several types of xenograft tissue valves are available and widely used. The stented valves are most common (either porcine or bovine pericardial), although stentless valves are being increasingly used by some groups. Stented tissue valves have the drawback of having higher gradients across the valve, particularly in smaller sizes. The limitations in flow characteristics observed in small sizes of stented tissue valves led to the development of stentless valves in an attempt to maximize the effective valve orifice area. Although the long-term durability of stentless valves has not yet been established, these valves offer excellent hemodynamics.

Homografts

Surgical alternatives to prosthetic valve replacement have been developed in an attempt to use the body's natural tissue and lower the incidence of valve-related complications. In the 1960s, Ross in England and Barrett-Boyes in New Zealand described a procedure for aortic valve replacement using antibiotic-preserved aortic homograft (allograft) valves. The main disadvantage of a homograft valve is its uncertain durability, especially in young patients, as structural degeneration of the valve tissue leads to graft dysfunction and valve failure.

Autografts

Ross described a potentially durable but more complicated alternative for aortic valve replacement with natural autologous tissue, using the patient's native pulmonary valve as an autograft for aortic valve replacement and replacing the pulmonary valve with a homograft. This operation, referred to as the Ross procedure, has the advantage of placing an autologous valve into the aortic position, which functions physiologically and does not require anticoagulation therapy. The Ross procedure may be indicated for younger patients who require aortic valve replacement and want to avoid the need for anticoagulation.

Valve Repair

Valve repair has become the procedure of choice for most patients with mitral valve insufficiency, although repair of the aortic valve is feasible in certain situations. The primary advance in mitral valve repair resulted from work by Carpentier in the 1970s. Valve repair has subsequently proved to be highly reproducible for correction of mitral insufficiency, with excellent durability and freedom from late valve-related complications. Repair lowers the risk of thromboembolic- and anticoagulant-related complications. Survival may also be improved in certain groups of patients after valve repair.

Mitral Valve Disease

Mitral Stenosis

Etiology. Mitral valve stenosis or mixed mitral stenosis and insufficiency almost always are caused by rheumatic heart disease, although a definite clinical history can be obtained in only 50 percent of patients. Congenital mitral stenosis is rarely seen in adults. Occasionally, intracardiac tumors such as left atrial myxoma may obstruct the mitral orifice and cause symptoms that mimic mitral stenosis.

Pathology. Rheumatic valvulitis produces three distinct degrees of pathologic change: fusion of the commissures alone, commissural fusion plus subvalvular shortening of the chordae tendineae, and extensive fixation of the valve and subvalvular apparatus with calcification and scarring of both leaflets and chordae.

Pathophysiology. Mitral stenosis usually has a prolonged course after the initial rheumatic infection, and symptoms may not appear for 10–20 years. The progression to valvular fibrosis and calcification may be related to repeated episodes of rheumatic fever, or may result from scarring produced by inflammation and turbulent blood flow. The normal cross-sectional area of the mitral valve is 4–6 cm². Symptoms may progressively develop with moderate stenosis, defined as a cross-sectional area 1.0–1.5 cm². Severe symptomatic stenosis occurs when the mitral valve area is less than 0.8–1.0 cm².

The pathophysiology associated with mitral stenosis results from an elevation in left atrial pressure, producing pulmonary venous congestion and pulmonary hypertension. Left ventricular function usually remains normal because the ventricle is protected by the stenotic valve.

Clinical manifestations. The main symptoms of mitral stenosis are exertional dyspnea and decreased exercise capacity. Dyspnea occurs when the left atrial pressure becomes elevated because of the stenotic valve, resulting in pulmonary congestion. Orthopnea and paroxysmal nocturnal dyspnea may also occur, or in advanced cases, hemoptysis. The most serious development is pulmonary edema. Atrial fibrillation develops in a significant number of patients with chronic mitral stenosis. Atrial thrombi result from dilation and stasis of the left atrium, with the left atrial appendage being especially susceptible to clot formation.

The characteristic auscultatory findings of mitral stenosis, called the auscultatory triad, are an increased first heart sound, an opening snap, and an apical diastolic rumble. A loud pansystolic murmur transmitted to the axilla usually indicates associated mitral insufficiency.

Diagnostic studies. The electrocardiogram may show atrial fibrillation, left atrial enlargement (P mitrale), and right-axis deviation, or it may be normal. On chest radiograph, enlargement of the left atrium typically is seen on the posteroanterior film as a double contour visible behind the right atrial shadow. Calcifications of the mitral valve also may be seen.

The Doppler echocardiogram is diagnostic. Transesophageal echocardiography provides enhanced resolution of the mitral valve and the posterior cardiac structures, including the left atrium and the atrial appendage. Echocardiography gives a very accurate measurement of the transvalvular gradient and the cross-sectional area of the mitral valve.

Indications for valvuloplasty or commissurotomy. Although percutaneous balloon valvuloplasty has become an acceptable alternative for many patients with uncomplicated mitral stenosis, open mitral commissurotomy remains a reproducible and durable option. Commissurotomy has the advantage of addressing nonpliable or calcified mitral valves, mobilize fused papillary muscles to correct subvalvular restrictive disease, repair patients with mixed stenosis and insufficiency, and remove left atrial clot. Either balloon valvuloplasty or open surgical commissurotomy is indicated for symptomatic patients with moderate (mitral valve area <1.5 cm²) or severe (mitral valve area <1.0 cm²) mitral stenosis.

Mitral Insufficiency

Etiology. Degenerative disease is the most common cause of mitral insufficiency in the United States, accounting for 50–60 percent of the patients requiring surgery. Other causes include rheumatic fever (15–20 percent), ischemic disease (15–20 percent), endocarditis, congenital abnormalities, and cardiomyopathy.

Pathology. The major structural components of the mitral valve are the annulus, the leaflets, the chordae tendinae, and the papillary muscles. A defect in any of these components may create mitral insufficiency. A functional classification for mitral insufficiency was proposed by Carpentier, who characterized three basic types of functionally diseased valves. Degenerative causes include myxomatous degeneration and fibroelastic deficiency. In patients with rheumatic disease, the chordae tendinae are thickened and foreshortened, producing restrictive leaflet motion. Posterior dilatation of the mitral annulus also usually is present. With ischemic insufficiency, ventricular injury results in tethering of the mitral leaflets, producing restrictive leaflet motion, and central insufficiency, often with secondary annular dilation.

Pathophysiology. The basic physiologic abnormality in patients with mitral insufficiency is regurgitation of a portion of the left ventricular stroke volume into the left atrium. This results in decreased forward blood flow and an elevated left atrial pressure, producing pulmonary congestion and volume overload of the left ventricle. However, decreased systolic function of the heart is a relatively late finding, because the ventricle is “unloaded” as a result of the valvular insufficiency. Once left ventricular dysfunction and heart failure develop, the left ventricle usually has been significantly and often irreversibly injured.

Clinical manifestations. In patients with acute mitral regurgitation, congestive heart failure develops suddenly, although in patients with chronic mitral insufficiency, the left atrium and ventricle become compliant, and symptoms do not develop until later in the course of the disease.

On physical examination the characteristic findings of mitral insufficiency are an apical holosystolic murmur and a forceful apical impulse. The apical murmur usually is harsh and transmitted to the axilla or to the left sternal border.

Diagnostic studies. The severity of mitral insufficiency can be determined accurately with echocardiography, along with the site of valvular prolapse or restriction, and the level of left ventricular function. An important measurement is the size of the cardiac chambers. If there is uncertainty about the physiologic significance of mitral insufficiency, exercise stress-echocardiography may be used. Normally the ejection fraction rises with exercise, but a fall in ejection fraction with exercise is an early sign of left ventricular systolic dysfunction.

Indications for operation. Delaying operation until the patient is severely symptomatic and the heart is markedly dilated often results in a certain degree of irreversible ventricular injury. According to ACC/AHA guidelines, mitral valve repair or replacement is recommended in any symptomatic patient with mitral insufficiency, even with normal left ventricular function (defined as ejection fraction > 60 percent and end-systolic dimension <45 mm). Surgery also is currently recommended in asymptomatic patients with severe mitral insufficiency if there are signs of left ventricular systolic. Recent onset of

atrial fibrillation, pulmonary hypertension, or an abnormal response to exercise testing are considered relative indications for surgery.

Operative Techniques

The traditional approach for mitral valve surgery is through a median sternotomy incision with cardiopulmonary bypass and cardioplegic arrest. The mitral valve is exposed through a left atrial incision, made posterior and parallel to the intraatrial groove. Alternative incisions for exposing the difficult mitral valve include a right atriotomy with transseptal incision, a superior approach through the dome of the atrium, and the biatrial transseptal approach.

Commissurotomy. Initially the atrial cavity is examined for thrombi, especially within the atrial appendage. The mitral valve is assessed by evaluating leaflet mobility, commissural fusion, and the degree of fibrosis in the subvalvular apparatus.

Once the commissure has been accurately identified and the chordae noted, a right-angle clamp is introduced beneath the fused commissure, stretching the adjacent chordae and leaflets, after which the commissure is carefully incised. The incision is made 2–3 mm at a time, serially confirming that the separated margins of the commissural leaflet remain attached to chordae tendineae. Once the commissurotomy is completed, any fused papillary muscle is incised as necessary to minimize restriction and improve mobility of the attached leaflet.

Mitral valve replacement. Mitral valve replacement is necessary when the extent of disease precludes commissurotomy or valve reconstruction. Valve replacement is most likely in patients with long-standing rheumatic disease. Once the valve is exposed and the need for valve replacement is determined, an incision is made in the anterior mitral leaflet, and most of the anterior leaflet is resected. The posterior leaflet is preserved whenever possible, and the chordal attachments to both leaflets are preserved or reattached to the annulus, as this has been shown to improve left ventricular function and lower the risk of posterior left ventricular free wall rupture.

Mitral valve reconstruction. The basic techniques of mitral valve reconstruction include resection of the posterior leaflet, chordal shortening, chordal transposition, artificial chordal replacement, and triangular resection for repair of the anterior leaflet disease. An annuloplasty to correct associated annular dilation also is recommended in most cases.

The intraoperative assessment of the valvular pathology is an important step in valve reconstruction. A localized roughened area of atrial endocardium, termed a jet lesion, may be present from regurgitant blood striking the endocardium, providing a guide to the location of the insufficiency. Subsequently the commissures are examined, noting whether these are prolapsed, fused, or malformed. The closing plane of the leaflets in the area supported by commissural chordae is determined next, and the anterior and posterior leaflets are then examined, noting areas of prolapse or restriction.

Posterior leaflet procedures. Quadrangular resection of the posterior leaflet has become the mainstay of mitral valve reconstruction. A rectangular excision is performed, cutting directly down to, but not through, the mitral annulus. Diseased tissue in the posterior leaflet is excised with a quadrangular excision, usually removing 1–2 cm of tissue. Strong chordae of proper length are identified on each side of the excised leaflet and encircled with retraction sutures. Once the quadrangular excision has been performed, the annulus of the excised

segment of leaflet is corrected either by simple annular plication, folding plasty, or sliding plasty.

The folding plasty technique, described by the group from NYU, involves folding down the cut vertical edges of the posterior leaflet to the annulus and closing the ensuing cleft. The sliding plasty technique reported by Carpentier also is successful in reducing posterior leaflet height and moving the edge of leaflet coaptation posteriorly.

Anterior leaflet procedures. Four primary techniques are used for anterior leaflet reconstruction: chordal shortening, chordal transposition, artificial chordal replacement, and triangular resection of anterior leaflet tissue with primary repair. With chordal shortening, the elongated chord is imbricated either onto the free edge of the leaflet or onto the papillary muscle. In contrast, the chordal transposition technique uses a segment of structurally intact posterior leaflet directly opposite the prolapsed anterior leaflet. Artificial chordae replacement has been used by some groups as an alternative for anterior leaflet repair. Finally, triangular resection and primary repair has been increasingly used at NYU for treatment of anterior leaflet prolapse.

Repair of leaflet perforation. Leaflet perforations can be repaired by primary suture closure or by closure with a pericardial patch. Extensive leaflet destruction is best managed with mitral valve replacement.

Annuloplasty. Use of a mitral valve annuloplasty device (ring or partial band) to correct annular dilation during valve repair decreases the risk of late repair failure. The primary purpose of an annuloplasty device is to correct the associated annular dilation that invariably occurs in patients with chronic mitral insufficiency. Various types of annuloplasty devices are available. The relative advantages of the different types of devices remain under investigation, but it is widely accepted that use of an annuloplasty device to correct annular dilation improves long-term repair durability.

Results

Commissurotomy. The operative risk for open mitral commissurotomy is less than 1 percent, and long-term results have been excellent. Antunes and colleagues reported 9-year actuarial freedom from reoperation was 98 percent, and 93 percent were in NYHA functional class I or II.

Balloon valvuloplasty. The choice between surgical commissurotomy and balloon valvuloplasty varies widely among centers. The main advantages of commissurotomy over balloon valvuloplasty are that during surgery the fused chordae can be surgically divided and mobility restored.

Valve replacement. The operative mortality rate for mitral valve replacement is 2–6 percent, depending on the number of comorbidities present. The major predictors of increased operative risk after mitral valve replacement are age, left ventricular function, emergency operation, NYHA functional status, previous cardiac surgery, associated coronary artery disease, and concomitant disease in another valve. The major factors influencing long-term survival are age, urgency of operation, NYHA functional status, mitral insufficiency (versus stenosis), ischemic etiology, pulmonary hypertension, and the need for concomitant coronary bypass or procedures on another valve.

Studies have shown freedom from reoperation at 15 years was 98 percent with mechanical valves and 79 percent with tissue valves. Thus whereas

mechanical valves and tissue valves result in similar long-term survival, there is an increased risk of late reoperation in patients receiving tissue valves.

Valve repair. The operative risk for mitral valve repair is less than 1–2 percent, and late results have demonstrated that compared to replacement, repair is associated with improved survival and better freedom from valve-related complications.

Minimally invasive mitral valve surgery. Newer techniques which allow mitral valve repair or replacement to be performed with a minimally invasive incision have been increasingly used over the last decade. At NYU minimally invasive mitral valve surgery has been performed through a small right anterior thoracotomy incision, entering the chest through the third or fourth intercostal space. Others have used partial upper sternotomy, partial lower sternotomy, or parasternal incisions.

Galloway and colleagues reported late results after minimally invasive valve repair, demonstrating that repair durability, freedom from valve-related complications, and survival were equivalent to results achieved with the traditional sternotomy approach. Thus the results after minimally invasive valve surgery are encouraging, and more widespread utilization of minimally invasive techniques is likely in the future.

New Developments

Edge-to-edge repair. In 1995, Alfieri described the “double-orifice” or “edge-to-edge” repair as an alternative technique for repair for mitral insufficiency. With this technique the free edge of the anterior leaflet is sutured to the opposing free edge of the posterior leaflet, converting the valve into a double-orifice “bow tie.”

Robotic mitral valve surgery. Recent technological achievements in optics and computerized telemanipulation have enabled robotically assisted mitral valve operations. It has been reported that the articulated wrist-like instruments and three-dimensional visualization enable precise tissue telemanipulation. These systems still have significant limitations, however, and may not be readily adaptable to performing the multiple complex tasks necessary for valve surgery.

Aortic Valve Disease

Effective surgical treatment of aortic valve disease became possible in 1960 with the development of satisfactory prosthetic valves by Starr and Edwards and by Harken and associates.

Aortic Stenosis

Etiology. In the adult North American population the primary causes of aortic stenosis include acquired calcific disease, bicuspid aortic valve, and rheumatic disease. Acquired calcific aortic stenosis typically occurs in the seventh or eighth decade of life, and is the most frequent etiology, accounting for over half of the cases. Bicuspid aortic valve accounts for approximately one third of the cases of aortic stenosis in adults, typically presenting in the fourth or fifth decade of life, after years of turbulent flow through the bicuspid valve results in damage and calcification.

The third major cause of aortic stenosis, rheumatic heart disease, accounts for approximately 10–15 percent of patients in North America, but is more

common in underdeveloped countries. Concomitant mitral valve disease almost always is present, although not always clinically significant.

Pathophysiology. Generally, the aortic valve must be reduced to one third its normal cross-sectional area before significant hemodynamic changes occur. A normal aortic valve has a cross-sectional area of 2.5–3.5 cm². Moderate aortic stenosis is defined as an aortic valve area between 0.8 and 1.2 cm², although severe stenosis is defined as a valve area less than 0.8 cm². Once the valve area is less than 0.5 cm², with a transvalvular gradient of 100 mm Hg or greater, the degree of stenosis is considered critical.

Myocardial ischemia develops in some patients with severe aortic stenosis, usually in response to exercise. The left ventricular mass and left ventricular systolic wall tension are increased, resulting in increased oxygen demand. Simultaneously, the cardiac output often is low and does not increase in response to exercise.

Clinical manifestations. The classic symptoms of aortic stenosis include exertional dyspnea, decreased exercise capacity, heart failure, angina, and syncope. Once the patient becomes symptomatic, prompt operation is indicated. If heart failure, angina, or syncope is present, the need for surgery is more urgent, as the risk of death exceeds 30–50 percent over the next 5 years. Sudden death, which accounts for a significant number of fatalities from aortic stenosis, possibly because of arrhythmias, becomes a more likely threat once the patient becomes severely symptomatic.

With auscultation the principal finding is a harsh, diamond-shaped (crescendo-decrescendo) systolic murmur at the base of the heart with radiation to the carotid arteries. The two components of the S2 may become synchronous, or aortic valve closure may even follow pulmonic valve closure, causing paradoxical splitting of the S2. The apical impulse has been described as a “prolonged heave,” although the pulse pressure in the peripheral circulation is usually narrow and sustained (pulsus parvus et tardus).

Diagnostic studies. On radiograph the heart size may be either normal or enlarged because of left ventricular hypertrophy. Calcification of the valve often is visible in older patients. The ECG may demonstrate left ventricular hypertrophy, but may also be normal. Atrial fibrillation generally indicates the presence of advanced disease with a prolonged elevation of intracardiac pressures. The diagnosis of aortic stenosis is now most frequently made by echocardiography, which provides an accurate estimate of the peak and mean systolic transvalvular gradients. The echocardiogram also can demonstrate the amount of calcium in the leaflets, the degree of leaflet immobility, the left atrial size, the degree of left ventricular hypertrophy, the end-systolic and end-diastolic dimensions of the left ventricle, and the left ventricular function. Cardiac catheterization readily confirms the diagnosis by measuring the aortic transvalvular gradient and permitting calculation of the cross-sectional area of the valve.

Operative indications. Patients with aortic stenosis typically respond well to aortic valve replacement, which immediately relieves the increased afterload. A special subgroup of patients includes those with critical aortic stenosis and advanced left ventricular systolic dysfunction. These patients have an increased operative risk, but may still have significant improvement after valve replacement as long as the ventricle is not irreversibly damaged.

Aortic valve replacement is indicated for virtually all symptomatic patients with aortic stenosis. In asymptomatic patients with moderate to severe stenosis, periodic echocardiographic studies are performed to assess the transvalvular gradient, valve area, left ventricular size, and left ventricular function. Surgery is indicated with the first sign of left ventricular systolic dysfunction.

Aortic Insufficiency

Etiology and pathology. A variety of diseases can produce aortic valve insufficiency, including degenerative diseases, inflammatory or infectious diseases (endocarditis, rheumatic fever), congenital diseases, aortoannular ectasia or aneurysm of the aortic root, and aortic dissection. Mixed valvular stenosis and insufficiency can develop in any patient with aortic stenosis, regardless of etiology.

Degenerative valvular disease is a manifestation of fibroelastic deficiency or myxomatous degeneration that produces thin and elongated valvular tissue. The aortic valve leaflets sag into the ventricular lumen, often with no other tissue abnormality, producing central aortic insufficiency. Infectious and inflammatory etiologies of aortic insufficiency include bacterial endocarditis and rheumatic fever. Streptococci, staphylococci, or enterococci are the most common bacteria involved, in decreasing order of frequency.

Patients who have a congenitally bicuspid aortic valve rarely become symptomatic during childhood, but prolonged turbulence may lead to aortic stenosis, mixed stenosis and insufficiency, or pure insufficiency later in life. Congenital causes of aortic insufficiency account for 10–15 percent of the patients operated on for aortic insufficiency as adults.

Aneurysmal dilation of the aortic root is thought to be secondary to idiopathic or known connective tissue disorders, with the idiopathic variety seen with increasing frequency as the average age of the population increases. Aortoannular ectasia with aneurysm of the aortic root occurs in its most extreme form in patients with Marfan syndrome or Ehlers-Danlos syndrome. Valvular insufficiency results from dilatation of both the aortic sinotubular junction and the aortic valve annulus. Acute aortic dissection may produce aortic valve insufficiency by detachment of the commissures and prolapse of the valve cusps, usually involving the noncoronary cusp and the commissure between the left and right cusps.

Pathophysiology. With aortic valve insufficiency, blood regurgitates into the left ventricle during diastole, producing left ventricular volume overload. A widened pulse pressure and low diastolic pressure result in diminished coronary perfusion. Because ventricular compliance is normal, the left ventricular diastolic pressure does not increase initially, and the patient usually remains asymptomatic. As the heart continues to dilate, however, the ventricular muscle can no longer compensate and the ratio of wall thickness to cavity size decreases. Further progression leads to left ventricular failure and pulmonary hypertension.

Clinical manifestations. Symptoms develop at variable rates in patients with aortic insufficiency. Frequently the patient who gradually develops moderate to severe insufficiency remains asymptomatic for many years, often 10 or more. Once symptoms appear, however, ventricular function usually is significantly depressed and rapid clinical deterioration occurs over the next 4–5 years. The terminal illness usually is progressive heart failure and arrhythmias.

The most common symptoms are dyspnea on exertion and decreased exercise capacity. These symptoms gradually increase in severity as the ventricle deteriorates. Palpitations also are common. NYHA class IV symptoms, angina, and right heart failure occur with advanced disease or with severe incompetence in which the regurgitant flow exceeds 50 percent of forward flow.

Palpation reveals an enlarged heart and a prominent cardiac impulse. The hallmark of aortic insufficiency is a high-pitched decrescendo diastolic murmur. A light systolic ejection murmur because of increased flow across the aortic valve may also be present. A mid-diastolic rumble at the apex that simulates mitral stenosis has been described, the Austin Flint murmur, produced by the aortic insufficiency impeding the opening of the mitral valve during diastole. The pulse pressure is widened, partly from an increase in systolic pressure, but principally from a decrease in diastolic pressure, which may be in the range of 30–40 mm Hg.

Diagnostic studies. The chest radiograph usually shows impressive cardiac enlargement, with the apex displaced downward and to the left. The ECG is normal early in the disease, but with cardiac enlargement, signs of left ventricular hypertrophy become prominent. Sinus rhythm usually is present initially, although atrial fibrillation is common later in the course of the disease.

Echocardiography is the primary diagnostic tool. The classic finding on cardiac catheterization is the reflux of contrast material from the aortic root into the ventricle with aortic root angiography, graded from 1+ to 4+. Aortic root angiography or MRI studies may be performed if aneurysmal disease is suspected.

Operative indications. The development of symptoms is an absolute indication for surgery in patients with aortic insufficiency. However, postponing surgery until the patient becomes severely symptomatic is potentially dangerous, as many patients will have already developed substantial ventricular enlargement and cardiac dysfunction by that time. Therefore, echocardiographic studies are routinely used to determine the appropriate timing for surgical intervention. Asymptomatic patients with severe aortic insufficiency should be referred for surgery at the first sign of deteriorating left ventricular systolic function on echocardiography. Operative results indicate that cardiac function will return to normal and long-term survival will be improved significantly if an operation is done at this stage.

In the authors' experience valve replacement should be performed even in patients with low ejection fractions and advanced NYHA class IV symptoms, especially if recruitable ventricular wall motion is present with inotropic stimuli. Most class IV patients will improve significantly after surgery, although the degree of improvement may be uncertain for 6–12 months. Evidence supports routine electrophysiologic testing and implantation of an automatic internal cardiac defibrillator (AICD) if inducible arrhythmias are present.

Operative Techniques

Aortic valve replacement. Aortic valve replacement has traditionally been performed through a median sternotomy incision, and this approach remains the standard in most cardiac centers. Cardiopulmonary bypass with moderate systemic hypothermia is used, the aorta is cross-clamped, and the heart is protected by cardioplegia delivered antegrade into the aortic root, directly into

the coronary ostia by hand-held cannulae, or retrograde through the coronary sinus.

After the heart has been arrested, an oblique or hockey stick-shaped aortotomy incision is made, beginning approximately 1 cm above the right coronary artery and extending medially toward the pulmonary artery and inferiorly into the noncoronary sinus. The aortic valve is excised totally, removing all leaflets and any fragments of calcium present in the annulus.

At NYU, pledgeted horizontal mattress sutures are routinely used, as this technique is thought to minimize the risk of paravalvular leakage. Care is taken to avoid damage to the coronary ostia, to the conduction bundle adjacent to the membranous septum between the right and the noncoronary valve cusps, and to the mitral valve posteriorly. The valve may be seated on the annulus in either of two ways.

Mechanical valves are widely used in younger patients. Two configurations are available, a single tilting disk and a bileaflet disk. The flow characteristics of the valve become important when the aortic annulus is small, to minimize the postoperative gradient across the smaller prosthesis. Patients with mechanical valves routinely require lifelong anticoagulation with warfarin to minimize the risk of thromboembolic complications. Tissue valves are most commonly used in older patients, although they now are increasingly used in younger patients who want to avoid the need for long-term anticoagulation therapy. Tissue valves may be either stented or stentless, with the traditional stented valves being easier to implant, and the stentless valves having better flow characteristics, particularly in smaller valve sizes. Current tissue valves have a projected durability of 15 years or longer and do not require long-term anticoagulation.

Results. The operative risk for aortic valve replacement is 1–5 percent for most patients, but may be considerably higher in elderly patients with multiple comorbidities and in patients with severely depressed left ventricular function. Chaliki and associates reported that aortic valve replacement in patients with aortic insufficiency and poor left ventricular function (ejection fraction less than 35 percent) resulted in increased operative risk, 14 percent compared to 3.7 percent in patients with ejection fractions above 50 percent. Ten-year survival was 70 percent in patients with good ventricular function, but only 42 percent in patients with ejection fractions less than 35 percent.

Postoperative care. Postoperative care is usually uneventful after aortic valve replacement in patients with normal left ventricular function. However, patients with significantly reduced left ventricular function may have a complicated postoperative course. Arrhythmias are relatively common, and continuous ECG monitoring is required for the first 48 h. Anticoagulation therapy is started 1 day after mechanical valve replacement, targeting an INR of 2.5–3 times normal. Antiplatelet therapy with aspirin is used in patients with tissue valves, homografts, or autografts.

Except for patients with severe ventricular dysfunction, most patients become asymptomatic and regain a normal range of physical activity within 1–2 months after operation. Thromboembolism, anticoagulant-related hemorrhage, endocarditis, and prosthetic valve failure are the principal late complications. Both thromboembolism and anticoagulant-related hemorrhage occur with incidences of 1–2 percent per year after mechanical valve replacement, despite careful anticoagulation therapy and monitoring. Patients with tissue valves have a risk of thromboembolism of 0.5–1 percent per year. Endocarditis

remains an infrequent but serious late hazard after valve replacement, and routine antibiotic prophylaxis is recommended lifelong for any invasive procedure that might produce a transient bacteremia.

Aortic valve repair. David and Yacoub independently described different techniques for valve repair in patients with aortic insufficiency, with encouraging results. David's approach is based on the principle that aortic insufficiency in patients with aortoannular ectasia is secondary to annular dilatation and distortion of the sinotubular junction. David's approach involved excising the aneurysmal portion of the aortic root and reimplanting the aortic valve inside a tubular Dacron graft. Yacoub reported a similar valve-sparing technique for patients with annuloaortic ectasia. With Yacoub's technique the aortic wall and sinuses of Valsalva are excised down to the anatomic annulus. The Dacron graft is sutured to the annulus, the valve is resuspended, and the coronary buttons are reimplanted.

Ross procedure. The Ross procedure involves replacement of the aortic valve with an autograft from the patient's native pulmonary valve. The resected pulmonary valve is then replaced with a pulmonary homograft. Variations of the technique of implantation of the autograft for the aortic valve replacement include free-hand replacement with resuspension of the valve commissures, and cylinder root replacement with reimplantation of the coronary artery ostia.

The Ross procedure has risks similar to those associated with standard aortic valve replacement, although the risk of bleeding may be slightly higher. The primary benefit is that patients do not require long-term anticoagulation and the risk of thromboembolism is negligible. However, progressive late aortic insufficiency has been described in a number of patients, along with calcification of the pulmonary homograft and pulmonary stenosis. The risk of late reoperation ranges from 30–50 percent at 15–20 years.

Minimally invasive aortic valve surgery. Minimally invasive approaches for aortic valve surgery have recently become an acceptable alternative to conventional median sternotomy. Both ministernotomy and minithoracotomy approaches have been used with excellent success. Several centers have reported results that are at least comparable to standard surgery, but with less need for blood transfusions and shorter hospital stays. At NYU, minimally invasive aortic valve replacement is performed through a right anterior minithoracotomy incision. A report by Grossi and colleagues demonstrated that patients treated with the minimally invasive approach had less need for blood transfusions, fewer infections, and a shorter hospital stay than matched patients receiving traditional surgery. Thus, minimally invasive approaches for aortic valve replacement appear promising and deserve further investigation.

Idiopathic Hypertrophic Subaortic Stenosis

Patients with hypertrophic subaortic stenosis or idiopathic hypertrophic cardiomyopathy (IHSS) have varying degrees of subaortic left ventricular outflow tract obstruction, usually associated with systolic anterior motion of the mitral valve. The degree of left ventricular outflow tract obstruction at rest is a strong predictor of progression to severe symptoms of heart failure and death. However, most patients with hypertrophic cardiomyopathy and subaortic obstruction will respond to medical therapy, and only a minority will require surgical intervention.

Operative Techniques

Surgical septal myotomy and myectomy, developed by Morrow, has shown consistent results and remains the primary technique for treatment of IHSS. This approach requires resection of a trough of muscle from the subaortic outflow tract. Typically the resection is 1 cm wide and 1 cm deep, and extends the length of the septum to below the lower edge of the anterior leaflet of the mitral valve.

Tricuspid Stenosis and Insufficiency

Acquired tricuspid valve disease can be classified as organic or functional. Organic disease is almost always a result of either rheumatic fever or endocarditis. In patients with rheumatic disease, tricuspid stenosis or insufficiency virtually never occurs as an isolated lesion, but only in association with extensive disease of the mitral valve. Rarely, blunt trauma produces rupture of a papillary muscle or chordae tendineae with resultant tricuspid insufficiency.

Functional tricuspid regurgitation is much more common than insufficiency from organic disease. Functional tricuspid regurgitation develops from dilatation of the tricuspid annulus and right ventricle as a result of pulmonary hypertension and right ventricular failure. These abnormalities usually result from mitral valve disease or from other conditions that result in left ventricular failure and pulmonary hypertension.

With tricuspid stenosis the pathologic changes are similar to those found with the more familiar mitral stenosis, with fusion of the commissures. With rheumatic disease, mixed tricuspid stenosis and insufficiency or pure insufficiency may result from fibrosis and contraction of the valve leaflets, often in association with shortening and fusion of chordae tendineae. Calcification is rare.

Pathophysiology

With tricuspid stenosis or severe insufficiency, the mean right atrial pressure becomes elevated to 10–20 mm Hg or higher. The higher pressures are found with a tricuspid valve orifice smaller than 1.5 cm² and a mean diastolic gradient between the atrium and ventricle of 5–15 mm Hg or in patients with pulmonary hypertension and severe insufficiency. When the mean right atrial pressure remains above 15 mm Hg, hepatomegaly, ascites, and leg edema usually appear.

Clinical Manifestations

The symptoms and signs of tricuspid valve disease are similar to those of right heart failure resulting from mitral valve disease. They result from chronic elevation of right atrial pressure above the range of 15–20 mm Hg. Clinical manifestations include jugulovenous distention, hepatomegaly, pedal edema, and ascites. The characteristic murmur of tricuspid stenosis is best heard as a diastolic murmur at the lower end of the sternum. Tricuspid insufficiency produces a prominent systolic murmur heard best at the left lower sternal border. The murmur often is found in association with an enlarged, pulsating liver and prominent and engorged jugular veins.

Diagnostic Studies

The x-ray shows enlargement of the right atrium and right ventricle. Echocardiography confirms the diagnosis and differentiates stenosis from insufficiency. Cardiac catheterization is no longer necessary in most cases.

Indications for Surgery

Indications for surgery are based primarily on clinical findings, which are correlated with echocardiographic findings and hemodynamics. Severe insufficiency is indicated by echocardiography when the area of the regurgitant jet occupies a large part of the atrium, the effective regurgitant orifice is greater than 40 mm². Severe tricuspid regurgitation should clearly be repaired because it has been widely demonstrated that annuloplasty provides excellent late results with little added morbidity.

Operative Techniques

In the small minority of patients whose tricuspid stenosis is secondary to pure commissural fusion, a commissurotomy may be performed, usually combined with an annuloplasty. More commonly, valve replacement is necessary when significant tricuspid stenosis is present, because the entire valve and subvalvular apparatus are damaged. When a prosthetic valve is inserted, care is required in suture placement along the septal leaflet in which the conduction bundle is located, and sutures should be placed more superficially in this area.

In patients with functional tricuspid insufficiency the annulus is markedly dilated, although the leaflets appear entirely normal. Virtually all such patients can be treated by annuloplasty. Alternatively, a flexible or rigid annuloplasty device may be used.

Results

Data on more than 300 patients from the authors' institution show that the suture annuloplasty repair for functional tricuspid insufficiency is reproducible in the absence of significant intrinsic leaflet disease. Other centers prefer the use of rigid or flexible annuloplasty devices for correction of tricuspid insufficiency. When tricuspid valve replacement is required, the options include use of either a tissue valve or a mechanical valve. Data suggest that the risk of valve thrombosis is increased in mechanical valves placed in the tricuspid position. Bioprostheses are therefore preferred for most patients requiring tricuspid valve replacement.

Multivalve Disease

Disease involving multiple valves is relatively common, particularly in patients with rheumatic disease. Prominent signs in one valve can readily mask disease in others. With aortic valve disease, functional mitral insufficiency can result from a progressive rise in the left ventricular end-diastolic pressure and volume. Similarly, mitral valve disease may result in pulmonary hypertension, right heart failure, and functional tricuspid insufficiency. Often these secondary functional changes resolve without treatment if the primary pathology is corrected in a timely fashion.

Aortic and Mitral Valve Disease

Nine combinations of valvular pathology can produce aortic and mitral valve disease (AV + MV), because each valve can be stenotic, insufficient, or both. Stenosis in both valves may lead to underestimation of the degree of aortic stenosis, because return of blood to the left ventricle is limited as a result of mitral stenosis. Aortic insufficiency, which produces the Austin Flint murmur, might overshadow and mask true mitral stenosis. With functional mitral insufficiency resulting from severe aortic disease, aortic valve replacement can lead

to resolution of insufficiency in some patients, but patients with more severe mitral insufficiency may require mitral repair or replacement.

Mitral and Tricuspid Valve Disease

Multiple combinations of valvular pathology are possible with mitral and tricuspid disease, but mitral disease with functional tricuspid insufficiency is the most common scenario, resulting from chronic pulmonary hypertension and right heart failure. The presence of associated tricuspid insufficiency increases the operative risk for patients undergoing mitral valve surgery. The risk for isolated mitral and tricuspid valve disease (MV + TV) is approximately 6 percent.

Triple-Valve Disease

Triple-valve surgery can be challenging because the clinical condition usually is a result of chronic aortic and mitral disease with severe pulmonary hypertension, biventricular failure, and functional tricuspid insufficiency. The degree of pulmonary hypertension is the most significant predictor of survival in patients with triple-valve disease.

PERICARDIAL DISEASES

Acute Pericarditis

Pericarditis results from acute inflammation of the pericardial space, resulting in substernal chest pain, ECG changes, and a pericardial friction rub on physical examination. Associated ECG changes frequently occur, most commonly sinus tachycardia with concave upward ST-segment elevation throughout the precordium. The ECG typically progresses to T-wave inversion, followed by the total resolution of all changes. The cause of acute pericarditis is variable, including infection, myocardial infarction, trauma, neoplasm, radiation, autoimmune diseases, drugs, nonspecific causes, and others.

Diagnosis

The diagnostic workup should attempt to determine the underlying cause of the pericarditis. Blood tests should include erythrocyte sedimentation rate, hematocrit level, white blood cell count, bacterial cultures, viral titers, blood urea nitrogen, T3, T4, thyroid-stimulating hormone, antinuclear antibody, rheumatoid factor, and myocardial enzyme levels. The ECG may be typical or nonspecific. The chest radiograph may be normal or may demonstrate an enlarged cardiac silhouette or a pleural effusion. An echocardiogram to evaluate the degree of pericardial effusion is essential. A pericardiocentesis or pericardial biopsy may be necessary when the diagnosis is uncertain.

Treatment

The preferred treatment depends on the underlying cause. Purulent pyogenic pericarditis requires drainage and prolonged intravenous antibiotic therapy. Postpericardiotomy syndrome, post-myocardial infarction syndrome, viral pericarditis, and idiopathic pericarditis often are self-limiting, but can require a short course of treatment with nonsteroidal antiinflammatory agents. If a significant pericardial effusion is present, surgical drainage is indicated if tamponade is suspected or if resolution is not prompt with antiinflammatory agents. A 5–7-day course of steroids is occasionally necessary.

Chronic Constrictive Pericarditis

Etiology

In the majority of patients, the cause of chronic constrictive pericarditis is unknown and probably is the end stage of an undiagnosed viral pericarditis. Tuberculosis is a rarity. Intensive radiation is a significant cause in some series. Constrictive pericarditis may develop after an open-heart operation. Previous cardiac surgery was reported to be the cause in 39 percent of the patients treated surgically for constrictive pericarditis at the authors' institution.

Pathology and Pathophysiology

The pericardial cavity is obliterated by fusion of the parietal pericardium to the epicardium, forming dense scar tissue that encases and constricts the heart. The physiologic handicap is limitation of diastolic filling of the ventricles. This results in a decrease in cardiac output from a decrease in stroke volume.

Clinical Manifestations

The disease is slowly progressive with increasing ascites and edema. Fatigability and dyspnea on exertion are common, but dyspnea at rest is unusual. Hepatomegaly and ascites often are the most prominent physical abnormalities. The heart size remains normal without murmurs or abnormal sounds.

Laboratory Findings

Venous pressure is elevated, often to 15–20 mm Hg or higher. The ECG, although not diagnostic, usually is abnormal with a low voltage and inverted T waves. The chest radiograph usually shows a heart of normal size, but pericardial calcification may be seen in a significant proportion of cases and often is the first clue to the diagnosis. Echocardiogram, MRI, or CT scan may demonstrate a thickened pericardium.

Findings on cardiac catheterization are highly characteristic. There is elevation of the right ventricular diastolic pressure with a change in contour, showing an early filling with a subsequent plateau, called the “square root” sign. There also is “equalization” of pressures in the different cardiac chambers. The one condition that cannot be excluded without myocardial biopsy is a restrictive cardiomyopathy.

Treatment

When the diagnosis has been made, pericardiectomy should be done promptly, because the disease relentlessly progresses. Operation can be done through a sternotomy incision or a long left anterolateral thoracotomy. The constricting pericardium should be removed from all surfaces of the ventricle. Cardiopulmonary bypass is not usually necessary, but may be needed in the event of significant hemorrhage. The pericardium is removed from the pulmonary veins on the right to the pulmonary veins on the left. Both phrenic nerves are mobilized and protected. Intracardiac pressures should be measured by direct needle puncture before and after pericardiectomy. Often with a complete pericardiectomy the characteristic pressure abnormalities are eliminated or greatly improved.

Results

After a radical pericardiectomy that corrects the hemodynamic abnormalities, patients improve promptly with a massive diuresis. The risk of operation varies with the age of the patient and the severity of the disease; the mortality rate usually is less than 5 percent. A good result can be anticipated for more than 95 percent of the patients.

CARDIAC NEOPLASMS

Primary cardiac neoplasms are rare, reported to occur with incidences ranging from 0.001–0.3 percent in autopsy series. Benign tumors account for 75 percent of primary neoplasms and malignant tumors account for 25 percent. The most frequent primary cardiac neoplasm is myxoma, comprising 30–50 percent. Other benign neoplasms, in decreasing order of occurrence, include lipoma, papillary fibroelastoma, rhabdomyoma, fibroma, hemangioma, teratoma, lymphangioma, and others. Most primary malignant neoplasms are sarcomas (angiosarcoma, rhabdomyosarcoma, fibrosarcoma, leiomyosarcoma, and liposarcoma), with malignant lymphomas accounting for 1–2 percent.

Metastatic cardiac neoplasms are more common than primary neoplasms, occurring in 4–12 percent of patients dying of cancer. Symptoms include dyspnea, fever, malaise, weight loss, arthralgias, and dizziness. Clinical findings may include murmurs of mitral stenosis or insufficiency, heart failure, pulmonary hypertension, and systemic embolization.

Usually, the diagnosis is readily established by two-dimensional echocardiography. Transesophageal echocardiography may be useful when transthoracic findings are equivocal or confusing. MRI has been of value in diagnosis, providing excellent cardiac definition. Cardiac catheterization may be necessary when other cardiac disease is suspected or if other diagnostic studies are equivocal.

Excision is the treatment of choice for most benign tumors. Care is taken to avoid deformity or destruction of adjacent cardiac structures, and reconstruction of the involved cardiac chamber is sometimes necessary. Total excision of metastatic or primary malignant neoplasms is less frequently possible but should be attempted. Otherwise incisional diagnostic biopsy is performed. Multimodality therapy with excision, chemotherapy, and radiotherapy is indicated for most malignant cardiac neoplasms.

Myxomas

Sixty to 75 percent of cardiac myxomas develop in the left atrium, almost always from the atrial septum near the fossa ovalis. Most other myxomas develop in the right atrium. Myxomas are true neoplasms, although their similarity to an organized atrial thrombus has led to considerable debate. Although they can recur locally, they do not invade or metastasize and are considered benign.

Pathology

The tumors usually are polypoid, projecting into the atrial cavity from a 1–2-cm stalk attached to the atrial septum. The size ranges from 0.5 cm to larger than 10.0 cm. Some myxomas grow slowly; a few patients have symptoms for many years. The friable consistency of a myxoma is of particular significance because fatal emboli have occurred after digital manipulation of the tumor at operation.

Pathophysiology

A myxoma may be completely asymptomatic until it grows large enough to obstruct the mitral or tricuspid valve or fragments to produce emboli. Embolization has been estimated to occur in 40–50 percent of patients. Intermittent acute obstruction of the mitral orifice has been reported to produce syncope and even sudden death. Some myxomas produce generalized symptoms resembling an autoimmune disorder, including fever, weight loss, digital clubbing, myalgia, and arthralgia.

Clinical Manifestations

Symptoms may include those of mitral valve obstruction that resemble mitral stenosis; peripheral embolization; or generalized autoimmune symptoms. The diagnosis often is made after an embolic episode from histologic examination of the surgically removed embolus, or as a result of subsequent diagnostic studies to determine the reason for embolism. The precision and reliability of two-dimensional echocardiography has greatly simplified diagnosis. Angiography is optional unless additional disease is suspected. CT scan has been reported to be helpful with small tumors, but MRI is more definitive.

Treatment

Surgery should be performed as soon as possible after the diagnosis has been established, because of the inherent risk of a disabling or fatal cerebral embolus. Either a sternotomy or a minimally invasive approach can be used. Palpation is avoided. The right atrium is opened and the fossa ovalis incised to expose the stalk of the myxoma. The left atrium is then opened in the interatrial groove. With the tumor visualized, the segment of atrial septum from which the tumor arises is excised, after which the tumor is removed through the left atrium. The defect in the atrial septum is closed primarily or with a small patch.

Metastatic Neoplasms

Cardiac metastases have been found in 4–12 percent of autopsies performed for neoplastic disease. Although they have occurred from primary neoplasms developing in almost every known site of the body, the most common have been carcinoma of the lung or breast, melanoma, and lymphoma. Cardiac metastases involving only the heart are very unusual. Similarly, a solitary cardiac metastasis is rare; usually there are multiple areas of involvement. The diagnosis of a primary cardiac malignant tumor may be suspected in a patient in whom an unexplained hemorrhagic pericardial effusion develops, especially in association with a bizarre cardiac shadow on the radiograph. Echocardiography should confirm the presence of an abnormal cardiac mass. Thoracotomy or sternotomy usually is required to establish the diagnosis. Combined chemotherapy and radiation is indicated, but only rarely is effective therapy possible.

Miscellaneous Tumors

Unusual benign lesions of the heart include fibromas, lipomas, angiomas, teratomas, and cysts. Fewer than 50 of each of these types of lesion have been reported. Fibromas have been found most frequently in the left ventricle, often as 2–5-cm nodules within the muscle. Sudden death, probably from a cardiac arrhythmia, has been reported with these tumors, and may be the reason that only 18 percent of tumors that have been reported have been found in adults.

Lipomas are rare asymptomatic tumors found projecting from the epicardial or endocardial surface of the heart in older patients. Angiomas are small, focal, vascular malformations of no clinical significance, although may be associated with heart block. Pericardial teratomas and bronchogenic cysts are rare lesions that can cause symptoms from compression of the right atrium and obstruction of venous return. Most of these occur in children.

Renal cell carcinoma, Wilms tumor, uterine tumors, and adrenal tumors may have intracardiac extension. Excision of these infradiaphragmatic tumors by radical surgery associated with cavoatrial thrombectomy has been suggested, and extracorporeal circulation and deep circulatory arrest provide an optimal technique for removing the tumor thrombus, even in the presence of metastatic disease, and have good early and long-term results.

POSTOPERATIVE CARE AND COMPLICATIONS

General Considerations

Postoperative care of cardiac surgical patients involves prevention, recognition, and correction of the metabolic and hemodynamic derangements that are frequently seen after cardiac surgery. Important areas include myocardial and pulmonary support, fluid and electrolyte management, and control of bleeding and coagulopathy. All patients are observed in a specialized recovery room or intensive care unit after cardiac surgery, in which hemodynamic data are continuously analyzed using both invasive and noninvasive monitoring. Additionally, important laboratory parameters, including arterial blood gases, enzymatic markers of cardiac injury, and mixed venous O₂ saturation, are measured serially.

Early postoperative complications include bleeding, cardiac tamponade, arrhythmias, myocardial infarction, graft occlusion, coronary spasm, low cardiac output syndrome, cardiac arrest, and stroke. Later complications include delayed bleeding, postpericardiotomy syndrome with pericardial effusion, renal dysfunction, ileus, mesenteric ischemia, gastrointestinal hemorrhage, pneumothorax, respiratory insufficiency, pneumonia, wound infection, and wound dehiscence. Although the incidence of serious complications is relatively low (3–6 percent), each complication is potentially life-threatening and can be associated with significant morbidity.

Hemodynamics

Maintenance of cardiac function is critical in any patient following heart surgery. Although adequate cardiac output may be reflected in the blood pressure and the urine output, exact determination may be obtained with invasive monitoring equipment. A cardiac index less than 2 L/min per square meter is an ominous finding, and should prompt immediate investigation into possible causes of decreased cardiac performance. The classic clinical findings of low cardiac output with inadequate oxygen transport include hypotension, vasoconstriction, oliguria, and metabolic acidosis. Untreated low cardiac output is ultimately fatal from either progressive renal failure or arrhythmias.

When evaluating low cardiac output in the postoperative setting, the first consideration is to exclude cardiac tamponade or hypovolemia because of intrathoracic bleeding. Once these have been excluded, the physiologic causes of low output should be reviewed in terms of preload, afterload, and intrinsic contractility of the heart.

Afterload reduction consists of reduction in peripheral vascular resistance with specific drugs that cause vasodilatation. If peripheral vascular resistance is elevated above the normal 1200 dynes/s/cm², afterload reduction should be one of the initial forms of therapy. The most popular drugs for intravenous infusion are nitroprusside or nitroglycerin. Vasodilation, or decreased peripheral resistance, should be treated with vasoconstrictors such as phenylephrine to maintain an adequate perfusion pressure.

Once bleeding and tamponade are excluded and preload and afterload have been optimized, inotropic agents may be used to augment myocardial contractility. First-line medications include milrinone and dobutamine, which may be augmented with nor-epinephrine or phenylephrine when the peripheral vascular resistance is low. Dopamine and epinephrine are useful second-line inotropic agents.

If the intrinsic cardiac rhythm is not sufficient to maintain optimal hemodynamics, cardiac pacing should be used to maintain both an adequate rate and rhythm. Optimal heart rate to maximize cardiac output without unduly increasing myocardial oxygen consumption generally is 80–90 beats per min.

If low cardiac output persists despite optimizing preload, afterload, and inotropic support, an intraaortic balloon pump (IABP) may be useful.

Electrocardiogram and Arrhythmias

The postoperative ECG is important for determining heart block, bundle-branch block, infarction (Q waves), ischemia (ST-segment elevation, T-wave inversion), and other signs of intraoperative injury. Acute ischemia or evolving infarction should be treated initially with nitrates and beta blockade. If ECG changes do not resolve promptly, acute graft occlusion should be considered, particularly if the patient is hemodynamically unstable.

In addition to serial 12-lead ECGs, continuous monitoring of the cardiac rhythm remains important in the postoperative setting. Life-threatening arrhythmias may develop unexpectedly despite the presence of a normal cardiac output and without any other signs of circulatory failure. Postoperative bradyarrhythmias and heart block are not uncommon, and for this reason temporary cardiac pacing wires are routinely placed in the right ventricle and right atrium at operation.

Other arrhythmias, including ventricular extrasystoles and ventricular tachycardia, may herald the development of ventricular fibrillation. Hypokalemia is an important cause of ventricular arrhythmias, as many patients undergoing cardiac surgery may have significant depletion of total body potassium stores from chronic diuretic therapy. Postoperatively serum potassium should be kept above 4.0 mEq/L. Continuous intravenous lidocaine or amiodarone has proven to be effective in controlling postoperative ventricular arrhythmias.

Atrial fibrillation remains the most common postoperative arrhythmia. Beta blockers should be initiated early postoperatively unless contraindicated, as this has been found to lower the risk of developing postoperative atrial fibrillation. If atrial fibrillation does develop, initial treatment involves heart rate control with beta blockers and intravenous digitalis. If atrial fibrillation persists, anticoagulation with heparin is indicated, followed by an attempt at cardioversion, usually pharmacologically. Amiodarone is effective in converting postoperative patients to sinus rhythm. If atrial fibrillation results in hemodynamic instability, the patient should be cardioverted with 50–100 J.

Cardiac Arrest and Resuscitation

Complete circulatory collapse in the postoperative cardiac surgical patient can occur without warning. Circulation must be restored within min or the brain and myocardium may suffer irreversible injury. Frequent causes of postoperative cardiac arrest include cardiac tamponade, arrhythmias, ischemia or graft occlusion, hypoxia, and drug toxicity.

Cardiac tamponade is a serious complication following cardiac surgery. It may occur early in the postoperative period from the accumulation of intrapericardial blood or later from a pericardial effusion. The classic findings of tamponade include: (1) elevation of central venous pressure; (2) equalization of central venous pressure, pulmonary artery diastolic pressure, and left atrial pressure; and (3) pulsus paradoxus of more than 10 mm Hg during inspiration. Clinical signs may include distended neck veins, muffled heart sounds, and hypotension. Extreme cases of tamponade may present with life-threatening hypotension or sudden circulatory collapse. A widening of the mediastinal shadow on chest radiograph or detection of significant pericardial effusion by echocardiography is suggestive of the diagnosis. No single test can exclude tamponade short of surgical exploration. Therefore any patient with suspected tamponade should be promptly returned to the operating room for definitive diagnosis and treatment. Moreover, any postoperative patient in extremis with suspected tamponade should undergo emergent re-exploration or subxiphoid drainage performed at the bedside to rule out tamponade.

Electrolyte imbalance, such as a deficiency of potassium or magnesium, also can cause serious arrhythmias leading to cardiac arrest or ventricular fibrillation. A serum potassium level below 3.0 mEq can produce severe cardiac irritability postoperatively. Difficulties with ventilation and hypoxia may lead to cardiac arrhythmias from low arterial oxygen tension and progressive metabolic acidosis. Common causes include inadequate ventilation from pneumothorax, dislodgment of the endotracheal tube, and plugging of the airway with secretions.

Drugs may induce bradycardia, heart block, ventricular fibrillation, or cardiac arrest, either from toxicity or from an idiosyncratic reaction. Digitalis is a common example because of its widespread use. The sensitivity of the myocardium to digitalis varies with a number of factors, one of the most important of which is the concentration of potassium. Procainamide and quinidine are examples of drugs with known proarrhythmic effects.

Profound bradycardia (heart rate < 60 beats per min) from any cause may result in escape beats leading to ventricular fibrillation and cardiac arrest. Ventricular arrhythmias may progress to bigeminy, ventricular tachycardia, and ventricular fibrillation.

Treatment

Advanced Cardiac Life Support (ACLS) guidelines include specific algorithms for the treatment of cardiac arrest and other causes of circulatory arrest. The immediate first steps in CPR are to secure an adequate airway and provide prompt ventilation. Effective perfusion with closed-chest massage or with inotropes or pressors may then be necessary. Effective CPR depends on adequate intermittent compression of the heart between the sternum and the vertebral column. The patient must be placed on a firm surface, usually by placing a board behind the back. The heel of the hand should be applied over the lower third of the

sternum with the other hand above it to depress the sternum intermittently for 3–4 cm. Massage should be at a rate of about 60/min.

In the postoperative cardiac surgery patient with cardiac arrest, closed-chest massage may be initiated immediately as part of a resuscitative effort that may also include defibrillation and the administration of pharmacologic agents. If cardiac activity is not quickly restored or if the cardiac arrest is thought to be because of a mechanical cause such as tamponade or hemorrhage, the sternotomy incision is reopened immediately at the bedside and internal cardiac massage is instituted. The patient may then be returned to the operating room once the chest is opened, and CPB is initiated for support. After the patient is resuscitated the surgeon must determine if further therapy such as mechanical support or additional bypass grafting is indicated.

Drugs and Fluids

Epinephrine, sodium bicarbonate, and calcium are the most useful pharmacologic agents. Again, the protocols suggested by the ACLS program are followed. Epinephrine, 1 mg, may be given intravenously or alternately by direct intracardiac injection. Calcium, 3–4 mL of a 10 percent solution, is another powerful stimulant of myocardial contraction. Lidocaine is given primarily for ventricular arrhythmias, followed by amiodarone for refractory ventricular tachycardia. Medications are usually ineffective if severe myocardial anoxia or significant acidosis is present. Small amounts of fluid should be rapidly infused because vasodilatation is usually present. An intravenous infusion of a vasoconstrictor, norepinephrine or phenylephrine, is often helpful to maintain perfusion pressure. Blood transfusion may be required in the postoperative patient for volume resuscitation and improved oxygen-carrying capacity.

Defibrillation

Ventricular fibrillation can be differentiated from asystole only by the electrocardiogram or by direct inspection of the myocardium. Intravenous lidocaine is promptly administered. If this is not quickly effective and an electrocardiogram is not available, empiric defibrillation may be tried briefly because most resuscitations are effective when defibrillation is done promptly. Asystole is treated by pacing the heart with a transcutaneous pacemaker, a transvenous pacemaker if access is readily available, or a temporary pacing lead that can be placed directly on the myocardium if the chest is open.

Closed-chest defibrillation is usually done by applying electrodes over the base and apex of the heart. Defibrillation is best done with a direct current of 200–360 J. When open-chest defibrillation is used, the electrodes are applied directly to the heart and an impulse of 20–40 J is delivered. Vigorous cardiac massage should precede defibrillation to oxygenate the myocardium sufficiently.

Following restoration of an adequate heart beat and blood pressure, the critical question is the extent of injury to the heart and to the central nervous system. A thorough search for reversible causes of the arrhythmia is undertaken immediately. If ischemia or graft occlusion is suspected, the patient is taken for cardiac catheterization or back to the operating room.

Blood Loss

Blood conservation and minimization of bleeding associated with cardiac surgery begin preoperatively. Preoperative workup routinely includes a

prothrombin time (PT), partial thromboplastin time (PTT), and platelet count. Patients with a history of abnormal bleeding or with chronic passive congestion of the liver receive full coagulation profiles and evaluation by a hematologist. Patients taking warfarin are instructed to discontinue the drug 3 to 4 days preoperatively so the PT can return to normal.

Because blood conservation is highly desirable, many patients operated on electively are able to donate autologous blood 1–3 weeks before surgery. Often erythropoietin is used after autologous donation to enhance the patient's red blood cell mass. Donor-directed blood units are solicited from family and friends.

Postoperative Bleeding

For most open heart cases coagulopathy is nonexistent and the postoperative blood loss is low. The normal total postoperative blood loss should range from 300 to 800 mL. Blood loss in excess of 300–500 mL/h or over 1–1.5 L total usually indicates active surgical bleeding, and is associated with a high incidence of hemodynamic compromise or cardiac tamponade.

The diagnosis of coagulopathy is made by the operating surgeon with the observation of abnormal bleeding from the operative field in the absence of a surgical source. Laboratory tests can confirm the diagnosis, but treatment should not be delayed until test results return, as this might further worsen the coagulation deficit, with fatal consequences.

Treatment of coagulopathy is urgent. Hypothermia should be corrected and extra protamine should be given until the activated clotting time returns to normal or until no further drop is seen in the activated clotting time. If abnormal bleeding persists, transfusion of platelets, fresh-frozen plasma, and cryoprecipitate is given until the clotting deficit is corrected. Antifibrinolytic agents such as ϵ -aminocaproic acid may be given to correct fibrinolysis. The pharmacologic prevention of coagulopathy is more effective if the protease inhibitor aprotinin is given preoperatively.

Ventilatory Support and Pulmonary Care

Nearly all cardiac surgical patients return to the recovery room intubated. Tidal volumes on the respirator are usually set at 10–15 mL/kg. Weaning the patient is done via the intermittent mandatory ventilation (IMV) mode or via progressive continuous positive airway pressure (CPAP) trials. With current preoperative preparation and intraoperative management, significant postoperative impairment of pulmonary function is uncommon, except in patients with preexisting pulmonary disease or advanced cardiac failure. If periods of ventilation longer than 3–4 days are anticipated, a cricothyroidotomy or tracheostomy should be considered.

General Care

Nutrition

The need for adequate postoperative nutrition cannot be overemphasized, particularly in elderly or chronically ill patients. The sick postoperative heart patient may require approximately 25–kcal/kg per day. Care should be taken to give adequate protein to patients with normal renal and hepatic function, although special formulas are available for patients with kidney or liver failure.

Wound Care

Early postoperative care of the surgical wound consists of the use of a sterile occlusive dressing for the first 24 h. Prophylactic antibiotics are started preoperatively and continued for 24–48 h postoperatively, usually until indwelling catheters and chest tubes are removed.

Fever

A moderate fever of 37.8–38.3°C (100–101°F) is common in the first 1–2 days, usually resulting from the systemic inflammatory response induced by the extracorporeal circulation and the stress of major surgery or from atelectasis. A fever occurring from 3–7 days postoperatively with a normal white blood cell count is frequently because of postpericardiotomy syndrome. The syndrome can be treated with nonsteroidal antiinflammatory agents or occasionally with a short course of steroids. Significant fevers should be evaluated with a chest radiograph and blood and urine cultures.

A serious sternal wound infection occurs in 1–2 percent of all open heart operations. Risk factors include diabetes, obesity, impaired nutrition, COPD, prolonged ventilatory support, harvest of bilateral internal mammary arteries, older age, low cardiac output, excessive mediastinal bleeding, re-exploration for bleeding, multiple transfusions, and prolonged CPB. *Staphylococcus aureus* and *Staphylococcus epidermidis* are the most common organisms isolated. Treatment requires prompt operation with either débridement and closure over antibiotic irrigation/drainage catheters or débridement followed by immediate or delayed closure with muscle flaps. The mortality rate from a sternal infection after cardiac surgery is 10–20 percent.

Rehabilitation

Most patients will benefit from early initiation of physical therapy and a cardiac rehabilitation program, but these treatments are especially important in elderly and debilitated patients. Physical therapy should begin early during the hospital stay and continue with a formalized rehabilitation program for an additional 1–2 weeks. Formal cardiac rehabilitation is usually available as either an inpatient or an outpatient program, depending on the patient's age and physical condition.

Thoracic Aortic Aneurysms and Aortic Dissection

Joseph S. Coselli and Scott A. LeMaire

THORACIC AORTIC DISEASE

The aorta consists of two major segments—the proximal aorta and the distal aorta—each of which has anatomic characteristics that impact clinical manifestations and treatment strategies. The proximal aortic segment includes the ascending aorta and the transverse aortic arch. The ascending aorta begins at the aortic valve and ends at the origin of the innominate artery. The first portion of the ascending aorta is the aortic root, which includes the aortic valve annulus and the three sinuses of Valsalva and joins the tubular portion of the ascending aorta at the sinotubular ridge. The transverse aortic arch is the segment from which the brachiocephalic branches arise. The distal aorta includes the descending thoracic aorta and the abdominal aorta. The descending thoracic aorta begins distal to the origin of the left subclavian artery and extends to the diaphragmatic hiatus, in which it joins the abdominal aorta. The descending thoracic segment gives rise to multiple bronchial and esophageal branches and the segmental intercostal arteries, which provide circulation to the spinal cord.

Conditions that disrupt the integrity of the aorta (i.e., aortic dissection, aneurysm rupture, or traumatic injury) have catastrophic consequences.

THORACIC AORTIC ANEURYSMS

Aortic aneurysm is defined as a permanent dilatation resulting in at least a 50 percent increase in diameter. The incidence of thoracic aortic aneurysms is estimated to be 5.9 per 100,000 persons annually. Causes of thoracic aortic aneurysms include degenerative disease of the aortic wall, aortic dissection, aortitis, infection, and trauma. Thoracoabdominal aortic aneurysms, for example, involve both the descending thoracic aorta and abdominal aorta. In the most extreme, the entire aorta is aneurysmal; this often is described as “mega-aorta.”

Aneurysms of the thoracic aorta consistently increase in size and progress to rupture, which is usually a fatal event. Aggressive treatment is indicated in all but the poorest surgical candidates. Small asymptomatic thoracic aortic aneurysms can be followed. Meticulous control of hypertension is the primary medical treatment.

Elective resection with graft replacement is indicated in asymptomatic patients with an aortic diameter of at least twice the normal diameter for the involved segment (5–6 cm in most thoracic segments). Contraindications to elective repair include severe coexisting cardiac or pulmonary disease, or a limited life expectancy. An emergency operation is required for any patient in whom a ruptured aneurysm is suspected.

Etiology and Pathogenesis

General Considerations

Table 21-1 lists causes of thoracic aortic aneurysms. These disparate pathologic processes share the final common pathway of progressive aortic expansion and

TABLE 21-1 Causes of Thoracic Aortic Aneurysms

Trauma

rupture. Hemodynamic factors clearly contribute to the process. The vicious cycle between increasing diameter and increasing wall tension, as characterized by the Laplace law (tension = pressure \times radius), is well established. Turbulent blood flow also is recognized as a factor. Poststenotic aortic dilatation, for example, occurs in some patients with aortic valve stenosis or coarctation of the descending thoracic aorta.

Atherosclerosis is commonly cited as a cause of thoracic aortic aneurysms. Although atherosclerotic disease often is found in conjunction with aortic aneurysms, the notion that atherosclerosis is a distinct cause of aneurysm formation has been challenged. Imbalances between proteolytic enzymes (e.g., matrix metalloproteinases) and their inhibitors contribute to abdominal aortic aneurysm formation.

Nonspecific Medial Degeneration

Nonspecific medial degeneration is the most common cause of thoracic aortic disease. Histologic findings of mild medial degeneration, including fragmentation of elastic fibers and loss of smooth muscle cells, are expected in the aging aorta. An advanced, accelerated form of medial degeneration leads to progressive weakening of the aortic wall, aneurysm formation, and eventual rupture and/or dissection.

Aortic Dissection

Aortic dissections usually begin as a tear in the inner aortic wall, which initiates a progressive separation of the medial layers, creating two channels within the aorta and a profoundly weakened outer wall. As the most common catastrophe involving the aorta, dissection represents a major, distinct cause of thoracic aortic aneurysms.

Genetic Disorders

Marfan syndrome. Marfan syndrome is an autosomal dominant genetic disorder characterized by a specific connective tissue defect that leads to aneurysm formation. The phenotype of patients with Marfan syndrome typically includes a tall stature, high palate, joint hypermobility, lens disorders, mitral valve prolapse, and aortic aneurysms. The aortic wall is weakened by fragmentation of elastic fibers and deposition of extensive amounts of mucopolysaccharides

(cystic medial degeneration). Patients with Marfan syndrome have a mutation involving the fibrillin gene located on the long arm of the chromosome 15. Abnormal fibrillin in the extracellular matrix decreases connective tissue strength in the aortic wall and produces abnormal elastic properties that predispose the aorta to dilatation from wall tension resulting from left ventricular ejection impulses. Seventy-five to 85 percent of patients with Marfan syndrome exhibit dilation of the ascending aorta with dilation of the aortic sinuses and annulus.

Ehlers-Danlos syndrome. Ehlers-Danlos syndrome includes a spectrum of inherited connective tissue disorders of collagen synthesis. Type IV Ehlers-Danlos syndrome is characterized by an autosomal dominant defect in type III collagen synthesis, and may produce life-threatening cardiovascular manifestations including aortic aneurysms. Spontaneous arterial rupture, usually involving the mesenteric vessels, is the most common cause of death in these patients.

Familial aortic aneurysms. Guo and colleagues demonstrated a linkage to the 5q locus in nine of 15 families with strong family histories (i.e., autosomal dominant transmission) of ascending aortic aneurysms and dissections. Similar studies have found linkages to chromosomes 3 and 11.

Congenital bicuspid aortic valve. Bicuspid aortic valve is the most common congenital malformation of the heart or great vessels, affecting nearly 1–2 percent of Americans. Patients with bicuspid aortic valves have an increased incidence of ascending aortic aneurysm formation and exhibit a more rapid rate of aortic enlargement. Aortic dissection occurs 10 times more often in patients with bicuspid valves. Patients with bicuspid aortic valves may have a congenital connective tissue abnormality that predisposes them to aneurysm formation in the setting of chronic turbulent flow through a deformed valve.

Infection

Primary infection of the aortic wall resulting in aneurysm formation is rare. Although termed mycotic aneurysms, the responsible pathogens are usually bacteria rather than fungi. Bacterial invasion of the aortic wall may result from bacterial endocarditis, endothelial trauma caused by an aortic jet lesion, or extension from an infected laminar clot within a preexisting aneurysm. The most common organisms include *Staphylococcus aureus*, *S. epidermidis*, *Salmonella*, and *Streptococcus* species. Infection often produces saccular aneurysms localized in areas destroyed by the infectious process.

Aortitis

Patients with preexisting degenerative thoracic aortic aneurysms can develop localized transmural inflammation and subsequent fibrosis. Although the severe inflammation is a superimposed problem rather than a primary cause, its onset within an aneurysm can further weaken the aortic wall and precipitate expansion.

Systemic autoimmune disorders also cause thoracic aortitis. Although Takayasu arteritis generally produces obstructive lesions related to severe intimal thickening, associated medial necrosis can lead to aneurysm formation. Patients with giant cell arteritis (temporal arteritis) may develop granulomatous inflammation involving the entire thickness of the aortic wall, causing intimal thickening and medial destruction. Rheumatoid aortitis, with medial

inflammation and fibrosis, can affect the aortic root, causing ascending aortic aneurysm.

Pseudoaneurysms

Pseudoaneurysms, or false aneurysms, of the thoracic aorta usually represent chronic leaks that are contained by surrounding tissue and fibrosis. By definition, the wall of a pseudoaneurysm is not formed by intact aortic tissue; rather, the wall develops from organized thrombus and associated fibrosis. Pseudoaneurysms arise from primary defects in the aortic wall or anastomotic leaks after cardiovascular surgery.

Natural History

Classically, the natural history is characterized as progressive aortic dilatation and eventual rupture and/or dissection. Average expansion rates are 0.07 cm per year in ascending aortic aneurysms and 0.19 cm per year for descending thoracic aortic aneurysms. Aortic diameter is a strong predictor of rupture, dissection, and mortality. For thoracic aortic aneurysms greater than 6 cm in diameter, annual rates of catastrophic complications are 3.6 percent for rupture, 3.7 percent for dissection, and 10.8 percent for death. Critical diameters, at which the incidences of complications are significantly increased, are 6.0 cm for aneurysms of the ascending aorta and 7.0 cm for aneurysms of the descending thoracic aorta.

Patients with Marfan syndrome have aneurysms that dilate at an accelerated rate and rupture or dissect at smaller diameters.

Clinical Manifestations

In many patients with thoracic aortic aneurysms, the aneurysm is discovered incidentally when imaging studies are obtained for unrelated reasons. Therefore patients often are asymptomatic at the time of diagnosis. When thoracic aortic aneurysms go undetected, they ultimately create symptoms and signs that correspond with the segment of aorta. These aneurysms produce a wide variety of manifestations, including compression or erosion of adjacent structures, aortic valve insufficiency, distal embolism, and rupture.

Local Compression and Erosion

Initially, expansion and impingement on adjacent structures causes mild chronic pain. The most common symptom in patients with ascending aortic aneurysms is anterior chest discomfort, frequently precordial in location, but may radiate to the neck and jaw, mimicking angina. Aneurysms of the ascending and transverse aortic arch can cause symptoms related to compression of the superior vena cava, the pulmonary artery, the airway, or the sternum. Expansion of the distal aortic arch can stretch the recurrent laryngeal nerve, resulting in left vocal cord paralysis and hoarseness. Descending thoracic and thoracoabdominal aneurysms cause back pain localized between the scapulae. Descending thoracic aortic aneurysms may cause varying degrees of airway obstruction, manifested as cough, wheezing, stridor, or pneumonitis. Compression or erosion of the esophagus creates dysphagia and hematemesis, respectively.

Aortic Valve Insufficiency

Ascending aortic aneurysms that involve the aortic root cause commissural displacement and annular dilatation, resulting in progressive aortic valve insufficiency, a widened pulse pressure and a diastolic murmur. These patients may present with progressive heart failure.

Distal Embolization

Thoracic aortic aneurysms are commonly lined with atheromatous plaque and mural thrombus. This debris may embolize distally, causing occlusion and thrombosis of the intercostals, visceral, renal, or lower-extremity branches.

Rupture

Patients with ruptured thoracic aortic aneurysms often experience sudden, severe pain in the anterior chest (ascending aorta), upper back or left chest (descending thoracic aorta), or left flank or abdomen (thoracoabdominal aorta). When ascending aortic aneurysms rupture, they usually bleed into the pericardial space, producing acute cardiac tamponade and death. Descending thoracic aortic aneurysms rupture into the pleural cavity, producing a combination of severe hemorrhagic shock and respiratory compromise.

Diagnostic Evaluation

Plain Radiographs

Plain radiographs of the chest, abdomen, or spine often provide enough information to support the initial diagnosis of thoracic aortic aneurysm. It is important to recognize that chest radiographs are commonly normal. Aortic root aneurysms, for example, are often hidden within the cardiac silhouette. Ascending aortic aneurysms produce a convex shadow to the right of the cardiac silhouette. Plain chest radiographs may demonstrate convexity in the right superior mediastinum, loss of the retrosternal space, or widening of the descending thoracic aortic shadow, which may be highlighted by a rim of calcification outlining the dilated aneurysmal aortic wall. Aortic calcification may also be seen in the upper abdomen on a standard roentgenogram made in the anteroposterior or lateral projections.

Echocardiography

Both transthoracic and transesophageal echocardiography provide excellent visualization of the ascending aorta, including the aortic root.

Computed Tomography

Computed tomographic (CT) scanning is widely available and provides visualization of the entire thoracic and abdominal aorta. Consequently, it is the most common—and arguably the most useful—imaging modality for evaluating thoracic aortic aneurysms. In addition to establishing the diagnosis, CT provides information regarding location, extent, anatomic anomalies, and relationship to major branch vessels. Contrast-enhanced CT provides information regarding the aortic lumen, and can detect mural thrombus, aortic dissection, inflammatory periaortic fibrosis, and mediastinal or retroperitoneal hematoma because of contained aortic rupture. It is particularly useful in determining the absolute diameter of the aorta.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) has become widely available and has the capability of assessing the entire aorta. MRA offers the advantage of avoiding exposure to nephrotoxic contrast and ionizing radiation. MRA offers excellent visualization of branch vessel details. The MRA environment is not appropriate for critically ill patients.

Aortography and Cardiac Catheterization

Diagnostic aortography was considered the standard criterion for evaluating thoracic aortic disease; CT and MRA have largely replaced this modality. Technologic improvements in CT and MRA provide excellent aortic imaging with less morbidity than catheter-based studies. If other imaging studies have not provided adequate detail, aortography can be obtained in patients with suspected branch vessel occlusive disease.

Cardiac catheterization continues to play a major role in diagnosis and preoperative planning, especially in patients with ascending aortic involvement. In addition to assessing the status of the coronary arteries and left ventricular function, proximal aortography evaluates the degree of aortic valve insufficiency, the extent of aortic root involvement, coronary ostial displacement, and the relationship of the aneurysm to the arch vessels.

The benefits of obtaining information from catheter-based diagnostic studies should be weighed against the established limitations and potential complications. Aortography only images the lumen, and may underestimate the size of large aneurysms that contain laminated thrombus. Manipulation of intraluminal catheters can result in embolization. Proximal aortography carries a 0.6–1.2 percent risk of stroke. Other risks include allergic reaction to contrast, iatrogenic aortic dissection, and bleeding at the arterial access site.

Management

Indications for Surgery

Thoracic aortic aneurysms are repaired to prevent fatal rupture. Therefore, elective operation is recommended when the diameter exceeds 5–6 cm, or when the rate of dilatation exceeds 1 cm/y. In patients with connective tissue disorders, such as Marfan and Ehlers-Danlos syndromes, the threshold for operation is lower for both absolute size and rate of growth. Smaller ascending aortic aneurysms (4–5 cm) also are considered for repair when they are associated with aortic valve insufficiency.

Many patients are asymptomatic at presentation and can undergo thorough preoperative evaluation and optimization. Symptomatic patients are at increased risk and warrant expeditious evaluation. The onset of new pain in patients with known aneurysms is especially concerning, and may herald significant expansion, leakage, or impending rupture. Emergent intervention is reserved for patients presenting with rupture or superimposed acute dissection.

Preoperative Assessment and Preparation

Cardiac evaluation. Coronary artery disease is common in patients with thoracic aortic aneurysms and is responsible for a substantial proportion of early and late postoperative deaths. Similarly, valvular pathology and myocardial dysfunction have important implications. Transthoracic echocardiography is a satisfactory noninvasive method for evaluating both valvular and biventricular

function. Dipyridamole-thallium myocardial scanning identifies regions of myocardium that have reversible ischemia. Cardiac catheterization with coronary arteriography is obtained in patients with evidence of coronary disease—based on history or noninvasive studies—or an ejection fraction of 30 percent or less. Patients who have asymptomatic distal aortic aneurysms and severe coronary artery occlusive disease undergo percutaneous transluminal angioplasty or surgical revascularization prior to aneurysm replacement.

Pulmonary evaluation. Pulmonary function screening with arterial blood gases and spirometry are routinely obtained. Patients with a forced expiratory volume in 1 second (FEV-1) greater than 1.0 L and a partial pressure of carbon dioxide (P_{CO_2}) less than 45 mm Hg are considered surgical candidates. In suitable patients, borderline pulmonary function can be improved by implementing smoking cessation, weight loss, exercise, and treatment of bronchitis for 1–3 months before surgery.

Renal evaluation. Renal function is assessed preoperatively via serum electrolytes, blood urea nitrogen, and creatinine measurements. Information regarding kidney size and perfusion are obtained from a CT scan or aortogram. Perfusion strategies and perioperative medications are adjusted based on renal function. Patients with thoracoabdominal aortic aneurysms and severe proximal renal occlusive disease undergo renal artery endarterectomy, stenting, or bypass grafting.

Operative Repair

Proximal thoracic aortic aneurysms. Operations for proximal aortic aneurysms—which involve the ascending aorta and/or transverse arch—are performed through a midsternal incision and require cardiopulmonary bypass. The spectrum of operations ranges from simple graft replacement of the tubular portion of the ascending aorta to graft replacement of the entire proximal aorta, including the aortic root, with reattachment of the coronary arteries and brachiocephalic branches. Options for managing aortic valve pathology, the aneurysm, and perfusion deserve detailed consideration (Table 21-2).

When aortic valvular disease is present and the sinus segment is normal, separate repair or replacement of the aortic valve and graft replacement of the tubular segment of the ascending aorta are carried out. Mild-to-moderate valve insufficiency with annular dilatation can be addressed by plicating the annulus with mattress sutures placed below each commissure. Valve replacement with a biologic or mechanical prosthesis is performed in patients with more severe valvular insufficiency or with valvular stenosis. Patients with Marfan syndrome or annuloaortic ectasia require full aortic root replacement.

In most cases, aortic root replacement employs a mechanical or biologic graft that has both a valve and aortic conduit. There are currently three commercially available graft options: (1) composite valve grafts, which consist of a mechanical valve attached to a polyester tube graft; (2) aortic root homografts, from cadavers and cryopreserved; and (3) stentless porcine aortic root grafts. A final option is valve-sparing aortic root replacement, which has evolved during the past decade. The valve-sparing technique that is currently favored is called aortic root reimplantation, and involves excision of the aortic sinuses, attachment of a prosthetic graft to the patient's annulus, and resuspension of the native aortic valve inside the graft. The avoidance of anticoagulation is a major advantage.

TABLE 21-2 Surgical Options During Proximal Aortic Surgery

<i>Options for treating aortic valve pathology</i>
Aortic valve annuloplasty (annular plication)
Aortic valve replacement with mechanical or biologic prosthesis
Aortic root replacement
Composite valve graft

Valve-sparing techniques
Pulmonary autograft (Ross procedure)
<i>Options for graft repair of the aortic aneurysm</i>
Patch aortoplasty
Ascending replacement only
Beveled hemiarch replacement
Total arch replacement with reattachment of brachiocephalic branches
Total arch replacement with separate grafts to each brachiocephalic branch
Elephant trunk technique
<i>Perfusion options</i>
Standard cardiopulmonary bypass
Profound hypothermic circulatory arrest without adjuncts
Profound hypothermic circulatory arrest with adjuncts
Retrograde cerebral perfusion
Selective antegrade cerebral perfusion
Combined antegrade and retrograde cerebral perfusion

Regardless of the type of conduit used, aortic root replacement requires reattachment of the coronary arteries to openings in the graft. As originally described by Bentall and DeBono, this was accomplished by suturing the intact aortic wall surrounding each coronary artery to the openings in the graft. The aortic wall was then wrapped around the graft to create hemostasis. However, this technique frequently resulted in pseudoaneurysm formation originating from leaks at the coronary reattachment sites. The Cabrol modification—in which a separate, small tube graft is sutured to the coronary ostia and the main aortic graft—achieves tension-free coronary anastomoses and reduces the risk of pseudoaneurysm formation. The Kochoucou button modification of the Bentall procedure is currently the most widely used technique. The aneurysmal aorta is excised, leaving buttons of aortic wall surrounding both coronary arteries, which are then mobilized and sutured to the aortic graft. The coronary suture lines may be reinforced with polytetrafluoroethylene (PTFE) felt or pericardium to enhance hemostasis. When adequate mobilization of the coronary arteries is not feasible because of extremely large aneurysms or scarring from previous surgery, the Cabrol technique or bypass using interposition saphenous vein grafts can be used.

Saccular aneurysms arising from the lesser curvature of the distal transverse arch, less than 50 percent of the aortic circumference, are treated by patch graft aortoplasty. For fusiform aneurysms, when the distal portion of the arch is a reasonable size, a single beveled replacement of the lower curvature (hemiarch) is performed. More extensive arch aneurysms require total replacement, with a distal anastomosis to the proximal descending thoracic aorta and separate reattachment of the brachiocephalic branches. In extreme cases, the aneurysm will involve the entire arch and extend into the descending thoracic aorta, and is approached using the Borst elephant trunk technique of total arch replacement.

The distal anastomosis is constructed with a portion of the graft left suspended within the proximal descending thoracic aorta. During a subsequent distal operation, this "trunk" is used to facilitate repair.

Aneurysms that are isolated to the ascending segment can be replaced using cardiopulmonary bypass and distal ascending aortic clamping. Aneurysms involving the transverse aortic arch cannot be clamped during the repair, and require a period without cardiopulmonary bypass support called circulatory arrest. To protect the brain and other vital organs during the circulatory arrest period, the patient undergoes profound cooling prior to stopping pump flow. An electroencephalogram is monitored during cooling. Once electrocerebral silence is achieved—indicating cessation of brain activity and minimization of metabolic requirements—the pump flow is stopped and the arch is repaired. Electrocerebral silence usually occurs when nasopharyngeal temperature falls below 20°C (68°F).

Two perfusion strategies have been developed to reduce the risks of circulatory arrest: retrograde cerebral perfusion and selective antegrade cerebral perfusion. Retrograde cerebral perfusion delivers cold, oxygenated blood from the pump into a cannula placed in the superior vena cava. The apparent benefits of this technique are likely because of maintenance of cerebral hypothermia and retrograde flushing of air and debris. Selective antegrade cerebral perfusion delivers blood directly into the brachiocephalic arteries while circulatory arrest is maintained in the rest of the body. Small, flexible, balloon perfusion catheters are inserted into one or more of the branch arteries. A method, rapidly gaining popularity because of its relative simplicity, involves cannulation of the right axillary artery. On initiating circulatory arrest and occluding the proximal innominate artery, the axillary artery cannula delivers blood flow into the cerebral circulation via the right common carotid artery. In the combined approach, antegrade perfusion is delivered during the arch reconstruction, and a brief period of retrograde perfusion is used to provide flushing immediately prior to resuming full cardiopulmonary bypass.

Many patients require staged operative procedures to achieve complete repair of extensive aneurysms. When the descending segment is not disproportionately large (compared to the proximal aorta) and is not causing symptoms, the proximal aortic repair is carried out first. An important benefit of this approach is that it allows treatment of valvular and coronary artery occlusive disease at the first operation. The elephant trunk technique is used to perform the aortic arch repair in these patients. This technique permits access to the distal portion of the graft at the second operation, without the need to dissect around the distal transverse aortic arch, reducing the risk of injuring the left recurrent laryngeal nerve, esophagus, and pulmonary artery.

Distal thoracic aortic aneurysms. Descending thoracic aortic aneurysms involve the aorta in between the left subclavian artery and the diaphragm. Thoracoabdominal aneurysms can involve the entire thoracoabdominal aorta, from the origin of the left subclavian artery to the aortic bifurcation, and are categorized based on the Crawford classification. Extent I thoracoabdominal aortic aneurysms involve most of the descending thoracic aorta, usually beginning near the left subclavian artery, and extend down to encompass the aorta at the origins of the celiac axis and superior mesenteric arteries; the renal arteries may also be involved. Extent II aneurysms also arise near the left subclavian artery, but extend distally into the infrarenal abdominal aorta and often reach the aortic bifurcation. Extent III aneurysms originate in the lower descending

thoracic aorta (below the sixth rib) and extend into the abdomen. Extent IV aneurysms begin within the diaphragmatic hiatus and often involve the entire abdominal aorta.

Descending thoracic aortic aneurysms are repaired through a left thoracotomy. In patients with thoracoabdominal aortic aneurysms, the thoracotomy is extended across the costal margin and into the abdomen. A double-lumen endobronchial tube allows selective ventilation of the right lung and deflation of the left lung. Transperitoneal exposure of the thoracoabdominal aorta is achieved by performing medial visceral rotation and circumferential division of the diaphragm. During a period of aortic clamping, the diseased segment is replaced with a polyester tube graft. Important branch arteries—including intercostal, celiac, superior mesenteric, and renal arteries—are reattached to openings made in the side of the graft. Options for correcting branch vessel stenosis include endarterectomy, direct arterial stenting, and bypass grafting.

Clamping the descending thoracic aorta creates ischemia of the spinal cord and abdominal viscera. Clinically significant manifestations of hepatic, pancreatic, and bowel ischemia are relatively uncommon. Spinal cord injury resulting in paraplegia or paraparesis and acute renal failure remain major causes of morbidity and mortality after these operations. Therefore several aspects of the operation are devoted to minimizing spinal and renal ischemia. The authors multimodality approach to spinal cord protection includes expeditious repair to minimize aortic clamping time, moderate systemic heparinization (1.0 mg/kg) to prevent small-vessel thrombosis, mild permissive hypothermia (32–34°C [89.6–93.2°F] nasopharyngeal temperature), and reattachment of segmental intercostal and lumbar arteries. During extensive thoracoabdominal aortic repairs (i.e., Crawford extents I and II), cerebrospinal fluid drainage and left heart bypass, which provides perfusion of the distal aorta and its branches during the clamping period, are used. Balloon perfusion cannulas connected to the left heart bypass circuit can be used to deliver blood directly to the celiac axis and superior mesenteric artery during their reattachment. Renal protection is achieved by perfusing the kidneys with cold (4°C [39.2°F]) crystalloid.

As discussed above, patients with extensive aneurysms involving the ascending, transverse arch, and descending thoracic aorta generally undergo staged operations to achieve complete repair. In this setting, when the descending or thoracoabdominal component is symptomatic (e.g., back pain or rupture) or disproportionately large (compared to the ascending aorta), the distal segment is treated during the initial operation, and repair of the ascending aorta and transverse aortic arch is performed as a second procedure. A reversed elephant trunk repair—in which a portion of the proximal end of the aortic graft is inverted down into the lumen—can be employed during the first operation; this facilitates the second-stage repair of the proximal aorta.

Recent Results

Improvements in anesthesia, surgical technique, and perioperative care have led to improvements in outcome. Tables 21-3 and 21-4 display the authors' results with surgical repair of proximal and distal aortic aneurysms, respectively.

Postoperative Considerations

During the initial 24 to 48 h, meticulous blood pressure control is maintained to protect the integrity of the anastomoses. Generally, the authors liberally use nitroprusside, beta antagonists, and calcium channel blockers to maintain the mean arterial blood pressure between 80 and 90 mm Hg. In patients with

friable aortic tissue, i.e., Marfan syndrome, we lower the target range to 70 to 80 mm Hg.

AORTIC DISSECTION

Pathology and Classification

Aortic dissection—the most common catastrophic event involving the aorta—is the progressive separation of the aortic wall layers that usually occurs after a tear forms in the intima and inner media. Propagation of the separation within the layers of the media results in the formation of two or more channels. The original lumen, which remains lined by the intima, is called the true lumen. The newly formed channel within the layers of the media is called the false lumen. Additional tears allow communication between the two channels and are called re-entry sites.

In most cases, dissection occurs in patients without aneurysms. The subsequent progressive dilatation of the weakened outer aortic wall results in an aneurysm. Alternatively, in patients with degenerative aneurysms, the ongoing deterioration of the aortic wall can lead to a superimposed dissection; the overused term “dissecting aneurysm” should be reserved for this specific situation.

The extensive disruption of the aortic wall has severe anatomic consequences. The outer wall of the false lumen is extremely thin and fragile, making it prone to expansion or rupture in the face of ongoing hemodynamic stresses. The expanding false lumen can compress the true lumen and interfere with blood flow in the aorta or any of the aortic branch vessels, including the coronary, carotid, intercostal, visceral, renal, and iliac arteries. When the separation

of layers occurs within the aortic root, the aortic valve commissures can become unhinged, resulting in an acutely incompetent valve.

Dissections are categorized based on anatomic location and extent. There are two traditional classification schemes: the DeBakey classification and the Stanford classification. Both of these methods describe the segments of aorta that are involved, rather than the site of the initial intimal tear.

Dissection is considered acute within the first 14 days. After 14 days, the dissection is described as chronic. The distinction between acute and chronic dissections has important implications in perioperative management strategies, techniques, and results.

Penetrating aortic ulcers are essentially disrupted atherosclerotic plaques. Eventually the ulcer can penetrate through the aortic wall, leading to dissection or rupture. An intramural hematoma is a collection of blood within the aortic wall without an intimal tear; accumulation of the hematoma ultimately results in dissection. The current consensus is that these variants of dissection should be treated identically to classic dissection.

Etiology and Natural History

Aortic dissection occurs in approximately 5–10 patients per million population per year. Without treatment, nearly one half of patients with acute proximal aortic dissection die within 24 h, and 60 percent of patients with acute distal aortic dissections die within 1 month.

Common general cardiovascular risk factors, such as smoking, hypertension, atherosclerosis, and hypercholesterolemia, are associated with aortic dissection. Patients with connective tissue disorders, aortitis, bicuspid aortic valve, or preexisting medial degenerative disease are at risk for dissection.

Clinical Manifestations

The onset of dissection often is associated with severe chest or back pain—classically described as “tearing”—that migrates distally as the dissection progresses along the length of the aorta. Pain in the anterior chest suggests involvement of the proximal aorta, although pain in the back and abdomen indicates involvement of the distal segment.

Proximal aortic dissection can directly injure the aortic valve. The severity of aortic valve insufficiency varies with the degree of commissural disruption. Patients with acute aortic valve regurgitation may complain of severe acute heart failure and worsening dyspnea.

Proximal dissections can extend into the coronary arteries creating acute coronary occlusion, most often the right coronary artery. By producing symptoms and signs consistent with myocardial ischemia, this presentation can mask the presence of aortic dissection, resulting in delayed diagnosis and treatment.

The thin and inflamed outer wall of a dissected ascending aorta often will produce a serosanguineous pericardial effusion that can accumulate and cause tamponade. Suggestive signs include jugular venous distention, muffled heart tones, pulsus paradoxus, and low-voltage electrocardiogram (ECG) tracings. Free rupture into the pericardial space produces rapid tamponade and generally is fatal.

Any branch vessel from the aorta can be compromised during progression of the dissection. Depending on which arteries are involved, dissection can produce acute stroke, paraplegia, hepatic failure, bowel infarction, renal failure, or a threatened ischemic limb.

Diagnostic Evaluation

Because of variations in severity and the wide variety of potential clinical manifestations, the diagnosis of acute aortic dissection can be challenging. Diagnostic delays are common; delays beyond 24 h after hospitalization occur in up to 39 percent of cases. A high index of suspicion is critical.

Most patients with acute aortic dissection (80–90 percent) experience severe pain in the chest, back, or abdomen. Classically, the pain occurs suddenly, has a “tearing” quality, and migrates distally as the dissection progresses along the aorta. For classification purposes (acute vs. subacute vs. chronic), the onset of pain is generally considered to represent the beginning of the dissection process. Most of the other common symptoms are nonspecific (Table 21-5).

A discrepancy in extremity pulse and/or blood pressure is the classic physical finding in patients with aortic dissection. This often occurs because of changes in flow in the true and false lumens. Involvement of the proximal aorta often creates differences between the right and left arms, although distal aortic dissection often causes differences between the upper and lower extremities.

Laboratory studies are of little help in diagnosing acute aortic dissection. Normal ECGs and serum markers in the setting of acute chest pain should

TABLE 21-5 Anatomic Complications of Aortic Dissection and Their Associated Symptoms and Signs

Anatomic manifestation	Symptoms and signs
Aortic valve insufficiency	Dyspnea Murmur Pulmonary rales Shock
Coronary malperfusion	Chest pain with characteristics of angina Nausea/vomiting Shock Ischemic changes on electrocardiogram Elevated cardiac enzymes
Pericardial tamponade	Dyspnea Jugular venous distention Pulsus paradoxus Muffled cardiac tones Shock Low-voltage electrocardiogram
Subclavian or iliofemoral artery malperfusion	Cold, painful extremity Extremity sensory and motor deficits Peripheral pulse deficit
Carotid artery malperfusion	Syncope Focal neurologic deficit (transient or persistent) Carotid pulse deficit Coma
Spinal malperfusion	Paraplegia Incontinence
Visceral malperfusion	Nausea/vomiting Abdominal pain
Renal malperfusion	Oliguria or anuria Hematuria

raise suspicion regarding the presence of aortic dissection. It is important to remember that when ECG changes and elevated serum markers indicate a myocardial infarction, they do not exclude the diagnosis of aortic dissection. Although chest radiographs may demonstrate a widened mediastinum or abnormal aortic contour, up to 16 percent of patients have a normal-appearing chest radiograph.

Once the diagnosis of dissection is considered, the thoracic aorta should be imaged with CT, MRA, or echocardiography. The diagnosis is usually established via contrast-enhanced CT. The classic diagnostic feature is a double-lumen aorta. Additionally, CT scans provide essential information regarding the segments of the aorta involved; the acuity of the dissection; aortic dilatation, including the presence of preexisting degenerative aneurysms; and the development of threatening sequelae, including pericardial effusion, early aortic rupture, and branch vessel compromise. The MRI suite is not well-suited for critically ill patients. In patients who cannot undergo contrast-enhanced CT or MRA, transthoracic echocardiography can be used to establish the diagnosis. Transesophageal echocardiography is excellent for determining and distinguishing the presence of dissection, aneurysm, and intramural hematoma in the ascending aorta.

In patients with proximal aortic dissection, coronary angiography is obtained prior to surgery in selected patients (i.e., those who have evidence of preexisting coronary artery disease).

Management

Initial Assessment and Management

Regardless of the location of the dissection, the initial management is the same for all patients with suspected or confirmed acute aortic dissection. Aggressive pharmacologic management is started once there is clinical suspicion of dissection, and is continued during the diagnostic evaluation. The goals of pharmacologic treatment are to stabilize the dissection and prevent rupture.

Patients are monitored closely in an intensive care unit. Indwelling radial arterial catheters are used to monitor blood pressure and optimize titration of antihypertensive agents. Pulmonary artery catheters are reserved for patients with severe cardiopulmonary dysfunction.

The initial evaluation focuses on whether any life-threatening complications are present. Particular attention is paid to changes in neurologic status, peripheral pulses, and urine output. Serial laboratory studies—including arterial blood gases, complete blood cell count, prothrombin and partial thromboplastin times, serum electrolytes, creatinine, blood urea nitrogen, and liver enzymes—are useful for determining the presence of organ ischemia.

The initial management strategy—commonly described as “antihypertensive therapy” or “blood pressure control”—focuses on reducing aortic wall stress, the force of left ventricular ejection, and the rate of change in blood pressure (dP/dT). Reductions in dP/dT are achieved by lowering both cardiac contractility and blood pressure. The drugs initially used to accomplish these goals include intravenous beta adrenergic blockers, direct vasodilators, calcium channel blockers, and angiotensin-converting enzyme inhibitors. These agents are used to achieve a heart rate between 60 and 80 beats/min, a systolic blood pressure between 100 and 110 mm Hg, and a mean arterial blood pressure between 60 and 75 mm Hg. These hemodynamic targets are maintained as long as urine output remains adequate and neurologic function is not impaired.

Adequate pain control with intravenous opiates such as morphine or fentanyl is important.

Beta antagonists are administered to all patients with acute aortic dissections, unless there are contraindications such as severe heart failure, bradyarrhythmia, high-grade atrioventricular conduction block, or bronchospastic disease. The dose of β antagonists is titrated to achieve a heart rate of 60–80 beats/min. In patients who cannot receive beta antagonists, calcium channel blockers such as diltiazem are an alternative. Nitroprusside, a direct vasodilator, can be administered once beta blockade is adequate. Enalapril and other angiotensin-converting enzyme inhibitors are useful in patients with renal malperfusion; the decrease in rennin release may improve renal blood flow.

Management of Proximal Aortic Dissection

Acute proximal dissection. The presence of an acute proximal aortic dissection has traditionally been an absolute indication for emergency surgical repair. However, specific patient groups may benefit from nonoperative management or delayed operation. Situations that warrant consideration of delayed repair include: (1) patients presenting with acute stroke or mesenteric ischemia; (2) older adult patients with substantial comorbidity; (3) stable patients who may benefit from transfer to specialized centers; and (4) patients who have undergone a cardiac operation in the remote past.

In the absence of the circumstances listed above, most patients with acute proximal aortic dissection undergo urgent graft replacement of the ascending aorta. The operation is conducted in a manner similar to that described for aneurysms of the transverse aortic arch. Intraoperative transesophageal echocardiography is commonly performed before beginning the operation to further assess baseline myocardial and valvular function and, if necessary, to confirm the diagnosis. The operation is performed via a median sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest. The patient is cooled until monitoring demonstrates electrocerebral silence. Cardiopulmonary bypass is then stopped and the ascending aorta is opened. The dissecting membrane that separates the true and false lumens is completely excised. After occluding the innominate artery with a clamp or balloon catheter, flow from the axillary artery cannula is used to provide selective antegrade cerebral perfusion. The transverse aortic arch is carefully inspected. Replacement of the entire arch is performed only if a primary tear is located in the arch or if the arch is aneurysmal; in most cases, a less extensive beveled “hemiarch” repair is adequate. The distal aortic cuff is prepared by tacking the inner and outer walls together and using surgical adhesive to obliterate the false lumen and strengthen the tissue. A polyester tube graft is sutured to the distal aortic cuff. The anastomosis between the graft and the aorta is fashioned so that blood flow will be directed into the true lumen. In the absence of annuloaortic ectasia or Marfan syndrome—which generally require aortic root replacement—aortic valve insufficiency can be corrected by resuspending the commissures onto the outer aortic wall. The proximal aortic cuff is prepared with tacking sutures and surgical adhesive prior to performing the proximal aortic anastomosis.

In the majority of patients, the dissection persists distal to the site of the operative repair. Extensive dilatation of the distal aortic segment develops in 16 percent of the survivors, and rupture of the dilated distal aorta is the most common cause of late death. Following proximal repair, patients require aggressive management of the remaining acute distal aortic dissection.

Management of Distal Aortic Dissection

Nonoperative management. Nonoperative management of acute distal aortic dissection results in lower morbidity and mortality rates than those achieved with surgical treatment. These patients are primarily managed with pharmacologic treatment. However, the most common causes of death during nonoperative treatment are aortic rupture and end-organ malperfusion. Therefore, patients are continually reassessed for the development of complications. Serial CT scans are compared to the initial scan to rule out significant aortic expansion.

Once the patient has been stabilized, pharmacologic management is shifted from intravenous to oral. Oral therapy, including a beta antagonist, is initiated when systolic pressure is consistently 100–110 mm Hg and the neurologic, renal, and cardiovascular systems are stable.

Long-term pharmacologic therapy is important with chronic aortic dissection. Beta blockers remain the drugs of choice. In a 20-year follow-up study, DeBakey and colleagues reported that inadequate blood pressure control was associated with late aneurysm formation. Aneurysms developed in only 17 percent with “good” blood pressure control and 45 percent with “poor” control.

Contrast-enhanced CT and MRA scans provide excellent aortic imaging and facilitate serial comparisons to detect progressive aortic expansion. The first surveillance scan is obtained approximately 6 weeks after the onset of dissection. Subsequent scans are obtained at least every 3 months for the first year, every 6 months for the second year, and annually thereafter. Patients who have undergone graft repair also are evaluated with annual CT or MRA.

Indications for surgery. Surgery is reserved for patients who experience complications. Surgical intervention for acute distal aortic dissection is directed toward prevention or repair of rupture and relief of ischemic manifestations.

During the acute phase, the specific indications for operative intervention include (1) aortic rupture, (2) increasing periaortic or pleural fluid, (3) rapidly expanding aortic diameter, (4) uncontrolled hypertension, and (5) persistent pain despite adequate medical therapy. Acute dissection superimposed on a preexisting aneurysm is considered a life-threatening condition.

Acute malperfusion syndromes warrant intervention. In the recent past, visceral and renal malperfusion were considered indications for operation. Advances in percutaneous interventions have largely replaced open surgery for these complications. Percutaneous fenestration of the dissecting membrane or placement of branch artery stents can restore organ perfusion. When unsuccessful, surgical options—which include graft replacement of the aorta, open aortic fenestration, and visceral/renal artery bypass—can be employed. Lower extremity ischemia usually is addressed surgically via extra-anatomic revascularization.

In the chronic phase, the indications for operative intervention are similar to those for degenerative thoracic aortic aneurysms. Operation is considered when the affected segment has reached 5–6 cm, or when an aneurysm has enlarged more than 1 cm during a 1-year period.

Operative repair. Surgical repair of the descending thoracic or thoracoabdominal aorta in the setting of acute aortic dissection is associated with high morbidity and mortality. Therefore, the primary goals of surgery are to prevent fatal rupture and restore branch vessel perfusion. A limited graft repair of the

symptomatic segment achieves these goals while minimizing risks. Because the most common site of rupture in distal aortic dissection is in the proximal third of the descending thoracic aorta, the upper descending thoracic aorta usually is repaired.

In patients with acute dissection, adjuncts that provide spinal cord protection are used liberally because of the increased risk of paraplegia. Cerebrospinal fluid drainage and left heart bypass often are employed. Proximal control is usually obtained between the left common carotid and left subclavian artery. The proximal and distal anastomoses use all layers of aortic wall, thereby excluding the false lumen.

A more aggressive replacement usually is performed during elective aortic repairs in patients with chronic dissection. In many regards, the operative approach in these patients is identical to that used for descending thoracic and thoracoabdominal aortic aneurysms. One key difference is the need to excise as much dissecting membrane as possible to clearly identify the true and false lumens and locate all important branch vessels. When the dissection extends into the visceral or renal arteries, the membrane can be fenestrated or the false lumen can be obliterated using sutures or intraluminal stents. When a distal dissection has progressed retrograde into the transverse aortic arch and placement of the proximal clamp is not technically feasible, hypothermic circulatory arrest can be used to facilitate the proximal portion of the repair.

Recent Results

Proximal aortic dissection. Table 21-6 displays these authors' results with proximal aortic dissection repair in 489 patients. Over 40 percent of repairs were performed in the acute setting. Compared to the lethality of unrepaired acute proximal aortic dissection, contemporary results of surgical treatment are excellent.

Distal aortic dissection. Despite aggressive pharmacologic management, 10–20 percent of patients die during the initial treatment phase. The primary causes of death during nonoperative management include rupture, malperfusion and cardiac failure. Risk factors associated with treatment failure—defined as death or need for surgery—include an enlarged aorta, persistent hypertension despitemaximal treatment, oliguria and peripheral ischemia. Table 21-7 displays the results of these authors with distal aortic dissection repair in 714 patients.

ENDOVASCULAR TREATMENT OF THORACIC AORTIC DISEASE

Although not yet considered standard therapy, endovascular stent-graft repairs are poised to play a major role in the armamentarium for treating thoracic aortic

disease. In 1991, Parodi reported using stent-grafts for repair of abdominal aortic aneurysms. Three years after this seminal report, Dake and colleagues reported endovascular descending thoracic aortic repair using “home-made” stent-grafts in 13 patients. Subsequent reports have applied this new, less-invasive option in patients with aortic dissection and traumatic, mycotic, and ruptured aneurysms of the descending thoracic aorta. Data demonstrating long-term effectiveness currently are not available.

General mortality and morbidity following endovascular repair of descending thoracic aortic aneurysms is currently difficult to assess. For example, in the Stanford experience with “first generation” stent grafts in 103 patients with descending thoracic aortic aneurysms, the operative mortality rate was 9 percent, stroke occurred in 7 percent, paraplegia/paraparesis occurred in 3 percent, and actuarial survival was only 73 ± 5 percent at 2 years. However, 62 (60 percent) patients were not considered candidates for thoracotomy and open surgical repair; as expected, this group experienced the majority of the morbidity and mortality.

As the experience with descending thoracic aortic stent grafts continues to increase, reports regarding complications specifically related to device deployment are emerging in the literature. Many of these complications are directly related to manipulation of the delivery system within the iliac arteries and aorta. Patients with small, calcified, tortuous iliofemoral arteries are at particular risk for life-threatening iliac artery rupture. A more common complication is acute iatrogenic aortic dissection into the aortic arch and ascending aorta. There are several reports of this complication, most involving “new generation” devices and requiring emergency repair of the ascending aorta and aortic arch via sternotomy and cardiopulmonary bypass. Such a dissection converts a localized descending thoracic aortic disease into an acute problem involving the entire thoracic aorta. Early reports have documented a 20–25 percent incidence of endoleak, this is expected to decline. Early type I endoleaks—which result from an incomplete seal between the graft and aorta at attachment sites—can precipitate aortic rupture. Therefore, aggressive intervention is recommended, if feasible, when type I endoleaks develop within weeks after the initial procedure. Other device-related problems include stent graft misdeployment, device migration, and endograft kinking.

In contrast to endovascular repair of descending thoracic aortic aneurysms, experience with endovascular treatment of proximal aortic disease remains limited and purely experimental. The unique anatomy of the aortic arch and need for uninterrupted cerebral perfusion pose difficult challenges. Similarly, the experience with endovascular thoracoabdominal aortic aneurysm repair remains anecdotal. Thoracoabdominal aortic aneurysms have been repaired using hybrid approaches, with stent graft coverage of the entire aneurysm including branch vessel ostia, followed by open visceral bypass grafting to restore organ perfusion.

EPIDEMIOLOGY

Peripheral arterial disease occurs in 12 percent of the adult population, affecting 8–10 million people in the United States. The most common symptomatic manifestation is intermittent claudication, which occurs at an annual incidence of 2 percent in people over the age of 65. These patients are at a significantly higher risk of death compared with healthy controls of similar age.

Clinical Manifestations of Vascular Disease

The Vascular History

Symptoms are elicited based on the presenting complaint. The patient with lower extremity pain on ambulation has intermittent claudication that occurs in certain muscle groups; for example, calf pain on exercise usually reflects superficial femoral artery disease, although pain in the buttocks reflects iliac disease. In most cases, the pain manifests in one muscle group below the level of the affected artery, occurs only with exercise, and is relieved with rest only to recur at the same location, hence the term “window-gazers disease.” Rest pain (a manifestation of severe underlying occlusive disease) is constant and occurs in the foot (not the muscle groups), typically at the metatarsophalangeal junction, and is relieved by dependency. Often the patient is prompted to sleep with their foot hanging off one side of the bed to increase the hydrostatic pressure.

The patient with carotid disease in most cases is totally asymptomatic, having been referred based on the finding of a cervical bruit or duplex finding of stenosis. Symptoms of carotid territory TIAs include transient monocular blindness (amaurosis), contralateral weakness or numbness, and dysphasia. Symptoms persisting longer than 24 h constitute a stroke.

Chronic mesenteric ischemia presents with postprandial abdominal pain and weight loss. The patient fears eating because of the pain, avoids food, and loses weight. It is very unlikely that a patient with abdominal pain who has not lost weight has chronic mesenteric ischemia.

Of particular importance in the previous medical history is noting prior vascular interventions (endovascular or open surgical), and all vascular patients should have inquiry made about their prior cardiac history and current cardiac symptoms. Approximately 30 percent of vascular patients will be diabetic. A smoking history should be elicited.

The Vascular Examination

Specific vascular examination includes pulse examination (femoral, popliteal, posterior tibial, and dorsalis pedis) of the lower extremity. The femoral pulse is located at the midinguinal point (midway between the anterior superior iliac spine and the pubic tubercle). The popliteal artery is best palpated with the knee flexed to 45 degrees and the foot flat and supported on the examination table to relax the calf muscles. Palpation of the popliteal artery is a bimanual technique.

Both thumbs are placed on the tibial tuberosity anteriorly and the fingers are placed into the popliteal fossa between the two heads of the gastrocnemius muscle. The popliteal artery is palpated by compressing it against the posterior aspect of the tibia just below the knee. The posterior tibial pulse is detected by palpation 2 cm posterior to the medial malleolus. The dorsalis pedis is detected 1 cm lateral to the hallucis longus extensor tendon (which dorsiflexes the great toe and is clearly visible) on the dorsum of the foot. Pulses are graded using a four-point scale: 2+ is normal; 1+ palpable, but reduced; 0 is absent to palpation (Doppler signals should be noted); and 3+ indicates aneurysmal enlargement. The foot should be carefully examined for pallor on elevation and rubor on dependency, as these findings are indicative of chronic ischemia. Ulceration and other findings specific to disease states are described in relevant sections below.

Upper extremity examination is necessary when an arteriovenous graft is to be inserted in patients who have symptoms of arm pain with exercise. Thoracic outlet syndrome (TOS) can result in occlusion or aneurysm formation of the subclavian artery. Distal embolization is a manifestation of TOS; consequently, the fingers should be examined for signs of ischemia and ulceration. The axillary artery enters the limb below the middle of the clavicle, where it can be palpated in thin patients. It is usually easily palpable in the axilla and medial upper arm. The brachial artery is most easily located at the antecubital fossa immediately medial to the biceps tendon. The radial artery is palpable at the wrist anterior to the radius. The ulnar is palpable or present on Doppler examination on the medial side of the wrist. Doppler signals, particularly in the thumb, are usually detectable on either side of the digits. Digital Doppler signals also frequently can be detected in the fingers. The Allen test is a test of patency of the palmar arch. The radial and ulnar pulses are localized at the wrist, and the examiner occludes both by digital pressure. Then after the patient opens and closes the hand, pressure over one artery is released. Failure in hand reperfusion from one side indicates an incomplete palmar arch and indicates that occlusion of one artery (by catheter placement or by using it for an anastomosis) may be more likely to result in hand ischemia.

There is increasing interest in the use of the ankle-brachial index (ABI) to evaluate patients at risk for cardiovascular events. An ABI less than 0.9 correlates with increased risk of myocardial infarction and indicates significant, although perhaps asymptomatic, underlying peripheral vascular disease. The ankle-brachial index is determined in the following ways. Blood pressure (BP) is measured in both upper extremities using the highest systolic BP as the denominator for the ABI. The ankle pressure is determined by placing a blood pressure cuff above the ankle and measuring the return to flow of the posterior tibial and dorsalis pedis arteries using a pencil Doppler over each artery. The ratio of the systolic pressure in each vessel divided by the highest arm systolic pressure can be used to express the ABI in both the posterior tibial and dorsalis pedis arteries. Normal is more than 1. Claudicants are in the 0.6–0.9 range, with rest pain and gangrene occurring at less than 0.3. The test is less reliable in patients with heavily calcified vessels because of noncompressibility (i.e., diabetes and end-stage renal disease).

Aortic Examination

The abdomen should be palpated for an abdominal aortic aneurysm, detected as an expansile pulse above the level of the umbilicus. Because the aorta

typically divides at the level of the umbilicus, an aortic aneurysm is most frequently palpable in the epigastrium. In thin individuals a normal aortic pulsation is palpable, although in obese patients even large aortic aneurysms may not be detectable. Suspicion of a clinically enlarged aorta should lead to the performance of an ultrasound scan for a more accurate definition of aortic diameter.

Carotid Examination

The carotids should be auscultated for the presence of bruits. A bruit at the angle of the mandible is a significant finding, leading to follow-up duplex scanning. Differential diagnosis is a transmitted murmur from a sclerotic or stenotic aortic valve. The carotid is palpable deep to the sternocleidomastoid muscle in the neck. Palpation, however, should be gentle and rarely yields clinically useful information. A prominent pulsation usually reflects tortuosity, although aneurysms occasionally occur.

The Vascular Graft Examination

The in situ lower extremity graft runs in the subcutaneous fat and can be palpated along most of its length. A change in pulse quality, aneurysmal enlargement, or a new bruit should be carefully noted and may represent development of stenoses or aneurysmal enlargement. Axillofemoral grafts, femoral-to-femoral grafts, and arteriovenous access grafts can usually be easily palpated as well.

The Noninvasive Vascular Laboratory and Vascular Testing

This includes duplex scanning, and measurement of segmental arterial pressures with pulse volume recordings (PVRs).

Duplex Scanning

Duplex implies two forms of ultrasound: B-mode, which is typically used to create a gray-scale anatomic image, and Doppler ultrasound. The latter allows moving structures to be imaged. Most physicians use the traditional pencil Doppler to detect nonpalpable blood vessels by sound. The more sophisticated duplex scanners display moving structures (in most cases red blood cells moving within a vascular structure) as a color map proportional to the flow velocity and as an auditory signal. Furthermore, the scanner permits an accurate graphical depiction of the velocity of the moving red blood cells, and this permits measurement of peak systolic velocity and end-diastolic velocity. It is the measurement of the end-diastolic flow velocity that is used to determine the degree of narrowing of a carotid artery.

Duplex scanning has become the first-line tool for imaging carotid arteries, lower extremity bypass grafts, the abdominal aorta, and for diagnosis of deep venous thrombosis.

For diagnosis of deep vein thrombosis (DVT), the B mode component of the scanner is of more importance. An occluded vein typically is larger than normal, not completely compressible, lacks respiratory variation, does not show flow augmentation with calf compression, and may have collateral flow.

Segmental Pressures

By placing serial blood pressure cuffs down the lower extremity and then measuring the pressure with a Doppler probe as flow returns to the artery below the cuff, it is possible to determine segmental pressures down the leg. This data can then be used to infer the level of the occlusion. The systolic pressure at each level is expressed as a ratio, with the highest systolic pressure in the upper extremities as the denominator. A pressure gradient of 20 mmHg between two subsequent levels is usually indicative of occlusive disease at that level. The most frequently used index is the ratio of the ankle pressure to the brachial pressure, the ABI. Normally the ABI is greater than 1.0, and a value less than 0.9 indicates some degree of arterial obstruction and has been shown to be correlated with an increased risk of coronary heart disease. Patients with claudication typically have an ABI in the 0.5–0.7 range, and those with rest pain are in the 0.3–0.5 range. Those with gangrene have an ABI less than 0.3. However, these ranges can vary depending on the degree of compressibility of the vessel.

In those patients with noncompressible vessels, segmental plethysmography can be useful. Cuffs placed at different levels on the leg detect changes in leg volume, which also can be used to localize levels of occlusion.

Angiography

Essential components to angiography are vascular access and catheter placement in the vascular bed to be imaged. The imaging system and the contrast agent are used to opacify the target vessel.

The preangiography checklist includes serum creatinine; medications such as anticoagulants and oral hypoglycemics, specifically metformin (which can cause lactic acidosis when combined with contrast agents); history of dye allergy; and hydration status. Contrast angiography should be avoided if possible in all patients with a serum creatinine level greater than 3.0. It should be performed only if it is truly necessary, and other imaging modalities cannot provide equivalent information in patients with a serum creatinine level greater than 2.0. All patients with a serum creatinine level greater than 1.7 mg/dL are premedicated with acetylcysteine 600 mg by mouth twice daily on the day before and the day of angiography.

Many patients give a history of dye allergy, which may vary from trivial to life-threatening. In those with a history of anaphylaxis, contrast is best avoided. However, most patients can be safely given contrast after appropriate preparation. The usual prophylactic treatment is oral prednisone 40 mg 12 h and 1 h prior to the procedure, and oral diphenhydramine hydrochloride 50 mg 1 hour prior to the procedure.

For angiography, the right femoral artery is most commonly accessed. The puncture should be over the femoral head and its position should be determined fluoroscopically (not estimated using skin landmarks). The artery is entered with an 18-gauge Seldinger needle. Good pulsatile flow confirms arterial access. A Bentsen wire is then inserted up into the aorta under fluoroscopic guidance. After removing the needle, a catheter is inserted over the wire. The catheter and wire can be steered to the target vascular bed and dye injected to opacify the vessels. Contrast angiography provides a lumenogram, so thrombus-filled aneurysms can be easily missed. Digital subtraction angiography (in which bony landmarks are electronically removed) provides the best

delineation of vascular pathology. Once the procedure is complete, the catheter is removed from the femoral artery and pressure applied. This technique forms the basis for all interventional procedures.

Brachial artery access is another option, but carries a significantly higher incidence of complications, mainly thrombosis and median nerve compression, and potential damage from extravasation.

Computed Tomographic Angiography

CTA is a noninvasive, contrast-dependent method for imaging the arterial system. It depends on intravenous infusion of iodine-based contrast agents. The patient is advanced through a rotating gantry, which images serial transverse slices. The contrast-filled vessels can be extracted from the slices and rendered in three-dimensional format. The extracted image can be rotated and viewed from several different directions.

Magnetic Resonance Angiography

MRA has the advantage of not requiring iodinated contrast agents to provide vessel opacification. Gadolinium is used as a contrast agent for MRA studies, and as it is generally not nephrotoxic, it can be used in patients with elevated creatinine.

MEDICAL MANAGEMENT OF PERIPHERAL ARTERIAL DISEASE

The cornerstone of medical management is reduction of vascular risk factors such as smoking cessation, control of blood pressure, reduction of blood lipid levels including statin therapy, correction of elevated homocysteine levels, and tight control of blood sugar in diabetics. Smoking cessation has been shown to result in a reduction of the 10-year mortality rate from 54 down to 18 percent. In one clinical trial, at 7 years, 16 percent of smokers compared to 0 percent of quitters had progressed to rest pain.

It has been well established that the treatment of hypertension reduces the risk of stroke and coronary events. However, lowering of blood pressure may worsen intermittent claudication.

Multiple studies have proven that lowering total cholesterol and low-density lipoprotein (LDL) levels reduces mortality and morbidity in patients with peripheral arterial disease (PAD), regardless of their baseline cholesterol or LDL levels.

Statin therapy is effective in the treatment of elevated LDL cholesterol, but has little effect on high-density lipoprotein (HDL), triglycerides, or Lp(a). Fibrates effectively lower triglycerides and raise HDL cholesterol. Niacin therapy has beneficial effects on all lipid parameters and is the only drug known to lower Lp(a). It is also the most effective agent for elevating HDL cholesterol. Slow-release niacin has increased tolerability and compliance and is emerging as an important therapy in patients with dyslipidemia.

Hyperhomocysteinemia

The incidence of hyperhomocysteinemia is as high as 60 percent in patients with vascular disease, compared with 1 percent in the general population. Elevated homocysteine levels can be treated with folic acid supplementation of 0.5–1.0 mg/day.

Diabetes Mellitus and Impaired Glucose Tolerance

Many studies have shown an association between diabetes mellitus and the development of vascular disease. Over the last decade, the importance and prevalence of the metabolic syndrome, which is characterized by obesity, non-insulin-dependent diabetes mellitus, hyperinsulinemia, hyperlipidemia, hypertension, hyperuricemia, and cardiovascular disease has become evident. Recognition of patients with metabolic syndrome is important so that they may be treated.

Exercise Programs

Exercise has been shown to improve function, reduce symptoms, and possibly prolong survival. It can produce an increase in walking distance of up to 150 percent—a clinically meaningful improvement—and has been associated with a 24 percent reduction in cardiovascular mortality. Exercise programs that consist of exercise for more than 30 min and more frequently than 3 times per week are most effective.

Specific Medical Therapy for Claudication

Other medical therapies directed specifically at peripheral disease rather than its risk factors include pentoxifylline and cilostazol.

Cilostazol is the more effective of the two, has been shown to significantly increase walking distance in patients with claudication in several randomized trials and to result in improvement in physical functioning and quality of life. Improvement has ranged from 35–100 percent. A trial of the drug is indicated in symptomatic patients. It should be continued for at least 3 months before a decision is made about efficacy. The most common adverse effects are headache, transient diarrhea, palpitations, and dizziness. It is contraindicated in patients with congestive heart failure because of its effects on phosphodiesterase.

Antiplatelet medications should be started on all patients with peripheral vascular disease (PVD). Aspirin has been found to reduce the vascular death rate by about 25 percent. Clopidogrel is more effective than aspirin in reducing cardiovascular outcome events, especially in the patient with lower extremity occlusive disease, but is much more expensive.

Because of the systemic nature of atherosclerosis, all patients with PAD, whether they have a history of coronary disease or not, should benefit from medical prevention strategies. These include aggressive management of smoking, statin therapy with a goal of lowering LDL cholesterol to at least 100 mg/dL, treatment of blood pressure to attain 130/85 mmHg, and management of diabetes mellitus to a glycohemoglobin level of 7 percent. Drugs shown to have particular benefit in these patients include the statins for LDL reduction, angiotensin-converting enzyme (ACE) inhibitors to treat blood pressure, and beta blockers for their cardioprotective effects. Additionally, all patients should be given a trial of cilostazol, clopidogrel, or aspirin. Patients should also be investigated for other dyslipidemias and hyperhomocysteinemia and treated accordingly.

ANEURYSMAL DISEASE

An aneurysm is defined as a dilation of an artery greater than 1.5 times its normal diameter. They can occur in almost any artery in the body, but the most

common locations are in the abdominal aorta, thoracic aorta, cerebral vessels, and iliac, popliteal, and femoral arteries.

Classification of Aneurysms

Aneurysms are classified in a variety of ways based on their shape, wall constituents, and etiology.

Shape

Fusiform, or spindle-shaped aneurysms Saccular, excentric with protrusion of one wall.

Wall Constituents

True Aneurysms: entirely contained by dilated arterial wall. Pseudoaneurysms or false aneurysms is composed partly of arterial wall and partly of adjacent structures.

Etiology

Dissecting Aneurysms: occur when the vessel wall is split and the vessel enlarged. Mycotic: vessel wall is infected leading to aneurysm formation. Traumatic: wall disrupted by trauma leading to aneurysm.

Abdominal Aortic Aneurysms

Natural History

Abdominal aortic aneurysms grow on average 0.4 cm/year. Risk of rupture is exponentially related to aneurysm diameter. Aneurysms 5.0 cm in diameter have an average yearly rupture rate of 3–5 percent. However, a 7-cm aneurysm carries a rupture rate of 19 percent per year. Currently, with perioperative mortality rates 3–5 percent, intervention is recommended for all aneurysms greater than 5 cm.

Epidemiology

AAA occur three times as frequently in males as in females and increase with age.

Etiology and Pathology

Although referred to as atherosclerotic aneurysms, the etiology is more complex. There is progressive loss of elastin in aortic aneurysms along with increased metalloprotease activity. Proteolysis and inflammation are the driving forces in abdominal aortic aneurysm (AAA) expansion. Normal aortic tissue contains 12 percent elastin, whereas aneurysmal tissue has only 1 percent elastin. There is a clear familial trend that is sex-linked and autosomally recessive. Presence of an aneurysm in a female usually is associated with aneurysms in family members. Estimated risk for first-degree relatives of affected family members is 11.6 times that of the rest of the population. Screening of siblings (over age 50) of patients with aneurysms revealed an aneurysm in 29 percent of brothers and 6 percent of sisters.

Clinical Manifestations

Symptoms. Most are asymptomatic, often being an incidental finding during evaluation of a concurrent condition. Calcified outer wall or a large soft tissue

shadow is noted on an abdominal radiograph, or they are detected during performance of an ultrasound or CT scan, of the abdomen. The most common symptoms are new-onset low-back pain and abdominal pain, which are occasionally because of compression/erosion of adjacent structures such as an aortocaval fistula, a ureteric obstruction, gastrointestinal (GI) bleeding from a primary aortoduodenal fistula, or rarely, they can be because of lower extremity embolization. When symptomatic, expeditious evaluation and treatment is indicated.

Examination. In a thin patient may show prominent epigastric/umbilical pulsatility. Careful palpation reveals expansile pulsatility. In large patients they may not be palpable. Examination of the femoral and distal pulses is mandatory for concurrent femoral or popliteal aneurysms.

Testing is dictated by aneurysm size. Aneurysms in the 4.5–5-cm range, observation is reasonable, although recent expansion or high anxiety on the patient's part should lead to intervention. Aneurysms greater than 5.0 cm should be repaired unless the patient is very high risk. Ultrasound is the most cost efficient screening tool. For preoperative evaluation, computed tomography (CT scan) is best.

Preoperative Preparation

All patients should have preoperative cardiac clearance. Risk factors for open aneurysm repair include myocardial infarction in the last 6 months without revascularization, congestive heart failure, and angina. A forced expiratory volume in 1 second (FEV-1) of less than 1 L and creatinine levels greater than 2.0 mg/dL are also risk factors. Preoperative pulmonary evaluation, with optimization of pulmonary function and renal protection with fenoldopam mesylate are used in patients with elevated creatinine levels. Epidural anesthesia is a useful supplement for postoperative pain control.

Surgery

The open approach can be accomplished through either a mid-line transperitoneal abdominal incision or via a retroperitoneal approach. The latter is preferred in patients with adhesions, abdominal stoma, and with severe chronic obstructive pulmonary disorder (COPD). Limitation include: inability to reach the right renal distal right common iliac artery. Most surgeons prefer a midline incision. The peritoneum over the aorta is incised from the iliac bifurcation superiorly, around the duodenum, and up to the level of the left renal vein. The duodenum is mobilized to the patient's right, exposing the underlying aorta. Rarely does aneurysmal disease extend beyond the common iliac bifurcation. After anticoagulation, the iliac arteries are clamped, followed by the aorta. The aneurysm is opened longitudinally and thrombus evacuated. A tube or bifurcated graft is sewn end-to-end inside the aneurysm using 3-0 polypropylene suture for the aortic anastomoses. The retroperitoneum is then also closed over the aneurysmal sac.

Postoperative Course

Patients are observed in the intensive care unit (ICU) overnight and are hospitalized for 4–5 days.

The mortality rate in large institutions is 2–4 percent with a morbidity rate of 20 percent.

Complications

Pneumonia, ileus, renal failure, lower extremity ischemia, colonic ischemia, spinal cord ischemia, aortoenteric fistula, graft infection, and anastomotic pseudoaneurysm are all complications of abdominal aortic aneurysm.

Aortic Endografting

Thirty to 50 percent of aneurysms are currently treated with endografts. Endografts are inserted via a cutdown on each common femoral artery. A transverse arteriotomy is made to permit insertion of the main body endografts over a previously inserted guide wire. This is advanced up through the ipsilateral iliac system under fluoroscopic control. The proximal markers are placed immediately below the lowest renal arteries and the device appropriately oriented, then deployed. The contralateral gate is then cannulated with a guidewire and its intragraft position confirmed by reconfirming a pigtail catheter and ensuring that it spins freely within the lumen of the grafts. A stiff wire is reinserted although the pigtail catheter and the contralateral limb advanced into the gate and deployed. Rapid changes in the type of endograft available and the options for the surgeon are presently occurring. Devices are now available for aortounilateral iliac aneurysms and for treatment of thoracic aortic aneurysms. Iliac artery injuries can occur from insertion of the device, which may manifest as rupture, dissection, or limb occlusion postendografting. Renal dysfunction can occur from dye toxicity, embolization, and occasionally inadvertent coverage of the renal artery by the device.

Complications: type I–IV endoleak, sac expansion, graft infection, migration of device, modular disconnection, limb occlusion.

Patients with endografts must be followed for life. Follow-up includes abdominal radiographs (e.g., anteroposterior [AP], lateral, and obliques), duplex ultrasound, and contrast-enhanced CT scanning. Endografts have significant advantages in high risk patients, permit a shorter hospital stay and earlier return to function than does open repair.

Juxtarenal Aneurysms

These extend to the renal arteries, thus requiring a suprarenal cross-clamp. Technical maneuvers that facilitate this are division of the left renal vein and a left retroperitoneal approach. Suprarenal clamping clearly increases the risk of renal dysfunction postprocedure. The graft can be sutured incorporating the inferior margin of the renal orifices.

Ruptured Abdominal Aortic Aneurysm

Fear of rupture is the driving force behind the elective repair of aneurysms. There has been almost no change in the mortality rate from ruptured AAAs in the last 20 years. Most patients die before reaching the hospital, and of those who do, the mortality remains close to 50 percent. This has led to some serious re-evaluation of the management of ruptured aneurysms, with increasing interest in the use of permissive hypotension and the use of emergent stent graft placement. These developments, however, remain to be validated.

Most patients with a ruptured aneurysm are often unaware of the presence of an aneurysm. Sudden-onset, severe abdominal pain and/or back pain are the principal presenting symptoms. Often there is a fainting episode that correlates with the initial aneurysm sac rupture, which is followed by a period of cardiovascular stability. Consequently the patient arrives in the emergency room with

little to distinguish a ruptured AAA from other intraabdominal catastrophes. Palpation of a pulsatile mass, the outline of a calcified AAA or soft tissue mass on abdominal x-rays (i.e., Kidney, ureter and bladder (KUB)) or a known history of AAA greatly facilitates the diagnosis. Where the diagnosis is clear-cut, the patient should go directly to the operating room for emergent repair. Often, however, the diagnosis is uncertain and established by CT scanning. As in shock resuscitation for trauma, current thinking is to avoid aggressive resuscitation and infuse fluids or blood only to keep the patient stable and cerebrating, without creating hypertension that may accelerate additional bleeding. A systolic pressure of 70 mmHg with a cerebrating patient is tolerable while preparations are made to go to the operating room.

In the operating room, the abdomen is prepped and draped with the patient awake. Decompression can occur with the induction of anesthesia and loss of abdominal wall splinting. Once the patient is anesthetized, a long midline abdominal incision is created. Usually a large hematoma contained within the retroperitoneum is apparent. The surgeon decides based on the extent and location of the hematoma whether to gain infrarenal control or supraceliac aortic control at the diaphragm. In the unstable patient, an aortic compressor can be used.

Several complications occur more frequently in ruptured than elective aneurysm repair, including venous injury (i.e., renal, iliac or inferior vena cava [IVC]), ureteral injury, and injury to the duodenum. Multisystem organ failure is common in survivors who have suffered significant blood loss.

The emerging endovascular approach involves placement of a descending aortic occlusion balloon that is inflated only if the patient's blood pressure cannot be maintained in the range of the low 70s of systolic pressure. A CT scan is rapidly performed or intravascular ultrasound and angiography are done in the operating room to allow appropriate endoluminal graft selection. The device is then placed as expeditiously as possible.

Mycotic Aortic Aneurysm

They are most frequently found in the aorta, most common organisms being staphylococci, followed by Salmonella. These aneurysms develop as a consequence of the infection, not as a result of infection in a preexisting aneurysm. Mycotic aneurysms can occur as a result of infected emboli that lodge in the artery and spread in the wall. Most commonly they arise from infected aortic and mitral valves. Other mycotic aneurysms occur from direct extension of an area of infection into the adjacent arterial wall. Because patients who are immunosuppressed (i.e., acquired immunodeficiency syndrome [AIDS] or organ transplant patients) are predisposed to infection, they are at an increased risk of developing mycotic aneurysms. Mycotic aneurysms often present with pain, are more rapidly progressive than degenerative aneurysms, and have a higher rupture rate.

Treatment is determined by location. Those arising within the visceral aortic segment have to be treated by débridement and in situ reconstruction. Cryopreserved aorta has been widely used for this purpose. Expanded polytetrafluoroethylene (ePTFE) grafts may also be more infection resistant than Dacron grafts, although antibiotic-impregnated Dacron grafts are being increasingly used. Aneurysms that occur in the infrarenal aorta can be treated by several techniques. The traditional approach is to revascularize the lower extremities via an extra-anatomic approach (axillobifemoral bypass), followed by aortic excision and oversewing of the aortic stump. This is associated with a 5 percent

risk of aortic stump blow-out, which is usually fatal. Rifampin-soaked Dacron grafts have been placed into the aortic bed after excision, débridement, and irrigation. More recently, Clagett has popularized the use of bilateral superficial femoral vein to replace infected aortic grafts. Antibiotic therapy is used as directed by culture results, and long-term antibiotic therapy for 3–6 months is warranted.

Para-Anastomotic Aneurysms

Definition. Aneurysmal disease after bypass grafting of the abdominal aorta is defined radiographically as a focal dilatation juxtaposed to the aortic suture line or an adjacent aortic diameter that is greater than or equal to 4 cm. It is important to distinguish true versus false aneurysms and to identify early versus late aneurysmal development. True aneurysms are a dilation of the remaining infrarenal aorta. False aneurysms occur because of degeneration of the old suture line and separation of the graft from the aortic wall.

Management. Elective surgical management of para-anastomotic aortic aneurysm (PAAA) lesions is the treatment of choice because these lesions progressively increase in size and may rupture with time. Morbidity and mortality rates are acceptable in asymptomatic patients undergoing elective repair, as reported in these authors' series and by others. The operative repair most frequently involves excising the diseased segment of the artery and graft and placement of an interposition prosthesis.

More recently, use of endografts has become an increasingly popular method for treating anastomotic pseudoaneurysms. They are most easily used when the initial graft has been implanted well below the renal arteries such that a suitable landing and seal zone is available for positioning the device. In patients who are at high risk, stent grafting across the renal arteries with revascularization from the visceral or iliac vessels will avoid aortic cross-clamping.

Other Anastomotic Aneurysms

The most common location for an aneurysm that develops at a suture line is at the femoral anastomosis of an aortobifemoral graft. They are detected by the presence of an enlarging pulsatile mass in the groin. Ultrasound confirms the diagnosis. Both groins should always be examined, and treatment is by surgical repair. The groin is entered via a vertical incision, and control of the inflow graft is necessary. Once this has been controlled, the patient is anticoagulated and the aneurysm opened. Fogarty catheters are used endoluminally to control the profunda femoris, the superficial femoral artery, and the native common femoral artery if it remains open. An interposition piece of Dacron or ePTFE is used to restore continuity. Proximally, it is sewn end-to-end to the previous graft. Distally, the graft usually has to be tailored around both the superficial femoral and profunda femoris arteries.

Iliac Artery Aneurysms

Occasionally isolated common iliac aneurysms are encountered. Internal iliac aneurysm may also be diagnosed, although isolated aneurysms of the external iliac artery are rare. Treatment options include open surgical replacement with prosthetic graft or endovascular stent grafting. In patients with suitable anatomy, namely the presence of proximal and distal landing zones, stent grafting has become the treatment of choice.

Internal iliac artery aneurysms are treated by proximal ligation with opening of the aneurysm and oversewing of the distal branches. Because the distal end of the aneurysm may be located deep in the pelvis, an emerging approach is embolization and stent grafting across the orifice of the hypogastric. Although unilateral sacrifice of a hypogastric is well tolerated, bilateral ligation can result in pelvic ischemia. Consequently, an attempt should be made to revascularize one hypogastric.

Popliteal Artery Aneurysms

Popliteal arterial aneurysms are the most common peripheral arterial aneurysms, accounting for 70 percent, and are commonly bilateral in 50–75 percent. Finding one popliteal aneurysm mandates evaluation of the contralateral popliteal artery, usually with ultrasound. They are more common in males. These aneurysms present by a process of chronic distal embolization or sudden-onset acute occlusion of the popliteal artery. Consequently the clinical presentation is by development of claudication; chronic foot ischemia; or sudden-onset, limb-threatening, acute ischemia below the knee. Rupture is rare. Frequently a pattern of acute or chronic ischemia occurs, and the presence of chronic embolization of the infrapopliteal vessels can markedly complicate revascularization.

Examination reveals a pulsatile mass, which can be massive, in the popliteal fossa. Smaller aneurysms may not be palpable. Foot pulses may be diminished if embolization has been occurring. In patients with acute occlusion of the aneurysm or with embolization, many have all the clinical features of acute ischemia. A thrombosed aneurysm may be palpated as a hard mass, and pulsation is absent. Occasionally these aneurysms can be massive, filling the entire popliteal fossa. Large aneurysms compress the adjacent popliteal vein and occasionally present with acute deep venous thrombosis. Diagnosis is by ultrasound aneurysms greater than 2 cm should be treated. Preoperative angiography is usually performed in both the acute and elective situation to demonstrate the run off vessels. In the presence of limb-threatening ischemia, revascularization is undertaken emergently.

Choice of treatment is based on degree of ischemia and the ability to demonstrate distal target vessels for revascularization. Where no run-off is identifiable, the approach is to attempt thrombolysis via a catheter placed into, and ideally through, the aneurysm. Lytic agents are then infused in an attempt to open up the tibial vessels and permit a bypass graft to be created. Alternately, surgical exploration is performed of the distal popliteal artery, and all three trifurcation vessels should be dissected and controlled. Fogarty embolectomy catheters (no 3) are gently passed down each artery, inflated, and the thrombus removed. Once outflow is established, revascularization is performed as described for elective popliteal arterial aneurysms below.

In the elective situation in which target outflow vessels are evident, two approaches are open to the surgeon: medial and posterior. For the medial approach, reversed saphenous vein is tunneled from the superior to the inferior incision, and end-to-side anastomoses are created. The popliteal artery is then ligated distal and proximal to the bypass graft.

The posterior approach (e.g., patient prone, foot supported on a pillow) is useful for smaller aneurysms limited to the midpopliteal artery or for exploring aneurysms which have continued to expand after ligation and bypass. A Z-type incision is made centered on the skin crease. An endoaneurysmorrhaphy is

easily performed by opening the aneurysm, oversewing tributaries, and placing an interposition reversed saphenous vein graft.

Femoral Artery Aneurysms

Femoral arterial aneurysms (FAAs) present as a pulsatile mass in the groin. They occur in older adult men, often with other manifestations of atherosclerosis. One third are bilateral and nearly two thirds are associated with aneurysms elsewhere (e.g., popliteal and aortic). Ultrasound is used to confirm the diagnosis, and although most are considered atherosclerotic in etiology, mycotic femoral arterial aneurysms are encountered, particularly in intravenous drug abusers. Femoral aneurysms can reach a large size and via thrombosis can create symptoms such as limb-threatening ischemia, embolization, or skin erosion; however, rupture is rarely encountered. FAAs are often asymptomatic, but local pain, distal embolization, rupture, and venous compression may all be presenting features.

Treatment. All aneurysms greater than 2.5 cm should be treated with resection and interposition grafting.

Hepatic Artery Aneurysms

Hepatic arterial aneurysms (HAAs) comprise 20 percent of splanchnic arterial aneurysms. Although not well-defined, the natural history of HAAs typically results in enlargement, rupture, and life-threatening hemorrhage. Hence, heightened clinical suspicion with conclusive diagnosis and effective treatment are imperative in the successful management of patients with these aneurysms.

Pseudoaneurysms typically affect younger male individuals and often reflect a traumatic etiology.

Plain abdominal radiographs or upper GI contrast studies may suggest an underlying HAA when a rim of calcification in the right hypochondrium or a smooth filling defect in the duodenum is demonstrated. Ultrasonography and contrast-enhanced CT scanning will provide the diagnosis in most cases. MRI has been applied to good effect in the diagnosis of HAAs. Color-flow duplex ultrasonography is particularly effective in demonstrating intrahepatic lesions.

Unless severe comorbidities disqualify the patient, all extrahepatic aneurysms greater than 2 cm in diameter should be treated. Pseudoaneurysms, most of which are intrahepatic and can be successfully embolized, are treated when greater than 1 cm.

Extrahepatic aneurysms warrant surgical treatment, except in high-risk patients and in saccular aneurysms. Common HAAs (i.e., those proximal to a patent gastroduodenal artery) may be ligated and excised.

As a rule, extrahepatic aneurysms involving the hepatic artery propria will need vascular reconstruction. Ligation and bypass is necessary for aneurysms of the true hepatic artery beyond the gastroduodenal artery.

Successful percutaneous embolization was first reported in 1977, and several reports have been published that support the use of this technique. An advantage of selective arterial embolization is its precision in limiting hepatic devascularization. It is of particular value in cases of posttraumatic pseudoaneurysms, and because of its lower morbidity, represents an attractive option in high-risk patients.

Splenic Artery Aneurysms

These are the most common visceral artery aneurysms and also most likely to develop pseudoaneurysms.

Symptoms and signs. Most are asymptomatic, usually being discovered incidentally. Chronic vague epigastric and left hypochondrial pain may be reported. The development of acute left upper quadrant pain indicates that rupture may have occurred, especially when signs of hypovolemia are present.

Investigations. The presence of a splenic artery aneurysm (SAA) may be suspected with the appearance of calcification in a corresponding area on a KUB radiograph. CT scanning is valuable in demonstrating size and location of these aneurysms. Angiography confirms the diagnosis, delineates the location and number of these aneurysms, and assists in determining whether an endovascular or open surgical approach should be selected.

Treatment

There is a general consensus that women anticipating pregnancy should have surgical treatment, and patients with symptomatic aneurysms should be promptly treated. Although widely recommended, the indications for treating aneurysms that are larger than 2 cm are less definite.

The recommended procedure for proximally situated aneurysms is exclusion of the lesion with proximal and distal ligation of the splenic artery. Occasionally, opening the aneurysm to oversee feeding vessels from within the lesion may be necessary.

Successful laparoscopic ligation has been reported. Percutaneous embolization with Gianturco coils and gelfoam sponges has been reported with favorable results.

Renal Artery Aneurysms

The incidence of renal arterial aneurysms (RAAs) is estimated to be between 0.09 and 0.7 percent of the population. The incidence rises to 2.5 percent among patients evaluated for hypertension, and is 9.2 percent among patients with fibromuscular disease (FMD) involving the renal artery. Complications are uncommon but can include renovascular hypertension; renal infarction from embolization, dissection, or thrombosis; and arteriovenous fistula formation.

Renal artery aneurysms are slightly more common in women than men and more frequently affect the right than the left renal artery.

The true risk of rupture for renal arterial aneurysms has been overestimated. A disproportionate number of ruptures have occurred in pregnancy.

Management options include observation, transcatheter occlusion, or surgical intervention. Indications for intervention include aneurysm size greater than 2.5 cm, renovascular hypertension with lateralizing serum renin level, symptomatic aneurysms, documented expansion, renal embolization, and young women anticipating pregnancy.

Embolization is particularly useful in patients with saccular aneurysms; small, bleeding aneurysms in patients with arteritis; and in high-risk patients. Transcatheter embolization is also the treatment of choice for intraparenchymal lesions.

Aneurysmectomy and arteriorrhaphy with or without patch angioplasty is the simplest method of aneurysm resection with reconstitution of the renal

artery. It is most easily applied to saccular aneurysms with a narrow neck on the patent artery. Ligation and bypass are appropriately applied to fusiform aneurysms. Opening of the aneurysm with oversewing of feeding vessels from within the sac is optimal to preclude progressive enlargement of a ligated aneurysm.

ACUTE ARTERIAL OCCLUSION

One of the most common vascular emergencies is acute lower extremity ischemia; however, sudden-onset acute occlusion of any major vessel (e.g., mesenteric, renal, or upper extremity) presents with severe symptoms, which reflect ischemia in the organ supplied by those vessels. Arteries that undergo slow progressive occlusion permit the development of collaterals such that patients may be asymptomatic or lack the severe symptoms associated with acute ischemia. In the absence of collaterals, however, acute ischemia can result in nonreversible changes within the target organ within h. Consequently, expeditious relief of the obstruction is mandatory, and revascularization of ischemic tissue, resulting in swelling and edema within the target tissues, and washout of lactic acid, myoglobin, and potassium. The vascular surgeon must know how to manage both the local and systemic effects of this postrevascularization syndrome.

Arterial Embolism

Cardiac Sources

The heart is the most common source of distal emboli. In fact, 70 percent of distal emboli are cardiac in origin (atrial fibrillation, ventricular aneurysm, mural thrombus over an area of infection, and endocarditis).

Lower Extremity Acute Ischemia

Clinical manifestations. Acute lower extremity ischemia manifests with the “five Ps”: pain, pallor, paresthesias, paralysis, and pulselessness, to which some add a sixth “P”—poikilothermia or “perishing cold.” Pain, however, is what causes a patient to present to the emergency room. The most common location for an embolus to lodge in the leg is at the common femoral bifurcation. Typically a patient will complain of foot and calf pain. In addition to absent pulses, there is a variable diminution of sensation, which varies from a mild reduction in sensation compared to the contralateral side to being completely insensate.

Absent bilateral femoral pulses in a patient with bilateral lower extremity ischemia is most likely because of saddle embolus to the aortic bifurcation. A palpable femoral pulse and absent popliteal and distal pulses may either be because of distal common femoral embolus (the pulse being palpable above the level of occlusion) or embolus to the superficial femoral or popliteal arteries. Typically, emboli lodge at bifurcations where there are sudden changes in arterial diameter. A popliteal trifurcation embolus will present with calf ischemia and absent pedal pulses, possibly with a popliteal pulse present. The finding of palpable contralateral pulses in the absence of ipsilateral pulses in the ischemic leg is suggestive of an embolus.

Medical therapy. In the absence of any significant contraindication, the patient with an ischemic lower extremity should be immediately anticoagulated.

Surgery. The groin is opened through a vertical incision, exposing the common femoral artery and its bifurcation. Frequently, the location of the embolus at the femoral bifurcation is readily apparent by the presence of a palpable proximal femoral pulse, which disappears distally. The artery is clamped and opened transversely over the bifurcation. Thrombus is extracted by passing a Fogarty balloon embolectomy catheter. Good back-bleeding and antegrade bleeding suggest that the entire clot has been removed. Completion angiography is advisable. The artery is then closed and the patient fully anticoagulated.

When an embolus lodges in the popliteal artery, in most cases it can be extracted via a femoral incision using the techniques previously described. A femoral approach is preferred because the larger arterial size results in a lessened likelihood of arterial compromise when the artery is closed. The disadvantage is that the embolectomy catheter cannot be specifically directed into each of the infrapopliteal arteries. This can be achieved from the groin using fluoroscopic imaging and an over-the-wire thrombectomy catheter, which can be specifically directed into each of the infrapopliteal vessels. Otherwise, a separate incision exposing the popliteal bifurcation may be necessary to ensure completeness of thrombectomy.

In the postoperative period it is important to seek the source of the embolus using echocardiography and CT scanning of the descending thoracic and abdominal aorta.

A more complex situation arises when a patient has preexisting peripheral vascular disease and in situ thrombosis on top of atheroma; frequently embolectomy catheters will not pass through these occlusions. There are essentially two options: surgical bypass or catheter-based lytic therapy. Angiography is necessary in both situations to determine the extent of the occlusion and to search for inflow and distal outflow vessels to which a bypass graft could be attached. Although the surgeon's preference tends to predominate in the approach to the ischemic limb, both approaches have been demonstrated to be fairly equivalent in terms of limb salvage. Criteria for selecting the appropriate approach are based on the presence or absence of good target vessels and availability of a suitable bypass conduit. If there are good distal vessels—usually inflow vessels are adequate or can be made adequate—and a good saphenous vein is available, surgical bypass is recommended, as it is fast and reliable. In the absence of a good distal target, absent saphenous vein, or in a patient at high risk for surgery, lysis is recommended.

Complications of reperfusion of the ischemic limb. Reperfusion of the ischemic limb is variable in its physiologic effects, which directly relates to the severity and extent of the ischemia. Patients with a saddle embolus of the aortic bifurcation and severely ischemic limbs may sustain the full-blown "reperfusion syndrome." At the other end of the spectrum, patients with minimal muscle ischemia who are rapidly reperfused may have essentially no effects. However, many of these patients have severe underlying cardiac disease and poorly tolerate even short ischemic periods. Complications occurring after revascularization of the lower extremity and causes of recurrent thrombosis are listed. Therapy is directed toward forced alkaline diuresis by adding bicarbonate to the intravenous fluid. Alkalinization increases the solubility of myoglobin in the urine, preventing it from crystallizing in the tubules, which is what promotes acute renal failure.

Compartment syndrome. Compartment syndrome occurs after prolonged ischemia followed by reperfusion. The capillaries leak fluid into the interstitial

space in the muscles, which are enclosed within a nondistensible fascial envelope. When the pressure inside the compartment exceeds the capillary perfusion pressure, nutrient flow ceases and progressive ischemia occurs, even in the presence of peripheral pulses. The most commonly affected compartment is the anterior compartment in the leg. Numbness in the web space between the first and second toes is diagnostic because of compression of the deep peroneal nerve. When skin changes occur over the compartment, this indicates advanced ischemia. Compartment pressure is measured by inserting an arterial line into the compartment and recording the pressure. Although controversial, pressures greater than 30 mmHg or below 30 mmHg diastolic are frequently cited. Treatment is by fasciotomy. In the leg, medial and lateral incisions are used via the medial incision. Long openings are then made in the fascia of the superficial and deep posterior compartments. Through the lateral incision, the anterior and peroneal compartments are opened.

Acute Aortic Occlusion

Acute aortic occlusion is a rare vascular catastrophe. It may result from an aortic saddle embolus, in situ thrombosis of a previously atherosclerotic abdominal aorta, sudden thrombosis of small abdominal aortic aneurysms, distal aortic dissection, or other etiologies that embolize to the aortic bifurcation. The diagnosis can easily go unrecognized and has a published mortality rate of 75 percent with conservative treatment. Additionally, the condition often presents with leg paralysis that occasionally leads clinicians to perform an extensive neurologic workup, even if patients have absent femoral pulses, which can lead to delays in diagnosis and operative therapy.

In all patients, an acute onset of bilateral lower extremity ischemia or a sudden exacerbation of preexisting chronic ischemia is the presenting syndrome.

Acute aortic occlusion is a different entity than chronic obstruction, in which a well-developed collateral circulation may minimize symptoms. When an embolus is large enough to occlude the aorta, the source is usually cardiac (i.e., mural thrombus over an infarct, a left ventricular aneurysm, or rheumatic heart disease).

Presenting symptoms. Symptoms include sudden onset of bilateral limb pain, pallor, paralysis, paresthesia, and the absence of palpable pulses. Mottling of the lower extremities, often to the level of the umbilicus, may also be present.

Physical examination. If the physical examination shows the absence of both femoral pulses, the diagnosis of acute aortic occlusion is established. The cause of the occlusion will significantly alter patient management, and thus a detailed history is important. Severe coronary artery disease, known arrhythmias, or ventricular aneurysms suggest a saddle embolus, whereas known aortoiliac disease or a previously diagnosed aortic aneurysm suggests an in situ thrombosis.

Investigations. Patients with suspected in situ abdominal aortic thrombosis with clinically unclear renal or mesenteric arterial involvement should have preoperative angiography. For all other patients, it is recommended that intraoperative angiography with a C-arm be used in the operating room, because it saves time and provides important information should it be needed.

Operative considerations. Because patient prognosis is time-dependent, early recognition, institution of supportive care, and prompt diagnosis (if possible)

are essential elements of management. The treatment of acute aortic occlusion is surgical. The cause of occlusion is important because transfemoral embolectomy is likely to restore perfusion in patients with saddle embolus, but is usually unhelpful in patients with in situ thrombosis. When the diagnosis is made, the patient should be heparinized immediately to prevent proximal and distal propagation of the thrombotic process. Bilateral transfemoral embolectomy is the first procedure of choice. If flow is re-established, the groin wounds are closed and postoperative anticoagulation is initiated. If flow cannot be re-established, more extensive surgery, such as aortoiliac bypass or axillobifemoral bypass, should be performed. The choice to perform axillobifemoral bypass versus aortobifemoral bypass is guided by the clinical condition of the patient.

Postoperative management. Postoperative management requires correction of any embolic diathesis. Transthoracic or transesophageal echocardiography should be obtained. A CT scan of the abdomen should be done if not performed preoperatively to rule out the presence of an abdominal aortic aneurysm. If an aneurysm is present and the patient is a reasonable candidate, the aneurysm may be ligated electively. If the patient is known to have an aneurysm that appears to have occluded, then replacement with a prosthetic graft is the procedure of choice. Long-term anticoagulation is necessary for all patients.

AORTOILIAC OCCLUSIVE DISEASE

The distal abdominal aorta and the iliac arteries are common sites of involvement with atherosclerosis. Aortoiliac occlusive disease occurs in a relatively younger group of patients (aged in their mid-50s), compared with patients with femoropopliteal disease. It alone is rarely limb-threatening. Symptoms typically consist of bilateral thigh or buttock claudication and fatigue. Men report diminished penile tumescence, and there may later be complete failure of erectile function. These symptoms constitute Leriche syndrome. Rest pain is unusual with isolated aortoiliac disease. Femoral pulses are usually diminished or absent. There are usually no stigmata of ischemia unless distal disease co-exists. Others may present with “trash foot,” representing microembolization into the distal vascular bed.

Noninvasive tests such as pulse volume recordings of the lower extremity with estimation or the thigh-brachial pressure index may be suggestive of aortoiliac disease. Definitive diagnosis, however, can only be established by arteriography.

Preferred Approach to Therapeutic Alternatives

Medical Treatment

There is no effective medical therapy for the management of aortoiliac disease. Patients should have good medical management for atherosclerosis and risk factor modification as described above.

Open Surgical Treatment or Endovascular Therapy

The decision to pursue an open rather than an endovascular approach is made based on the extent of the occlusive disease. The Trans-Atlantic Intersocietal Commission (TASC) has classified the distribution and extent of atherosclerosis and has suggested a therapeutic approach based on this classification. TASC

type A lesions are best treated with a catheter-based approach. TASC type D lesions should have open bypass. TASC types B and C remain controversial. However, this is a rapidly evolving field and it is likely that aortoiliac disease will be increasingly treated with a catheter-based approach.

Indications for surgery. Indications for surgery include disabling claudication (severely limiting work or lifestyle), rest pain, limb-threatening ischemia, and microembolization of the toes in which no other source is identified.

Surgical options. Surgical options consist of aortobifemoral bypass grafting, extra-anatomic bypass grafting, and aortoiliac endarterectomy. The procedure selected is determined by several factors, including anatomic distribution of the disease, clinical condition of the patient, and personal preference of the surgeon. Aortobifemoral bypass grafting is an excellent procedure for good risk patients. It reliably relieves symptoms, has an excellent long-term patency of 60–75 percent at 10 years, and can be completed with a tolerable mortality of 2–3 percent.

Procedure. Both femoral arteries are initially exposed to ensure that they are adequate for the distal anastomoses. The abdomen is then opened at the midline. A collagen-impregnated, knitted Dacron graft is then sewn in either end-to-end or end-to-side fashion using 3-0 polypropylene suture.

The limbs of the graft are then tunneled through the retroperitoneum to the groin, where an end-to-side anastomosis is fashioned between the graft and the bifurcation of the common femoral artery using 5-0 polypropylene suture.

Extra-anatomic (axillofemoral) bypass grafting from the axillary artery is an option for those patients with intercurrent medical problems that prohibit a laparotomy.

Postoperative management. All aortic patients are observed in the ICU overnight. Distal pulses are monitored hourly. Loss of a pulse that had been present postoperatively is suggestive of graft occlusion and warrants angiography to assess for re-exploration if the graft has failed.

The patient gets out of bed and into a chair on the second postoperative day and ambulates on the third day. Most patients may be discharged from the hospital 5–7 days postoperatively.

Percutaneous Transluminal Dilatation

Angioplasty is most useful in the treatment of isolated iliac stenoses of less than 4 cm in length. When used for stenoses rather than occlusion, a 2-year patency of 86 percent can be achieved. The complication rate is approximately 2 percent, consisting of distal embolization, medial dissection, and acute thrombosis.

Femoropopliteal Occlusive Disease

One of the most common sites for occlusive disease is in the distal superficial femoral artery (SFA) as it passes deep through the adductor canal. It may be that the entrapment by the adductor hiatus prevents the compensatory dilation that occurs in atherosclerotic vessels. Stenoses, which develop here, progress to occlusion of the distal third of the superficial femoral artery. Although often originating in this location, the SFA is frequently the site of diffuse disease with posterior plaque, which spirals along the artery. When distal SFA occlusion develops slowly it may be totally asymptomatic, and collaterals from

the proximal SFA or the profunda femoris artery (PFA) bypass the occlusion and reconstitute the popliteal artery. Symptom development is a function of the extent of occlusion, adequacy of collaterals, and also the activity level of the patients.

Clinical Manifestations

Presenting symptoms of femoropopliteal occlusive disease are broadly classified into two types: limb-threatening and non-limb-threatening ischemia. Claudication (calf pain with exercise) is non-limb-threatening. Rest pain, ulceration, and gangrene are limb-threatening and demand intervention.

In greater than 70 percent of claudicants, the disease is stable, particularly with risk factor modification. It does not lead to progressive occlusion, and in most cases is not limb-threatening. This is extremely important for both the patient and physician to understand. Progression is more likely to occur in patients with diabetes and those who continue to smoke or fail to modify their atherosclerotic risk factors.

In contrast, rest pain is constant, usually occurring in the forefoot across the metatarsophalangeal joint. It is worse at night and requires foot dependency to improve symptoms. Patients may report that they either sleep in a chair or hang the foot off the side of the bed.

Ischemic ulceration most commonly involves the toes and often will progress to gangrene.

Differential Diagnosis

Night cramps often wake patients from sleep with painful calf muscle spasms and are not associated with arterial disease. However, foot ulceration, arterial ulcers that occur on the toes or lateral side of the foot, and venous ulcers, which are quite common and occur above the medial malleolus, usually in an area with the skin changes of lipodermatosclerosis, are associated with arterial disease.

Physical Examination

Diminished popliteal and distal pulses indicate SFA occlusive disease.

Investigations

Segmental pressure measurement and pulse volume recordings (PVRs) will demonstrate the level at which the pressure fall occurs and assist in localizing the affected segment. A pressure drop of greater than 30 mmHg between two adjacent segments is suggestive of significant occlusive disease at that level. Exercise testing with measurement of the ABI after exercise will help identify those patients who, despite significant occlusive disease, have palpable pedal pulses by showing an abrupt fall in ABI after exercise.

Angiography continues to be the best and most reliable test for imaging the entire lower extremity vasculature. Although magnetic resonance angiography (MRA) and computed tomographic angiography (CTA) continue to improve, it has not yet replaced DSA for lower-extremity angiography as anticipated. Lower-extremity duplex arterial mapping is increasing in popularity, but there remain only a few select centers that routinely use this technique for preoperative planning.

Age and comorbidities. Evaluation of the risk benefit ratio is particularly important in the claudicant. A femoral-popliteal bypass in the 50-year-old

patient who has to walk as part of their employment is warranted. In contrast, the same operation in an 80-year-old patient is usually not indicated.

Extent of disease. Generally, localized disease (i.e., stenoses and short segment occlusions) is more amenable to a catheter-based approach.

Medical Therapy

Cilostazol has been demonstrated to be effective when compared with both placebo and pentoxifylline in improving walking distance. Likewise, for patients with non-limb-threatening ischemia, an exercise program should be initiated.

Open Surgical Procedures

Endarterectomy. Endarterectomy has a limited, albeit important role in lower extremity occlusive disease. It is most frequently used when there is disease of the common femoral artery or involving the profunda femoris artery. In this procedure, the surgeon opens the diseased segment longitudinally and develops a cleavage plane within the media that is developed proximally and distally.

Bypass grafting. Bypass grafting remains the primary intervention for lower-extremity occlusive disease. The type of bypass and the type of conduit are important variables. Those patients with occlusive disease limited to the SFA, with reconstitution of at least 4 cm (ideally 10 cm) of normal popliteal artery above the knee joint, and with at least one continuous vessel to the foot are treated with an above-knee femoral-to-popliteal bypass graft. In this location (i.e., not crossing the knee joint) the differential in patency between prosthetic (ePTFE) and vein graft is relatively small, therefore either conduit can be used.

Complications. Fifteen percent of vein grafts will develop intrinsic stenoses within the first 18 months following implantation. Consequently all patients with a vein graft should enter a duplex surveillance protocol. Scanning should be performed in the postoperative period at 3, 6, 12, and 18 months. Stenoses greater than 50 percent should be repaired, usually with patch angioplasty.

Wound infection. Because the most common inflow vessel for distal bypass is the common femoral artery, groin infection occurs in 7 percent of cases.

Alternate Bypass Techniques

In diabetic patients the SFA may be spared, and it is appropriate to shorten the bypass graft by performing popliteal-to-tibial grafts. In patients in whom both greater saphenous veins (GSVs) have been harvested, alternate vein sources include the short saphenous veins and upper extremity cephalic and basilic veins.

Endovascular Procedures

Endovascular procedures are undergoing rapid change. Presently, endovascular procedures in the infrainguinal area have a limited role and are confined to short segment stenoses or occlusions. Longer lesions, although treatable, have limited durability because of neointimal hyperplasia.

Mesenteric Artery Occlusive Disease

Blood flow to the intestine is supplied by three vessels: the celiac artery (CA), the superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA). These are the arteries to the foregut (stomach to second part of duodenum), midgut (second part of duodenum to right two thirds of transverse colon), and hind gut (distal third of the transverse colon to the rectum), respectively. Anastomoses exist between the celiac and superior mesenteric arteries via the pancreaticoduodenal arcade, and between the SMA and IMA via the marginal artery of Drummond and the Riolo arc; however, these collateral pathways are inconsistent and cannot be relied on to suffice in either acute or chronic occlusion of the visceral arteries.

Occlusive disease of the mesenteric arteries usually occurs in individuals who are medically debilitated with generalized atherosclerosis. The disease process may evolve in a chronic fashion, as in the case of progressive luminal plaque narrowing because of atherosclerotic progression. On the other hand, mesenteric ischemia can occur suddenly, as in the case of thromboembolism. Despite recent progress in perioperative management and better understanding in pathophysiology, mesenteric ischemia is one of the most lethal vascular disorders, with mortality rates ranging from 50–75 percent. Delay in diagnosis and treatment are the main contributing factors to the high mortality rate. Early recognition and prompt treatment prior to the onset of irreversible intestinal ischemia are essential to improve the outcome.

Types of Mesenteric Artery Occlusive Disease

There are four major types of visceral ischemia involving the mesenteric arteries: (1) acute embolic mesenteric ischemia, (2) acute thrombotic mesenteric ischemia, (3) chronic mesenteric ischemia, and (4) nonocclusive mesenteric ischemia. Despite the variability of these syndromes, a common anatomic pathology is involved in these processes. The SMA is the most commonly involved vessel in acute mesenteric ischemia. Acute thrombotic mesenteric ischemia frequently occurs in patients with underlying mesenteric atherosclerosis, which usually involves the origin of the mesenteric arteries while sparing the collateral branches. The development of collateral vessels is more likely when the occlusive process is a gradual, rather than a sudden, ischemic event. In acute embolic mesenteric ischemia, the emboli typically originate from a cardiac source, and frequently occur in patients with atrial fibrillation or following myocardial infarction. Nonocclusive mesenteric ischemia is characterized by a low-flow state in otherwise normal mesenteric arteries. In contrast, chronic mesenteric ischemia is a functional consequence of a long-standing atherosclerotic process that typically involves at least two of the three main mesenteric vessels, the CA, the SMA, and the IMA.

Several less common syndromes of visceral ischemia involving the mesenteric arteries can also cause serious debilitation. Chronic mesenteric ischemic symptoms can occur because of extrinsic compression of the celiac artery by the diaphragm, which is termed the median arcuate ligament syndrome. Acute visceral ischemia may occur following an aortic operation, because of ligation of the IMA in the absence of adequate collateral vessels. Furthermore, acute visceral ischemia may develop in aortic dissection, which involves the mesenteric arteries. Finally, other unusual causes of ischemia include mesenteric arteritis, radiation arteritis, and cholesterol emboli.

Clinical Presentation

Severe abdominal pain, out of proportion to the findings on exam is the classic presentation in patients with acute mesenteric ischemia. Sudden onset of abdominal cramps with bowel emptying may occur, perhaps with bloody diarrhea. Diffuse abdominal tenderness, rebound, and rigidity are ominous signs and usually herald bowel infarction.

Symptoms of thrombotic mesenteric ischemia may initially be more insidious than those of embolic mesenteric ischemia. Approximately 70 percent of patients with chronic mesenteric ischemia have a history of abdominal angina. In these patients, the chronicity of mesenteric atherosclerosis is important, as it permits collateral vessel formation. The precipitating factor leading to chronic mesenteric occlusion is often an unrelated illness that results in dehydration, such as diarrhea or vomiting, which may further confuse the actual diagnosis. If the diagnosis is not recognized promptly, symptoms may worsen that can lead to progressive abdominal distention, oliguria, increasing fluid requirements, and severe metabolic acidosis.

Abdominal pain is only present in approximately 70 percent of patients with nonocclusive mesenteric ischemia. When present, pain is usually severe, but may vary in location, character, and intensity. In the absence of abdominal pain, progressive abdominal distention with acidosis may be an early sign of ischemia and impending bowel infarction.

Diagnostic Studies

Laboratory evaluation is neither sensitive nor specific in the diagnosis of mesenteric ischemia. Complete blood count (CBC) may reveal hemoconcentration and leukocytosis. Metabolic acidosis develops as a result of anaerobic metabolism. Elevated serum amylase and lactate levels are nonspecific findings. Hyperkalemia and azotemia may occur in the late stages of ischemia. Plain abdominal radiographs may provide helpful information to exclude other abdominal pathologies such as bowel perforation, obstruction, or volvulus, which may exhibit symptoms mimicking intestinal ischemia. Radiographic appearance of an adynamic ileus with a gasless abdomen is the most common finding in patients with acute mesenteric ischemia. Embolic sources should be sought as described under acute ischemia.

The definitive diagnosis of mesenteric thrombosis is made by biplanar mesenteric arteriography, which should be performed promptly in any patient with suspected mesenteric occlusion. It typically shows occlusion or near-occlusion of the CA and SMA at or near their origins from the aorta. In most cases, the IMA has been previously occluded secondary to diffuse infrarenal aortic atherosclerosis. The differentiation of the four different types of mesenteric arterial occlusion may be suggested with a biplanar mesenteric arteriogram. Mesenteric emboli typically lodge in the SMA at the origin of the middle colic artery, creating a "meniscus sign" with an abrupt cutoff of a normal proximal SMA several centimeters from its origin on the aorta. Mesenteric thrombosis, in contrast, occurs at the most proximal SMA, which tapers off at 1–2 cm from its origin. In the case of chronic mesenteric occlusion, the appearance of collateral circulation is usually present. Nonocclusive mesenteric ischemia produces an arteriographic image of segmental mesenteric vasospasm with a relatively normal-appearing main SMA trunk.

Mesenteric arteriography also can play a therapeutic role. Once the diagnosis of nonocclusive mesenteric ischemia is made on the arteriogram, an infusion

catheter can be placed at the SMA orifice, and vasodilating agents such as papaverine can be administered intraarterially. The papaverine infusion may be continued postoperatively to treat persistent vasospasm, a common occurrence following mesenteric reperfusion. Transcatheter thrombolytic therapy has little role in the management of thrombotic mesenteric occlusion. Although thrombolytic agents may transiently recannulate the occluded vessels, the underlying occlusive lesions require definitive treatment. Furthermore, thrombolytic therapy typically requires a prolonged period of time to restore perfusion, and the intestinal viability may be difficult to assess.

Treatment

Initial management of patients with acute mesenteric ischemia includes fluid resuscitation and systemic anticoagulation with heparin to prevent further thrombus propagation. Significant metabolic acidosis should be corrected with sodium bicarbonate. The operative management of acute mesenteric ischemia is dictated by the cause of the occlusion. It is helpful to obtain a preoperative mesenteric arteriogram to confirm the diagnosis and to plan appropriate treatment options. However, the diagnosis of mesenteric ischemia frequently cannot be established prior to surgical exploration, and therefore patients in a moribund condition with acute abdominal symptoms should undergo immediate surgical exploration, avoiding the delay required to perform an arteriogram.

Acute embolic mesenteric ischemia. The primary goal of surgical treatment in embolic mesenteric ischemia is to restore arterial perfusion with removal of the embolus from the vessel. The abdomen is explored through a midline incision, which often reveals variable intestinal ischemia from the midjejunum to the ascending or transverse colon. The SMA is approached at the root of the small bowel mesentery and a transverse arteriotomy is made to extract the embolus, using standard balloon embolectomy catheters. Following the restoration of SMA flow, an assessment of intestinal viability must be made, and nonviable bowel must be resected. A second-look procedure should be considered in many patients, and is performed 24–48 h following embolectomy.

Acute thrombotic mesenteric ischemia. In embolic mesenteric ischemia, the SMA itself is normal, and thromboembolectomy will usually suffice to restore mesenteric circulation. However, thrombotic mesenteric ischemia usually involves a severely atherosclerotic vessel, typically the proximal CA and SMA. Therefore, these patients require a reconstructive procedure to the distal SMA. The saphenous vein is the graft material of choice, and prosthetic materials should be avoided in patients with nonviable bowel, because of the risk of bacterial contamination if resection of necrotic intestine is performed. The bypass graft may originate from the aorta (either above the celiac or below the renals or iliac artery).

Chronic mesenteric ischemia. The therapeutic goal in patients with chronic mesenteric ischemia is to revascularize mesenteric circulation and prevent the development of bowel infarction. Mesenteric occlusive disease can be treated successfully by either transaortic endarterectomy or mesenteric artery bypass. Transaortic endarterectomy is indicated for ostial lesions of patent CA and SMA. For occlusive lesions located 1–2 cm distal to the mesenteric origin, mesenteric artery bypass should be performed. Multiple mesenteric arteries are typically involved in chronic mesenteric ischemia, and both the CA and SMA should be revascularized whenever possible; a collateral called the arc of

Riolan may fill the distal SMA from the IMA. In general, bypass grafting may be performed either antegrade from the supraceliac aorta or retrograde from either the infrarenal aorta or iliac artery. Both autogenous saphenous vein grafts and prosthetic grafts have been used with satisfactory and equivalent success. An antegrade bypass also can be performed using a small-caliber bifurcated graft from the supraceliac aorta to both the CA and SMA, which yields an excellent long-term result.

Nonocclusive mesenteric ischemia. The treatment of nonocclusive mesenteric ischemia is primarily pharmacologic, with selective mesenteric arterial catheterization followed by infusion of vasodilatory agents such as tolazoline or papaverine. Once the diagnosis is made via mesenteric arteriography, intraarterial papaverine is given at a dose of 30–60 mg/h.

Celiac Artery Compression Syndrome

Abdominal pain because of narrowing of the origin of the CA may occur as a result of extrinsic compression or impingement by the median arcuate ligament. This condition is known as celiac artery compression syndrome or median arcuate ligament syndrome. CA compression syndrome has been implicated in some variants of chronic mesenteric ischemia. However, significant compression of the CA can be observed frequently on a lateral aortogram in the complete absence of symptoms. A decision to intervene is therefore based on both an appropriate symptom complex and the finding of CA compression in the absence of other findings to explain the symptoms. The patient should be cautioned that relief of the celiac compression cannot be guaranteed to relieve the symptoms. Most patients are young females between 20 and 40 years of age. Abdominal symptoms are nonspecific, but the pain is localized in the upper abdomen and may be precipitated by meals. The treatment goal is to release the ligamentous structure that compresses the proximal CA and to correct any persistent stricture by bypass grafting.

Renal Artery Occlusive Disease

Obstructive lesions of the renal artery can produce hypertension, resulting in a condition known as renovascular hypertension, which is the most common form of hypertension amenable to therapeutic intervention. Renovascular hypertension is believed to affect 5–10 percent of all hypertensive patients in the United States. Patients with renovascular hypertension are at an increased risk for irreversible renal dysfunction if inappropriate pharmacologic therapies are used to control the blood pressure (e.g., ACE inhibitors). In the rare event that a critically ischemic kidney cannot be revascularized, nephrectomy may also be effective in improving hypertension and preserving contralateral renal function.

Causes of Renal Artery Stenosis

Nearly 70 percent of all renal artery occlusive lesions are caused by atherosclerosis, typically occur near the renal artery ostia, and are usually less than 1 cm in length.

Patients with this disease are usually older adult males that have other atherosclerotic disease such as ischemic heart disease and peripheral vascular disease; however, a growing number of patients develop restenosis of previously placed stents.

The second most common cause of renal artery stenosis is fibromuscular dysplasia. Fibromuscular dysplasia of the renal artery represents a heterogeneous group of lesions that produce specific pathologic lesions in various regions of the vessel wall, including the intima, media, or adventitia. The most common variety consists of medial fibroplasia, in which thickened fibromuscular ridges alternate with attenuated media, producing the classic angiographic "string of beads" appearance. It occurs most commonly in young women, who are often multiparous.

Other less common causes of renal artery stenosis include renal artery aneurysm (compressing the adjacent normal renal artery), arteriovenous malformations, neurofibromatosis, renal artery dissections, renal artery trauma, Takayasu disease, and renal artery thrombosis.

Diagnostic Studies

Nearly all diagnostic studies for renovascular hypertension evaluate either the anatomic stenosis or renal parenchymal dysfunction attributed to the stenosis. Functional tests have been largely replaced by direct imaging.

Renal duplex scanning is a noninvasive test assessing renal artery stenosis both by visualization of the vessel and by measurement of the effect of stenosis on blood flow velocity and waveforms. The presence of a severe renal artery stenosis correlates with peak systolic velocities of greater than 180 cm/s and a ratio of these velocities to those in the aorta of greater than 3.5. However, many renal artery ultrasounds are difficult to perform or interpret because of obesity or increased bowel gas pattern. Additionally, renal ultrasonography does not differentiate among renal artery stenoses exceeding 60 percent cross-sectional stenosis. Because this test is highly dependent on the operator's expertise, its role as an effective screening test remains limited. Conventional renal artery angiography is critical to the evaluation of patients with possible renovascular hypertension. A flush aortogram is performed first so that any accessory renal arteries can be detected and the origins of all the renal arteries are adequately displayed. The presence of collateral vessels circumventing a renal artery stenosis strongly supports the hemodynamic importance of the stenosis. A pressure gradient of 10 mmHg or greater is necessary for collateral vessel development, which is also associated with activation of the renin-angiotensin cascade. MRA, particularly with gadolinium contrast enhancement, has become a useful diagnostic tool for renal artery occlusive disease, because of its ability to provide high-resolution images. CT angiography is also being increasingly used.

Treatment

Medical therapy. The development of a new generation of antihypertensive medications including β blockers, calcium channel blockers, and ACE inhibitors has greatly enhanced the ability to control high blood pressure in many patients with renovascular hypertension. Refractory hypertension, particularly that because of bilateral disease or unilateral renal artery stenosis with contralateral parenchymal disease, may respond to the addition of diuretic medications.

If the renal function remains stable and the blood pressure is satisfactorily controlled by medications, it is appropriate to maintain medical therapy for renovascular hypertension. However, a reduction in systemic pressure by drug therapy frequently reduces renal perfusion, which may lead to progressive renal failure. Because renal artery occlusive disease frequently progresses

with concomitant loss of renal mass and function, a definitive therapy to restore normal renal blood flow may provide a greater long-term benefit than antihypertensive medical therapy.

Transluminal balloon angioplasty and stenting. Percutaneous transluminal angioplasty of the renal artery is being performed with increasing frequency. A guidewire is inserted into the renal artery from a femoral artery approach and then passed across the stenosis. An angioplasty balloon catheter is next inserted over the guidewire and positioned across the renal artery stenosis. Inflation of the balloon creates a controlled disruption of the vessel wall, thereby eliminating the intraluminal stenosis.

Percutaneous balloon angioplasty has a high success and low recurrence rate as a treatment for fibromuscular dysplasia, particularly of the medial fibroplastic type. More than two-thirds of patients with fibromuscular dysplasia are cured following balloon angioplasty and maintain diastolic pressure below 90 mmHg without antihypertensive medication. Most of the remainder of patients have significant improvement in their renovascular hypertension, although they may require antihypertensive medication.

Renal artery atherosclerotic lesions are typically an extension of aortic disease and are limited to the renal artery ostium where it joins the aorta. Balloon angioplasty in this setting is usually ineffective in achieving satisfactory dilatation because of recoil. Intravascular stents placed during balloon angioplasty are now widely used to support renal angioplasty as primary stenting has become common. Current data suggest that stenting may prove useful in patients with ostial disease, those who develop restenosis after percutaneous balloon angioplasty, or those with complications resulting from percutaneous transluminal renal angioplasty (PTRA), such as dissection. Primary renal artery stenting in patients with atherosclerotic ostial renal artery stenosis has a high technical success rate, with restenosis rates ranging from 10–20 percent at 4 years.

Surgical revascularization. The proper selection of an operative approach relates to the extent of the renal artery occlusive disease, the degree of concomitant aortic atherosclerotic disease, and the preference of the surgeon performing the procedure.

Transaortic renal artery endarterectomy is appropriate for atherosclerotic lesions, but is not applicable in fibrodysplastic disease of the renal artery. The procedure may be accomplished through a transaortic exposure in which the aorta is clamped and opened at the level of the renal arteries via a transverse aortotomy.

Renal artery bypass is the most common approach to correct renal artery stenoses and occlusions. The choice of the type of renal reconstruction depends on the status of the abdominal aorta. An aortorenal bypass is the procedure of choice when the aorta is relatively spared from atherosclerotic change and clamping will not produce injury or distal embolization.

In the event that the aorta is so heavily calcified that it poses a daunting technical challenge to perform an aortorenal grafting procedure, an alternative donor vessel source can be considered. Saphenous vein bypass from the hepatic artery to the right renal artery or splenic artery bypass to the left renal artery are the most appropriate alternatives. Both procedures avoid the embolic and hemodynamic consequences of aortic clamping. Splenorenal grafts are performed by transecting the splenic artery and constructing an anastomosis of one end of the splenic artery to one end or side of the left renal artery, and

collateral flow from the short gastric vessels obviates the need for splenectomy. Alternatively, the gastroduodenal artery itself, which communicates between the celiac artery and superior mesenteric artery, can be divided distally and anastomosed to the right renal artery if it is long enough. Reconstructions based on the visceral arteries should only be performed if significant mesenteric artery occlusive disease has been excluded on angiography. Occasionally concurrent aortic disease mandates synchronous aortic reconstruction. Kidney autotransplantation may be a useful treatment modality when dealing with distal renal artery occlusive disease.

Nephrectomy is appropriate in patients with severe renovascular hypertension when the involved kidney is the source of renin production but is so severely damaged from chronic ischemia (< 6 cm in length) that the prospects for retrieval of renal function are poor.

Carotid Artery Occlusive Disease

An occlusive lesion at the origin of the internal carotid artery remains the most common cause of cerebrovascular accidents, which is the third most common cause of death and accounts for 160,000 deaths annually in the United States. Management of cerebrovascular accidents consumes \$45 billion annually and is responsible for more than 1 million hospital admissions each year in the United States.

Nomenclature of Cerebrovascular Ischemia

Focal cerebral ischemic disease, or stroke, is defined as a loss of cerebral function lasting more than 24 h that is because of ischemic vascular etiology.

A transient ischemic attack (TIA) is defined in the same manner as is stroke, but lasts less than 24 h. In fact most TIAs resolve within min rather than h. When the frequency of TIAs is greater than two or three per day, it is referred to as crescendo TIA. When the ischemic focal neurologic symptoms last longer than 24 h, but resolve within 3 weeks, the term reversible ischemic neurologic deficit (RIND) is applied. Neurologic deficits lasting longer than 3 weeks are considered completed strokes.

Pathogenesis of Stroke and Transient Ischemic Attacks

Hemispheric symptoms are frequently caused by emboli from the carotid circulation. Vertebrobasilar symptoms originate from either flow-limiting or embolic lesions of the aortic arch vessels, the vertebral arteries, or the basilar artery. The predominant causes of stroke and TIA arise from the occlusive lesion of the extracranial carotid artery, and include internal carotid artery thrombosis, flow-related ischemic events, and cerebral embolization.

Carotid artery thrombosis. Thrombosis of the internal carotid artery represents the terminal event of the atherosclerotic progression of the carotid artery bifurcation. The clinical sequelae of carotid thrombosis depend on several factors, including the presence of cerebral collateral vessels provided by the circle of Willis, the chronicity of the thrombosis, and the extent of the thrombosis. Once the internal carotid artery becomes thrombosed, the column of thrombus usually propagates distally to the ophthalmic artery. However, the thrombus may occasionally extend beyond the ophthalmic artery and propagate into the circle of Willis. If the distal propagation of the thrombus stops at the ophthalmic artery and remains stable, the event of total occlusion may be silent if

collateral flow is sufficient. If the thrombus progresses beyond the ophthalmic artery into the middle cerebral artery, a hemispheric event varying from a TIA to a profound stroke occurs.

Carotid artery embolization. Nearly one half of all ischemic carotid territory strokes are because of cholesterol or platelet-fibrin emboli that dislodged from atherosclerotic plaques within the internal carotid artery (ICA) and subsequently occluded distal branches of the ICA, including territories supplied by either the middle cerebral artery and/or the anterior cerebral artery. This mechanism accounts for the occurrence of the Hollenhorst plaques, which are platelet-fibrin aggregates or cholesterol crystals obstructing branches of the retinal artery which are frequently observed during an ophthalmologic exam. TIA or stroke as a consequence of a carotid stenosis has been extensively studied, with clear benefit established in the the North American Symptomatic Carotid Endarterectomy Trial (NASCET) for stenoses greater than 75 percent. The Asymptomatic Carotid Atherosclerosis Study (ACAS) demonstrated benefit even in asymptomatic patients for stenoses greater than 60 percent.

Cardiogenic embolization. Cardiogenic embolization is responsible for less than 10 percent of all ischemic carotid territory strokes.

Miscellaneous causes. Miscellaneous causes account for less than 5 percent of ischemic carotid territory strokes, and include migraine, oral contraceptive use, trauma, dissection, giant cell arteritis, Takayasu arteritis, systemic lupus erythematosus, polyarteritis nodosa, amyloid angiopathy, cocaine abuse, fibromuscular dysplasia, and radiation arteritis. Fibromuscular dysplasia (FMD) is the most common nonatherosclerotic disease affecting the ICA. Approximately one quarter of patients with carotid FMD have associated intracranial aneurysms, and up to two thirds of these patients will have bilateral carotid FMD.

Carotid artery aneurysms. As with aneurysms anywhere else in the body, carotid aneurysms may be either true or false. In the past, most true aneurysms have traditionally been classified as part of the atherosclerotic process. However, emerging evidence suggests that aneurysmal disease may be yet another manifestation of abnormalities of matrix metalloproteinase unless it is associated with other distinct pathologies (e.g., arteritis [giant cell or Takayasu] or FMD). False aneurysms may arise as a consequence of iatrogenic injury, blunt trauma, or carotid patch infection because of prior carotid endarterectomy.

Carotid dissection. Acute carotid dissection can complicate atherosclerosis, FMD, cystic medial necrosis, and blunt trauma. Angiographic studies suggest that the most likely mechanism of acute carotid dissection is an intimal tear followed by an acute intimal dissection, which produces luminal occlusion because of secondary thrombosis. This appears as a flame-shaped occlusion 2–3 cm beyond the bifurcation. Autopsy studies typically reveal a sharply demarcated transition between the normal carotid artery and the dissected carotid segment. The ICA is commonly affected, with the dissection plane typically occurring in the outer medial layer. Treatment is with anticoagulation, and in most cases this results in complete resolution within 1–2 months. Recently there has been increasing use of stenting in severely symptomatic patients.

Carotid body tumor. A carotid body tumor typically presents as a palpable and painless mass over the carotid bifurcation region in the neck. Cranial nerve palsy may occur in up to 25 percent of patients, particularly involving

the vagus and hypoglossal nerves. The differential diagnosis includes cervical lymphadenopathy, carotid artery aneurysm, brachial cleft cyst, laryngeal carcinoma, and metastatic tumor.

The treatment of choice of carotid body tumors is surgical excision. Because these tumors are highly vascularized, preoperative tumor embolization may be an advantage to minimize operative blood loss when dealing with tumors greater than 3 cm in diameter. An important surgical principle in carotid body tumor resection is to maintain a dissecting plane along the subadventitial space, which will invariably allow complete tumor removal without interrupting the carotid artery integrity.

Diagnosis

The most important tool in the diagnosis of carotid artery disease is a careful history and complete neurologic examination, which should localize the area of cerebral ischemia responsible for the neurologic deficit. The neurologic examination of the patient should be complemented by a complete physical examination to determine the presence of vascular occlusive disease in either the coronary or peripheral arteries, and to define the other risk factors for stroke, such as acute arrhythmia. The diagnosis of carotid bifurcation disease is facilitated by the relatively superficial location of the carotid artery, rendering it accessible to auscultation and palpation. The cervical carotid pulse is usually normal in patients with carotid bifurcation disease, because the common carotid artery is the only palpable vessel in the neck and is rarely diseased. Carotid bifurcation bruits may be heard just anterior to the sternocleidomastoid muscle near the angle of the mandible. Bruits do not become audible until the stenosis is severe enough to reduce the luminal diameter by at least 50 percent. Bruits may be absent in extremely severe lesions because of the extreme reduction of flow across the stenosis.

The utility of noninvasive carotid imaging modalities has provided more accurate information regarding the nature and severity of the carotid artery lesion. Color-flow duplex scanning uses real-time, B-mode ultrasound and color-enhanced pulsed Doppler flow measurements to determine the extent of the carotid stenosis with reliable sensitivity and specificity. Real-time, B-mode imaging permits localization of the disease and determination of the presence or absence of calcification within the plaque. Determination of the extent of stenosis is based largely on velocity criteria. As the stenosis increasingly obliterates the lumen of the vessel, the velocity of blood must increase in the area of the stenosis so that the total volume of flow remains constant within the vessel. Thus, the velocity is correlated with the extent of carotid artery stenosis.

MRI and MRA have been evaluated as a means of imaging the carotid arteries. These are highly sensitive imaging tools for the evaluation of patients with symptomatic cerebrovascular disease. MRI is more sensitive than CT scanning for the detection of an acute stroke. MRI can detect a stroke immediately after the infarction occurs, whereas CT scanning cannot. MRA, which is evolving rapidly, permits evaluation of both the extracranial and intracranial cerebral circulations. The precision of MRA in determining the extent of stenosis, although improving rapidly, remains inferior to that achieved by conventional angiography. Nonetheless, MRA will likely play an increasingly important role in the diagnostic evaluation of patients with cerebrovascular disease.

Carotid angiography has been the traditional diagnostic tool for the evaluation of cerebrovascular disease. However, fewer hospitals now perform routine

contrast angiography on all patients prior to surgery. This is partly because of the potential for angiography-related complications, and improved diagnostic accuracy of noninvasive imaging modalities. Angiography remains the only method that allows complete and detailed visualization of both the intracranial and extracranial arterial circulations.

Surgical Treatment

Carotid endarterectomy is indicated for treatment of patients with hemispheric TIAs and stroke associated with carotid bifurcation occlusive disease. Additionally, prophylactic carotid endarterectomy for asymptomatic patients with high-grade stenosis or complex ulcerated plaques is indicated. A brief overview of three important clinical trials, including the European Carotid Surgery Trial (ECST), NASCET, and ACAS is discussed below.

Overview of the European carotid surgery trial and the North American symptomatic carotid endarterectomy trial. The benefit of carotid endarterectomy for patients with symptomatic cerebrovascular disease has recently been established by both the ECST and NASCET trials. These studies randomized nearly 6000 patients in 200 hospitals around the world comparing “best medical therapy” against “best medical therapy” plus carotid endarterectomy. These studies documented a significant reduction in cerebrovascular events following the procedure compared with patients managed only medically. Both trials showed that carotid endarterectomy conferred significant benefit in symptomatic patients with a 70–99 percent stenosis. Although the NASCET trial observed a small but significant benefit in patients with 50–69 percent stenoses, the ECST trial found no evidence of benefit in patients with lesser degrees of disease. The reason for these apparent discrepancies lies in the method for calculating the degree of stenosis. ECST compared the residual luminal diameter against the diameter of the carotid artery at the level of the stenosis (usually the carotid bulb). NASCET compared the residual luminal diameter against the diameter of the ICA at least 1 cm above the stenosis. As a consequence, ECST tends to systematically overestimate stenoses (as compared with NASCET), particularly in those with mild to moderate disease. In reality, a 60 percent NASCET stenosis is approximately equivalent to an 80 percent ECST stenosis.

The ECST and NASCET trials have identified predictive factors that are associated with a significantly higher risk of late stroke in medically treated patients. These factors include male sex, 90–94 percent stenosis, surface irregularity/ulceration, coexistent intracranial disease, no recruitment of intracranial collaterals, hemispheric symptoms, cerebral events within 2 months, multiple cerebral events, contralateral occlusion, multiple concurrent risk factors, and age of more than 75 years.

Overview of the asymptomatic carotid atherosclerosis study. The ACAS trial was a prospective study that randomized 1600 patients with asymptomatic stenosis of 60 percent or greater to either carotid endarterectomy and aspirin or aspirin alone. This study was interrupted because of a significant benefit identified in patients undergoing carotid endarterectomy. At the time of interruption of the study, a relative reduction in stroke rate by 50 percent was observed by patients undergoing carotid endarterectomy. The benefit was much greater in men than in women. This study used stroke as its primary endpoint.

This group has since substantiated unequivocally the effectiveness of carotid endarterectomy in good-risk patients identified to have high-grade stenosis.

These prospective trials firmly established the role of carotid endarterectomy in the prevention of strokes in patients with high-grade carotid artery stenosis, regardless whether the lesion is symptomatic or asymptomatic. All the patients in these clinical trials were carefully selected, and the carotid endarterectomy was performed by surgeons with proven successful outcomes and low complication rates. For patients with carotid occlusive disease to benefit from surgical intervention, the operation must be performed by experienced surgeons with proven low operative morbidity and mortality rates.

Technique of carotid endarterectomy. The carotid bifurcation is usually approached via a longitudinal incision based on the anterior border of the sternocleidomastoid muscle. Dissection continues medial to the jugular vein, and the common carotid bifurcation is mobilized and exposed. The patient is systemically heparinized and the carotid arteries cross-clamped. If the surgeon chooses to shunt the patient, it is inserted at this time. The plaque is endarterectomized, tacking sutures are inserted if required, and the ECA origin is cleared of plaque using the eversion technique. The carotid arteriotomy is closed primarily using a running suture, and if the ICA is small, a patch angioplasty is performed.

Although carotid endarterectomy has been performed for more than four decades, a wide variety of surgical and anesthetic approaches can be used. This operation can be performed under general endotracheal anesthesia, regional cervical block, or local.

Complications of carotid endarterectomy. The most serious complication of carotid endarterectomy is that of perioperative stroke. Stroke can occur during or after carotid endarterectomy secondary to a variety of mechanisms, including inadequate collateral blood flow to the brain during temporary ICA occlusion, embolization during dissection of the carotid artery, or embolism or thrombosis of the reconstruction during the early postoperative period. Embolization after carotid endarterectomy is usually secondary to platelet aggregates forming on the surface of the endarterectomized vessel. In contrast, thrombosis after carotid endarterectomy usually is a result of sudden intimal dissection because of a loose flap or inadequate distal endarterectomy endpoint.

Postoperative cranial nerve dysfunction can occur in up to 35 percent of patients undergoing carotid endarterectomy, which can occur because of cranial nerve damage resulting from nerve division, excessive traction, or perineural dissection. Common cranial nerve injuries include dysfunction of the recurrent laryngeal nerve, causing hoarseness; dysfunction of the hypoglossal nerve, causing deviation of the tongue toward the side of the injury; and superior laryngeal nerve dysfunction, causing easy fatigability of the voice. Less common is injury of the marginal mandibular nerve, which results in drooping of the nasolabial fold ipsilateral to the injury.

Residual or recurrent carotid artery stenosis can be detected in up to 30 percent of patients undergoing careful postoperative surveillance with carotid duplex scanning. However, less than 3 percent of patients experience symptomatic recurrence.

Carotid balloon angioplasty and stenting. Carotid stent trials (Sapphire Trial, Archer Trial) have now demonstrated that carotid angioplasty and stenting is equal to carotid endarterectomy in terms of stroke and death rate in high risk

surgical patients. It is likely that there will be a trend toward increasing stenting and reduced numbers of open endarterectomy.

Non Atherosclerotic Vascular Disease

Popliteal artery. There are three distinct nonatherosclerotic disease entities that may result in lower extremity claudication, predominantly occurring in 40–50-year-old men. Adventitial cystic disease, popliteal artery entrapment syndrome, and Buerger disease should be considered in any young patients presenting with intermittent claudication.

Adventitial Cystic Disease

Adventitial cystic disease is a rare arterial condition occurring at an incidence of 0.1 percent, usually in the popliteal artery. This disease affects men in a ratio of approximately 5:1 and appears predominantly in the fourth and fifth decades. Besides claudication as a symptom, this diagnosis should be considered in young patients who have a mass in a nonaxial vessel in proximity to a related joint. These synovial-like, mucin-filled cysts reside in the subadventitial layer of the vessel wall and have a similar macroscopic appearance to ganglion cysts.

Patients presenting at a young age with bilateral lower extremity claudication and minimal risk factors for atheroma formation should be evaluated for adventitial cystic disease, and the other two nonatherosclerotic vascular lesions described here. Because of luminal encroachment and compression, peripheral pulses may be present in the limb when extended, but then can disappear during knee joint flexion. Noninvasive studies may suggest arterial stenosis with elevated velocities. Color-flow duplex scanning followed by T2-weighted MRI now appears to be the best diagnostic choice. Angiography will demonstrate a smooth, well-defined, crescent-shaped filling defect, the classic “scimitar” sign.

The recommended treatments are excision of the cyst with the cystic wall, enucleation, or simple aspiration when the artery is stenotic. Retention of the cystic lining leads to continued secretion of the cystic fluid and recurrent lesions. In 30 percent of patients who have an occluded artery, resection of the affected artery, followed by an interposition graft using autogenous saphenous vein, is recommended.

Popliteal Artery Entrapment Syndrome

Love and colleagues first coined the term popliteal artery entrapment in 1965 to describe a syndrome combining muscular involvement with arterial ischemia occurring behind the knee, with the successful surgical repair having taken place 6 years earlier. This is a rare disorder with an estimated prevalence of 0.16 percent that occurs with a male-to-female ratio of 15:1. Five types of anatomic entrapment have been defined, according to the position of the medial head of the gastrocnemius muscle, abnormal muscle slips or tendinous bands, or the course of the popliteal artery itself. Concomitant popliteal vein impingement occurs in up to 30 percent. Twenty-five percent of cases are bilateral.

The typical patient presents with swelling and claudication of isolated calf muscle groups following vigorous physical activity. Noninvasive studies with ankle-brachial indices should be performed with the knee extended and the foot in a neutral, forced plantar, and dorsiflexed position. A drop in pressure of 50 percent or greater or dampening of the plethysmographic waveforms in plantar or dorsiflexion is a classic finding. The sudden onset of signs and symptoms of acute ischemia with absent distal pulses is consistent with

popliteal artery occlusion secondary to entrapment. Although CT and MRI have been employed, angiography remains the most widely used test. Angiography performed with the foot in a neutral position may demonstrate classical medial deviation of the popliteal artery or normal anatomic positioning. Coexisting abnormalities may include stenosis, luminal irregularity, delayed flow, aneurysm, or complete occlusion. Diagnostic accuracy is increased with the use of ankle stress view-active plantar flexion and passive dorsiflexion.

The treatment of popliteal artery entrapment consists of surgical decompression of the impinged artery with possible arterial reconstruction. Division of the anomalous musculotendinous insertion site with or without saphenous vein interposition grafting to bypass the damaged arterial segment has been described to be the procedure of choice. The natural history of entrapment is progressive arterial degeneration leading to complete arterial thrombosis. In such instances, thrombolytic therapy is needed with subsequent release of the functional arterial impairment. Lysis will improve distal runoff and may improve limb-salvage and bypass patency rates.

Buerger Disease (Thromboangiitis Obliterans)

Buerger disease, also known as thromboangiitis obliterans, is a progressive nonatherosclerotic segmental inflammatory disease that most often affects small and medium-sized arteries, veins, and nerves of the upper and lower extremities. The typical age range for occurrence is 20–50 years, and the disorder is more frequently found in males who smoke. The upper extremities may be involved, and a migratory superficial phlebitis may be present in up to 16 percent of patients, thus indicating a systemic inflammatory response. In young adults presenting to the Mayo Clinic (1953–1981) with lower limb ischemia, Buerger disease was diagnosed in 24 percent. Conversely, the diagnosis was made in 9 percent of patients with ischemic finger ulcerations. The cause of thromboangiitis obliterans is unknown; however, use of or exposure to tobacco is essential to both the diagnosis and progression of the disease.

Pathologically, thrombosis occurs in small to medium size arteries and veins with associated dense polymorphonuclear leukocyte aggregation, microabscesses, and multinucleated giant cells. Buerger's disease typically presents in young male smokers, with symptoms beginning prior to age 40. Patients initially present with foot, leg, arm, or hand claudication, which may be mistaken for joint or neuromuscular problems. Progression of the disease leads to calf claudication and eventually ischemic rest pain and ulcerations on the toes, feet, or fingers. Characteristic angiographic findings show disease confinement to the distal circulation, usually infrapopliteal and distal to the brachial artery. The occlusions are segmental and show "skip" lesions with extensive collateralization, the so-called "corkscrew collaterals."

Treatment involve strict smoking cessation. In patients who are able to abstain, disease remission is impressive and amputation avoidance is increased. The role of surgical intervention is minimal in Buerger's disease, as there is often no acceptable target vessel for bypass. Furthermore, autogenous vein conduits are limited secondary to coexisting migratory thrombophlebitis.

Inflammatory Arteritis and Vasculitides

Chronic inflammatory arteritides and vasculitides include a spectrum of disease processes caused by immunologic mechanism. This results in a necrotizing

transmural inflammation of the vessel wall associated with antigen-antibody immune complex deposition within the endothelium and pronounced cellular infiltration in the adventitia, thickened intimal fibrosis, and organized thrombus. Most are treated by corticosteroid therapy or chemotherapeutic agents.

Takayasu Arteritis

Takayasu arteritis is an inflammatory disease of the large medial vessels, affecting primarily the aorta, its main branches and the pulmonary artery. This rare autoimmune disease occurs predominantly in women between the ages of 10 and 40 years who are of Asian descent. Vascular inflammation leads to arterial wall thickening, stenosis, and eventually, fibrosis and thrombus formation. The pathologic changes produce stenosis, dilation, aneurysm formation, and/or occlusion.

The clinical course of Takayasu arteritis begins with a “prepulseless” phase in which the patient demonstrates constitutional symptoms. These include fever, anorexia, weight loss, general malaise, arthralgias, and malnutrition. As the inflammation progresses and stenoses develop, more characteristic features of the disease become evident. During the chronic phase, the disease is inactive or “burned out.” It is during this latter stage that patients most frequently present with bruits and vascular insufficiency according to the arterial bed involved. Laboratory data may show elevations in erythrocyte sedimentation rate, C-reactive protein, white blood cell count, or conversely, anemia may predominate. Characteristic clinical features during the second phase vary according to the involved vascular bed, and include hypertension reflecting renal artery stenosis, retinopathy, aortic regurgitation, cerebrovascular symptoms, angina and congestive heart failure, abdominal pain or gastrointestinal bleeding, pulmonary hypertension, or extremity claudication.

The standard criterion for diagnosis remains angiography showing narrowing or occlusion of the entire aorta or its primary branches, or focal or segmental changes in large arteries in the upper or lower extremities. Six types of Takayasu arteritis exist and are graded in terms of severity: type I, affecting the aorta and arch vessels; type IIa, affecting the ascending aorta, aortic arch, and branches; type IIb, affecting the ascending aorta, aortic arch and branches, and thoracic descending aorta; type III, affecting the thoracic descending aorta, abdominal aorta, and/or renal arteries; type IV, affecting the abdominal aorta and/or renal arteries; and type V, with combined features of types IIb and IV.

Treatment consists of steroid therapy initially, with cytotoxic agents used in patients who do not achieve remission. Surgical treatment is performed only in advanced stages, and bypass needs to be delayed during active phases of inflammation. There is no role for endarterectomy, and synthetic or autogenous bypass grafts need to be placed onto disease-free segments of vessels. For focal lesions, there have been reports of success with angioplasty.

Giant Cell Arteritis (Temporal Arteritis)

Patients tend to be white women older than the age of 50 years, with a high incidence in Scandinavia and women of Northern European descent. The inflammatory process typically involves the aorta and its extracranial branches, of which the superficial temporal artery is specifically affected.

The clinical syndrome begins with a prodromal phase of constitutional symptoms, including headache (most common), fever, malaise, and myalgias.

The patients may be initially diagnosed with coexisting polymyalgia rheumatica; an HLA-related association may exist between the two diseases. As a result of vascular narrowing and end-organ ischemia, complications may occur such as visual alterations, including blindness and mural weakness, resulting in acute aortic dissection that may be devastating. Ischemic optic neuritis resulting in partial or complete blindness occurs in up to 40 percent of patients and is considered a medical emergency. Cerebral symptoms occur when the disease process extends to the carotid arteries. Jaw claudication and temporal artery tenderness may be experienced. Aortic lesions are usually asymptomatic until later stages and consist of thoracic aneurysms and aortic dissections.

The diagnostic standard criterion is a temporal artery biopsy, which will show the classic histologic findings of multinucleated giant cells with a dense perivascular inflammatory infiltrate. Treatment regimens are centered on corticosteroids, and giant cell arteritis tends to rapidly respond. Remission rates are high, and treatment tends to have a beneficial and preventative effect on the development of subsequent vascular complications.

Behçet Disease

Behçet disease is a rare syndrome characterized by oral and genital ulcerations and ocular inflammation, affecting males in Japan and the Mediterranean. Vascular involvement is seen in 7–38 percent of patients, and is localized to the abdominal aorta, femoral artery, and pulmonary artery. Vascular lesions may also include venous complications such as deep venous thrombosis or superficial thrombophlebitis. Arterial aneurysmal degeneration can occur; however, this is an uncommon, albeit potentially devastating, complication. Multiple true aneurysms and pseudoaneurysms may develop, and rupture of an aortic aneurysm is the major cause of death in patients with Behçet disease. Multiple aneurysms are relatively common, with a reported occurrence of 36 percent in affected Japanese patients. Furthermore, pseudoaneurysm formation after surgical bypass is common at anastomotic suture lines because of the vascular wall fragility and medial destruction. Systemic therapy with corticosteroids and immunosuppressive agents may diminish symptoms related to the inflammatory process; however, they have no effect on the rate of disease progression and arterial degeneration.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is another systemic inflammatory disease process, which is characterized by a necrotizing inflammation of medium-sized or small arteries that spares the smallest blood vessels (i.e., arterioles and capillaries). This disease predominantly affects men over women by a 2:1 ratio. PAN develops subacutely, with constitutional symptoms that last for weeks to months. Intermittent, low-grade fevers, malaise, weight loss, and myalgias are common presenting symptoms. As medium-sized vessels lie within the deep dermis, cutaneous manifestations occur in the form of livedo reticularis, nodules, ulcerations, and digital ischemia. Skin biopsies of these lesions may be sufficient for diagnosis. Inflammation may be seen histologically, with pleomorphic cellular infiltrates and segmental transmural necrosis leading to aneurysm formation.

Neuritis from nerve infarction occurs in 60 percent of patients, and gastrointestinal complications in up to 50 percent. Additionally, renal involvement is found in 40 percent, and manifests as microaneurysms within the kidney or segmental infarctions. Cardiac disease is a rare finding except

at autopsy, where thickened, diseased coronary arteries may be seen, and patchy myocardial necrosis. Patients may succumb to renal failure, intestinal hemorrhage, or perforation. End-organ ischemia from vascular occlusion or aneurysm rupture can be disastrous complications with high mortality rates. The mainstay of treatment is steroid and cytotoxic agent therapy. Up to 50 percent of patients with active PAN will experience remission with high dosing.

Raynaud Syndrome

Raynaud syndrome is a heterogeneous symptom array associated with peripheral vasospasm, more commonly occurring in the upper extremities. The characteristically intermittent vasospasm classically follows exposure to various stimuli, including cold temperatures, tobacco, or emotional stress. Formerly, a distinction was made between Raynaud “disease” and Raynaud “phenomenon” for describing a benign disease occurring in isolation or a more severe disease secondary to another underlying disorder, respectively. However, many patients develop collagen vascular disorders at some point after the onset of vasospastic symptoms; progression to a connective tissue disorder ranges from 11–65 percent in reported series. Therefore, the term Raynaud’s syndrome is now used to encompass both the primary and secondary conditions. Characteristic color changes occur in response to the arteriolar vasospasm, ranging from intense pallor to cyanosis to redness as the vasospasm occurs. The digital vessels then relax, eventually leading to reactive hyperemia. The majority of patients are young women younger than 40 years of age. Up to 70–90 percent of reported patients are women, although many patients with only mild symptoms may never present for treatment. Certain occupational groups, such as those that use vibrating tools, may be more predisposed to Raynaud syndrome or digital ischemia. The exact pathophysiologic mechanism behind the development of such severe vasospasm remains elusive, and much attention has focused on increased levels of α_2 -adrenergic receptors and their hypersensitivity in patients with Raynaud syndrome, and abnormalities in the thermoregulatory response, which is governed by the sympathetic nervous system.

The diagnosis of severe vasospasm may be made using noninvasive measurements in the vascular laboratory. Angiography is usually reserved for those who have digital ulceration and an embolic or obstructive cause is believed to be present and potentially surgically correctable. Different changes in digital blood pressure will occur in patients with Raynaud syndrome. Normal individuals will show only a slight decrease in digital blood pressure in response to external cold stimuli, whereas those with Raynaud syndrome will show a similar curve until a critical temperature is reached. It is at this point that arterial closure acutely occurs.

There is no cure for Raynaud syndrome, thus all treatments mainly palliate symptoms and decrease the severity and perhaps frequency of attacks. Conservative measures predominate, including the wearing of gloves, use of electric or chemically activated hand warmers, avoiding occupational exposure to vibratory tools, abstinence from tobacco, or relocating to a warmer, dryer climate. The majority (90 percent) of patients will respond to avoidance of cold and other stimuli. The remaining 10 percent of patients with more persistent or severe syndromes can be treated with a variety of vasodilatory drugs, albeit with only a 30–60 percent response rate. Calcium-channel blocking agents

such as diltiazem and nifedipine are the drugs of choice. The selective serotonin reuptake inhibitor fluoxetine has been shown to reduce the frequency and duration of vasospastic episodes. Intravenous infusions of prostaglandins have been reserved for nonresponders with severe symptoms.

Surgical therapy is limited to débridement of digital ulcerations and amputation of gangrenous digits, which are rare complications. Upper extremity sympathectomy may provide relief in 60–70 percent of patients; however, the results are short-lived with a gradual recurrence of symptoms in 60 percent within 10 years.

Fibromuscular Dysplasia

FMD is a vasculopathy of uncertain etiology that is characterized by segmental arterial involvement. Histologically, fibrous tissue proliferation, smooth muscle cell hyperplasia, and elastic fiber destruction alternate with mural thinning. The characteristic beaded appearance of FMD is because of areas of medial thinning alternating with areas of stenosis. The most commonly affected are medium-sized arteries, including the internal carotid, renal, vertebral, subclavian, mesenteric, and iliac arteries. The internal carotid artery is the second most common site of involvement after the renal arteries. FMD occurs most frequently in women (90 percent) and is recognized at approximately 55 years of age. Only 10 percent of patients with FMD will have complications attributable to the disease. Pathologically, FMD is a heterogeneous group of four distinct types of lesions which are subgrouped based on the predominant site of involvement within the vessel wall. Of the four types (medial fibroplasia, intimal fibroplasia, medial hyperplasia, and perimedial dysplasia), medial fibroplasia is the most common pathologic type, affecting the ICA and the renal artery, and occurring in 85 percent of reported cases.

The two main clinical syndromes associated with FMD are transient ischemic attacks from disease in the ICA, and hypertension from renal artery involvement. Symptoms produced by FMD are generally secondary to associated arterial stenosis, and are clinically indistinguishable from those caused by atherosclerotic disease. Often, asymptomatic disease is found incidentally on conventional angiographic studies being performed for other reasons. Within the ICA, FMD lesions tend to be located higher in the extracranial segment than with atherosclerotic lesions, and may not be readily demonstrated by duplex scan.

Clinically, symptoms are because of encroachment on the vessel lumen and a reduction in flow. Additionally, thrombi may form in areas of mural dilatation from a stagnation of flow, leading to distal embolization. Surgical treatment has been favored for symptomatic patients with angiographically proven disease. Owing to the distal location of FMD lesions in the extracranial carotid artery, resection and repair is not usually feasible. Instead, graduated luminal dilatation under direct vision has been used successfully in patients, with antiplatelet therapy continued postoperatively. Percutaneous transluminal angioplasty has been used effectively in patients with FMD-induced hypertension. Several series have documented a high technical success rate, with recurrence rates of 8–23 percent at more than 1 year. However, the therapeutic effect of blood pressure control may continue to be observed despite restenosis. Surgical reconstruction of the renal arteries for FMD has good long-term results and is recommended for recurrent lesions after angioplasty. Open balloon angioplasty of the ICA has been described,

which allows for precise fluoroscopic guidance, rather than blind dilatation with calibrated metal probes, and back-bleeding after dilatation to eliminate cerebral embolization. Distal neuroprotective devices may allow this procedure to be performed completely percutaneously, by lessening the threat of cerebral emboli.

UPPER EXTREMITY ARTERIAL DISEASE

Upper extremity arterial disease is much less common than disease in the lower extremity. Indeed most arterial problems in the arms are related to the establishment of arteriovenous access grafts. Although atherosclerosis remains the most common cause of naturally occurring upper extremity vascular disease, there is a much higher incidence of nonatherosclerotic arterial disease in the upper extremity than in the leg. The details of these nonatherosclerotic vascular disorders are described in more detail in that section.

Symptoms

The most common location for atherosclerosis affecting the upper limb is at the origin of the subclavian artery, most commonly the left subclavian artery. Frequently there are no symptoms, because of rich collaterals and reversed flow in the ipsilateral vertebral artery. Symptoms when they do occur manifest as arm pain, described as aching and weakness in the extremity, made worse with exercise of the arm and relieved by rest. Subclavian steal syndrome occurs when posterior circulation symptoms (dizziness, drop attacks, and diplopia) occur during arm exercise in patients with proximal subclavian artery occlusion. This syndrome is relatively rare. Another unusual manifestation of subclavian artery occlusion is coronary-subclavian steal syndrome. This occurs in the setting of proximal (usually left) subclavian artery occlusion in a patient with a prior left internal mammary artery (LIMA) to left anterior descending artery (LAD) graft. Arm exercise may lead to reversed flow in the LIMA and lead to development of chest pain from myocardial ischemia. Because of the collaterals, the limb is threatened only rarely; however, distal embolization can occur from atherosclerotic stenoses or from an axillosubclavian aneurysm, both of which can complicate thoracic outlet syndrome. Embolization usually manifests as small areas of digital gangrene.

Examination

This begins with pulse examination: axillary, brachial, radial, and ulnar. Both the infraclavicular and supraclavicular fossae should be palpated and auscultated for aneurysms and bruits. The blood pressure should be recorded for both brachial arteries. A difference of greater than 20 mmHg is likely to be significant and suggestive of proximal occlusive disease.

Investigations

The subclavian artery is inaccessible for examination and duplex scanning. However, the finding of a pressure difference between the arms and reversed flow in the ipsilateral vertebral artery by duplex scanning is highly suggestive of proximal subclavian stenosis. If this is not associated with symptoms, then further investigation may not be necessary. However, in a symptomatic patient or in a patient in whom an IMA to LAD bypass has been performed, further investigation is warranted. Spiral CT and MRA can be used, but the definitive

procedure remains arch angiography. The angiographer should specifically look for reversed flow in the ipsilateral vertebral artery, which leads to late filling of the distal subclavian artery. This is an important observation to determine treatment options and select a distal site for bypass grafting.

Treatment

Intervention is indicated only for patients who are symptomatic. In patients with symptoms suggestive of subclavian steal syndrome and concurrent carotid stenoses, the carotid stenosis is usually treated first. If the carotid lesion is at the origin of the carotid required for carotid subclavian bypass, then synchronous retrograde stenting of the common carotid artery (CCA) origin prior to creating the bypass can be performed.

Both endovascular and open treatment options are available for subclavian disease. We prefer angioplasty and stenting for stenoses and reserve carotid subclavian bypass for total occlusion or for stenoses that have been actively embolizing or where there is intraluminal thrombus on angiography. The open procedure most commonly performed is carotid to subclavian bypass. This is performed through a supraclavicular incision, exposing the proximal CCA. The subclavian is exposed by dividing the scalenus anterior muscle. A short 8-mm Dacron graft is tunneled posterior to the jugular vein between the two arteries and should restore a palpable pulse to the extremity. Transposition of the subclavian artery into the common carotid is another option, made easier if the subclavian is high and tortuous. Although subclavian endarterectomy has been described, these authors believe this is fraught with hazard and should be abandoned. Other revascularization options employed when there is concurrent occlusive disease involving the other supraortic trunks include subclavian to subclavian bypass, axillosubclavian bypass, and in patients with disease involving all the supra-aortic vessels, direct revascularization from the aorta may be necessary.

When arm ischemia occurs because of more distal axillary or brachial artery disease, the physician must verify that the patient does not have atherosclerotic disease. In most cases bypass with reversed saphenous vein is the treatment of choice.

Subclavian stenting can be performed by either a transfemoral or retrograde brachial approach. Primary stenting is most commonly performed to minimize the risk of embolization down the limb or up the vertebral artery.

Subclavian Artery Aneurysms

Subclavian artery aneurysms are uncommon and difficult to treat. They are typically atherosclerotic in etiology and located at the origin of the subclavian artery. Clinical manifestations include pain from arm ischemia secondary to thrombosis or embolization. Additionally, right-sided aneurysms can present with hoarseness because of stretching of the recurrent laryngeal nerve.

An aberrant right subclavian artery, arising from the aortic arch distal to the left subclavian artery, is particularly predisposed to undergoing aneurysmal degeneration, often referred to as a Kommerell diverticulum. Aneurysms of an aberrant right subclavian artery also can present with dysphagia because of compression of the esophagus.

The left subclavian artery and an aberrant right subclavian artery surgically are in very inaccessible locations. An aneurysm of the left subclavian artery is

best approached through a left posterolateral thoracotomy. This permits both proximal subclavian or aortic control. The aneurysm is opened, and a 10-mm interposition Dacron graft can be inserted. Care is required when clamping the aorta because of the presence of the left recurrent laryngeal nerve hooking around the aorta medial to the left subclavian artery. On the right side, proximal control is gained via a median sternotomy. Depending on the extent of the aneurysm, distal control can be achieved via either a supraclavicular or infraclavicular incision.

Because of the difficulty in approaching these aneurysms, there has been increasing interest in the use of endovascular grafts to repair these aneurysms. Endografts can be delivered via either a femoral approach or via a retrograde brachial approach. Aneurysms with an adequate proximal and distal neck (>1 cm) are suitable for endografting. Ideally the vertebral artery should be spared; however, if the contralateral vertebral is normal, the ipsilateral vertebral can be sacrificed.

An alternate approach to a proximal subclavian artery aneurysm is ligation with embolization of the vertebral stump and carotid subclavian bypass to maintain antegrade perfusion to the arm and retrograde perfusion to the vertebral artery.

VENOUS STRUCTURE/PHYSIOLOGY/ANATOMY

Venous blood flow is dependent on multiple factors such as gravity, venous valves, the cardiac and respiratory cycles, blood volume, and the calf muscle pump. Alterations in the balance of these factors may result in venous pathology.

In the supine patient, normal lower extremity venous flow is phasic, decreasing with inspiration and increasing with expiration. When the patient is upright muscular contractions of the calf, and the one-way venous valves, are required to promote venous return. Flow also can be increased by leg elevation or compression and decreased by sudden elevation of intraabdominal pressure (Valsalva maneuver).

Veins are thin-walled, highly distensible, and collapsible. Unidirectional blood flow is achieved with multiple venous valves. The number of valves is greatest below the knee and decrease in number in the more proximal veins.

Lower extremity veins are divided into superficial, deep, and perforating veins. The superficial venous system lies above the uppermost fascial layer of the leg and thigh and consists of the greater saphenous vein (GSV) and lesser saphenous vein (LSV) and their tributaries. The GSV courses medially and enters the femoral vein approximately 4 cm inferior and lateral to the pubic tubercle. The LSV courses cephalad in the posterior calf. The termination of the LSV is variable. It most often joins the popliteal vein in the popliteal fossa but may enter the deep venous system as high as the mid-posterior thigh.

In the lower leg, paired veins parallel the course of the arteries and join to form the popliteal vein. The popliteal vein continues through the adductor hiatus to become the femoral vein. In the proximal thigh, the femoral vein joins with the deep femoral vein to form the common femoral vein. The common femoral vein becomes the external iliac vein at the inguinal ligament. Perforator veins traverse the deep fascia to connect the superficial and deep venous systems. Venous sinuses are thin-walled, large veins located within the substance of the soleus and gastrocnemius muscles. A large amount of blood can be stored in the venous sinuses. With each contraction of the calf muscle bed, blood is pumped out through the venous channels into the main conduit veins to return to the heart.

There are also deep and superficial veins in the upper extremity. Deep veins follow the named arteries. Superficial veins of the upper extremity are the cephalic and basilic veins and their tributaries. The cephalic vein courses over the ventral surface of the forearm and terminates in the axillary vein. The basilic vein runs medially and joins the deep brachial veins to become the axillary vein.

The axillary vein becomes the subclavian vein at the lateral border of the first rib. At the medial border of the scalenus anterior muscle, the subclavian vein joins with the internal jugular vein to become the brachiocephalic vein. The left and right brachiocephalic veins join to become the superior vena cava.

Clinical Evaluation

Evaluation of the venous system begins with a detailed history and physical examination. Risk factors for venous disease are identified and include increased age, history of prior venous thromboembolism, malignancy, trauma, obesity, pregnancy, and hypercoagulable states, and the postoperative state. Signs suggestive of superficial venous disease are varicose and telangiectatic veins, distended subdermal venules near the ankle (corona phlebectatica) and hyperpigmentation of the distal calf and ankle region. Deep veins cannot be directly assessed clinically.

Chronic venous insufficiency (CVI) may lead to characteristic changes in the skin and subcutaneous tissues in the affected limb. CVI results from incompetence of venous valves, venous obstruction, or both. Most CVI involves venous reflux. Severe CVI often reflects a combination of reflux and obstruction. A typical leg affected by CVI is edematous, indurated and pigmented with eczema and dermatitis.

Fibrosis occurs from impaired nutrition, chronic inflammation, and fat necrosis (lipodermatosclerosis). Hemosiderin deposition causes the characteristic pigmentation of chronic venous disease. Ulceration can develop with long-standing venous hypertension. Most commonly venous ulcers are approximately 3 cm proximal to the medial malleolus.

VENOUS THROMBOEMBOLISM

Epidemiology

Deep venous thrombosis (DVT) and pulmonary embolism (PE) are important preventable sources of morbidity and mortality. Venous thromboembolism (VTE) results in approximately 250,000 deaths annually. DVT also causes long-term disability. The 20-year cumulative incidence rate is 26.8 percent and 3.7 percent for the development of venous stasis changes and venous ulcers, respectively, after an episode of DVT.

Risk Factors

Stasis of blood flow, endothelial damage, and hypercoagulability contribute to VTE. Hypercoagulability appears most important in cases of spontaneous DVT. Stasis and endothelial damage play a greater role in DVT following surgical procedures and trauma. Table 23-1 lists specific risk factors for VTE.

TABLE 23-1 Risk Factors for Venous Thromboembolism

History of venous thromboembolism

Age
Major surgery
Malignancy
Obesity
Trauma
Varicose veins/superficial thrombophlebitis
Cardiac disease
Hormones
Prolonged immobilization/paralysis
Pregnancy
Venous catheterization
Hypercoagulable states (most prevalent; resistance to activated protein C)

Over 90 percent of patients hospitalized for VTE have more than one risk factor. The number of risk factors increases with age and the risk of DVT increases dramatically with multiple risk factors.

The risk for VTE in surgical patients is multifactorial. Surgical patients may have a period of activated coagulation, transient depression of fibrinolysis, be immobilized, or have a malignancy. Spinal cord injury (odds ratio 8.59) and femur or tibia fracture (odds ratio 4.82) are among the strongest risk factors for VTE.

Diagnosis

Clinical Evaluation

Venous thrombosis is thought to begin in the calf in an area of relative stasis, such as a soleal sinus vein or downstream to a venous valve. Proximal DVT without tibial vein thrombosis is unusual. Early in the course of a DVT, there may be no clinical findings. Even extensive DVT may be asymptomatic. History and physical examination are unreliable for the diagnosis of DVT. Objective studies are required to confirm or exclude a diagnosis of DVT. DVT has been found with venogram or duplex ultrasound in 50 percent or less of patients where it was clinically suspected. Clinical symptoms are usually worse with DVT that involves the proximal deep veins. Massive DVT can cause a condition called phlegmasia alba dolens. This condition is characterized by pain, pitting edema, and blanching. There is no associated cyanosis. When the thrombosis extends to the collateral veins, massive fluid sequestration and more significant edema ensues, resulting in phlegmasia cerulea dolens. Phlegmasia cerulea dolens is preceded by phlegmasia alba dolens in 50–60 percent of patients. Phlegmasia cerulea dolens is extremely painful, with severe edema, and cyanosis, and may be associated with arterial insufficiency, compartment syndrome and venous gangrene. Venous gangrene may require major amputation.

Duplex Ultrasound

DUS for detection of DVT has a sensitivity and specificity greater than 95 percent in symptomatic patients. DVT can be diagnosed by any of the following DUS findings: lack of spontaneous flow, inability to compress the vein, absence of color filling of the lumen, loss of respiratory flow variation, and venous distention. The primary method of detecting DVT with ultrasound is demonstration of lack of compressibility of the vein with probe pressure on B-mode imaging. Normally, the vein walls coapt with pressure. Lack of coaptation indicates thrombus. Several studies comparing B-mode ultrasound to venography for the detection of femoropopliteal DVT in patients clinically suspected to have DVT report sensitivities greater than 91 percent and specificities greater than 97 percent. DUS ability to assess isolated calf vein DVT varies, with sensitivities reported from 50–93 percent and specificities approaching 100 percent.

Venography

Venography is the most definitive test for the diagnosis of DVT. A small catheter is placed in the dorsum of the foot and contrast injected. A positive study is failure to fill the deep systems with a passage of the contrast medium into the superficial system, or demonstration of discrete filling defects. A normal

study virtually excludes the presence of DVT. Venography is, however, no longer routinely used for diagnosis of DVT having been supplanted by duplex ultrasound.

Venous Thromboembolism (VTE) Prophylaxis

The goal of prophylaxis is to prevent the mortality and morbidity of VTE. Without prophylaxis, patients undergoing surgery for intraabdominal malignancy have a 25 percent incidence of DVT, whereas orthopedic patients undergoing hip fracture surgery have a 40–50 percent incidence of DVT. Patients at highest risk for DVT are older adults and undergoing major surgery or those with previous VTE, malignancy, or paralysis.

Prophylaxis involves use of one or more pharmacologic or mechanical modalities. Methods of VTE prophylaxis include low-dose heparin (LDH), low-molecular-weight heparin (LMWH), elastic stockings (ES), intermittent pneumatic compression (IPC), and warfarin. Aspirin alone is not adequate for DVT prophylaxis.

LMWH appears to be more effective than LDH for DVT prophylaxis with a similar risk of major bleeding. There is a 30 percent risk reduction of DVT in patients given LMWH versus those given LDH. LMWH for VTE prophylaxis is contraindicated in patients with intracranial bleeding, spinal hematoma, ongoing and uncontrolled hemorrhage, or coagulopathy. Recommendations for VTE prophylaxis from the American College of Chest Physicians (ACCP) Table 23-2 summarizes the ACCP consensus statement.

Prophylactic insertion of IVC filters has been suggested for VTE prophylaxis in high-risk trauma patients and in patients with malignancy and contraindications to LMWH. A 5-year study of prophylactic IVC filter placement in 132 trauma patients at high risk of PE reported a 0 percent incidence of symptomatic PE in patients with a correctly positioned IVC filter. IVC patency was 97.1 percent at 3 years.

The ACCP recommends IVC filters be placed only if a proximal DVT is present and anticoagulation contraindicated. IVC filter insertion is not recommended for primary prophylaxis. Retrievable IVC filters have been developed for use in patients with a temporarily increased risk of PE. Some of these devices may be removed up to 3 months postinsertion as long as there are no significant emboli contained by the filter. The device can be left in place if it traps a significant embolus.

Treatment Venous Thromboembolism

The theoretic goals of VTE treatment are to prevent mortality and morbidity associated with PE and to prevent the postphlebotic syndrome. However, the only proven benefit of anticoagulation treatment of DVT is to prevent death from PE. Treatment may include antithrombotics (heparin and warfarin), thrombolytics, vena cava interruption, and surgical thrombectomy.

Heparin

Intravenous unfractionated heparin (UFH) has traditionally been the initial treatment for VTE. UFH binds to antithrombin and potentiates antithrombin's inhibition of thrombin and activated factor X (Xa). UFH also catalyzes the inhibition of thrombin by heparin cofactor II.

TABLE 23-2 Recommendations for Venous Thromboembolism Prophylaxis

Indication	Prophylaxis methods
Low-risk general surgery (minor surgery, age < 40, no risk factors)	Early ambulation
Moderate-risk general surgery (minor surgery with risk factors; major surgery, age > 40, no risk factors)	LDH, LMWH, ES, or IPC
High-risk general surgery (minor surgery with risk factors, age > 60; major surgery, age > 40 or additional risk factors)	LDH, LMWH, or IPC
Very high-risk general surgery (multiple risk factors present)	LDH or LMWH combined with ES or IPC
Elective hip replacement	LMWH (started 12 h before surgery) or warfarin (started preoperatively or immediately after surgery with international normalized ratio [INR] target 2.5)
Elective knee replacement	LMWH or warfarin (INR = 2.5)
Hip fracture surgery	LMWH or warfarin (INR = 2.5)
Neurosurgery	IPC with or without ES and LMWH or LDH if feasible
Trauma	ES and/or IPC, LMWH if feasible
Acute spinal cord injury	LMWH with continuation of LMWH or conversion to warfarin (INR = 2.5) in the rehabilitation phase

ES = elastic compression stockings; IPC = intermittent pneumatic compression; LDH = low-dose heparin; LMWH = low molecular weight heparin.

Unfractionated heparin therapy begins with a bolus intravenous (IV) injection followed by a continuous infusion. The half-life is approximately 90 min. The level of anticoagulation should be monitored every 6 h with activated partial thromboplastin time (aPTT) determinations until aPTT levels reach a steady state. Thereafter, aPTT can be obtained daily. aPTT levels must be kept at or above 1.5 times control levels. Weight-based UFH dosages are more effective than standard fixed boluses in rapidly achieving therapeutic levels. Weight-based dosing of UFH is initiated with a bolus of 80 IU/kg IV, and a maintenance continuous infusion is started at 18 IU/kg per hour IV.

Oral anticoagulation with warfarin is started after 1 day of UFH infusion. UFH and warfarin are then administered concurrently for approximately 4 to 5 days. The daily dose of warfarin is adjusted to reach an international normalized ratio (INR) of 2–3. UFH is stopped 2 days after the patient's INR reaches 2–3 on warfarin therapy.

Hemorrhage is the primary complication of UFH therapy. The rate of major hemorrhage is 1 percent in medical patients and 8 percent in surgical patients. Anticoagulation with UFH can be reversed with protamine sulfate. Protamine is administered slowly. The infusion is terminated if side effects occur. Side effects of protamine include hypotension, pulmonary edema, and anaphylaxis. One milligram of protamine will reverse 100 units of UFH. Heparin has other complications. Heparin-induced thrombocytopenia (HIT) results from antibodies against platelet factor 4. It occurs in 1–5 percent of patients being

TABLE 23-3 Recommendations for Long-Term Anticoagulation

Indication	Duration
First VTE event with reversible risk factor (transient immobilization, estrogen use, surgery, trauma)	3–6 months
First idiopathic VTE event	≥ 6 months

treated with heparin. The major form of HIT can lead to disastrous venous or arterial thrombotic complications. Because of HIT, platelet counts should be checked after 3 days of heparin therapy. Heparin should be stopped with a drop in platelet count to $< 100,000/\mu\text{L}$. Another complication of prolonged high-dose heparin therapy is osteopenia.

Warfarin

Warfarin is the only currently available oral anticoagulant. It acts by inhibiting synthesis of vitamin K–dependent procoagulants (II, VII, IX, X) and anticoagulants (proteins C and S). Warfarin takes several days to achieve its full effect because residual normal coagulation factors have to be cleared. Therefore heparin should be continued for 2 days after achieving a therapeutic INR. The anticoagulation response to warfarin is variable. Warfarin has a half-life of 40 h. It must be withheld 2–3 days prior to any procedure with significant bleeding risk. The recommended INR for VTE therapy in most cases is between 2 and 3.

The major complication of warfarin is hemorrhage. The risk of hemorrhage is related to the magnitude of INR prolongation. Bleeding complications are treated with fresh-frozen plasma or with intravenous vitamin K.

A unique complication of warfarin is skin necrosis. It usually occurs in the first days of therapy and is associated with protein C or S deficiency or malignancy. When individuals with protein C or S deficiency are exposed to warfarin, the sudden decline in proteins C and S leads to thrombus formation in venules with extensive skin and subcutaneous fat necrosis.

Warfarin is not recommended in pregnant patients. It has been associated with spontaneous abortion and birth defects. Pregnant patients with VTE should be treated with heparin and monitored for the development of osteopenia.

Warfarin therapy reduces VTE recurrence after an acute event. The duration of oral anticoagulation for VTE is dependent on the patient's risk factors for VTE. Patients with an initial VTE with identified reversible risk factors such as transient immobilization or estrogen use should be treated for at least 3 months. Patients without identifiable risk factors are at a higher risk of recurrence and should be treated for at least 6 months. Patients with recurrent VTE or irreversible risk factors such as cancer or a hypercoagulable state should be treated for 12 months or longer. Table 23-3 summarizes current ACCP recommendations for duration of warfarin therapy.

Low-Molecular-Weight-Heparins

LMWHs differ from UFH in several ways. LMWHs, like UFH, bind to antithrombin via a specific pentasaccharide sequence. However, unlike UFH, LMWHs lack additional saccharide units to bind to and inactivate thrombin (factor IIa). In comparison to UFH, LMWHs have increased bioavailability, a longer half-life, and more predictable elimination rates.

The anticoagulant response of LMWH is predictable when given in weight-based subcutaneous doses. There is no need for laboratory monitoring of aPTT. LMWHs are eliminated through the kidneys and must be used with caution in patients with creatinine clearance less than 30 mL/min. When required, activity of LMWHs is performed by monitoring anti-Xa levels. Patients who should be monitored include children < 50 kg, obese patients > 120 kg receiving weight-adjusted doses, pregnant patients, and those with renal failure. LMWHs differ in their anti-Xa and anti-IIa activities. The treatment regimen recommended for one LMWH cannot be extrapolated for use with another one. LMWHs are only partially reversed with protamine sulfate.

LMWHs are at least as effective as, and perhaps safer than, UFH. HIT is seen in only 2–3 percent of patients receiving LMWHs but platelet counts should still be ascertained weekly in patients receiving LMWHs.

A major benefit of LMWHs is the ability to treat selected patients with VTE as outpatients. In a randomized study comparing intravenous UFH and the LMWH nadroparin-Ca, there was no significant difference in recurrent thromboembolism or major bleeding complications. There was a 67 percent reduction in mean days in the hospital for the LMWH group.

Pentasaccharides

Fondaparinux is a commercially available, chemically synthesized agent that contains the five-polysaccharide chain that binds and activates antithrombin. It does not affect thrombin (factor IIa). It is administered as a fixed subcutaneous dose and is at least as effective as the LMWH enoxaparin for the prevention of VTE after elective hip and knee replacement surgery. It is specific to antithrombin, does not bind to platelets, and minimizes the risk of HIT.

Hirudin

Hirudin is a class of direct thrombin inhibitors first derived from leeches. The commercially available hirudin, lepirudin, is manufactured by recombinant deoxyribonucleic acid (DNA) technology. Hirudins complex with thrombin and inhibit conversion of fibrinogen to fibrin and thrombin-induced platelet aggregation independent of antithrombin. Hirudins do not bind platelet factor 4. They can be used in patients who develop HIT as a complication of heparin therapy. Lepirudin is administered intravenously with a loading dose of 0.4 mg/kg followed by a continuous infusion of 0.15 mg/kg per h. The aPTT is used to monitor the effects of hirudins. The dose must be adjusted in patients with renal failure. There is no reversal agent. Plasma exchange can reverse the anticoagulant effect of hirudin.

Argatroban

Argatroban is a synthetic direct thrombin inhibitor that reversibly binds to thrombin. It is approved as an anticoagulant for prophylaxis or treatment of thrombosis in patients with heparin-induced thrombocytopenia and for patients with, or at risk for, heparin-induced thrombocytopenia undergoing percutaneous coronary intervention. Argatroban does not require the presence of antithrombin. Argatroban has a half-life of 39–51 min and reaches a steady state with intravenous infusion in 1–3 h. Argatroban can be monitored by the aPTT. There is no reversal agent.

Thrombolytic Agents

Thrombolytic therapy may reverse the hemodynamic consequences of PE and be lifesaving. In clinical practice few patients with PE (< 10 percent) are candidates for thrombolytic therapy. A major complication of systemic thrombolytic therapy is bleeding. Thrombolytic therapy is absolutely contraindicated in patients with active internal bleeding, a recent (< 2 months) cerebrovascular accident, and intracranial pathology. Relative major contraindications include major trauma, uncontrolled hypertension, active gastrointestinal pathology, recent (< 10 days) major surgery, and ocular pathology.

Thrombolytic agents currently available for clinical use are streptokinase, and recombinant tissue plasminogen activator (rtPA). Both activate plasminogen to plasmin, leading to fibrin degradation and thrombolysis. Plasmin also limits thrombus formation by degrading coagulation factors V, VIII, XII, and prekallikrein.

Streptokinase is antigenic and can cause allergic reactions. It can be inactivated by circulating antibodies and requires plasminogen as a cofactor. For PE, streptokinase is given as a 250,000-IU IV loading dose followed by 100,000 IU/h IV for 24 h. Readministration of streptokinase is not recommended between 5 days and 1–2 years of initial use or after recent streptococcal infection because of the presence of neutralizing antibodies.

TPA is found in all human tissues. A recombinant form, rTPA, is available for commercial use. It is more specific than streptokinase for fibrin-bound plasminogen, but is not superior for dissolution of thrombi or for reducing bleeding complications. rTPA to treat PE is given as a 100-mg infusion over 2 h.

There is no clear benefit for thrombolytic therapy in the large majority of patients with DVT. Thrombolytic therapy can be used in patients with massive iliofemoral DVT in an attempt to improve acute symptoms and to decrease the incidence of postthrombotic syndrome. Systemic administration of thrombolytic agents for DVT is not effective as the majority of the thrombus is not exposed to the circulating agent. In an effort to increase efficacy, catheter-directed thrombolytic techniques have been developed for the treatment of symptomatic DVT. In catheter-directed therapy, the lytic agent is administered directly into the thrombus through a catheter.

Catheter-directed thrombolytic therapy in patients with acute (>10 days) iliofemoral DVT has a reasonable chance of clearing the thrombosis. Long-term benefit in preventing the postthrombotic syndrome is unknown. Currently, the ACCP recommends that thrombolytic therapy be considered in patients with hemodynamically unstable PE or massive iliofemoral thrombosis with low bleeding potential.

Vena Caval Filters

Vena cava filters are placed percutaneously through the femoral or internal jugular vein under fluoroscopic or ultrasound guidance. Complications associated with IVC filter placement include insertion site thrombosis, filter migration, erosion of the filter into the IVC wall, and IVC obstruction. The rate of fatal complications is less than 0.12 percent.

Accepted indications for IVC filter placement in a patient with DVT or PE are contraindications to anticoagulation and failure of anticoagulation in a patient who has had a PE or is at high risk of PE. IVC filter placement does not prolong early or late survival in patients with proximal DVT, but does

decrease the rate of PE. An increased rate of recurrent DVT has been observed in patients with IVC filters.

Surgical Treatment

Surgical therapy for DVT is generally reserved for patients with phlegmasia cerulea dolens or impending venous gangrene. A fasciotomy of the calf compartments is first performed. For iliofemoral DVT, a longitudinal venotomy is made in the common femoral vein (CFV) and a embolectomy catheter passed through the thrombus into the IVC and pulled back several times until no further thrombus is extracted. Distal thrombus in the leg is removed by application of a tight rubber elastic wrap beginning from the foot and extending to the thigh. If the thrombus in the femoral vein is old and cannot be extracted, the vein is ligated. For a thrombus that extends into the IVC, the IVC is exposed transperitoneally and the IVC is controlled below the renal veins. The IVC is opened and the thrombus is removed by massage. A completion venogram is performed to determine if any residual thrombus or stenosis is present. If a residual iliac vein stenosis is present, angioplasty and stenting can be performed. In most cases, an arteriovenous fistula is created by anastomosing the GSV end-to-side to the superficial femoral artery. Heparin is administered postoperatively and warfarin anticoagulation is maintained for at least 6 months. Complications of iliofemoral thrombectomy include PE in up to 20 percent and death in less than 1 percent of patients. Patients should wear compression stockings for at least 1-year post thrombectomy.

Emergency pulmonary embolectomy for acute PE is rarely indicated. Patients with preterminal massive PE who have failed thrombolysis or have contraindications to thrombolytics may be candidates for this procedure. Mortality rates range between 20 and 40 percent.

Percutaneous techniques for removal of PE involve mechanical thrombus fragmentation or embolectomy with suction devices. Mechanical clot fragmentation is followed by catheter-directed thrombolysis. Results of catheter-based fragmentation are documented in small case series only. Transvenous catheter pulmonary suction embolectomy has been performed for acute massive PE with a reported 76 percent successful extraction rate and a 30-day survival rate of 70 percent.

OTHER FORMS OF VENOUS THROMBOSIS

Superficial Venous Thrombophlebitis

Superficial venous thrombophlebitis (SVT) most commonly occurs in lower extremity varicose veins but can occur in normal superficial veins. This condition arises frequently in veins with indwelling catheters. Upper extremity SVT occurs in up to 38 percent of patients with peripherally inserted central catheters. When SVT recurs at variable sites in normal superficial veins, termed thrombophlebitis migrans, it may signify a hidden malignancy.

Clinical signs of SVT include erythema, warmth, and tenderness along the distribution of the affected vein. There is often a palpable cord. Patients with suppurative SVT may have fever and leukocytosis. DUS should be performed to confirm the diagnosis and to determine if any associated DVT is present. DVT is present in 5–40 percent of patients with SVT. A follow-up DUS should be performed in 5–7 days in patients who have SVT in the proximal GSV. They are at risk for the extension of thrombus into the femoral vein. Ten to

20 percent of patients with SVT in the proximal GSV will progress to deep venous involvement within 1 week.

Treatment of SVT is dependent on the location of the thrombus and severity of symptoms. In patients with GSV SVT >1 cm from the saphenofemoral junction or SVT in varicose veins, treatment consists of compression, warm packs, and administration of antiinflammatory medications. If GSV SVT extends proximally to within 1 cm of the saphenofemoral junction, anticoagulation for 6 weeks or GSV ligation are equally effective in preventing thrombus extension into the deep system. In patients with suppurative SVT, antibiotics and removal of any existing indwelling catheters is mandatory. Excision of the vein may be necessary.

Axillary-Subclavian Vein Thrombosis

Axillary-subclavian vein thromboses (ASVT) are classified into two forms. In primary ASVT, no clear cause for the thrombosis is readily identifiable at initial evaluation. A minority of patients have performed repetitive motions with their upper extremities resulting in damage to the subclavian vein, usually where it passes between the head of the clavicle and the first rib. This condition is known as venous thoracic outlet syndrome. Secondary ASVT is more common and is usually associated with an indwelling catheter or hypercoagulable state.

A patient with ASVT may be asymptomatic or present with upper extremity swelling and tenderness. DUS can confirm the diagnosis. Anticoagulation prevents PE and decrease symptoms. Patients presenting with acute symptomatic primary ASVT may be candidates for thrombolytic therapy. A venogram is performed through a catheter placed in the basilic vein to document the extent of the thrombus. A catheter is placed within the thrombus and a lytic agent infused. Heparin is also administered. After completion of thrombolytic therapy, a follow-up venogram is performed to identify any correctable anatomic abnormalities. Following thrombolytic therapy balloon angioplasty for residual venous narrowing and first rib resection for decompression of the thoracic outlet may be performed.

Mesenteric Venous Thrombosis

Five to 15 percent percent of acute mesenteric ischemia is as a result of mesenteric venous thrombosis (MVT). Mortality rates are as high as 50 percent. Usually the presentation is nonspecific abdominal pain, perhaps followed with diarrhea and nausea and vomiting. Peritoneal signs are present in less than 50 percent. MVT is more common in patients with a hypercoagulable state and malignancy.

In patients with MVT, plain abdominal radiographs usually demonstrate a nonspecific bowel gas pattern and are nondiagnostic. Contrast-enhanced abdominal CT scanning is the diagnostic study of choice in patients with suspected MVT.

Patients with MVT and no peritoneal findings require fluid resuscitation and anticoagulation evaluation for a hyper-coagulable disorder, and close follow up. Urgent laparotomy is indicated in patients with peritoneal findings. Findings at laparotomy are edema and cyanosis of the mesentery and bowel wall and thrombus in the mesenteric veins. The arterial supply of the bowel is usually intact. Nonviable bowel is resected, and primary anastomoses can be performed. If viability of any remaining bowel is in question, a second-look

operation is performed within 24 to 48 h. Most patients with MVT are maintained on life-long anticoagulation.

VARICOSE VEINS

Varicose veins are present in 10 percent of the population. Varicose veins include dilated and tortuous veins, telangiectasias, and fine reticular varicosities. Risk factors are obesity, female sex, inactivity, and family history. Varicose veins can be classified as primary or secondary. Primary varicose veins result from intrinsic abnormalities of the venous wall. Secondary varicose veins are associated with venous insufficiency.

Patients with varicose veins may complain of aching, heaviness, and early leg fatigue. Symptoms worsen with prolonged standing and are relieved by leg elevation. Mild edema is often present. More severe signs include thrombophlebitis, hyperpigmentation, lipodermatosclerosis, ulceration, and bleeding.

Elastic compression stockings are effective treatment for many patients with varicose veins. Usually 20–30-mmHg stockings are sufficient.

Additional interventions are indicated in patients with symptoms unrelieved with compression therapy or who have signs of lipodermatosclerosis. Cosmetic concerns also can lead to intervention.

Varicose veins may be managed by injection sclerotherapy or surgical excision or a combination of both techniques. Injection sclerotherapy can be successful in varicose veins less than 3 mm in diameter and in telangiectatic vessels. Sclerosing agents include hypertonic saline, sodium tetradecyl sulfate, and polidocanol. An elastic bandage is worn continuously for 3–5 days postsclerotherapy. Complications of sclerotherapy include allergic reaction, pigmentation, thrombophlebitis, DVT, and possible skin necrosis.

Larger varicose veins are best treated by surgical excision. Standard treatment of residual varicosities is removal by the “stab/avulsion” technique. Two-millimeter incisions are made directly over branch varicosities. The varicosity is dissected proximally and distally as far as possible and is then avulsed with no attempt at ligation. Bleeding is controlled with manual pressure.

In patients with symptomatic GSV reflux, the GSV can be treated with open surgical or catheter based techniques. Surgical excision consists of GSV stripping from the groin to just below the knee. Complications associated with GSV stripping include ecchymosis, lymphocele, infection, and transient numbness in the saphenous nerve distribution. Stripping of the GSV is preferred by most surgeons over simple ligation of the GSV in the groin.

CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency (CVI) affects an estimated 600,000 patients in the United States. Patients complain of leg fatigue, discomfort, and heaviness. Signs of CVI may include varicose veins, pigmentation, lipodermatosclerosis, and venous ulceration. Severe CVI can be present without varicose veins. The most severe form of CVI is venous ulceration. Sixty five percent of chronic leg ulcer patients have severe pain, 81 percent have decreased mobility, and 100 percent experienced a negative impact of their disease on their work capacity. Venous leg ulcers result in an estimated 2 million lost workdays per year.

CVI results from venous reflux, venous obstruction, calf muscle pump dysfunction, or a combination of these factors. Venous reflux is the most important factor in the majority of patients with CVI. Primary valvular incompetence is diagnosed when there is no known underlying etiology of valvular dysfunction.

Secondary valvular reflux is diagnosed when an identifiable etiology is present. The most frequent secondary etiology is DVT.

Evaluation of CVI

Clinical Evaluation

The Trendelenburg test can help determine whether incompetent valves are present, and in the superficial, deep, or perforator veins. With the patient supine, the leg is elevated 45 degrees to empty the veins, and the GSV is occluded with a tourniquet. The patient stands and the superficial veins are observed for filling. When compression on the GSV is released the superficial veins are observed for increased filling. No clinically evident venous reflux is indicated by gradual filling of the veins. A positive result is the sudden filling of veins with standing or release of GSV compression. The perforator veins are thought to be normal with competent valves if the first component of the test is negative. If this part of the test is positive, there are incompetent valves in deep and perforator veins. The GSV valves are competent if the second component of the test is negative, and the GSV valves are incompetent if the second component of the test is positive. The Trendelenburg test is subjective. It has been largely supplanted by more objective noninvasive vascular laboratory tests.

Diagnostic Studies

Early diagnostic studies to evaluate CVI required invasive measurements of venous pressures after exercise. Currently noninvasive studies are preferred.

Plethysmography

Plethysmography methods are based on the measurement of volume changes in the leg. In photoplethysmography (PPG) a light-emitting diode is placed just above the medial malleolus and the patient performs a series of tip-toe maneuvers. PPG measures venous recovery time (VRT), the time required for venous volume in the skin to return to baseline after exercise. In limbs with CVI, VRT is shortened compared to a normal limb. VRT does not localize the site of reflux.

Air plethysmography (APG) also can be used to assess reflux and overall venous function. An air-filled plastic pressure bladder is placed on the calf to detect volume changes in the leg during a standard set of maneuvers. Based on measurements during these maneuvers, venous filling index (a measure of reflux), ejection fraction (a measure of calf muscles function), and residual volume fraction (a measure of overall venous function) are calculated. Theoretically, patients with an increased venous filling index and normal ejection fraction (indicating the presence of reflux with normal calf pump function) would benefit from antireflux surgery, whereas patients with a normal venous filling index and a diminished ejection fraction would not.

Venous Duplex Ultrasound

Duplex ultrasound can be used to evaluate reflux in individual venous segments of the leg. The patient is standing and the leg to be examined is non-weight bearing. Pneumatic pressure cuffs are placed around the thigh, calf, and forefoot. The ultrasound scan head is positioned just proximal to the pneumatic cuff over the venous segment to be examined. The cuff is then inflated to a standard pressure for 3 s and then rapidly deflated and reflux assessed. Reflux

for greater than 0.5 s is abnormal. Typically, the common femoral, femoral, popliteal, and posterior tibial, and the greater and lesser saphenous veins, are evaluated.

Nonoperative Treatment of Chronic Venous Insufficiency

Compression Therapy

Prior to the initiation of therapy for CVI a definitive diagnosis of CVI must be made. Patients must be educated about their chronic disease and the need to comply with treatment. Compression therapy is the mainstay of CVI management. Compression can be achieved with elastic compression stockings, paste gauze boots (Unna boot), multilayer elastic wraps/dressings, or pneumatic compression devices. The exact mechanism by which compression therapy can improve CVI remains uncertain. Compression therapy is most commonly achieved with gradient elastic compression stockings. Elastic compression stockings are available in various compositions, strengths, and lengths, and can be customized.

The benefits of elastic compression stocking therapy have been well documented. In a retrospective review of 113 venous ulcer patients, the use of below-knee, 30–40-mm Hg elastic compression stockings, resulted in 93 percent healing. Complete ulcer healing occurred in 99 of 102 (97 percent) patients compliant with stocking use versus 6 of 11 patients (55 percent) who were non-compliant ($p < 0.0001$). The mean time to ulcer healing was 5 months. Ulcer recurrence was less in patients compliant with compression therapy; 29 percent at 5 years for compliant patients and 100 percent at 3 years for noncompliant patients.

Elastic compression therapy can improve quality of life in patients with CVI. In a recent study, 112 patients with CVI documented by DUS and treated with compression stockings were administered a questionnaire to quantify the symptoms of swelling, pain, skin discoloration, cosmesis, activity tolerance, depression, and sleep alterations. Symptom severity scores improved at 1 month after initiation of treatment. Further improvements were noted at 16 months.

The Unna boot is another method of compression consisting of a three-layer dressing. It requires application by trained personnel. A rolled gauze bandage impregnated with calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum silicate is first applied with graded compression from the forefoot to just below the knee. The next layer consists of a 4-inch wide continuous gauze dressing followed by an outer layer of elastic wrap applied with graded compression. The Unna boot is changed weekly or sooner if there is significant drainage.

Other forms of compressive dressings for CVI include multilayered dressings and various legging orthoses. The efficacy of multilayered dressings is dependent on the wrapping technique of health care personnel. A commercially available legging orthosis consisting of multiple adjustable loop-and-hook closure compression bands provides compression similar to the Unna boot and can be applied daily by the patient.

Skin Substitutes

Bioengineered skin ranges in composition from acellular skin substitutes to partial-living skin substitutes. They may serve as delivery vehicles for various growth factors and cytokines important in wound healing.

Apligraf is a bilayered living skin construct that closely approximates human skin. Apligraf is between 0.5 and 1.0 mm thick and is supplied as a disk of living tissue.

A prospective randomized study comparing multilayer compression therapy alone to treatment with Apligraf in addition to multilayered compression therapy has been performed in treatment of venous ulcers. More patients treated with Apligraf had ulcer healing at 6 months (63 vs. 49 percent, $p = 0.02$). The median time to complete ulcer closure was shorter in patients treated with Apligraf (61 days vs. 181 days, $p = 0.003$). The ulcers that showed the greatest benefit were large ($>1000 \text{ mm}^2$) or were long-standing (>6 months).

Surgical Therapy of Chronic Venous Insufficiency

Perforator Vein Ligation

Perforator vein incompetence may contribute to development of venous ulcers. The classic technique described by Linton had a high incidence of wound complications and has largely been abandoned. A minimally invasive technique termed subfascial endoscopic perforator vein surgery (SEPS) is now available.

DUS is performed preoperatively to document deep venous competence and to identify perforating veins. An Esmarck bandage and a thigh tourniquet are used to exsanguinate the limb. The knee is flexed, and two small incisions are made in the proximal medial leg away from areas of maximal induration at the ankle. Laparoscopic trocars are then positioned, and the subfascial dissection is performed with a combination of blunt and sharp dissection. Carbon dioxide is then used to insufflate the subfascial space. The thigh tourniquet is inflated to prevent air embolism. Perforators are identified, clipped and divided. After completion of the procedure, the leg is wrapped in a compression bandage for 5 days.

In a report from a large North American registry of 146 patients undergoing SEPS, healing was achieved in 88 percent of ulcers (75 of 85) at 1 year. Adjunctive procedures, primarily superficial vein stripping, were performed in 72 percent of patients. Ulcer recurrence was predicted to be 16 percent at 1 year and 28 percent at 2 years by life table analysis. The efficacy of the technique has not been confirmed in a randomized trial.

Venous Reconstruction

In the absence of significant deep venous valvular incompetence, saphenous vein stripping and perforator vein ligation can be effective in the treatment of CVI. However, in patients with a combination of superficial and deep venous valvular incompetence, the addition of deep venous valvular reconstruction may improve ulcer healing. Many techniques of deep venous valve correction have been reported. These techniques consist of repair of existing valves, transplant of venous segments from the arm, and transposition of an incompetent vein onto an adjacent competent vein.

Successful long-term outcomes of 60–80 percent have been reported for venous valve reconstructions by internal suture repair. However, in patients who initially had ulceration, 40–50 percent still have persistence or recurrence of ulcers. Valve transplantation involves replacement of a segment of incompetent femoral vein or popliteal vein with a segment of axillary or brachial vein with competent valves. Early results are similar to those of venous valve reconstruction. However, the transplanted segments tend to develop incompetence, and

long-term outcomes are poorer than those of venous valve reconstructions. The outcomes for venous transposition are similar to those of valve transplantation.

Lymphedema

Pathophysiology

Lymphedema is swelling that results from a reduction in lymphatic transport. Primary lymphedema is subdivided into congenital, praecox, and tarda. Congenital lymphedema is typically present at birth. It can involve a single extremity, multiple limbs, the genitalia, or the face. Lymphedema praecox accounts for 94 percent of cases of primary lymphedema. The onset of swelling is during the childhood or teenage years and involves the foot and calf; 90 percent of patients are female. Lymphedema tarda, accounts for less than 10 percent of cases of primary lymphedema. The onset of edema is later in life than in lymphedema praecox.

Secondary lymphedema is far more common than primary lymphedema. Secondary lymphedema develops as a result of acquired lymphatic obstruction or disruption. Globally, filariasis, is the most common cause of secondary lymphedema. Lymphedema of the arm following axillary node dissection is the most common cause of secondary lymphedema in the United States. Other causes of secondary lymphedema include radiation therapy, trauma, or malignancy.

Diagnosis

Clinical Findings

In most patients the diagnosis of lymphedema is made by history and physical exam alone. There are complaints of heaviness and fatigue in the affected extremity. Limb size increases during the day and decreases over night. The limb never completely normalizes. Swelling involves the dorsum of the foot. The toes have a squared-off appearance. In advanced cases, hyperkeratosis of the skin develops. Recurrent cellulitis is a common complication. Repeated infection results in further lymphatic damage.

Distinguishing lymphedema from other causes of leg swelling can be difficult. Venous insufficiency is often confused with lymphedema. However, patients with advanced venous insufficiency typically have lipodermatosclerosis in the gaiter region, skin ulceration, and greater resolution of swelling with leg elevation.

Imaging Studies

Duplex Ultrasound

It is often difficult to distinguish lymphedema from venous insufficiency. Duplex ultrasound of the venous system can determine if venous reflux is present. Additional studies include:

Lymphoscintigraphy

A radiolabeled sulfur colloid is injected into the subdermal, interdigital region of the affected limb. Lymphatic transport is monitored with a gamma camera. Major lymphatics and nodes can be visualized.

Radiologic Lymphology

Radiologic lymphology visualizes lymphatics with colored dye injected into the hand or foot. The lymphatic channels and nodes are then visualized with traditional roentgenograms.

Management

There is no cure for lymphedema. Goals of treatment are to minimize swelling and to prevent infections. Controlling the chronic limb swelling can improve discomfort, heaviness, and tightness, and potentially reduce the progression of disease.

Bed Rest and Leg Elevation

Elevation is often the first recommended intervention. However, elevation throughout the day can interfere with quality of life. Elevation is an adjunct to lymphedema therapy, but is not the mainstay of treatment.

Compression Garments

Graded compression stockings reduce swelling in the involved extremity. Compression stockings are associated with long-term maintenance of reduced limb circumference. They may also protect the tissues against chronically elevated intrinsic pressures, which lead to thickening of the skin and subcutaneous tissue.

The degree of compression required for controlling lymphedema ranges from 20–60 mmHg and varies among patients. Stockings can be custom-made or prefabricated. The stockings should be worn during waking h and replaced approximately every 6 months.

Sequential External Pneumatic Compression

Intermittent pneumatic compression for 4–6 h per day reduces edema and provides adjunct to compression stockings. Compression stockings are necessary to maintain the volume reduction when the patient is no longer supine.

Lymphatic Massage

Manual lymphatic drainage is a form of massage. In combination with compression stockings, manual lymphatic drainage is associated with a long-term reduction in edema and fewer infections per patient per year.

Antibiotic Therapy

Patients with lymphedema are at increased risk of cellulitis in the affected extremity. Staphylococcus or β -hemolytic Streptococcus are the most common organisms causing soft tissue infection. Aggressive antibiotic therapy is recommended at the earliest signs or symptoms of cellulitis. The drug of choice is penicillin, usually 500 mg orally 3–4 times per day. Patients with a history of lymphedema and recurrent cellulitis should be given a prescription for antibiotics that can be kept at home and initiated at the first sign of infection.

Surgery

Surgical treatment involves either excision of extra tissue or anastomoses of a lymphatic vessel to another lymphatic or vein. With excisional procedures, part or all of the edematous tissue is removed. Microsurgical procedures involve the creation of a lymphaticolymphatic or lymphaticovenous anastomosis, theoretically improving lymphatic drainage. Operative therapy for lymphedema is not well accepted. Operative intervention can further obliterate lymphatic channels, worsening edema.

Summary

Lymphedema is a chronic condition caused by ineffective lymphatic transport that results in edema and skin damage. Lymphedema is not curable but can be controlled with a combination of elastic compression stockings, limb elevation, pneumatic compression, and massage.

Esophagus and Diaphragmatic Hernia

Jeffrey H. Peters and Tom R. DeMeester

SURGICAL ANATOMY

The esophagus is a muscular tube that starts as the continuation of the pharynx and ends as the cardia of the stomach.

Manometrically, the length of the esophagus between the lower border of the cricopharyngeus and upper border of the lower sphincter varies according to the height of the individual. The musculature of the esophagus can be divided into an outer longitudinal and an inner circular layer. The upper 2–6 cm of the cervical esophagus contain only striated muscle fibers. From there on, smooth muscle fibers gradually become more abundant. When a surgical myotomy is indicated for a cricopharyngeal disorder, the myotomy incision needs to extend over this distance. Below this distance smooth muscle fibers gradually become more abundant. Most clinically significant esophageal motility disorders involve only the smooth muscle in the lower two thirds of the esophagus and the function of the cervical esophagus is normal.

The lymphatics of the esophagus located in the submucosa of the esophagus are so dense and interconnected that they constitute a single plexus. There are more lymph vessels than blood capillaries in the submucosa. Lymph flow in the submucosal plexus runs in a longitudinal direction, and on injection of a contrast medium, the longitudinal spread is seen to be about 6 times that of the transverse spread. In the upper two-thirds of the esophagus the lymphatic flow is mostly cephalad, and in the lower third caudad. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in the adventitia. As a consequence of this nonsegmental lymph drainage, a primary tumor can extend for a considerable length superiorly or inferiorly in the submucosal plexus. Consequently, free tumor cells can follow the submucosal lymphatic plexus in either direction for a long distance before they pass through the muscularis and on into the regional lymph nodes. The cervical esophagus has a more direct segmental lymph drainage into the regional nodes, and as a result, lesions in this portion of the esophagus have less submucosal extension and a more regionalized lymphatic spread.

The efferent lymphatics from the cervical esophagus drain into the paratracheal and deep cervical lymph nodes, and those from the upper thoracic esophagus empty mainly into the paratracheal lymph nodes. Efferent lymphatics from the lower thoracic esophagus drain into the subcarinal nodes and nodes in the inferior pulmonary ligaments. The superior gastric nodes receive lymph not only from the abdominal portion of the esophagus, but also from the adjacent lower thoracic segment.

PHYSIOLOGY

Swallowing Mechanism

The act of alimentation requires the passage of food and drink from the mouth into the stomach. One-third of this distance consists of the mouth and hypopharynx, and two thirds is made up by the esophagus. To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a mechanical model in which the tongue and pharynx function as a piston pump with three valves, and the body of the esophagus and cardia function as a worm-drive pump with a single valve. The three valves in the pharyngeal cylinder are the soft palate, the epiglottis, and the cricopharyngeus. The valve of the esophageal pump is the lesser esophageal sphincter (LES). Failure of the valves or the pumps leads to abnormalities in swallowing—that is, difficulty in food propulsion from mouth to stomach—or regurgitation of gastric contents into the esophagus or pharynx.

Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. Once initiated, swallowing is entirely a reflex act. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx. Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, for example, after a cerebrovascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly, elevating the larynx and opening the retrolaryngeal space, bringing the epiglottis under the tongue. The backward tilt of the epiglottis covers the opening of the larynx to prevent aspiration. The entire pharyngeal part of swallowing occurs within 1.5 s.

During swallowing, the pressure in the hypopharynx rises abruptly, to at least 60 mmHg, because of the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the less-than-atmospheric mid-esophageal or intrathoracic pressure. This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or upper esophageal sphincter relaxes. The bolus is both propelled by peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus. Critical to receiving the bolus is the compliance of the cervical esophagus; when compliance is lost because of muscle pathology, dysphagia can result. The upper esophageal sphincter closes within 0.5 s of the initiation of the swallow, with the immediate closing pressure reaching approximately twice the resting level of 30 mmHg. The postrelaxation contraction continues down the esophagus as a peristaltic wave. The high closing pressure and the initiation of the peristaltic wave prevents reflux of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed farther down the esophagus, the pressure in the upper esophageal sphincter returns to its resting level.

The pharyngeal phase of swallowing can be started at will, or it can be reflexively elicited by the stimulation of areas in the mouth and pharynx, among them the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagus nerves.

Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through cranial nerves V, VII, X, XI, and XII, and the motor neurons of C1–C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 s. Little is known about the organization of the swallowing center, except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. Following a cerebrovascular accident, this coordinated outflow may be altered, causing mild to severe abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted, leading to repetitive aspiration.

The striated muscles of the cricopharyngeus and the upper third of the esophagus are activated by efferent motor fibers distributed through the vagus nerve and its recurrent laryngeal branches. The integrity of innervation is required for the cricopharyngeus to relax in coordination with the pharyngeal contraction, and resume its resting tone once a bolus has entered the upper esophagus. Operative damage to the innervation can interfere with laryngeal, cricopharyngeal, and upper esophageal function, and predispose the patient to aspiration.

The pharyngeal phase of swallowing initiates the esophageal phase. The body of the esophagus functions as a worm-drive propulsive pump because of the helical arrangement of its circular muscles, and is responsible for transferring a bolus of food into the stomach. The esophageal phase of swallowing represents esophageal work done during alimentation, in that food is moved into the stomach from a negative-pressure environment of -6 mmHg intrathoracic pressure, to a positive-pressure environment of 6 mmHg intraabdominal pressure, or over a gradient of 12 mmHg. Effective and coordinated smooth muscle function in the lower third of the esophagus is therefore important in pumping the food across this gradient.

The peristaltic wave generates an occlusive pressure varying from 30–120 mmHg. The wave rises to a peak in 1 s, lasts at the peak for about 0.5 s, and then subsides in about 1.5 s. The whole course of the rise and fall of occlusive pressure may occupy one point in the esophagus for 3–5 s. The peak of a primary peristaltic contraction initiated by a swallow (primary peristalsis) moves down the esophagus at 2–4 cm/s and reaches the distal esophagus about 9 s after swallowing starts. Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is rapidly repeated, the esophagus remains relaxed and the peristaltic wave occurs only after the last movement of the pharynx. Progress of the wave in the esophagus is caused by sequential activation of its muscles, initiated by efferent vagal nerve fibers arising in the swallowing center.

Continuity of the esophageal muscle is not necessary for sequential activation if the nerves are intact. If the muscles, but not the nerves, are cut across, the pressure wave begins distally below the cut as it dies out at the proximal end above the cut. This allows a sleeve resection of the esophagus to be done without destroying its normal function. Afferent impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. Afferent nerves, however, do go to the swallowing center from the esophagus, because if the esophagus is distended at any point, a contractual wave begins with a forceful closure of the upper esophageal sphincter and sweeps down the esophagus. This secondary contraction occurs without any movements of the mouth or pharynx. Secondary peristalsis can occur as an independent local reflex to clear the esophagus of ingested

material left behind after the passage of the primary wave. Current studies suggest that secondary peristalsis is not as common as once thought. Despite the powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If a subject attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that can be overcome is 5–10 g. Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

The LES provides a pressure barrier between the esophagus and stomach and acts as the valve on the worm-drive pump of the esophageal body. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that in humans, the sphincter-like function is related to the architecture of the muscle fibers at the junction of the esophageal tube with the gastric pouch. The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens by a relaxation that coincides with a pharyngeal swallow. The LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus. Consequently, reflux of gastric juice that may occur through the open valve during a swallow is cleared back into the stomach.

If the pharyngeal swallow does not initiate a peristaltic contraction, then the coincident relaxation of the LES is unguarded and reflux of gastric juice can occur. This may be an explanation for the observation of spontaneous lower esophageal relaxation, thought by some to be a causative factor in gastroesophageal reflux disease. The power of the worm-drive pump of the esophageal body is insufficient to force open a valve that does not relax. In dogs, a bilateral cervical parasympathetic blockade abolishes the relaxation of the LES that occurs with pharyngeal swallowing or distention of the esophagus. Consequently, vagal function appears to be important in coordinating the relaxation of the LES with esophageal contraction. The antireflux mechanism in human beings is composed of three components: a mechanically effective LES, efficient esophageal clearance, and an adequately functioning gastric reservoir. A defect of any one of these three components can lead to increased esophageal exposure to gastric juice and the development of mucosal injury.

Physiologic Reflux

On 24-h esophageal pH monitoring, healthy individuals have occasional episodes of gastroesophageal reflux. This physiologic reflux is more common when awake and in the upright position than during sleep in the supine position. When reflux of gastric juice occurs, normal subjects rapidly clear the acid gastric juice from the esophagus regardless of their position. There are several explanations for the observation that physiologic reflux in normal subjects is more common when they are awake and in the upright position than during sleep in the supine position. First, reflux episodes occur in healthy volunteers primarily during transient losses of the gastroesophageal barrier, which may be because of a relaxation of the LES or intragastric pressure overcoming sphincter pressure. Gastric juice can also reflux when a swallow-induced relaxation of the LES is not protected by an oncoming peristaltic wave. The average frequency of these “unguarded moments” or of transient losses of the gastroesophageal barrier is far less while asleep and in the supine position than while

awake and in the upright position. Consequently, there are fewer opportunities for reflux to occur in the supine position. Second, in the upright position there is a 12-mmHg pressure gradient between the resting, positive intraabdominal pressure measured in the stomach and the most negative intrathoracic pressure measured in the esophagus at midthoracic level. This gradient favors the flow of gastric juice up into the thoracic esophagus when upright. The gradient diminishes in the supine position. Third, the LES pressure in normal subjects is significantly higher in the supine position than in the upright position. This is because of the apposition of the hydrostatic pressure of the abdomen to the abdominal portion of the sphincter when supine. In the upright position, the abdominal pressure surrounding the sphincter is negative compared with atmospheric pressure, and as expected, the abdominal pressure gradually increases the more caudally it is measured. This pressure gradient tends to move the gastric contents toward the cardia and encourages the occurrence of reflux into the esophagus when the individual is upright. By contrast, in the supine position the gastroesophageal pressure gradient diminishes, and the abdominal hydrostatic pressure under the diaphragm increases, causing an increase in sphincter pressure and a more competent cardia.

ASSESSMENT OF ESOPHAGEAL FUNCTION

A thorough understanding of the patient's underlying anatomic and functional deficits prior to making therapeutic decisions is fundamental to the successful treatment of esophageal disease. The diagnostic tests as presently employed may be divided into five broad groups: (1) tests to detect structural abnormalities of the esophagus; (2) tests to detect functional abnormalities of the esophagus; (3) tests to detect increased esophageal exposure to gastric juice; (4) tests to provoke esophageal symptoms; and (5) tests of duodenogastric function as they relate to esophageal disease.

Tests to Detect Structural Abnormalities

Radiographic Evaluation

The first diagnostic test in patients with suspected esophageal disease should be a barium swallow including a full assessment of the stomach and duodenum. Esophageal motility is optimally assessed by observing several individual swallows of barium traversing the entire length of the organ, with the patient in the horizontal position. Hiatal hernias are best demonstrated with the patient prone because the increased intraabdominal pressure produced in this position promotes displacement of the esophagogastric junction above the diaphragm. To detect lower esophageal narrowing, such as rings and strictures, fully distended views of the esophagogastric region are crucial. The density of the barium used to study the esophagus can potentially affect the accuracy of the examination. Esophageal disorders shown clearly by a full-column technique include circumferential carcinomas, peptic strictures, large esophageal ulcers, and hiatal hernias. A small hiatal hernia is usually not associated with significant symptoms or illness, and its presence is an irrelevant finding unless the hiatal hernia is large, the hiatal opening is narrow and interrupts the flow of barium into the stomach, or the hernia is of the paraesophageal variety. Lesions extrinsic but adjacent to the esophagus can be reliably detected by the full-column technique if they contact the distended esophageal wall. Conversely, a number of important disorders may go undetected if this is the

sole technique used to examine the esophagus. These include small esophageal neoplasms, mild esophagitis, and esophageal varices. Thus, the full-column technique should be supplemented with mucosal relief or double-contrast films to enhance detection of these smaller or more subtle lesions.

Motion-recording techniques greatly aid in evaluating functional disorders of the pharyngeal and esophageal phases of swallowing. Cine- and videoradiography are more useful to evaluate function than to detect structural abnormalities.

The radiographic assessment of the esophagus is not complete unless the entire stomach and duodenum have been examined. A gastric or duodenal ulcer, partially obstructing gastric neoplasm, or scarred duodenum and pylorus may contribute significantly to symptoms otherwise attributable to an esophageal abnormality.

When a patient's complaints include dysphagia and no obstructing lesion is seen on the barium swallow, it is useful to have the patient swallow a barium-impregnated marshmallow, a barium-soaked piece of bread, or a hamburger mixed with barium. This test may bring out a functional disturbance in esophageal transport that can be missed when liquid barium is used.

Endoscopic Evaluation

In any patient complaining of dysphagia, esophagoscopy is indicated, even in the face of a normal radiographic study. A barium study obtained prior to esophagoscopy is helpful to the endoscopist by directing attention to locations of subtle change, and alerting the examiner to such potential danger spots as a cervical vertebral osteophyte, esophageal diverticulum, a deeply penetrating ulcer, or a carcinoma. Regardless of the radiologist's interpretation of an abnormal finding, each structural abnormality of the esophagus should be confirmed visually.

The flexible fiberoptic esophagoscope is the instrument of choice because of its technical ease, patient acceptance, and the ability to simultaneously assess the stomach and duodenum. When gastroesophageal reflux disease is the suspected diagnosis, particular attention should be paid to detecting the presence of esophagitis and Barrett columnar-lined esophagus. When endoscopic esophagitis is seen, severity and the length of esophagus involved are recorded. Grade I esophagitis is defined as small, circular, nonconfluent erosions. Grade II esophagitis is defined by the presence of linear erosions lined with granulation tissue that bleeds easily when touched. Grade III esophagitis represents a more advanced stage, in which the linear or circular erosions coalesce into circumferential loss of the epithelium, or the appearance of islands of epithelium which on endoscopy appears as a "cobblestone" esophagus. Grade IV esophagitis is the presence of a stricture. Its severity can be assessed by the ease of passing a 36F endoscope. When a stricture is observed, the severity of the esophagitis above it should be recorded. The absence of esophagitis above a stricture suggests a chemical-induced injury or a neoplasm as a cause. The latter should always be considered and is ruled out only by evaluation of a tissue biopsy of adequate size.

Barrett esophagus (BE) is a condition in which the tubular esophagus is lined with columnar epithelium, as opposed to the normal squamous epithelium. Histologically it is identified by the presence of goblet cells, the marker of intestinal metaplasia. It is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location, and by the appearance of a redder, more luxuriant mucosa than is normally seen in the

lower esophagus. Its presence is confirmed by biopsy. Multiple biopsies should be taken in a cephalad direction to determine the level at which the junction of Barrett epithelium with normal squamous mucosa occurs. BE is susceptible to ulceration, bleeding, stricture formation, and most important, malignant degeneration. The earliest sign of the latter is severe dysplasia or intramucosal adenocarcinoma. These dysplastic changes can have a patchy distribution, so a minimum of four biopsy samples spaced 2 cm apart should be taken from the Barrett-lined portion of the esophagus. Changes seen in one biopsy are significant. Nishimaki has determined that 85 percent of tumors occur in an area of specialized columnar epithelium near the squamocolumnar junction in and within 2 cm of the squamocolumnar junction in virtually all patients. Particular attention should be focused in this area in patients suspected of harboring a carcinoma.

Abnormalities of the geometry of the gastroesophageal junction can be visualized by retroflexion of the endoscope. Hill has graded the appearance of the gastroesophageal junction from I–IV according to the deterioration of the normal valve architecture. The appearance of the valve correlates with the presence of increased esophageal acid exposure, occurring predominantly in patients with grade III and IV valves.

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura, identified by having the patient sniff. A prominent sliding hiatal hernia frequently is associated with increased esophageal exposure to gastric juice. When a paraesophageal hernia is observed, particular attention is taken to exclude a gastric ulcer or gastritis within the pouch. The intragastric retroflex or J maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach.

When an esophageal diverticulum is seen, it should be carefully explored with the flexible endoscope to exclude ulceration or neoplasia. When a submucosal mass is identified, biopsies are usually not performed. Normally a submucosal leiomyoma or reduplication cyst can be easily dissected away from the intact mucosa, but if a biopsy sample is taken, the mucosa may become fixed to the underlying abnormality. This complicates the surgical dissection by increasing the risk of mucosal perforation.

Tests to Detect Functional Abnormalities

In many patients with symptoms of an esophageal disorder, standard radiographic and endoscopic evaluation fails to demonstrate a structural abnormality. In these situations, esophageal function tests are necessary to identify a functional disorder.

Stationary Manometry

Esophageal manometry is a widely used technique to examine the motor function of the esophagus and its sphincters. Manometry is indicated whenever a motor abnormality of the esophagus is suspected on the basis of complaints of dysphagia, odynophagia, or noncardiac chest pain, and the barium swallow or endoscopy does not show a clear structural abnormality. Esophageal manometry is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders (i.e., achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive LES). It also identifies nonspecific esophageal motility abnormalities and motility disorders secondary to systemic

TABLE 24-1 Normal Manometric Values of the Distal Esophageal Sphincter, n = 50

	Median	Percentile	
		2.5	97.5
Pressure (mmHg)	13	5.8	27.7

disease such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disease. In patients with symptomatic gastroesophageal reflux disease, manometry of the esophageal body can identify a mechanically defective LES, and evaluate the adequacy of esophageal peristalsis and contraction amplitude. Manometry has become an essential tool in the preoperative evaluation of patients prior to antireflux surgery, allowing selection of the appropriate procedure based on the patient's underlying esophageal function.

Table 24-1 shows the values for parameters of the LES in 50 normal volunteers without subjective or objective evidence of a foregut disorder. A mechanically defective sphincter is identified by having one or more of the following characteristics: an average LES pressure of less than 6 mmHg, an average length exposed to the positive-pressure environment in the abdomen of 1 cm or less, and/or an average overall sphincter length of 2 cm or less. Compared with the normal volunteers, these values are below the 2.5 percentile for sphincter pressure and overall length and for abdominal length. It has been shown that the resistance of the sphincter to reflux of gastric juice is determined by the integrated effects of radial pressures extended over the entire length, resulting in three-dimensional computerized imaging of sphincter pressures. Calculating the volume of this image reflects the sphincter's resistance and is called the sphincter pressure vector volume (SPVV).

Patients with gastroesophageal reflux disease and an SPVV below the fifth percentile of normal, or a deficiency of one, two, or all three mechanical components of an LES on standard manometry, have a mechanical defect of their antireflux barrier that a surgical antireflux procedure is designed to correct.

To assess the relaxation and postrelaxation contraction of the LES, a pressure transducer is positioned within the high-pressure zone, with the distal transducer located in the stomach and the proximal transducer within the esophageal body. Ten wet swallows (5 mL water each) are performed. The normal pressure of the LES should drop to the level of gastric pressure during each wet swallow.

The function of the esophageal body is assessed with the five pressure transducers located in the esophagus. The standard procedure is to locate the most proximal pressure transducer 1 cm below the well-defined cricopharyngeal sphincter, allowing a pressure response throughout the whole esophagus to

be obtained on one swallow. The relationship of the esophageal contractions following a swallow is classified as peristaltic or simultaneous.

The relaxation of the upper esophageal sphincter is studied by straddling pressure transducers across the sphincter so that one is in the pharynx, one in the sphincter and another in the upper esophagus.

Video- and Cineradiography

High-speed video recording of radiographic studies allows re-evaluation by reviewing the studies at various speeds. This technique is more useful than manometry in the evaluation of the pharyngeal phase of swallowing. Observations suggesting oropharyngeal or cricopharyngeal dysfunction include misdirection of barium into the trachea or nasopharynx, prominence of the cricopharyngeal muscle, a Zenker diverticulum, a narrow pharyngoesophageal segment, and stasis of the contrast medium in the valleculae or hypopharyngeal recesses. These findings are usually not specific, but rather common manifestations of neuromuscular disorders affecting the pharyngoesophageal area. Studies using liquid barium, barium-impregnated solids, or radiopaque pills, aid the evaluation of normal and abnormal motility in the esophageal body. Loss of the normal stripping wave or segmentation of the barium column with the patient in the recumbent position correlates with abnormal motility of the esophageal body. In addition, structural abnormalities such as small diverticula, webs, and minimal extrinsic impressions of the esophagus may be recognized only with motion-recording techniques. The simultaneous computerized capture of videofluoroscopic images and manometric tracings is now available, and is referred to as manofluorography. Manofluorographic studies allow precise correlation of the anatomic events, such as opening of the upper esophageal sphincter, with manometric observations, such as sphincter relaxation. Manofluorography, although not widely available, is presently the best means available to evaluate complex functional abnormalities.

Tests to Detect Increased Exposure to Gastric Juice

24-H Ambulatory pH Monitoring

The most direct method of measuring increased esophageal exposure to gastric juice is by an indwelling pH electrode, or more recently via a radiotelemetric pH monitoring capsule that can be clipped to the esophageal mucosa. The latter consists of an antimony pH electrode fitted inside a small capsule-shaped device accompanied by a battery and electronics that allow 48-h monitoring and transmission of the pH data via transcutaneous radio telemetry to a waist-mounted data logger. The device can be introduced either transorally or transnasally, and clipped to the esophageal mucosa using a suction fastening techniques. It passes spontaneously within 3–7 days. Prolonged monitoring of esophageal pH is performed by placing the pH probe or telemetry capsule 5 cm above the manometrically measured upper border of the distal sphincter for 24 h. It measures the actual time the esophageal mucosa is exposed to gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient's symptoms. A 24–48-h period is necessary so that measurements can be made over one or two complete circadian cycles. This allows measuring the effect of physiologic activity, such as eating or sleeping, on the reflux of gastric juice into the esophagus.

TABLE 24-2 Normal Values for Esophageal Exposure to pH < 4 (n = 50)

Component	Mean	SD	95%
Total time	1.51	1.36	4.45
Upright time	2.34	2.34	8.42
Supine time	0.63	1.0	3.45
No. of episodes	19.00	12.76	46.90
No. > 5 min	0.84	1.18	3.45
Longest episode	6.74	7.85	19.80

SD = Standard deviation.

The 24-h esophageal pH monitoring should not be considered a test for reflux, but rather a measurement of the esophageal exposure to gastric juice. The measurement is expressed by the time the esophageal pH was below a given threshold during the 24-h period. This single assessment, although concise, does not reflect how the exposure has occurred; that is, did it occur in a few long episodes or several short episodes? Consequently, two other assessments are necessary: the frequency of the reflux episodes and their duration.

The units used to express esophageal exposure to gastric juice are (1) cumulative time the esophageal pH is below pH 4, expressed as the percentage of the total, upright, and supine monitored time; (2) frequency of reflux episodes below pH 4, expressed as number of episodes per 24 h; and (3) duration of the episodes, expressed as the number of episodes greater than 5 min per 24 h, and the time in min of the longest episode recorded. Table 24-2 shows the normal values for these components of the 24-h record from 50 normal asymptomatic subjects. The upper limits of normal were established at the ninety-fifth percentile.

To combine the result of the six components into one expression of the overall esophageal acid exposure below a pH threshold, a pH score was calculated by using the standard deviation of the mean of each of the six components measured in the 50 normal subjects as a weighting factor. The upper limits of normal for the composite score for pH threshold less than 4 is 14.7.

Twenty-four hour esophageal pH monitoring has a sensitivity and specificity of 96 percent. (Sensitivity is the ability to detect a disease when known to be present; specificity is the ability to exclude the disease when known to be absent.) This gave a predictive value of a positive and a negative test of 96 percent, and an overall accuracy of 96 percent. Based on extensive clinical experience, 24-h esophageal pH monitoring has emerged as the standard criterion for the diagnosis of gastroesophageal reflux disease.

24-Hour Ambulatory Bile Monitoring

The potentially injurious components that reflux into the esophagus include gastric secretions, such as acid and pepsin, and biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. The presence of duodenal contents within the esophagus can now be determined via an indwelling spectrophotometric probe capable of detecting bilirubin. Bilirubin serves as a marker for the presence of duodenal juice. Ambulatory bilirubin monitoring can be used to identify patients who are at risk for esophageal mucosal injury, and are thus candidates for surgical antireflux treatment.

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is a common disease that accounts for approximately 75 percent of esophageal pathology. Despite its high prevalence, it can be one of the most challenging diagnostic and therapeutic problems in benign esophageal disease. A contributing factor to this is the lack of a universally accepted definition of the disease.

The simplest approach is to define the disease by its symptoms. However, symptoms thought to be indicative of GERD, such as heartburn or acid regurgitation, are very common in the general population, and many individuals consider them to be normal and do not seek medical attention. Even when excessive, these symptoms are not specific for GERD, and can be caused by other diseases such as achalasia, diffuse spasm, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease. In addition, patients with GERD can present with atypical symptoms, such as nausea, vomiting, postprandial fullness, chest pain, choking, chronic cough, wheezing, and hoarseness. Furthermore, bronchiolitis, recurrent pneumonia, idiopathic pulmonary fibrosis, and asthma can be primarily because of GERD. To confuse the issue more, GERD can coexist with cardiac and pulmonary disease. Thus using clinical symptoms to define GERD lacks sensitivity and specificity.

An alternative definition for GERD is the presence of endoscopic esophagitis. Using this criterion for diagnosis assumes that all patients who have esophagitis have excessive regurgitation of gastric juice into their esophagus. This is true in 90 percent of patients, but in 10 percent the esophagitis has other causes, the most common being unrecognized chemical injury from prescribed drug ingestion. In addition, the definition leaves undiagnosed those patients who have symptoms of gastroesophageal reflux but do not have endoscopic esophagitis. A third approach to defining GERD is to measure the basic pathophysiologic abnormality of the disease; that is, increased exposure of the esophagus to gastric juice. In the past this was inferred by the presence of a hiatal hernia, later by endoscopic esophagitis, and more recently by a hypotensive LES pressure. The development of miniaturized pH electrodes and data recorders allowed measurement of esophageal exposure to gastric juice by calculating the percentage of time the pH was less than 4 over a 24-h period. This provided an opportunity to objectively identify the presence of the disease.

The Human Antireflux Mechanism and the Pathophysiology of Gastroesophageal Reflux

The human antireflux mechanism consists of a pump, the esophageal body, and a barrier, the LES. The common denominator for virtually all episodes of gastroesophageal reflux in both patients and normal subjects is the loss of the barrier to reflux. This is usually secondary to low or reduced LES resistance. The loss of this resistance may be either permanent or transient. A structurally defective barrier results in a permanent loss of LES resistance, and permits unhampered reflux of gastric contents into the esophagus throughout the circadian cycle. Transient loss of the barrier may occur secondary to gastric abnormalities, including gastric distention with air or food, increased intragastric or intraabdominal pressure, and delayed gastric emptying. These transient losses of sphincter resistance occur in the early stages of GERD, and are likely

the mechanism for both physiologic and pathophysiologic postprandial reflux. Thus, GERD may begin with abnormalities of the stomach over eating.

Data have shown that transient loss of sphincter resistance is because of gastric distention. This results in shortening of the LES, upright reflux, and inflammatory changes at the gastroesophageal junction secondary to unfolding of esophageal squamous mucosa into the gastric environment with shortening. Over time, persistent inflammation results in the permanent loss of LES function.

Several studies support the biomechanical effects of a distended stomach in the pathogenesis of GERD, and provide a mechanical explanation for why patients with a structurally normal LES may have increased esophageal acid exposure. In vivo baboon studies have shown that as gastric volume or distention increases, sphincter length decreases. Furthermore, as the sphincter length decreases, its resting pressure, as measured by a perfused catheter, also decreases. The decrease usually occurs suddenly when an inefficient length of sphincter is reached usually between 1 and 2 cm.

The mechanism by which gastric distention contributes to shortening of sphincter length so that its resistance drops and reflux occurs provides a mechanical explanation for "transient relaxations" of the LES without invoking a neuromuscular reflex. Rather than a "spontaneous" muscular relaxation, there is a mechanical shortening of the sphincter length as a consequence of gastric distention, to the point where it becomes incompetent. After gastric venting, sphincter length is restored and competence returns until distention again shortens the sphincter and encourages further venting and reflux. This sequence results in the common complaints of repetitive belching and bloating heard from patients with GERD. Gastric distention may initially occur because of overeating, stress aerophagia, or delayed gastric emptying, secondary to fatty diet or a systemic disorder. The distention is augmented by an increased swallowing frequency that occurs in patients as they repetitively swallow their saliva in an effort to neutralize the acid refluxed into their esophagus.

The consequence of fundic distention, with the LES being "taken up" into the stretched fundus, is that the squamous epithelium of the sphincter is exposed to gastric juice and mucosal injury. This initial step in the pathogenesis of GERD explains why mild esophagitis is usually limited to the very distal esophagus. Erosions in the terminal squamous epithelium caused by this mechanism may also explain the complaint of epigastric pain so often registered by patients with early disease. It may also be the stimulus to increase the swallowing of saliva to bathe the erosions to alleviate the discomfort induced by exposure to gastric acid. With increased swallowing come aerophagia, gastric distention, bloating, and repetitive belching. During this process there is repeated exposure of the squamous epithelium to gastric juice, because of the sphincter being "taken up" into the stretched fundus, which may cause erosion, ulceration, fibrosis (ring formation), and cardiac metaplasia of the terminal squamous mucosa.

In summary, GERD starts in the stomach. It is caused by gastric distention because of overeating or ingestion of fried foods, typical of the Western diet, which delays gastric emptying. Gastric distention causes unfolding of the sphincter as it is taken up by the distended fundus and exposure of the terminal squamous epithelium within the sphincter to noxious gastric juice. Signs of injury to the exposed squamous epithelium are erosions, ulceration, fibrosis, and columnar metaplasia, with an inflammatory infiltrate or foveolar hyperplasia.

Intestinal metaplasia within the sphincter may result, as in Barrett metaplasia of the esophageal body. This process results in the loss of muscle function, and the sphincter becomes mechanically defective, allowing free reflux with progressively higher degrees of mucosal injury.

The first component of the human antireflux mechanism is a functional LES. The most common cause of a structurally defective LES is inadequate sphincter pressure, secondary to inflammatory injury. The reduced pressure is most likely because of an abnormality of myogenic function. This is supported by two observations. First, the location of the LES, in either the abdomen or the chest, is not a major factor in the genesis of the sphincter pressure, because it can still be measured when the chest and abdomen are surgically opened and the distal esophagus is held free in the surgeon's hand. Second, Biancani and coworkers have shown that the distal esophageal sphincter's muscle response to stretch is reduced in patients with an incompetent cardia. This suggests that sphincter pressure depends on the length and tension properties of the sphincter's smooth muscle. Surgical fundoplication has been shown to improve the mechanical efficiency of the sphincter by restoring normal length-tension characteristics.

Although an inadequate pressure is the most common cause of a structurally defective sphincter, the efficiency of a sphincter with normal pressure can be nullified by an inadequate abdominal length or an abnormally short overall resting length. An adequate abdominal length is important in preventing reflux caused by increases in intraabdominal pressure, and an adequate overall length is important in providing the resistance to reflux caused by gastric distention independent of intraabdominal pressure. Therefore, patients with a low sphincter pressure or those with a normal pressure but a short abdominal length are unable to protect against reflux caused by fluctuations of intraabdominal pressure that occur with daily activities or changes in body position. Patients with a low sphincter pressure or those with a normal pressure but short overall length are unable to protect against reflux related to gastric distention caused by outlet obstruction, aerophagia, gluttony, delayed gastric emptying associated with a fatty diet, or various gastropathies. Persons who have a short overall length on a resting motility study are at a disadvantage in protecting against excessive gastric distention secondary to eating, and suffer postprandial reflux. This is because with normal dilatation of the stomach, sphincter length becomes shorter, and if already shortened in the resting state, there is little tolerance for further shortening before incompetence occurs.

The second component of the human antireflux mechanism is an effective esophageal pump that clears the esophagus after physiologic reflux episodes. Ineffective esophageal clearance can result in an abnormal esophageal exposure to gastric juice in individuals who have a normal LES and gastric function, but fail to clear physiologic reflux episodes. This situation is relatively rare, and ineffectual clearance is more apt to be seen in association with a structurally defective sphincter, which augments the esophageal exposure to gastric juice by prolonging the duration of each reflux episode.

Four factors important in esophageal clearance are gravity, esophageal motor activity, salivation, and anchoring of the distal esophagus in the abdomen. The loss of any one can augment esophageal exposure to gastric juice by contributing to ineffective clearance. This explains why in the absence of peristalsis, reflux episodes are prolonged in the supine position. The bulk of refluxed gastric juice is cleared from the esophagus by a primary peristaltic wave

initiated by a pharyngeal swallow. Secondary peristaltic waves are initiated by either distention of the lower esophagus or a drop in the intraesophageal pH. Ambulatory motility studies indicate that secondary waves are less common and play less of a role in clearance than previously thought.

Salivation contributes to esophageal clearance by neutralizing the minute amount of acid that is left following a peristaltic wave. Return of esophageal pH to normal takes significantly longer if salivary flow is reduced, such as after radiotherapy, and is shorter if saliva is stimulated by sucking lozenges.

A hiatal hernia can also contribute to an esophageal propulsion defect because of loss of anchorage of the esophagus in the abdomen. This results in a reduction in the efficiency of acid clearance.

The third component of the human antireflux mechanism is the gastric reservoir. Abnormalities of the gastric reservoir that increase esophageal exposure to gastric juice include gastric distention, increased intragastric pressure, persistent gastric reservoir, and increased gastric acid secretion. The effects of gastric distention on reflux are discussed above. Increased intragastric pressure may be the result of outlet obstruction because of a scarred pylorus or duodenum, or the result of a vagotomy; it can also be found in the diabetic patient with gastroparesis. The latter two conditions are secondary to abnormalities of the normal adaptive relaxation of the stomach. The increase in intragastric pressure because of alteration in the pressure-volume relationship in these abnormalities can overcome the sphincter resistance and results in reflux.

A persistent gastric reservoir results from delayed gastric emptying and increases the exposure of the esophagus to gastric juice by accentuating physiologic reflux. It is caused by myogenic abnormalities such as gastric atony in advanced diabetes, diffuse neuromuscular disorders, anticholinergic medications, and postviral infections. Nonmyogenic causes are vagotomy, antropyloric dysfunction, and duodenal dysmotility. Delayed gastric emptying can result in increased exposure of the gastric mucosa to bile and pancreatic juice refluxed from the duodenum into the stomach, with the development of gastritis.

Gastric hypersecretion can increase esophageal exposure to gastric acid juice by the physiologic reflux of concentrated gastric acid. Barlow has shown that 28 percent of patients with increased esophageal exposure to gastric juice measured by 24-h pH monitoring have gastric hypersecretion. A mechanically defective sphincter seems to be more important than gastric hypersecretion in the development of complications of reflux disease. In this respect, GERD differs from duodenal ulcer disease, as the latter is specifically related to gastric hypersecretion.

Complications of Gastroesophageal Reflux

The complications of gastroesophageal reflux result from the damage inflicted by gastric juice on the esophageal mucosa or respiratory epithelium, and changes caused by their subsequent repair and fibrosis. Complications because of repetitive reflux are esophagitis, stricture, and Barrett esophagus; repetitive aspiration may lead to progressive pulmonary fibrosis. The severity of the complications is directly related to the prevalence of a structurally defective sphincter (Table 24-3). The observation that a structurally defective sphincter occurs in 42 percent of patients without complications (most of whom have one or two components failed) suggests that disease may be confined to the sphincter

TABLE 24-3 Complications of Gastroesophageal Reflux Disease: 150 Consecutive Cases with Proven Gastroesophageal Reflux Disease (24-H Esophageal pH Monitoring Endoscopy, and Motility)

Complication	No.	Structurally normal sphincter	Structurally defective sphincter
None	59	58%	42%

because of compensation by a vigorously contracting esophageal body. Eventually all three components of the sphincter fail, allowing unrestricted reflux of gastric juice into the esophagus and overwhelming its normal clearance mechanisms. This leads to esophageal mucosal injury with progressive deterioration of esophageal contractility, as is commonly seen in patients with strictures and BE. The loss of esophageal clearance increases the potential for regurgitation into the pharynx with aspiration.

The potential injurious components that reflux into the esophagus include gastric secretions such as acid and pepsin, and biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. There is a considerable body of experimental evidence to indicate that maximal epithelial injury occurs during exposure to bile salts combined with acid and pepsin. These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, although the combination of duodenal juice and gastric acid is particularly noxious (Table 24-4).

Experimental animal studies have shown that the reflux of duodenal contents into the esophagus enhances inflammation, increases the prevalence of BE, and results in the development of esophageal adenocarcinoma. The component of duodenal juice thought to be most damaging is bile acids. In order for bile acids to injure mucosal cells, it is necessary that they be both soluble and un-ionized, so that the un-ionized nonpolar form may enter mucosal cells. Before the entry of bile into the gastrointestinal (GI) tract, 98 percent of bile acids are conjugated with either taurine or glycine in a ratio of about 3:1. Conjugation increases the solubility and ionization of bile acids by lowering their pKa. At the normal duodenal pH of approximately 7, over 90 percent of bile salts are in solution and completely ionized. At pH ranges from 2–7, there is a mixture of the ionized salt and the lipophilic, nonionized acid. Acidification of bile to below pH 2

TABLE 24-4 Relation of the Type of Reflux to Injury

	No injury	Esophagitis	Uncomplicated Barrett	Complicated Barrett
Gastric reflux	15 (54%)	13 (38%)	8 (32%)	1 (8%)
Gastroduodenal reflux	13 (38%)	21 (62%)	17 (68%)	12 (92%)

results in an irreversible bile acid precipitation. Consequently, under normal physiologic conditions, bile acids precipitate and are of minimal consequence when an acid gastric environment exists. On the other hand, in a more alkaline gastric environment, such as occurs with excessive duodenogastric reflux and after acid suppression therapy or vagotomy and partial or total gastrectomy, bile salts remain in solution, are partially dissociated, and when refluxed into the esophagus can cause severe mucosal injury by crossing the cell membrane and damaging the mitochondria.

The fact that the combination of refluxed gastric and duodenal juice is more noxious to the esophageal mucosa than gastric juice alone may explain the repeated observation that 25 percent of patients with reflux esophagitis develop recurrent and progressive mucosal damage, often despite medical therapy. A potential reason is that acid suppression therapy is unable to consistently maintain the pH of refluxed gastric and duodenal juice above the range of 6. Lapses into pH ranges from 2–6 encourage the formation of undissociated, nonpolarized, soluble bile acids, which are capable of penetrating the cell wall and injuring mucosal cells. To assure that bile acids remain completely ionized in their polarized form, and thus unable to penetrate the cell, requires that the pH of the refluxed material be maintained above 7, 24 h a day, 7 days a week, for the patient's lifetime. In practice this would not only be impractical but likely impossible, unless very high doses of medications were used. The use of lesser doses would allow esophageal mucosal damage to occur while the patient was relatively asymptomatic. Antireflux operative procedures re-establish the barrier between stomach and esophagus, protecting the esophagus from damage in patients with mixed gastroesophageal reflux. If reflux of gastric juice is allowed to persist and sustained or repetitive esophageal injury occurs, two sequelae can result. First, a luminal stricture can develop from submucosal and eventually intramural fibrosis. Second, the tubular esophagus may become replaced with columnar epithelium. The columnar epithelium is resistant to acid and is associated with the alleviation of the complaint of heartburn. This columnar epithelium often becomes intestinalized, identified histologically by the presence of goblet cells. This specialized intestinal metaplasia is currently required for the diagnosis of BE. Endoscopically, BE can be quiescent or associated with complications of esophagitis, stricture, Barrett ulceration, and dysplasia. The complications associated with BE may be because of the continuous irritation from refluxed duodenogastric juice. This continued injury is pH dependent and may be modified by medical therapy. The incidence of metaplastic Barrett epithelium becoming dysplastic and progressing to adenocarcinoma is approximately 0.5–1 percent per year.

An esophageal stricture can be associated with severe esophagitis or Barrett's esophagus. In the latter situation, it occurs at the site of maximal inflammatory injury (i.e., the columnar-squamous epithelial interface). As the columnar epithelium advances into the area of inflammation, the inflammation extends higher into the proximal esophagus, and the site of the stricture moves progressively up the esophagus. Patients who have a stricture in the absence of Barrett esophagus should have the presence of gastroesophageal reflux documented before the presence of the stricture is ascribed to reflux esophagitis. In patients with normal acid exposure, the stricture may be because of cancer or a drug-induced chemical injury, the latter resulting from the lodgment of a capsule or tablet in the distal esophagus. In such patients, dilation usually corrects the problem of dysphagia. Heartburn, which may have occurred only because of the chemical injury, need not be treated. It

is also possible for drug-induced injuries to occur in patients who have underlying esophagitis and a distal esophageal stricture secondary to gastroesophageal reflux. In this situation, a long string-like stricture progressively develops as a result of repetitive caustic injury from capsule or tablet lodgment on top of an initial reflux stricture. These strictures are often resistant to dilation.

When the refluxed gastric juice is of sufficient quantity, it can reach the pharynx, with the potential for pharyngeal tracheal aspiration, causing symptoms of repetitive cough, choking, hoarseness, and recurrent pneumonia. This is often an unrecognized complication of GERD, because either the pulmonary or the GI symptoms may predominate in the clinical situation and focus the physician's attention on one to the exclusion of the other. Three factors are important in these patients. First, it may take up to 7 days for the recovery of the respiratory epithelium secondary to the aspiration of gastric contents, and a chronic cough that is not related to a reflux episode may develop between episodes of aspiration. Second, the presence of an esophageal motility disorder is observed in 75 percent of patients with reflux-induced aspiration, and is believed to promote the aboral movement of the refluxate toward the pharynx. Third, if the pH in the cervical esophagus in patients with increased esophageal acid exposure is below 4 for less than 1 percent of the time, there is a high probability that the respiratory symptoms have been caused by aspiration. Increasingly, benign pulmonary pathology is recognized as being secondary to GERD, including asthma, idiopathic pulmonary fibrosis, and bronchiectases.

Symptomatic Assessment of Gastroesophageal Reflux Disease

Gastroesophageal reflux disease is a functional disorder often accompanied by non-reflux-related GI and respiratory symptoms that will not improve or may be worsened by antireflux surgery. Symptoms consistent with irritable bowel syndrome, such as alternating diarrhea and constipation, bloating, and crampy abdominal pain, should be sought and detailed separately from GERD symptoms. Likewise, symptoms suggestive of gastric pathology including nausea, early satiety, epigastric abdominal pain, anorexia, and weight loss are important. It has become increasingly recognized that oral symptoms such as mouth and tongue burning and sore throat rarely improve with antireflux surgery.

The patient's perception of what each symptom means should be explored in an effort to avoid their misinterpretation. Of equal importance is the classification of symptoms as primary or secondary, for prioritization of therapy and to allow an estimate of the probability of relief of each of the particular symptoms. The response to acid-suppressing medications predicts success and symptom relief after surgery. In contrast to the widely held belief that failure of medical therapy is an indication for surgery, a good response to proton pump inhibitors is desirable, as it predicts that the symptoms are actually because of reflux of gastric contents.

GERD-related symptoms can be classified into "typical" symptoms of heartburn, regurgitation and dysphagia, and "atypical" symptoms of cough, hoarseness, asthma, aspiration, and chest pain. Because there are fewer mechanisms for their generation, typical symptoms are more likely to be secondary to increased esophageal acid exposure than are atypical symptoms. The relationship of atypical symptoms such as cough, hoarseness, wheezing, or sore throat to

heartburn and/or regurgitation should be established. Other, more common factors that may contribute to respiratory symptoms also should be investigated. The patient must be made aware of the relatively diminished likelihood of success of surgery when atypical symptoms are the primary symptoms. Of note is the comparatively longer duration required for the respiratory symptoms to improve after surgery.

Medical Therapy

GERD is such a common condition that most patients with mild symptoms carry out self-medication. When first seen with symptoms of heartburn without obvious complications, patients can reasonably be placed on 8–12 weeks of simple antacids before extensive investigations are carried out. In many situations, this successfully terminates the attacks. Patients should be advised to elevate the head of the bed; avoid tight clothing; eat small, frequent meals; avoid eating their nighttime meal shortly before retiring; lose weight; and avoid alcohol, coffee, chocolate, and peppermint, which may aggravate the symptoms.

In patients with persistent symptoms, the mainstay of medical therapy is acid suppression. High-dosage regimens of hydrogen potassium proton pump inhibitors can reduce gastric acidity by as much as 80–90 percent. This usually heals mild esophagitis. In severe esophagitis, healing may occur in only half of the patients. In patients who reflux a combination of gastric and duodenal juice, acid-suppression therapy may give relief of symptoms, although still allowing mixed reflux to occur. This can allow persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80 percent of patients have a recurrence of symptoms.

Once initiated, most patients with GERD will require lifelong treatment with proton pump inhibitors, both to relieve symptoms and control any coexistent esophagitis. Although control of symptoms has historically served as the endpoint of therapy, the wisdom of this approach has recently been questioned, particularly in patients with BE. Evidence suggesting that reflux control may prevent the development of adenocarcinoma and lead to regression of dysplastic and nondysplastic Barrett segments has led many to consider control of reflux, and not symptom control, a better therapeutic endpoint. However, complete control of reflux can be difficult, as has been highlighted by studies of acid breakthrough while on proton pump inhibitor (PPI) therapy.

Suggested Therapeutic Approach

The traditional stepwise approach to the therapy of GERD should be re-examined in view of a more complete understanding of the pathophysiology of gastroesophageal reflux, and the rising incidence of BE. The approach should be to identify risk factors for persistent and progressive disease early in the course of the disease, and encourage surgical treatment when these factors are present. The following approach is suggested.

Patients presenting for the first time with symptoms suggestive of gastroesophageal reflux may be given initial therapy with PPI. In view of the availability of these as over-the-counter medications, many patients will have already self-medicated their symptoms. Failure of PPIs blockers to control the symptoms, or immediate return of symptoms after stopping treatment, suggests either that the diagnosis is incorrect or that the patient has relatively severe

disease. Endoscopic examination at this stage of the patient's evaluation provides the opportunity for assessing the severity of mucosal damage and the presence of BE. Both of these findings on initial endoscopy are associated with a high probability that medical control of the disease will be difficult. A measurement of the degree and pattern of esophageal exposure to gastric and duodenal juice, via 24-h pH and bilirubin monitoring, should be obtained at this point. The status of the LES and the function of the esophageal body should also be measured. These studies identify features such as the following, which are predictive of a poor response to medical therapy, frequent relapses, and the development of complications: supine reflux, poor esophageal contractility, erosive esophagitis (or a columnar-lined esophagus at initial presentation), bile in the refluxate, and a structurally defective sphincter. Patients who have these risk factors should be given the option of surgery as a primary therapy, with the expectation of long-term control of symptoms and complications.

Surgical Therapy

Preoperative Evaluation

Before proceeding with an antireflux operation, several factors should be evaluated. First, the propulsive force of the body of the esophagus should be evaluated by esophageal manometry to determine if it has sufficient power to propel a bolus of food through a newly reconstructed valve. Patients with normal peristaltic contractions do well with a 360-degree Nissen fundoplication. When peristalsis is absent or severely disordered, or the amplitude of the contraction is below 20 mm Hg throughout the lower esophagus, a two-thirds partial fundoplication may be the procedure of choice.

Second, anatomic shortening of the esophagus can compromise the ability to do an adequate repair without tension, and lead to an increased incidence of breakdown or thoracic displacement of the repair. Esophageal shortening is identified on a barium swallow roentgenogram by a sliding hiatal hernia that will not reduce in the upright position, or that measures larger than 5 cm between the diaphragmatic crura and gastroesophageal junction on endoscopy. When esophageal shortening is present, a gastropasty should be performed. In patients who have a global absence of contractility, and have dysphagia or a history of several failed previous antireflux procedures, esophageal resection should be considered as an alternative.

Third, the surgeon should specifically query the patient for complaints of nausea, vomiting, and loss of appetite. In such patients, these symptoms may persist after an antireflux procedure, and patients should be given this information before the operation. In these patients, 24-h bilirubin monitoring and gastric emptying studies can be performed to detect and quantify duodenogastric abnormalities.

Principles of Surgical Therapy

The primary goal of antireflux surgery is to safely restore the structure of the sphincter or to prevent its shortening with gastric distention, although preserving the patient's ability to swallow normally, to belch to relieve gaseous distention, and to vomit when necessary. Regardless of the choice of the procedure, this goal can be achieved if attention is paid to five principles in reconstructing the cardia. First, the operation should restore the pressure of the distal esophageal sphincter to a normal level and its length to at least 3 cm. The

fundoplication augments sphincter characteristics in patients in whom they are reduced prior to surgery and prevents unfolding of a normal sphincter in response to gastric distention.

Second, the operation should place an adequate length of the distal esophageal sphincter in the positive-pressure environment of the abdomen by a method that ensures its response to changes in intraabdominal pressure. The permanent restoration of 1.5–2 cm of abdominal esophagus in a patient whose sphincter pressure has been augmented to normal levels will maintain the competency of the cardia over various challenges of intraabdominal pressure.

Third, the operation should allow the reconstructed cardia to relax on deglutition. In normal swallowing, a vagally mediated relaxation of the distal esophageal sphincter and the gastric fundus occurs. The relaxation lasts for approximately 10 s and is followed by a rapid recovery to the former tonicity. To ensure relaxation of the sphincter, three factors are important: (1) only the fundus of the stomach should be used to buttress the sphincter, because it is known to relax in concert with the sphincter; (2) the gastric wrap should be properly placed around the sphincter and not incorporate a portion of the stomach or be placed around the stomach itself, because the body of the stomach does not relax with swallowing; and (3) damage to the vagal nerves during dissection of the thoracic esophagus should be avoided because it may result in failure of the sphincter to relax.

Fourth, the fundoplication should not increase the resistance of the relaxed sphincter to a level that exceeds the peristaltic power of the body of the esophagus. The resistance of the relaxed sphincter depends on the degree, length, and diameter of the gastric fundoplication, and on the variation in intraabdominal pressure. A 360-degree gastric fundoplication should be no longer than 2 cm and constructed easily over a 60F bougie. This will ensure that the relaxed sphincter will have an adequate diameter with minimal resistance. This is not necessary when constructing a partial wrap.

Fifth, the operation should ensure that the fundoplication can be placed in the abdomen without undue tension, and maintained there by approximating the crura of the diaphragm above the repair. Leaving the fundoplication in the thorax converts a sliding hernia into a paraesophageal hernia, with all the complications associated with that condition. Maintaining the repair in the abdomen under tension predisposes to an increased incidence of recurrence. This is likely to occur in patients who have a stricture or BE, and is because of shortening of the esophagus from the inflammatory process. This problem can be resolved by lengthening the esophagus with a Collis gastroplasty.

Procedure Selection

A laparoscopic approach is used in patients with normal esophageal contractility and length. Patients with questionable esophageal length may be best approached transthoracically, in which full esophageal mobilization serves as a lengthening procedure. Those with a failed esophagus characterized by absent esophageal contractions and/or absent peristalsis such as those with scleroderma are best treated either medically or with a partial fundoplication to avoid the increased outflow resistance associated with a complete fundoplication. If the esophagus is short after it is mobilized from diaphragm to aortic arch, a Collis gastroplasty is done to provide additional length and avoid placing the repair under tension. In the majority of patients who have good

esophageal contractility and normal esophageal length, the laparoscopic Nissen fundoplication is the procedure of choice for a primary antireflux repair.

Primary Antireflux Repairs

Nissen Fundoplication

The most common antireflux procedure is the Nissen fundoplication. The procedure can be performed through an abdominal or a chest incision, and through a laparoscope. Rudolph Nissen described the procedure as a 360-degree fundoplication around the lower esophagus for a distance of 4–5 cm. Although this provided good control of reflux, it was associated with a number of side effects that have encouraged modifications of the procedure as originally described. These include using only the gastric fundus to envelop the esophagus in a fashion analogous to a Witzel jejunostomy, sizing the fundoplication with a 60F bougie, and limiting the length of the fundoplication to 1–2 cm. The essential elements necessary for the performance of a transabdominal fundoplication are common to both the laparoscopic and open procedures and include the following:

1. Crural dissection, identification, and preservation of both vagi, and the anterior hepatic branch
2. Circumferential dissection of the esophagus
3. Crural closure
4. Fundic mobilization by division of short gastric vessels
5. Creation of a short, loose fundoplication by placing the posterior fundic wall posterior, and the anterior fundus anterior, to the esophagus, meeting at the right lateral position.

The laparoscopic approach. Laparoscopic fundoplication has become commonplace and has replaced the open abdominal Nissen fundoplication as the procedure of choice.

Transthoracic Nissen fundoplication. The indications for performing an antireflux procedure by a transthoracic approach are as follows:

1. A patient who has had a previous hiatal hernia repair. In this situation, a peripheral circumferential incision in the diaphragm is made to provide simultaneous exposure of the upper abdomen. This allows safe dissection of the previous repair from both the abdominal and thoracic sides of the diaphragm.
2. A patient who has a short esophagus. This is usually associated with a stricture or BE. In this situation, the thoracic approach is preferred to allow maximum mobilization of the esophagus, and to perform a Collis gastroplasty to place the repair without tension below the diaphragm.
3. A patient with a sliding hiatal hernia that does not reduce below the diaphragm during a roentgenographic barium study in the upright position. This can indicate esophageal shortening, and again, a thoracic approach is preferred for maximum mobilization of the esophagus, and if necessary, the performance of a Collis gastroplasty.
4. A patient who has associated pulmonary pathology. In this situation, the nature of the pulmonary pathology can be evaluated and the proper pulmonary surgery, in addition to the antireflux repair, can be performed.

5. An obese patient. In this situation, the abdominal repair is difficult because of poor exposure, particularly in men, in whom the intraabdominal fat is more abundant.

Outcome After Fundoplication

Nearly all published reports of laparoscopic fundoplication show that this procedure relieves the typical symptoms of gastroesophageal reflux—heartburn, regurgitation, and dysphagia—in greater than 90 percent of patients. The incidence of persistent postoperative dysphagia has decreased to the 3–5 percent range with increasing experience and attention to the technical details in constructing the fundoplication. Resting LES characteristics and esophageal acid exposure return to normal in nearly all patients. Morbidity after laparoscopic fundoplication is similar to that after open fundoplication, averaging 10–15 percent. Unrecognized perforation of the esophagus or stomach is the most life-threatening complication. Perforations occur most often during hiatal and circumferential dissection of the esophagus, and their incidence is also related to the surgeon's experience. Intraoperative recognition and repair are the keys to preventing a life-threatening complication.

BARRETT'S ESOPHAGUS

The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950. He incorrectly believed it to be congenital in origin. It is now realized that it is an acquired abnormality, occurs in 7–15 percent of patients with GERD, and represents the end stage of the natural history of this disease. It is also thought to be distinctly different from the congenital condition in which islands of gastric fundic epithelium are found in the upper half of the esophagus.

The definition of BE has evolved considerably over the past decade. Traditionally, BE was identified by the presence of columnar mucosa extending at least 3 cm into the esophagus. It is now recognized that the specialized intestinal type epithelium found in the Barrett mucosa is the only tissue predisposed to malignant degeneration. Consequently, the diagnosis of BE is presently made given any length of endoscopically identifiable columnar mucosa that proves on biopsy to show intestinal metaplasia. Although long segments of columnar mucosa without intestinal metaplasia do occur, they are less uncommon today than they were previously.

The hallmark of intestinal metaplasia is the presence of intestinal goblet cells. There is a high prevalence of biopsy-demonstrated intestinal metaplasia at the cardia, on the gastric side of the squamocolumnar junction, in the absence of endoscopic evidence of a columnar-lined esophagus. Evidence is accumulating that these patches of what appears to be Barrett in the cardia have a similar malignant potential as the longer segments, and may be the precursors for carcinoma of the cardia.

The long-term relief of symptoms remains the primary reason for performing antireflux surgery in patients with BE. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with BE are no different than the broader population of patients with gastroesophageal reflux. They should be considered for antireflux surgery when patient data suggest severe disease or predict the need for long-term medical management. Most patients with BE are symptomatic. Although

TABLE 24-5 Symptomatic Outcome of Surgical Therapy for Barrett Esophagus

Author	Year	No. of patients	% Excellent to good response	Mean follow-up, years
Starnes	1984	8	75	2
Williamson	1990	37	92	3
DeMeester	1990	35	77	3
McDonald	1996	113	82.2	6.5
Ortiz	1996	32	90.6	5

it has been argued that some patients with BE may not have symptoms, careful history taking will reveal the presence of symptoms in most, if not all, patients.

The typical complications in BE include ulceration in the columnar-lined segment, stricture formation, and a dysplasia-cancer sequence. Barrett's ulceration is unlike the erosive ulceration of reflux esophagitis in that it more closely resembles peptic ulceration in the stomach or duodenum, and has the same propensity to bleed, penetrate, or perforate. The strictures found in BE occur at the squamocolumnar junction, and are typically higher than peptic strictures in the absence of BE. Ulceration and stricture in association with BE were commonly reported prior to 1975, but with the advent of potent acid suppression medication they have become less common. In contrast, the complication of adenocarcinoma developing in Barrett mucosa has become more common. Adenocarcinoma developing in Barrett mucosa was considered a rare tumor prior to 1975. Today it occurs in approximately one in every 100 patient-years of follow-up, which represents a risk 40 times that of the general population. Most if not all cases of adenocarcinoma of the esophagus arise in Barrett epithelium.

Few studies have focused on the alleviation of symptoms after antireflux surgery in patients with BE (Table 24-5). Those that are available document excellent to good results in 72–95 percent of patients at 5 years following surgery.

Farrell and associates also reported symptomatic outcome of laparoscopic Nissen fundoplication in 50 patients with both long- and short-segment BE. Mean scores for heartburn, regurgitation, and dysphagia all improved dramatically post-Nissen. Importantly, there was no significant decrement in symptom scores when 1-year results were compared to those at 2–5 years postoperatively. They did find a higher prevalence of “anatomic” failures requiring re-operation in patients with BE when compared to non-Barrett patients with GERD. Others have reported similar results. Taken together these studies document the ability of antireflux surgery to provide long-term symptomatic relief in patients with BE.

Three relevant questions arise concerning the fate, over time, of the metaplastic tissue found in BE: (1) Does antireflux surgery cause regression of Barrett epithelium? (2) Does it prevent progression? and (3) Can the development of Barrett metaplasia be prevented by early antireflux surgery in patients with reflux disease?

The common belief that Barrett epithelium cannot be reversed is likely false. DeMeester and associates reported that after antireflux surgery, loss of intestinal metaplasia (IM) in patients with visible BE was rare, but occurred in 73 percent of patients with inapparent IM of the cardia. This suggests that the metaplastic process may indeed be reversible if reflux is eliminated early

in its process, that cardiac mucosa is dynamic, and that as opposed to IM extending several centimeters into the esophagus, IM of the cardia is more likely to regress following antireflux surgery.

Recent evidence suggests that the development of BE may even be preventable. Although a very difficult hypothesis to study, Oberg and coworkers followed a cohort of 69 patients with short-segment, nonintestinalized, columnar-lined esophagus (CLE) over a median of 5 years of surveillance endoscopy. Forty-nine of the patients were maintained on PPI therapy and 20 had antireflux surgery. Patients with antireflux surgery were 10 times less likely to develop IM in these CLE segments over a follow-up span of nearly 15 years than those on medical therapy. This rather remarkable observation supports the two-step hypothesis of the development of BE (cardiac metaplasia followed by intestinal metaplasia), and suggests that the second step can be prevented if reflux disease is recognized and treated early and aggressively.

There is a growing body of evidence to attest to the ability of fundoplication to protect against dysplasia and invasive malignancy. Three studies suggest that an effective antireflux procedure can impact the natural history of BE in this regard. Two prospective randomized studies found less adenocarcinoma in the surgically treated groups. Parrilla and associates reported that although the development of dysplasia and adenocarcinoma was no different overall, the subgroup of surgical patients with normal postoperative pH studies developed significantly less dysplasia and had no adenocarcinoma. Spechler identified one adenocarcinoma 11–13 years after antireflux surgery, compared to four following medical treatment. Most of these authors concluded that there is a critical need for future trials exploring the role of antireflux surgery in protecting against the development of dysplasia in patients with BE.

Atypical Reflux Symptoms

Chronic respiratory symptoms, such as chronic cough, recurrent pneumonias, episodes of nocturnal choking, waking up with gastric contents in the mouth, or soiling of the bed pillow, may also indicate the need for surgical therapy. Patients suffering from repetitive pulmonary aspiration secondary to gastroesophageal reflux often shows signs of pleural thickening, bronchiectasis, and chronic interstitial pulmonary fibrosis on their chest radiograph. If 24-h pH monitoring confirms the presence of increased esophageal acid exposure, and manometry shows normal esophageal body motility, an antireflux procedure can be done with an expected good result. However, these patients usually have a nonspecific motor abnormality of the esophageal body, which tends to propel the refluxed material toward the pharynx. In some of these patients, the motor abnormality will disappear after a surgical antireflux procedure. In others, the motor disorder will persist and contribute to postoperative aspiration of swallowed saliva and food. Consequently, the results of an antireflux procedure in patients with a motor disorder of the esophageal body are variable.

Chest pain may be an atypical symptom of gastroesophageal reflux, and is often confused with coronary artery disease. Fifty percent of patients in whom a cardiac cause of the chest pain has been excluded will have increased esophageal acid exposure as a cause of the episode of pain. An antireflux

procedure provides relief of the chest pain more consistently than medical therapy.

Dysphagia, regurgitation, or chest pain on eating in a patient with normal endoscopy and esophageal function studies can be an indication for an antireflux procedure. These symptoms are usually related to the presence of a large paraesophageal hernia, intrathoracic stomach, or a small hiatal hernia with a narrow diaphragmatic hiatus. A Schatzki ring may be present with the latter. All these conditions are easily identified with an upper GI radiographic barium examination done by a knowledgeable radiologist. These patients may have no heartburn, because the LES is usually normal and reflux of gastric acid into the esophagus does not occur. The surgical repair of the hernia usually includes an antireflux procedure because of the potential of destroying the competency of the cardia during the surgical dissection.

MOTILITY DISORDERS OF THE PHARYNX AND ESOPHAGUS

Clinical Manifestations

Difficulty in swallowing (dysphagia) is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying abnormality causing the dysphagia, and the adjustment made by the patient in altering eating habits. Consequently, any complaint of dysphagia must include an assessment of the patient's dietary history. It must be known whether the patient experiences pain, chokes, or vomits with eating; whether the patient requires liquids with the meal, is the last to finish, or is forced to interrupt a social meal; and whether he or she has been admitted to the hospital for food impaction. These assessments, plus an evaluation of the patient's nutritional status, help to determine how severe the dysphagia is and evaluate the indications for surgical therapy.

A surgical myotomy is designed to improve the symptoms of dysphagia caused by a motility disorder. The results can profoundly improve the patient's ability to ingest food, but rarely return the function of the foregut to normal. The principle of the procedure is to destroy esophageal contractility to correct a defect in esophageal motility, resulting in improvement but never a return to normal function. To use a surgical myotomy to treat the problem of dysphagia, the surgeon needs to know the precise functional abnormality causing the symptom. This usually entails a complete esophageal motility evaluation. A clear understanding of the physiologic mechanism of swallowing, and identification of the motility abnormality giving rise to the dysphagia, are essential for determining if surgery is indicated and the extent of the myotomy to be performed. Endoscopy is necessary only to exclude the presence of tumor or inflammatory changes as the cause of dysphagia.

Motility Disorders of the Pharyngoesophageal Segment

Disorders of the pharyngoesophageal phase of swallowing result from a discoordination of the neuromuscular events involved in chewing, initiation of swallowing, and propulsion of the material from the oropharynx into the cervical esophagus. They can be categorized into one or a combination of the following abnormalities: (1) inadequate oropharyngeal bolus transport; (2) inability to pressurize the pharynx; (3) inability to elevate the larynx; (4) discoordination of pharyngeal contraction and cricopharyngeal relaxation; and

(5) decreased compliance of the pharyngoesophageal segment secondary to muscle pathology. The latter results in incomplete anatomic relaxation of the cricopharyngeus and cervical esophagus.

Pharyngoesophageal swallowing disorders are usually because of acquired disease involving the central and peripheral nervous system. This includes cerebrovascular accidents, brain stem tumors, poliomyelitis, multiple sclerosis, Parkinson disease, pseudobulbar palsy, peripheral neuropathy, and operative damage to the cranial nerves involved in swallowing. Muscular diseases such as radiation-induced myopathy, dermatomyositis, myotonic dystrophy, and myasthenia gravis are less common causes. Rarely, extrinsic compression by thyromegaly, cervical lymphadenopathy, or hyperostosis of the cervical spine can cause pharyngoesophageal dysphagia.

Zenker Diverticulum

In the past, the most common recognized sign of pharyngoesophageal dysfunction was the presence of a Zenker diverticulum, originally described by Ludlow in 1769. The eponym resulted from Zenker classic clinicopathologic descriptions of 34 cases published in 1878. Pharyngoesophageal diverticula have been reported to occur in 0.1 percent of 20,000 routine barium examinations, and classically occur in older adult, white males. Zenker diverticula tend to enlarge progressively with time because of the decreased compliance of the skeletal portion of the cervical esophagus that occurs with aging.

Presenting symptoms include dysphagia associated with the spontaneous regurgitation of undigested, bland material, often interrupting eating or drinking. The symptom of dysphagia is due initially to the loss of muscle compliance in the pharyngoesophageal segment, later augmented by the presence of an enlarging diverticulum. On occasion, the dysphagia can be severe enough to cause debilitation and significant weight loss. Chronic aspiration and repetitive respiratory infection are common associated complaints. Once suspected, the diagnosis is established by a barium swallow. Endoscopy is usually difficult in the presence of a cricopharyngeal diverticulum, and potentially dangerous, owing to obstruction of the true esophageal lumen by the diverticulum and the attendant risk of diverticular perforation.

Pharyngocricoesophageal Myotomy

The myotomy can be performed under local or general anesthesia through an incision along the anterior border of the left sternocleidomastoid muscle. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid muscle and carotid sheath laterally, and the thyroid, trachea, and larynx medially. When a pharyngoesophageal diverticulum is present, localization of the pharyngoesophageal segment is easy. The diverticulum is carefully freed from the overlying areolar tissue to expose its neck, just below the inferior pharyngeal constrictor and above the cricopharyngeus muscle. It can be difficult to identify the cricopharyngeus muscle in the absence of a diverticulum. A benefit of local anesthesia is that the patient can swallow and demonstrate an area of persistent narrowing at the pharyngoesophageal junction. Furthermore, before closing the incision, gelatin can be fed to the patient to ascertain whether the symptoms have been relieved, and to inspect the opening of the previously narrowed pharyngoesophageal segment. Under general anesthesia, and in the absence of a diverticulum, the placement of a nasogastric tube to

the level of the manometrically determined cricopharyngeal sphincter helps in localization of the structures. The myotomy is extended cephalad by dividing 1 to 2 cm of inferior constrictor muscle of the pharynx, and caudad by dividing the cricopharyngeal muscle and the cervical esophagus for a length of 4–5 cm. The cervical wound is closed only when all oozing of blood has ceased, because a hematoma after this procedure is common, and is often associated with temporary dysphagia while the hematoma absorbs. Oral alimentation is started the day after surgery. The patient is usually discharged on the first or second postoperative day.

If a diverticulum is present and is large enough to persist after a myotomy it may be sutured in the inverted position to the prevertebral fascia using a permanent suture (i.e., diverticulopexy). If the diverticulum is excessively large so that it would be redundant if suspended, or if its walls are thickened, a diverticulectomy should be performed.

Endoscopic stapled diverticulotomy recently has been described. The procedure uses a Weerda diverticuloscope with two retractable valves passed into the hypopharynx. The lips of the diverticuloscope are positioned so that one lip lies in the esophageal lumen and the other in the diverticular lumen. The valves of the diverticuloscope are retracted appropriately so as to visualize the septum interposed between the diverticulum and the esophagus. An endoscopic linear stapler is introduced into the diverticuloscope and positioned against the common septum with the anvil in the diverticulum and the cartridge in the esophageal lumen. Firing of the stapler divides the common septum between the posterior esophageal and the diverticular wall over a length of 30 mm, placing three rows of staples on each side. More than one stapler application may be needed, depending on the size of the diverticulum. The patient is allowed to resume liquid feeds either on the same day or the day after, and is usually discharged the day after surgery. Complications are rare and may include perforation at the apex of the diverticulum, and can be repaired with minimally invasive techniques.

Postoperative complications include fistula formation, abscess, hematoma, recurrent nerve paralysis, difficulties in phonation, and Horner's syndrome. The incidence of the first two can be reduced by performing a diverticulopexy. Recurrence of a Zenker diverticulum occurs late, and is more common after diverticulectomy without myotomy, presumably because of persistence of the underlying loss of compliance of the cervical esophagus when a myotomy is not performed.

Motility Disorders of the Esophageal Body and Lower Esophageal Sphincter

Disorders of the esophageal phase of swallowing result from abnormalities in the propulsive pump action of the esophageal body or the relaxation of the LES. These disorders result from either primary esophageal abnormalities, or from generalized neural, muscular, or collagen vascular disease (Table 24-6). The use of standard esophageal manometry techniques has allowed specific primary esophageal motility disorders to be identified out of a pool of non-specific motility abnormalities. These include achalasia, diffuse esophageal spasm, the so-called nutcracker esophagus, the hypertensive LES, and ineffective esophageal motility. Table 24-7 shows the manometric characteristics of these disorders.

TABLE 24-6 Esophageal Motility Disorders

Primary esophageal motility disorders

Achalasia, "vigorous" achalasia
 Diffuse and segmental esophageal spasm
 Nutcracker esophagus
 Hypertensive lower esophageal sphincter
 Nonspecific esophageal motility disorders

Secondary esophageal motility disorders

Collagen vascular diseases: progressive systemic sclerosis, polymyositis and dermatomyositis, mixed connective tissue disease, systemic lupus erythematosus, etc.
 Chronic idiopathic intestinal pseudo-obstruction
 Neuromuscular diseases
 Endocrine and metastatic disorders

Achalasia

The best known and best understood primary motility disorder of the esophagus is achalasia, with an incidence of six per 100,000 population per year. Although complete absence of peristalsis in the esophageal body has been proposed as the major abnormality, present evidence indicates achalasia is a primary disorder of the LES. The observation that esophageal peristalsis can return in patients with classic achalasia following dilation or myotomy provides support that achalasia is a primary disease of the LES.

The pathogenesis of achalasia is presumed to be a neurogenic degeneration, which is either idiopathic or because of inflammation. In experimental animals, the disease has been reproduced by destruction of the nucleus ambiguus and the dorsal motor nucleus of the vagus nerve. In patients with the disease, degenerative changes have been shown in the vagus nerve and in the ganglia in the Auerbach plexus of the esophagus itself. This degeneration results in hypertension of the LES, a failure of the sphincter to relax on deglutition, elevation of intraluminal esophageal pressure, esophageal dilatation, and a subsequent loss of progressive peristalsis in the body of the esophagus. The esophageal dilatation results from the combination of a nonrelaxing sphincter, which causes a functional retention of ingested material in the esophagus, and elevation of intraluminal pressure from repetitive pharyngeal air swallowing. With time, the functional disorder results in anatomic alterations seen on radiographic studies, such as a dilated esophagus with a tapering, beak-like narrowing of the distal end. There is usually an air-fluid level in the esophagus from the retained food and saliva, the height of which reflects the degree of resistance imposed by the nonrelaxing sphincter. As the disease progresses, the esophagus becomes massively dilated and tortuous.

Diffuse and Segmental Esophageal Spasm

Diffuse esophageal spasm is characterized by substernal chest pain and/or dysphagia. Diffuse esophageal spasm differs from classic achalasia in that it is primarily a disease of the esophageal body, produces a lesser degree of dysphagia, causes more chest pain, and has less effect on the patient's general condition. True symptomatic diffuse esophageal spasm is a rare condition, occurring about 5 times less frequently than achalasia.

TABLE 24-7 Manometric Characteristics of the Primary Esophageal Motility Disorders

Achalasia

Incomplete lower esophageal sphincter (LES) relaxation ($< 75\%$ relaxation)
 Aperistalsis in the esophageal body
 Elevated LES pressure ≤ 26 mm Hg
 Increased intraesophageal baseline pressures relative to gastric baseline

Diffuse Esophageal Spasm (DES)

Simultaneous (nonperistaltic contractions) ($> 20\%$ of wet swallows)
 Repetitive and multi-peaked contractions
 Spontaneous contractions
 Intermittent normal peristalsis
 Contractions may be of increased amplitude and duration

Nutcracker Esophagus

Mean peristaltic amplitude (10 wet swallows) in distal esophagus ≥ 180 mm Hg
 Increased mean duration of contractions (> 7.0 s)
 Normal peristaltic sequence

Hypertensive Lower Esophageal Sphincter

Elevated LES pressure (≥ 26 mm Hg)
 Normal LES relaxation
 Normal peristalsis in the esophageal body

Ineffective Esophageal Motility Disorders

Decreased or absent amplitude of esophageal peristalsis (< 30 mm Hg)
 Increased number of nontransmitted contractions

Source: Reproduced with permission from DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): *Shackelford's Surgery of the Alimentary Tract*, 3rd ed, Vol. I. Philadelphia: WB Saunders, 1991, p 115.

The causation and neuromuscular pathophysiology of diffuse esophageal spasm are unclear. The basic motor abnormality is rapid wave progression down the esophagus secondary to an abnormality in the latency gradient. Hypertrophy of the muscular layer of the esophageal wall and degeneration of the esophageal branches of the vagus nerve have been observed in this disease, although these are not constant findings. Manometric abnormalities in diffuse esophageal spasm may be present over the total length of the esophageal body, but usually are confined to the distal two-thirds. In segmental esophageal spasm, the manometric abnormalities are confined to a short segment of the esophagus.

The classic manometric findings in these patients are characterized by the frequent occurrence of simultaneous waveforms and multi-peaked esophageal contractions, which may be of abnormally high amplitude or long duration. Key to the diagnosis of diffuse esophageal spasm is that there remain some peristaltic waveforms in excess of those seen in achalasia. A criterion of 20 percent or more simultaneous waveforms out of 10 wet swallows has been

used to diagnose diffuse esophageal spasm. However, this figure is arbitrary and often debated.

The LES in patients with diffuse esophageal spasm usually shows a normal resting pressure and relaxation on deglutition. In patients with advanced disease, the radiographic appearance of tertiary contractions appears helical, and has been termed corkscrew esophagus or pseudodiverticulosis. Patients with segmental or diffuse esophageal spasm can compartmentalize the esophagus and develop an epiphrenic or midesophageal diverticulum.

Diverticula of the Esophageal Body

Radiographic abnormalities such as segmental spasm, corkscrewing, compartmentalization, and diverticulum are the anatomic results of disordered motility function. Of these, the most persistent and easiest to demonstrate is an esophageal diverticulum. Diverticula occur most commonly with nonspecific motility disorders, but can occur with all of the primary motility disorders. In the latter situation, the motility disorder is usually diagnosed before the development of the diverticulum. When present, a diverticulum may temporarily alleviate the symptom of dysphagia by becoming a receptacle for ingested food, and substitute the symptoms of postprandial pain and the regurgitation of undigested food. If a motility abnormality of the esophageal body or LES cannot be identified, a traction or congenital cause for the diverticulum should be considered. Because development in radiology preceded development in motility monitoring, diverticula of the esophagus were considered historically to be a primary abnormality, the cause, rather than the consequence, of motility disorders. Consequently, earlier texts focused on them as specific entities based on their location.

Epiphrenic diverticula arise from the terminal third of the thoracic esophagus and are usually found adjacent to the diaphragm. They have been associated with distal esophageal muscular hypertrophy, esophageal motility abnormalities, and increased luminal pressure. They are "pulsion" diverticula, and have been associated with diffuse spasm, achalasia, or nonspecific motor abnormalities in the body of the esophagus.

Whether the diverticulum should be surgically resected or suspended depends on its size and proximity to the vertebral body. When diverticula are associated with esophageal motility disorders, esophageal myotomy from the distal extent of the diverticulum to the stomach is indicated; otherwise, one can expect a high incidence of suture line rupture because of the same intraluminal pressure that initially gave rise to the diverticulum. If the diverticulum is suspended to the prevertebral fascia of the thoracic vertebra, a myotomy is begun at the neck of the diverticulum and extended across the LES. If the diverticulum is excised by dividing the neck, the muscle is closed over the excision site and a myotomy is performed on the opposite esophageal wall, starting at the level of diverticulum. When a large diverticulum is associated with a hiatal hernia, the diverticulum is excised, a myotomy is performed if there is an associated esophageal motility abnormality, and the hernia is repaired because of the high incidence of postoperative reflux when it is omitted.

Midesophageal or traction diverticula were first described in the nineteenth century. At that time they were frequently noted in patients who had mediastinal lymph node involvement with tuberculosis. It was theorized that adhesions form between the inflamed mediastinal nodes and the esophagus. By contraction, the adhesions exerted traction on the esophageal wall and led to a localized

diverticulum. This theory was based on the findings of early dissections, in which adhesions between diverticula and lymph nodes were commonly found. It is now believed that some diverticula in the midesophagus may also be caused by motility abnormalities.

Most midesophageal diverticula are asymptomatic and incidentally discovered during investigation for nonesophageal complaints. In such patients, the radiologic abnormality may be ignored. Patients with symptoms of dysphagia, regurgitation, chest pain, or aspiration, in whom a diverticulum is discovered, should be thoroughly investigated for an esophageal motor abnormality and treated appropriately. Occasionally, a patient will present with a bronchoesophageal fistula manifested by a chronic cough on ingestion of meals. The diverticulum in such patients is most likely to have an inflammatory etiology.

The indication for surgical intervention is the degree of symptomatic disability. Usually midesophageal diverticula can be suspended because of their proximity to the spine. If motor abnormality is documented, a myotomy should be performed similarly to that described for an epiphrenic diverticulum.

Operations

Long esophageal myotomy for motor disorders of the esophageal body. A long esophageal myotomy is indicated for dysphagia caused by any motor disorder characterized by segmental or generalized simultaneous waveforms in a patient whose symptoms are not relieved by medical therapy. Such disorders include diffuse and segmental esophageal spasm, vigorous achalasia, and nonspecific motility disorders associated with a mid- or epiphrenic esophageal diverticulum. However, the decision to operate must be made by a balanced evaluation of the patient's symptoms, diet, lifestyle adjustments, and nutritional status, with the most important factor being the possibility of improving the patient's swallowing disability. The symptom of chest pain alone is not an indication for a surgical procedure.

Twenty-four-h ambulatory motility monitoring has greatly aided in the identification of patients with symptoms of dysphagia and chest pain who might benefit from a surgical myotomy. Ambulatory motility studies have shown that when the prevalence of "effective contractions" (i.e., peristaltic waveforms consisting of contractions with an amplitude above 30 mm Hg) drops below 50 percent during meals, the patient is likely to experience dysphagia. This would suggest that relief from the symptom could be expected with an improvement of esophageal contraction amplitude or amelioration of nonperistaltic waveforms. Prokinetic agents may increase esophageal contraction amplitude, but do not alter the prevalence of simultaneous waveforms. Patients in whom the efficacy of esophageal propulsion is severely compromised because of a high prevalence of simultaneous waveforms usually receive little benefit from medical therapy. In these patients, a surgical myotomy of the esophageal body can improve the patients' dysphagia, provided the loss of contraction amplitude in the remaining peristaltic waveforms, caused by the myotomy, has less effect on swallowing function than the presence of the excessive simultaneous contractions. This situation is reached when the prevalence of effective waveforms during meals drops below 30 percent, i.e., 70 percent of esophageal waveforms are ineffective.

In patients selected for surgery, preoperative manometry is essential to determine the proximal extent of the esophageal myotomy. Most surgeons extend the myotomy distally across the LES to reduce outflow resistance. Consequently, some form of antireflux protection is needed to avoid gastroesophageal reflux

if there has been extensive dissection of the cardia. In this situation, most authors prefer a partial, rather than a full, fundoplication, in order not to add back-resistance that will further interfere with the ability of the myotomized esophagus to empty. If the symptoms of reflux are present preoperatively, 24-hour pH monitoring is required to confirm its presence.

The procedure may be performed either open or via thoracoscopy. The open technique is performed through a left thoracotomy in the sixth intercostal space. An incision is made in the posterior mediastinal pleura over the esophagus, and the left lateral wall of the esophagus is exposed. The esophagus is not circumferentially dissected unless necessary. A 2-cm incision is made into the abdomen through the parietal peritoneum at the midportion of the left crus. A tongue of gastric fundus is pulled into the chest. This exposes the gastroesophageal junction and its associated fat pad. The latter is excised to give a clear view of the junction. A myotomy is performed through all muscle layers, extending distally over the stomach 1–2 cm below the gastroesophageal junction, and proximally on the esophagus over the distance of the manometric abnormality. The muscle layer is dissected from the mucosa laterally for a distance of 1 cm. Care is taken to divide all minute muscle bands, particularly in the area of the junction. The gastric fundic tongue is sutured to the margins of the myotomy over a distance of 3–4 cm and replaced into the abdomen. This maintains separation of the muscle and acts as a partial fundoplication to prevent reflux.

If an epiphrenic diverticulum is present, it is excised by dividing the neck and closing the muscle. The myotomy is then performed on the opposite esophageal wall. If a midesophageal diverticulum is present, the myotomy is made so that it includes the muscle around the neck, and the diverticulum is inverted and suspended by attaching it to the paravertebral fascia of the thoracic vertebra.

The results of myotomy for motor disorders of the esophageal body have improved in parallel with the improved preoperative diagnosis afforded by manometry. Previous published series report between 40 and 92 percent improvement of symptoms, but interpretation is difficult because of the small number of patients involved and the varying criteria for diagnosis of the primary motor abnormality. When myotomy is accurately done, 93 percent of the patients have effective palliation of dysphagia after a mean follow-up of 5 years, and 89 percent would have the procedure again if it was necessary. Most patients gain or maintain rather than lose weight after the operation. Postoperative motility studies show that the myotomy reduces the amplitude of esophageal contractions to near zero and eliminates simultaneous peristaltic waves. If the benefit of obliterating the simultaneous waves exceeds the adverse effect on bolus propulsion caused by the loss of peristaltic waveforms, the patient's dysphagia is likely to be improved by the procedure. If not, the patient is likely to continue to complain of dysphagia and to have little improvement as a result of the operation. Preoperative motility studies are thus crucial in deciding which patients are most likely to benefit from a long esophageal myotomy.

Myotomy of the lower esophageal sphincter. Second only to reflux disease, achalasia is the most common functional disorder of the esophagus to require surgical intervention. The goal of treatment is to relieve the functional outflow obstruction secondary to the loss of relaxation and compliance of the LES. This requires disrupting the LES muscle. When performed adequately (i.e., reducing sphincter pressure to < 10 mm Hg), and done early in the course

of disease, LES myotomy results in symptomatic improvement with the occasional return of esophageal peristalsis. Reduction in LES resistance can be accomplished intraluminally by hydrostatic balloon dilation, which ruptures the sphincter muscle, or by a surgical myotomy that cuts the sphincter. The difference between these two methods appears to be the greater likelihood of reducing sphincter pressure to less than 10 mm Hg by surgical myotomy as compared with hydrostatic balloon dilation. However, patients whose sphincter pressure has been reduced by hydrostatic balloon dilation to less than 10 mm Hg have an outcome similar to those after surgical myotomy. In performing a surgical myotomy of the LES, there are four important principles: (1) minimal dissection of the cardia, (2) adequate distal myotomy to reduce outflow resistance, (3) prevention of postoperative reflux, and (4) preventing rehealing of the myotomy site. In the past, the drawback of a surgical myotomy was the need for an open procedure. With the advent of limited-access technology, the myotomy can now be performed laparoscopically.

The therapeutic decisions regarding the treatment of patients with achalasia center around three issues. The first issue is the question of whether newly diagnosed patients should be treated with pneumatic dilation or a surgical myotomy. Long-term follow-up studies have shown that pneumatic dilation achieves adequate relief of dysphagia and pharyngeal regurgitation in 50–60 percent of patients. Close follow-up is required, and if dilation fails, myotomy is indicated. For those patients who have a dilated and tortuous esophagus or an associated hiatal hernia, balloon dilation is dangerous and surgery is the better option. Whether it is better to treat a newly diagnosed esophageal achalasia patient by forceful dilation or by operative cardiomyotomy remains undecided. The outcome of the one controlled randomized study (38 patients) comparing the two modes of therapy suggests that surgical myotomy as a primary treatment gives better long-term results. There are several large retrospective series that report the outcome obtained with the two modes of treatment (Table 24-8). Despite objections regarding variations in surgical and dilation techniques and the number of physicians performing the procedures, these collective data would appear to support operative myotomy as the initial treatment of choice, when performed by a surgeon of average skill and experience.

TABLE 24-8 Series with >100 Patients Giving Follow-Up Results of Myotomy of Balloon Dilation for Achalasia

Author	Year	No. of patients	Follow-up years	Good-to-excellent response
<i>Surgical myotomy</i>				
Black et al	1976	108	4	65%
Menzies Gow	1978	102	8	98%
Okike et al	1979	456	1–17	85%
Ellis et al	1984	113	3.5	91%
Csendes et al	1988	100	6.8	92%
<i>Balloon dilation</i>				
Sanderson et al	1970	408	...	81%
Vantrappen et al	1979	403	7.8	76%
Okike et al	1979	431	1–18	65%

The second issue is the question of whether a surgical myotomy should be performed through the abdomen or the chest. Myotomy of the LES can be accomplished via either an abdominal or thoracic approach. Recent data suggest that a transabdominal approach is preferable, particularly when done using minimally invasive techniques.

The third issue—and one that has been long debated—is the question of whether an antireflux procedure should be added to a surgical myotomy. A recent preoperative randomized study supports the need for antireflux protection. Further support for an antireflux procedure is the fact that the development of a reflux-induced stricture after an esophageal myotomy is a serious problem, and usually necessitates esophagectomy for relief of symptoms. If an antireflux procedure is used as an adjunct to esophageal myotomy, a complete 360-degree fundoplication should be avoided. Rather, a 270-degree partial fundoplication or a Dor hemifundoplication should be used to avoid the long-term esophageal dysfunction secondary to the outflow obstruction afforded by the fundoplication itself.

Laparoscopic esophageal myotomy. The laparoscopic approach is similar to the Nissen fundoplication in terms of the trocar placement and exposure. The procedure begins by division of the short gastric vessels in preparation for fundoplication. Exposure of the gastroesophageal junction (GEJ) via removal of the gastroesophageal fat pad follows. The anterior vagus nerve is swept right laterally along with the fat pad. Once completed, the GEJ and the left lateral 4–5 cm of esophagus should be bared of any overlying tissue. A left lateral esophageal myotomy is performed. It is generally easiest to begin the myotomy 1–2 cm above the GEJ. Either scissors or a hook-type electrocautery can be used to initiate the incision in the longitudinal and circular muscle. Distally, the myotomy is carried across the GEJ and onto the proximal stomach along the greater curvature for approximately 3 cm. After completion, the muscle edges are separated bluntly from the esophageal mucosa for approximately 50 percent of the esophageal circumference. An antireflux procedure follows completion of the myotomy. A left lateral partial fundoplication that augments the angle of His (Dor) or a posterior lateral partial fundoplication (Toupet) can be performed. The Dor type fundoplication is slightly easier to perform, and does not require disruption of the normal posterior gastroesophageal attachments (a theoretical advantage in preventing postoperative reflux).

Outcome assessment of the therapy for achalasia. Critical analysis of the results of therapy for motor disorders of the esophagus requires objective measurement. The use of symptoms alone as an endpoint to evaluate therapy for achalasia may be misleading. The propensity for patients to unconsciously modify their diet to avoid difficulty swallowing is underestimated, making an assessment of results based on symptoms unreliable. Insufficient reduction in outflow resistance may allow progressive esophageal dilatation to develop slowly, giving the impression of improvement because the volume of food able to be ingested with comfort increases. A variety of objective measurements may be used to assess success, including LES pressure, esophageal baseline pressure, and scintigraphic or time barium swallow assessment of esophageal emptying time. Esophageal baseline pressure is usually negative when compared to gastric pressure. Given that the goal of therapy is to eliminate the outflow resistance of a nonrelaxing sphincter, measurement of improvements in esophageal baseline pressure and transit time may be better indicators of success, but are rarely reported.

TABLE 24-9 Reasons for Failure of Esophageal Myotomy

Reason	Author, procedure (n)		
	Ellis, myotomy only (n = 81)	Goulbourne, myotomy only (n = 65)	Malthaner, myotomy + antireflux (n = 22)
Reflux	4%	5%	18%
Inadequate myotomy	2%	...	9%
Megaesophagus	2%
Poor emptying	4%	3%	...
Persistent chest pain	1%

Source: Data from Malthaner RA, Tood TR, Miller L, Pearson FG: Long-term results in surgically managed esophageal achalasia. *Ann Thorac Surg* 58:1343, 1994; Ellis FH Jr.: Oesophagomyotomy for achalasia: A 22-year experience. *Br J Surg* 80:882, 1993; and Goulbourne IA, Wallbaum PR: Long-term results of Heller's operation for achalasia. *J Royal Coll Surg* 30, 1985.

Bonavina and colleagues reported good to excellent results with trans-abdominal myotomy and Dor fundoplication in 94 percent of patients after a mean follow-up of 5.4 years. No operative mortality occurred in either of these series, attesting to the safety of the procedure. Malthaner and Pearson reported the long-term clinical results in 35 patients with achalasia, having a minimum follow-up of 10 years (Table 24-9). Twenty-two of these patients underwent primary esophageal myotomy and Belsey hemifundoplication at the Toronto General Hospital. Excellent to good results were noted in 95 percent of patients at 1 year, declining to 68, 69, and 67 percent at 10, 15, and 20 years, respectively. Two patients underwent early reoperation for an incomplete myotomy, and three underwent an esophagectomy for progressive disease. They concluded that there was a deterioration of the initially good results after surgical myotomy and hiatal repair for achalasia, which is because of late complications of gastroesophageal reflux.

Ellis reported his lifetime experience with transthoracic short esophageal myotomy without an antireflux procedure. One hundred seventy-nine patients were analyzed at a mean follow-up of 9 years, ranging from 6 months to 20 years. Overall 89 percent of patients were improved at the 9-year mark. He also observed that the level of improvement deteriorated with time, with excellent results (patients continuing to be symptom free) decreasing from 54 percent at 10 years to 32 percent at 20 years. Both studies document nearly identical results 10–15 years following the procedure, and both report deterioration over time, probably because of progression of the underlying disease. The addition of an antireflux procedure if the operation is performed transthoracically has no significant effect on the outcome.

The outcome of laparoscopic myotomy and hemifundoplication has been well documented. Two reports of over 100 patients have documented relief of dysphagia in 93 percent of patients. Richter and coworkers reviewed published reports to date, including 254 patients with an average success rate of 93 percent at 2.5 years. Conversion to an open procedure occurs in 0–5 percent of patients. Complications are uncommon, occurring in less than 5 percent of patients. Intraoperative complications consist largely of mucosal perforation, and have been more likely to occur after botulinum toxin injection.

CARCINOMA OF THE ESOPHAGUS

Squamous carcinoma accounts for the majority of esophageal carcinomas worldwide. Its incidence is highly variable, ranging from approximately 20 per 100,000 in the United States and Britain, to 160 per 100,000 in certain parts of South Africa and the Honan Province of China, and even 540 per 100,000 in the Guriev district of Kazakhstan. The environmental factors responsible for these localized high-incidence areas have not been conclusively identified, although additives to local foodstuffs (nitroso compounds in pickled vegetables and smoked meats) and mineral deficiencies (zinc and molybdenum) have been suggested. In Western societies, smoking and alcohol consumption are strongly linked with squamous carcinoma. Other definite associations link squamous carcinoma with long-standing achalasia, lye strictures, tylosis (an autosomal dominant disorder characterized by hyperkeratosis of the palms and soles), and human papillomavirus.

Adenocarcinoma of the esophagus, once an unusual malignancy, is diagnosed with increasing frequency, and now accounts for over 50 percent of esophageal cancer in most Western countries. The shift in the epidemiology of esophageal cancer from predominantly squamous carcinoma seen in association with smoking and alcohol, to adenocarcinoma in the setting of BE, is one of the most dramatic changes that have occurred in the history of human neoplasia. Although esophageal carcinoma is a relatively uncommon malignancy, its prevalence is exploding, largely secondary to the well-established association between gastroesophageal reflux, BE, and esophageal adenocarcinoma. Once a nearly uniformly lethal disease, survival is improving with advances in surveillance, improvements in staging, and surgical techniques, and possibly neoadjuvant therapy have made clinically relevant improvements in the everyday care of patients.

Furthermore, the clinical picture of esophageal adenocarcinoma is changing. It now occurs not only considerably more frequently, but in younger patients, and is often detected at an earlier stage. These facts support rethinking the traditional approach to patients with the disease. The historical focus on palliation of dysphagia in an older adult patient with comorbidities should change when dealing with a young patient with dependent children and a productive life ahead. The potential for cure becomes of paramount importance.

Microscopically, adenocarcinoma almost always originates in metaplastic Barrett mucosa, and resembles gastric cancer. Rarely it arises in the submucosal glands, and forms intramural growths that resemble the mucoepidermal and adenoid cystic carcinomas of the salivary glands.

The most important etiologic factor in the development of primary adenocarcinoma of the esophagus is a metaplastic columnar-lined or BE, which occurs as a complication in approximately 10–15 percent of patients with GERD. When studied prospectively, the incidence of adenocarcinoma in a patient with BE is one in 100–200 patient-years of follow up (i.e., for every 100 patients with BE followed for 1 year, one will develop adenocarcinoma). Although this risk appears to be small, it is at least 30–40 times that expected for a similar population without BE. This risk is similar to the risk for developing lung cancer in a person with a 20-pack-per-year history of smoking. Endoscopic surveillance for patients with BE is recommended for two reasons: (1) at present there is no reliable evidence that medical therapy removes the risk of neoplastic transformation, and (2) malignancy in BE is curable if detected at an early stage.

Clinical Manifestations

Esophageal cancer generally presents with dysphagia, although increasing numbers of relatively asymptomatic patients are now identified on surveillance endoscopy, and/or present with nonspecific upper GI symptoms and undergo upper endoscopy. Extension of the primary tumor into the tracheobronchial tree can cause stridor, and if a tracheoesophageal fistula develops, coughing, choking, and aspiration pneumonia result. Rarely, severe bleeding from erosion into the aorta or pulmonary vessels occurs. Either vocal cord may be invaded, causing paralysis, but most commonly, paralysis is caused by invasion of the left recurrent laryngeal nerve by the primary tumor or lymph node metastasis. Systemic organ metastases are usually manifested by jaundice or bone pain. The situation is different in high-incidence areas in which screening is practiced. In these communities, the most prominent early symptom is pain on swallowing rough or dry food.

Dysphagia usually presents late in the natural history of the disease, because the lack of a serosal layer on the esophagus allows the smooth muscle to dilate with ease. As a result, the dysphagia becomes severe enough for the patient to seek medical advice only when more than 60 percent of the esophageal circumference is infiltrated with cancer. Consequently, the disease is usually advanced if symptoms herald its presence. Tracheoesophageal fistula may be present in some patients on their first visit to the hospital, and more than 40 percent will have evidence of distant metastases. With tumors of the cardia, anorexia and weight loss usually precede the onset of dysphagia. The physical signs of esophageal tumors are those associated with the presence of distant metastases.

Staging of Esophageal Carcinoma

At the initial encounter with a patient diagnosed as having carcinoma of the esophagus, a decision must be made regarding whether he or she is a candidate for curative surgical therapy, palliative surgical therapy, or nonsurgical palliation. Making this decision is difficult, because evaluating the pretreatment disease stage of esophageal carcinoma is imprecise because of the difficulty of measuring the depth of tumor penetration of the esophageal wall and the inaccessibility of the organ's widespread lymphatic drainage.

The introduction of endoscopic ultrasound has made it possible to identify patients who are potentially curable prior to surgical therapy. Using an endoscope, the depth of the wall penetration by the tumor and the presence of five or more lymph node metastases can be determined with 80 percent accuracy. A curative resection should be encouraged if endoscopic ultrasound indicates that the tumor has not invaded adjacent organs, and/or fewer than five enlarged lymph nodes are imaged. Thoracoscopic and laparoscopic staging of esophageal cancer have been recommended; preliminary results indicate that using these techniques, correct staging of esophageal carcinomas approaches 90 percent. If these results are confirmed and the cost is not prohibitive, then thoracoscopic and laparoscopic staging are likely to become valuable tools to determine the extent of disease prior to therapy. At the present time, despite the modern techniques of computed tomography, magnetic resonance imaging, endoscopic ultrasound, and laparoscopic and thoracoscopic technology, pretreatment staging still remains imprecise. This underscores the need for an intraoperative assessment of the potential for cure in each individual patient.

Experience with esophageal resections in patients with early disease has identified characteristics of esophageal cancer that are associated with improved survival. A number of studies suggest that only metastasis to lymph nodes and tumor penetration of the esophageal wall have a significant and independent influence on prognosis. The beneficial effects of the absence of one factor persists, even when the other is present. Factors known to be important in the survival of patients with advanced disease, such as cell type, degree of cellular differentiation, or location of tumor in the esophagus, have no effect on survival of patients who have undergone resection for early disease. Studies also showed that patients having five or fewer lymph node metastases have a better outcome.

Clinical Approach to Carcinoma of the Esophagus and Cardia

The selection of a curative versus a palliative operation for cancer of the esophagus is based on the location of the tumor, the patient's age and health, the extent of the disease, and intraoperative staging.

Tumor Location

The selection of surgical therapy for patients with carcinoma of the esophagus depends not only on the anatomic stage of the disease and an assessment of the swallowing capacity of the patient, but also on the location of the primary tumor.

It is estimated that 8 percent of the primary malignant tumors of the esophagus occur in the cervical portion. They are almost always squamous cell lesions, with a rare adenocarcinoma arising from a congenital inlet patch of columnar lining. These tumors, particularly those in the postcricoid area, represent a separate pathologic entity for a number of reasons: (1) they are more common in females and appear to be a unique entity in this regard; and (2) the efferent lymphatics from the cervical esophagus drain completely differently from those of the thoracic esophagus. The latter drain directly into the paratracheal and deep cervical or internal jugular lymph nodes with minimal flow in a longitudinal direction. Except in advanced disease, it is unusual for intrathoracic lymph nodes to be involved.

Low cervical lesions that reach the level of the thoracic inlet are usually unresectable because of early invasion of the great vessels and trachea. The length of the esophagus below the cricopharyngeus is insufficient to allow intubation or construction of a proximal anastomosis for a bypass procedure. Consequently, palliation of these tumors is difficult, and patients afflicted with disease at this site have a poor prognosis. Upper airway obstruction or the development of tracheoesophageal fistulas in such tumors may require surgical intervention for palliation. If possible, these tumors should be resected after a preoperative course of chemoradiotherapy has reduced their size.

Tumors that arise within the middle or upper third of the thoracic esophagus lie too close to the trachea and aorta to allow an en bloc resection without removal of these vital structures. Consequently, in this location only tumors that have not penetrated through the esophageal wall and have not metastasized to the regional lymph nodes are potentially curable. The resection for a tumor at this level is done similarly whether for palliation or cure, and long-term survival is a chance phenomenon. This does not mean that when resecting such tumors, efforts to remove the adjacent lymph nodes should be abandoned. To do so may inadvertently leave unrecognized metastatic disease behind and

compromise the patient's overall survival, because of recurrent local disease and compression of the trachea. It is recommended that a course of preoperative chemoradiotherapy should be given before resection to shrink the size of the tumor. It is recommended that the radiotherapy be limited to 3.5 Gy to allow for tissue healing after surgery.

Tumors of the lower esophagus and cardia are usually adenocarcinomas. However, squamous cell carcinoma of the lower esophagus does occur. Both types of tumor are amenable to en bloc resection. Unless preoperative and intraoperative staging clearly demonstrates an incurable lesion, an en bloc resection in continuity with a lymph node dissection should be performed. Because of the propensity of GI tumors to spread for long distances submucosally, long lengths of grossly normal GI tract should be resected. The longitudinal lymph flow in the esophagus can result in skip areas, with small foci of tumor above the primary lesion, which underscores the importance of a wide resection of esophageal tumors. Wong has shown that local recurrence at the anastomosis can be prevented by obtaining a 10-cm margin of normal esophagus above the tumor. Anatomic studies have also shown that there is no submucosal lymphatic barrier between the esophagus and the stomach at the cardia.

Cardiopulmonary Reserve

Patients undergoing esophageal resection should have sufficient cardiopulmonary reserve to tolerate the proposed procedure. The respiratory function is best assessed with the forced expiratory volume in 1 second (FEV-1), which ideally should be 2 L or more. Any patient with an FEV-1 of less than 1.25 L is compromised for surgery. Clinical evaluation and electrocardiogram are not sufficient indicators of cardiac reserve. Echocardiography and dipyridamole thallium imaging provide accurate information on wall motion, ejection fraction, and myocardial blood flow. A defect on thallium imaging may require further evaluation with preoperative coronary angiography. A resting ejection fraction of less than 40 percent, particularly if there is no increase with exercise, is an ominous sign.

Clinical Stage

Clinical factors that indicate an advanced stage of carcinoma and exclude surgery with curative intent are recurrent nerve paralysis, Horner syndrome, persistent spinal pain, paralysis of the diaphragm, fistula formation, and malignant pleural effusion. Factors that make surgical cure unlikely include a tumor greater than 8 cm in length, abnormal axis of the esophagus on a barium radiogram, multiple enlarged lymph nodes on computed tomography (CT), a weight loss more than 20 percent, and loss of appetite. In patients in whom these findings are not present, staging depends primarily on the degree of wall penetration and lymph node metastasis seen with endoscopic ultrasound.

Surgical Treatment

A patient's nutritional status before surgery has a profound effect on the outcome of an esophageal resection. Low serum protein levels have a deleterious effect on the cardiovascular system, and a poor nutritional status affects the host resistance to infection and the rate of anastomotic and wound healing. A serum albumin level of less than 3.4 g/dL on admission indicates poor caloric intake and an increased risk of surgical complications, including
