anastomotic breakdown. A feeding jejunostomy tube provides the most reliable and safest method for nutritional support in patients who cannot consume an oral diet and have a functionally normal small bowel. In severely malnourished patients, the jejunostomy is performed as a separate procedure to allow for preoperative nutritional support. In these patients the abdomen is entered through a small supraumbilical midline incision. Otherwise, the jejunostomy tube is placed at the time of esophageal resection, and feeding is begun on the third postoperative day.

Control of the local and regional disease forms the basis for the classic en bloc resection. Nodal recurrence in the field of the resection following en bloc resection is only 1 percent. Six to 10 percent of patients will develop nodes lying along the recurrent laryngeal nerve chains, which are not routinely removed. Performing a more extended mediastinal dissection combined with a radical neck dissection has been advocated by some authors. The increased morbidity and the possibility of permanent hoarseness associated with this approach have discouraged its widespread application. It has been reported that the finding of metastatic disease involving the celiac nodes precludes survival beyond 2 years. By contrast, other authors have reported prolonged survival in patients with celiac axis involvement.

Cervical and Upper Thoracic Esophageal Cancer

It was hoped that the prognosis for patients with cervical esophageal cancer might be better than for those with carcinoma of the thoracic esophagus, but this has not proved to be the case. Early experience with resection of the cervical esophagus resulted in a high mortality rate, and reconstruction by neck flaps often required multiple operations. Because of these complexities and the generally disappointing results, radiotherapy frequently was elected. Immediate mortality decreased, but control of the tumor was not satisfactory.

The difference between the two forms of therapy is the manner in which the disease recurs. Tumors treated with radiation therapy initially tend to recur locally and systemically, and cause unmanageable local disease with eventual erosion into neck vessels and trachea, causing hemorrhage and dyspnea. Patients who undergo surgical therapy have few local recurrences of the tumor, provided total excision is possible, but they succumb to metastatic disease. Collin has reported a local failure rate of 80 percent after definitive radiation therapy, and 20 percent of these patients required palliative surgery to control the disease locally. Improvements in the techniques of immediate esophageal reconstruction have reduced the complications of the surgical treatment of this disease and encouraged a more aggressive surgical approach. The data reported by Collin suggest that an initial aggressive surgical resection yields longer survival than radiation therapy. Positive surgical margins, tracheal invasion that cannot be removed, and vocal cord paralysis correlate with a significantly shorter survival following surgery. Palliation was better achieved in patients who underwent esophagectomy with immediate gastric pull-up than in those who underwent primary radiation therapy or chemotherapy.

Lesions that are not fixed to the spine, do not invade the vessels or trachea, and do not have fixed cervical lymph node metastases should be resected. If lymph node metastases are present or the tumor comes in close proximity to the cricopharyngeus muscle, a course of preoperative chemo- and radiotherapy should be given before surgical resection. This usually consists of two to three cycles of chemotherapy and no more than 3.5 Gy of radiation therapy.

Neoadjuvant therapy is given in an attempt to salvage the larynx, because the larynx is often invaded by microscopic tumors, and in the past, a total laryngectomy in combination with esophagectomy was usually necessary. A simultaneous en bloc dissection of the superior mediastinum and cervical lymph nodes is done, sparing the jugular veins on both sides.

Tumors in the upper thoracic esophagus are removed via a right posterolateral thoracotomy with a corresponding lymphadenectomy. The continuity of the GI tract is re-established by pulling the stomach up through the esophageal bed. If removing the larynx is necessary, a permanent tracheostomy stoma is constructed in the lower flap of the cervical incision. The division of the trachea in some patients may preclude the possibility of a permanent cervical standard tracheostomy, because the remaining tracheal stump distal to the tumor will not reach the suprasternal notch. Removal of the medial head of the clavicles and the manubrium down to the sternal angle of Louis provides excellent exposure and allows the construction of a mediastinal tracheostomy. A bipedicle skin flap over the pectoralis muscle can be advanced upward, or a single-pedicle musculocutaneous flap including the pectoralis muscle and its overlying skin can be rotated to cover the defect. A circular incision in the flap can be used as a port through which the tracheal remnant is brought out to the skin.

Tumors of the Thoracic Esophagus and Cardia

For tumors that arise below the carina, the preference is either an en bloc resection for cure or a transhiatal removal for palliation. A curative procedure is performed according to the principles of an en bloc resection in continuity with the regional lymph nodes. It is attempted in a patient whose preresection physical condition and tumor characteristics have the potential for long-term survival. The en bloc resection is done through three incisions in the following order: (1) right posterolateral thoracotomy, en bloc dissection of the distal esophagus, mobilization of the esophagus above the aortic arch, closure of the thoracotomy, repositioning of the patient in the recumbent position; (2) upper midline abdominal incision, en bloc dissection of the stomach and associated lymph nodes; and (3) left neck incision and proximal division of the esophagus. The specimen is removed transhiatally and the stomach is tubed, preserving the antrum. GI continuity is re-established with a cervical esophagogastric anastomosis. A standard left thoracotomy with intrathoracic anastomosis for lower lesions or an Ivor Lewis combined approach for higher lesions is not advocated because of (1) the proven need to resect long lengths of the esophagus to eradicate submucosal spread, (2) the higher morbidity associated with a thoracic anastomotic leak, and (3) the high incidence of esophagitis secondary to reflux following an intrathoracic anastomosis.

En Bloc Esophagogastric Resection versus Transhiatal Resection for Carcinoma of the Lower Esophagus and Cardia

Many strategies for treatment of esophageal carcinoma limit the role of surgery to removing the primary tumor, with the hope that adjuvant therapy will increase cure rates by destroying systemic disease. This approach emphasizes the concept of biological determinism (i.e., that the outcome of treatment in esophageal cancer is determined at the time of diagnosis, and that surgical therapy aimed at removing more than the primary tumor is not helpful). Lymph node metastases are considered simply markers of systemic disease; the systematic removal of involved nodes is not considered beneficial. The belief that

removal of the primary tumor by transhiatal esophagogastrectomy results in the same survival rates as a more extensive en bloc resection is based on the same kind of reasoning.

In the transhiatal procedure there is no specific attempt made to remove lymph node-bearing tissue in the posterior mediastinum. By contrast, the en bloc esophagectomy removes the tumor covered on all surfaces with a layer of normal tissue. A long length of foregut above and below the lesion is resected to incorporate submucosal spread of the tumor. Appropriate cervical mediastinal and abdominal lymph node dissections are included using an en bloc technique to remove potentially involved regional nodes.

Hagen and colleagues recently reviewed 100 consecutive patients who underwent en bloc esophagectomy for esophageal adenocarcinoma. No patient received pre- or postoperative chemotherapy or radiation therapy. The aim of the study was to relate the extent of disease to prognostic features, timing and mode of recurrence, and survival following en bloc resection. The median follow-up of surviving patients was 40 months, with 24 patients surviving 5 years or more. Overall actuarial survival at 5 years was 52 percent. Fifty-five of the tumors were transmural and 63 patients had lymph node involvement. Metastases to celiac ($n = 16$) or other distant node sites ($n = 26$) were not associated with decreased survival. Remarkably, local recurrence was seen in only one patient. Latent nodal recurrence outside the surgical field occurred in nine, and systemic metastases in 31. The authors concluded that long-term survival from adenocarcinoma of the esophagus can be achieved in over half of the patients who undergo en bloc resection. One-third of patients with lymph node involvement survived 5 years, and the authors concluded that local control is excellent following en bloc resection.

Controversy persists over the extent of resection necessary for cure of esophageal adenocarcinoma. Several retrospective studies have shown a benefit to the more extensive node dissection accomplished with a transthoracic en bloc esophagectomy as compared to the transhiatal esophagectomy. These studies have been criticized as suffering from selection bias and for inaccuracy in preoperative staging. Performance of a more complete node dissection also results in the potential for stage migration. Hulscher has reported a prospective randomized control trial that compared transthoracic en bloc to transhiatal esophagectomy. The results were inconclusive but showed a trend toward better survival with the en bloc resection. This trial eliminated many of the criticisms of the retrospective studies but included patients with various stages of disease. This may have obscured the benefits of systematic node dissection by the unequal distribution of patients with early stage disease who did not need a formal lymphadenectomy, and those with advanced disease with extensive lymph node metastases who were not curable by surgery alone. An alternative approach to compare transthoracic en bloc to transhiatal resection has been done by Johansson using a retrospective case control study between nonrandomized patients having similar size transmural (T3) tumors with lymph node metastases (N1). The aim of the study was to determine whether patients with locally advanced (T3N1) esophageal cancer benefit from the performance of a transthoracic en bloc resection. This approach removes the influence of inaccurate preoperative staging and minimizes the influence of postoperative stage migration on survival because all patients had N1 disease. Further, all patients had 20 or more lymph nodes in the surgical specimen which allowed confirmation that the extent of lymph node disease in both groups was comparable. These conditions focused the question regarding which procedure

was associated with a better survival. The results, show that a transthoracic en bloc resection confers a survival benefit over a transhiatal resection in patients with transmural (T3) esophageal carcinomas when eight or fewer lymph nodes are involved (N1). The most likely explanation for the improved survival following transthoracic en bloc resection is a more complete removal of local-regional disease, which is unrecognized disease that is removed with an en bloc lymph node dissection but left behind with a transhiatal lymph node dissection. Consequently, transthoracic en bloc resection results in better control of local-regional disease. Indeed, in clinical trials neoadjuvant radiochemotherapy has been added to transhiatal esophagectomy in an effort to control local-regional disease without great success. A more prudent approach would be to use a transthoracic en bloc dissection to control local-regional disease and focus postoperative adjuvant therapy on eliminating systemic disease.

These studies showed that for early cancers of the lower esophagus and cardia, en bloc esophagogastrectomy results in significantly better survival rates than transhiatal esophagogastrectomy. This finding cannot be explained by a bias in the stage of disease resected, a difference in operative mortality, or death from nontumor causes. Rather, it appears to be because of the type of operation performed. Ideally, the question regarding which procedure is the best should be resolved by a prospective randomized study of similarly staged patients.

Extent of Resection to Cure Disease Confined to the Mucosa

The development of surveillance programs for the detection of early squamous cell carcinoma in endemic areas and for early adenocarcinoma in patients with BE has given rise to controversy over how to manage tumors confined to the mucosa. Some authors have endoscopically resected squamous carcinomas after using endoscopic ultrasound to determine that the depth of the tumor was limited to the mucosa. Surprisingly, large areas of squamous mucosa can be resected without perforation or bleeding, leaving the smooth surface of the muscularis mucosae intact. Re-epithelialization of the large artificially induced ulcer is usually complete in 3 weeks. In order not to miss a squamous cancer that has invaded deeper than expected, it is important to examine the deep margins of the resected specimen carefully, and to perform periodic endoscopic follow-up examinations with vital staining techniques. This technique is not appropriate for multiple and widespread or circumferential squamous lesions because of the risk of developing a stricture during the healing process. In this situation, those acquainted with endoscopic resection would advocate an esophagectomy.

Several studies have shown that intraepithelial carcinoma (i.e., carcinoma in situ or high-grade dysplasia), and intramucosal tumors (i.e., invasive cancer limited by the muscular mucosae), are quite different in their biologic behavior from submucosal tumors. This disfunction is independent of histology (squamous or adenocarcinoma) and histologic grade. Vessel invasion and lymph node metastasis do not occur in severe dysplasia, are uncommon in the intramucosal tumors, but are the rule in submucosal tumors. Consequently, the 5-year survival for intramucosal tumors is significantly better than for submucosal tumors. These findings indicate that both severe dysplasia and intramucosal cancers represent early malignant lesions of the esophagus. A critical issue to be resolved is whether an intramucosal tumor can be correctly

discriminated from a submucosal tumor before surgery. The results of using endoscopic ultrasound for determining the depth of tumors confined to the esophageal wall are of questionable accuracy. The resolution of present-day endoscopic ultrasonographic systems is not sufficient to predictably differentiate the fine detail of tumor infiltration when it is limited to the esophageal wall. Currently there is no dependable way, before surgery, of determining whether a tumor extends beyond the muscularis mucosae.

Another complicating factor is that up to 5 percent of patients with intramucosal tumors have lymph node metastases, although the number of involved nodes per patient is usually no more than one. Akiyama and others have reported that even though the number of involved nodes may be small, they can spread to distant nodal regions, including cervical and abdominal nodes.

We have recently used the presence or absence of an endoscopically visible lesion in patients with biopsy-proven high-grade dysplasia (HGD) or intramucosal carcinoma as a predictor of tumor depth and nodal metastases. The data indicate that a positive biopsy in the absence of an endoscopically visible lesion almost always corresponds to an intramucosal tumor without nodal metastases. Of patients with HGD, 43 percent proved to harbor occult adenocarcinoma at resection. Importantly, when there was no visible lesion on endoscopy, 88 percent of the tumors were intramucosal and 12 percent submucosal. Only one of 10 patients with no visible lesion had lymph node involvement, either histologically or immunohistochemically. In contrast, patients with endoscopically visible tumors had a high prevalence of tumors that penetrated beyond the mucosa (75 percent), and 56 percent had positive nodes.

Patients with HGD and intramucosal carcinoma are best treated by a total esophagectomy, removing all Barrett tissue and any potential associated adenocarcinoma. Options include transhiatal esophagectomy, or more recently, vagal-sparing esophagectomy. The vagal-sparing approach is suitable only given confidence of the absence of regional nodal disease. Reconstruction is accomplished with either the stomach (transhiatal) or colon (vagal sparing) with the anastomosis in the neck. The mortality associated with this procedure should be less than 5 percent, particularly in centers experienced in esophageal surgery. Functional recovery is excellent, particularly in the vagal-sparing group.

As the understanding of the pathology of esophageal cancer improves and experience with its resection increases, evidence is accumulating that the best chance for cure of patients with an intramural tumor in the distal esophagus or cardia is an en bloc esophagectomy and proximal gastrectomy, with GI continuity re-established with a either gastric or colon interposition. For patients with a tumor in the upper or cervical esophagus, the best chance for cure is an en bloc esophagectomy and a cervical lymph node dissection with GI continuity re-established with a gastric pull-up. Table 24-10 presents a summary of the extent of resection for tumors extending various depths into the esophageal wall.

Alternative Therapies

Radiation Therapy

Primary treatment with radiation therapy does not produce results comparable with those obtained with surgery. Currently, the use of radiotherapy is restricted to patients who are not candidates for surgery. Palliation of dysphagia is short

TABLE 24-10 Recommended Surgical Therapy for Esophageal Carcinoma

Lesion	Resection
1. Confined areas of high-grade dysplasia (intraepidermal cancer)	Endoscopic mucosal resection (at present only applicable to squamous carcinoma).
2. Widespread or circumferential area of high-grade dysplasia (intraepidermal cancer)	Transhiatal or vagal sparing esophagectomy.
3. Tumor invading through the basement membrane but not through the muscularis mucosae (intramucosal tumors)	Transhiatal or vagal sparing esophagectomy.
4. Tumor deeper than the muscularis mucosae but not through the esophageal wall (intramural tumors)	En bloc esophagectomy with appropriate systematic lymphadenectomy of the cervical, upper mediastinal (above the tracheal bifurcation), lower mediastinal (below the tracheal bifurcation) and abdominal nodes. (For upper and middle third cancers, mediastinal dissection must include the node along the left recurrent laryngeal nerve. For lower third esophageal and cardia cancers, omit cervical and upper mediastinal node dissection, but include the proximal stomach in the resection. For upper third esophageal cancers, omit abdominal lymph node dissection.) Reconstruction with gastric pull-up for middle and upper third tumors, and with colon interposition for lower third and cardia tumors that involve a segmental portion of the stomach.
5. Tumor extending through the muscularis propria (transmural tumors)	Same as for intramural tumors.

term, generally lasting only 2–3 months. Furthermore, the length and course of treatment are difficult to justify in patients with a limited life expectancy. Consequently there is a reluctance to treat patients with advanced disease.

Adjuvant Chemotherapy

The proposal to use adjuvant chemotherapy in the treatment of esophageal cancer began when it became evident that most patients develop postoperative systemic metastasis without local recurrence. This observation led to the hypothesis that undetected systemic micrometastasis had been present at the time of diagnosis, and if effective systemic therapy was added to local regional therapy, survival should improve.

Recently this hypothesis has been supported by the observation of epithelial tumor cells in the bone marrow in 37 percent of patients with esophageal cancer who were resected for cure. These patients had a greater prevalence of relapse at 9 months after surgery compared to those patients without such cells. Such

studies emphasize that hematogenous dissemination of viable malignant cells occurs early in the disease, and that systemic chemotherapy may be helpful if the cells are sensitive to the agent. On the other hand, systemic chemotherapy may be a hindrance, because of its immunosuppressive properties, if the cells are resistant. Unfortunately, current technology is not able to test tumor cell sensitivity to chemotherapeutic drugs. This requires that the choice of drugs be made solely on the basis of their clinical effectiveness against grossly similar tumors.

The decision to use preoperative rather than postoperative chemotherapy was based on the ineffectiveness of chemotherapeutic agents when used after surgery, and animal studies suggesting that agents given before surgery were more effective. The claim that patients who receive chemotherapy before resection are less likely to develop resistance to the drugs is unsupported by hard evidence. The claim that drug delivery is enhanced because blood flow is more robust before patients undergo surgical dissection is similarly flawed, because of the fact that if enough blood reaches the operative site to heal the wound or anastomosis, then the flow should be sufficient to deliver chemotherapeutic drugs. There are, however, data supporting the claim that preoperative chemotherapy in patients with esophageal carcinoma can, if effective, facilitate surgical resection by reducing the size of the tumor. This is particularly beneficial in the case of squamous cell tumors above the level of the carina. Reducing the size of the tumor may provide a safer margin between the tumor and the trachea, and allow an anastomosis to a tumor-free cervical esophagus just below the cricopharyngeus. Involved margin at this level usually requires a laryngectomy to prevent subsequent local recurrence.

Preoperative chemotherapy. Three randomized prospective studies with squamous cell carcinoma have shown no survival benefit with preoperative chemotherapy over surgery alone (Table 24-11). This includes a recent U.S. trial reported by Kelson. The possibility that preoperative neoadjuvant 5-fluorouracil (5-FU)/platinum-based chemotherapy may indeed provide a small benefit was recently raised by a medical research council trial in the United Kingdom. This trial is one of the few to include enough patients (800) to detect small differences. Two-thirds had adenocarcinoma and distal third tumors. The trial had a 10 percent absolute survival benefit at 2 years for the neoadjuvant chemotherapy group.

With the exception of the potential to improve resectability of tumors located above the carina, the benefits cited by those in favor of preoperative chemotherapy are questionable. Preoperative chemotherapy alone potentially can downstage the tumor, particularly squamous cell carcinoma. It can also potentially eliminate or delay the appearance of metastasis. There is little evidence, however, that it can prolong survival of patients with resectable carcinoma of the esophagus. Most failures are because of distant metastatic disease, underscoring the need for improved systemic therapy. Postoperative septic and respiratory complications may be more common in patients receiving chemotherapy.

Preoperative combination chem- and radiotherapy. Preoperative chemoradiotherapy using cisplatin and 5-FU in combination with radiotherapy has been reported by several investigators to be beneficial in both adenomatous and squamous cell carcinoma of the esophagus. There has been six randomized prospective studies: four with squamous cell carcinoma, one with both

TABLE 24-11 Esophageal Carcinoma: Randomized Preoperative Chemotherapy Versus Surgery Alone

Author	Year	No. preop chemotherapy/no. surgery alone	Cell type	Regimen	Complete response to chemotherapy	Survival chemotherapy vs. surgery alone
Roth	1988	19/20	Squamous	P, V, B	6%	NS
Nygaard	1992	50/41	Squamous	P, B	...	NS
Schlag	1992	21/24	Squamous	P, 5-FU	5%	NS

Kelson	1998	233/234	Squamous and adenomatous	P, 5-FU	2.5%	NS

B = bleomycin; 5-FU = 5-fluorouracil; NS = not significant; P = cisplatin; V = vindesine.

squamous and adenocarcinoma, and one with only adenocarcinoma (Table 24-12). Only one showed any survival benefit with preoperative chemoradiotherapy over surgery alone. Most authors report substantial morbidity and mortality to the treatment. However, many have been encouraged by the observation that some patients who had a complete response had remained free of recurrence at 3 years.

Caution must be exercised in trying to isolate the effects of chemotherapy, because the addition of preoperative radiation therapy to chemotherapy elevates the complete response rate and inflates the benefit of chemotherapy. With chemoradiation the complete response rates for adenocarcinoma range from 17–24 percent (Table 24-13). When radiation is removed, the complete response falls to 0–5 percent, which suggests that the effects of chemotherapy are negligible. If radiotherapy is the factor responsible for the improved response rate, surgery alone could do the job as well, because numerous studies in the past have shown that the combination of surgery and radiation does not provide any survival advantages.

The better question is whether a patient with carcinoma of the esophagus should go through three cycles of chemotherapy on the 5 percent chance that they may get a complete response in the primary tumor, and in the face of the paucity of evidence that such a response controls systemic disease. Studies have shown that the rates of infection, anastomotic breakdown, incidence of acute respiratory distress syndrome, and long-term use of a respirator were greater in patients receiving adjuvant therapy as compared with surgery alone.

Current data support giving chemoradiotherapy as a matter of routine in a limited number of clinical settings, including: (1) preoperatively to reduce tumor size in a young person with surgically incurable squamous cell carcinoma above the carina, and (2) chemotherapy as salvage therapy for patients who have not had previous chemotherapy and develop recurrent systemic disease after surgical resection. Adjuvant therapy in patients not in those categories should be limited to the setting of a controlled clinical trial. At present, the strongest predictors of outcome of patients with esophageal cancer are the anatomic extent of the tumor at diagnosis and the completeness of tumor removal by surgical resection. After incomplete resection of an esophageal cancer, the 5-year survival rates are 0–5 percent. In contrast, after complete resection, independent of stage of disease, 5-year survival ranges from 15–40 percent, according to selection criteria and stage distribution. The importance of early recognition and adequate surgical resection cannot be overemphasized.

BENIGN TUMORS AND CYSTS

Benign tumors and cysts of the esophagus are relatively uncommon. From the perspectives of both the clinician and the pathologist, benign tumors may be divided into those that are within the muscular wall and those that are within the lumen of the esophagus.

Intramural lesions are either solid tumors or cysts, and the vast majority are leiomyomas. They are made up of varying portions of smooth muscle and fibrous tissue. Fibromas, myomas, fibromyomas, and lipomyomas are closely related and occur rarely. Other histologic types of solid intramural tumors have been described, such as lipomas, neurofibromas, hemangiomas, osteochondromas, granular cell myoblastomas, and glomus tumors, but they are medical curiosities.

TABLE 24-12 Esophageal Carcinoma: Randomized Preoperative Chemo- or Radiotherapy Versus Surgery Alone

Intraluminal lesions are polypoid or pedunculated growths that usually originate in the submucosa, develop mainly into the lumen, and are covered with normal stratified squamous epithelium. The majority of these tumors are composed of fibrous tissue of varying degrees of compactness with a rich vascular supply. Some are loose and myxoid (e.g., myxoma and myxofibroma), some are more collagenous (e.g., fibroma), and some contain adipose tissue (e.g., fibrolipoma). These different types of tumor are frequently collectively designated as fibrovascular polyps, or simply as polyps. Pedunculated intraluminal tumors should be removed. If the lesion is not too large, endoscopic removal with a snare is feasible.

Leiomyoma

Leiomyomas constitute more than 50 percent of benign esophageal tumors. The average age at presentation is 38, which is in sharp contrast to that seen with esophageal carcinoma. Leiomyomas are twice as common in males. Because they originate in smooth muscle, 90 percent are located in the lower two thirds of the esophagus. They are usually solitary, but multiple tumors have been found on occasion. They vary greatly in size and shape. Tumors as small as 1 cm in diameter and as large as 10 lb have been removed.

Typically, leiomyomas are oval. During their growth, they remain intramural, having the bulk of their mass protruding toward the outer wall of the esophagus. The overlying mucosa is freely movable and normal in appearance. Neither their size nor location correlates with the degree of symptoms. Dysphagia and pain are the most common complaints, the two symptoms occurring more frequently together than separately. Bleeding directly related to the tumor is rare, and when hematemesis or melena occurs in a patient with an esophageal leiomyoma, other causes should be investigated.

A barium swallow is the most useful method to demonstrate a leiomyoma of the esophagus. In profile the tumor appears as a smooth, semilunar, or crescent-shaped filling defect that moves with swallowing, is sharply demarcated, and is covered and surrounded by normal mucosa. Esophagoscopy should be performed to exclude the reported observation of a coexistence with carcinoma. The freely movable mass, which bulges into the lumen, should not be biopsied because of an increased chance of mucosal perforation at the time of surgical enucleation.

Despite their slow growth and limited potential for malignant degeneration, leiomyomas should be removed unless there are specific contraindications. The majority can be removed by simple enucleation. If during removal the mucosa is inadvertently entered, the defect can be repaired primarily. After tumor removal, the outer esophageal wall should be reconstructed by closure of the muscle layer. The location of the lesion and the extent of surgery required will dictate the approach. Lesions of the proximal and middle esophagus require a right thoracotomy, whereas distal esophageal lesions require a left thoracotomy. Videothoroscopic approaches have been reported. The mortality rate associated with enucleation is less than 2 percent, and success in relieving the dysphagia is near 100 percent. Large lesions or those involving the gastroesophageal junction may require esophageal resection.

ESOPHAGEAL PERFORATION

Perforation of the esophagus constitutes a true emergency. It most commonly occurs following diagnostic or therapeutic procedures. Spontaneous perforation, referred to as Boerhaave syndrome, accounts for only 15 percent

of cases of esophageal perforation, foreign bodies for 14 percent, and trauma for 10 percent. Pain is a striking and consistent symptom and strongly suggests that an esophageal rupture has occurred, particularly if located in the cervical area following instrumentation of the esophagus, or substernally in a patient with a history of resisting vomiting. If subcutaneous emphysema is present, the diagnosis is almost certain.

Spontaneous rupture of the esophagus is associated with a high mortality rate because of the delay in recognition and treatment. Although there usually is a history of resisting vomiting, in a small number of patients the injury occurs silently, without any antecedent history. When the chest radiogram of a patient with an esophageal perforation shows air or an effusion in the pleural space, the condition is often misdiagnosed as a pneumothorax or pancreatitis. An elevated serum amylase caused by the extrusion of saliva through the perforation may fix the diagnosis of pancreatitis in the mind of an unwary physician. If the chest radiogram is normal, a mistaken diagnosis of myocardial infarction or dissecting aneurysm is often made.

Spontaneous rupture usually occurs into the left pleural cavity or just above the gastroesophageal junction. Fifty percent of patients have concomitant gastroesophageal reflux disease, suggesting that minimal resistance to the transmission of abdominal pressure into the thoracic esophagus is a factor in the pathophysiology of the lesion. During vomiting, high peaks of intragastric pressure can be recorded, frequently exceeding 200 mmHg, but because extragastric pressure remains almost equal to intragastric pressure, stretching of the gastric wall is minimal. The amount of pressure transmitted to the esophagus varies considerably, depending on the position of the gastroesophageal junction. When it is in the abdomen and exposed to intraabdominal pressure, the pressure transmitted to the esophagus is much less than when it is exposed to the negative thoracic pressure. In the latter situation, the pressure in the lower esophagus will frequently equal intragastric pressure if the glottis remains closed. Cadaver studies have shown that when this pressure exceeds 150 mmHg, rupture of the esophagus is apt to occur. When a hiatal hernia is present and the sphincter remains exposed to abdominal pressure, the lesion produced is usually a Mallory-Weiss mucosal tear, and bleeding rather than perforation is the problem. This is because of the stretching of the supradiaphragmatic portion of the gastric wall. In this situation, the hernia sac represents an extension of the abdominal cavity, and the gastroesophageal junction remains exposed to abdominal pressure.

Diagnosis

Abnormalities on the chest radiogram can be variable and should not be depended on to make the diagnosis. This is because the abnormalities are dependent on three factors: (1) the time interval between the perforation and the radiographic examination, (2) the site of perforation, and (3) the integrity of the mediastinal pleura. Mediastinal emphysema, a strong indicator of perforation, takes at least 1 hour to be demonstrated, and is present in only 40 percent of patients. Mediastinal widening secondary to edema may not occur for several h. The site of perforation also can influence the radiographic findings. In cervical perforation, cervical emphysema is common and mediastinal emphysema rare; the converse is true for thoracic perforations. Frequently, air will be visible in the erector spinae muscles on a neck radiogram before it can be palpated or seen on a chest radiogram. The integrity of the mediastinal

pleura influences the radiographic abnormality in that rupture of the pleura results in a pneumothorax, a finding that is seen in 77 percent of patients. In two-thirds of patients the perforation is on the left side, in one fifth it is on the right side, and in one tenth it is bilateral. If pleural integrity is maintained, mediastinal emphysema (rather than a pneumothorax) appears rapidly. A pleural effusion secondary to inflammation of the mediastinum occurs late. In 9 percent of patients the chest radiogram is normal.

The diagnosis is confirmed with a contrast esophagogram, which will demonstrate extravasation in 90 percent of patients. The use of a water-soluble medium such as Gastrografin is preferred. Of concern is that there is a 10 percent false-negative rate. This may be because of obtaining the radiographic study with the patient in the upright position. When the patient is upright, the passage of water-soluble contrast material can be too rapid to demonstrate a small perforation. The studies should be done with the patient in the right lateral decubitus position. In this position the contrast material fills the entire length of the esophagus, allowing the actual site of perforation and its interconnecting cavities to be visualized in almost all patients.

Management

The key to optimum management is early diagnosis. The most favorable outcome is obtained following primary closure of the perforation within 24 h, resulting in 80–90 percent survival. The most common location for the injury is the left lateral wall of the esophagus, just above the gastroesophageal junction. To get adequate exposure of the injury, a dissection similar to that described for esophageal myotomy is performed. A flap of stomach is pulled up and the soiled fat pad at the gastroesophageal junction is removed. The edges of the injury are trimmed and closed using a modified Gambee stitch. The closure is reinforced by the use of a pleural patch or construction of a Nissen fundoplication.

Mortality associated with immediate closure varies between 8 and 20 percent. After 24 h survival, decreases to less than 50 percent, and is not influenced by the type of operative therapy (i.e., drainage alone or drainage plus closure of the perforation). If the time delay prior to closing a perforation approaches 24 h and the tissues are inflamed, division of the cardia and resection of the diseased portion of the esophagus are recommended. The remainder of the esophagus is mobilized, and as much normal esophagus as possible is saved and brought out as an end cervical esophagostomy. In some situations the retained esophagus may be so long that it loops down into the chest. The contaminated mediastinum is drained and a feeding jejunostomy tube is inserted. The recovery from sepsis is often immediate, dramatic, and reflected by a marked improvement in the patient's condition over a 24-h period. On recovery from the sepsis, the patient is discharged and returns on a subsequent date for reconstruction with a substernal colon interposition. Failure to apply this aggressive therapy can result in a mortality rate in excess of 50 percent in patients in whom the diagnosis has been delayed.

Nonoperative management of esophageal perforation has been advocated in select situations. The choice of conservative therapy requires skillful judgment and necessitates careful radiographic examination of the esophagus. This course of management usually follows an injury occurring during dilation of esophageal strictures or pneumatic dilations of achalasia. Conservative management should not be used in patients who have free perforations into

the pleural space. Cameron proposed three criteria for the nonoperative management of esophageal perforation: (1) the barium swallow must show the perforation to be contained within the mediastinum and drain well back into the esophagus, (2) symptoms should be mild, and (3) there should be minimal evidence of clinical sepsis. If these conditions are met, it is reasonable to treat the patient with hyperalimentation, antibiotics, and cimetidine to decrease acid secretion and diminish pepsin activity. Oral intake is resumed in 7–14 days, dependent on subsequent radiographic examinations.

CAUSTIC INJURY

Accidental caustic lesions occur mainly in children, and in general, rather small quantities of caustics are taken. In adults or teenagers, the swallowing of caustic liquids is usually deliberate, during suicide attempts, and greater quantities are swallowed. Alkalies are more frequently swallowed accidentally than acids, because strong acids cause an immediate burning pain in the mouth.

Pathology

The swallowing of caustic substances causes both an acute and a chronic injury. During the acute phase, care focuses on controlling the immediate tissue injury and the potential for perforation. During the chronic phase, the focus is on treatment of strictures and disturbances in pharyngeal swallowing. In the acute phase the degree and extent of the lesion are dependent on several factors: the nature of the caustic substance, its concentration, the quantity swallowed, and the time the substance is in contact with the tissues. Acids and alkalies affect tissue in different ways. Alkalies dissolve tissue, and therefore penetrate more deeply, although acids cause a coagulative necrosis that limits their penetration. Animal experiments have shown that there is a correlation between the depth of the lesion and the concentration of sodium hydroxide (NaOH) solution. When a solution of 3.8 percent comes into contact with the esophagus for 10 s, it causes necrosis of the mucosa and the submucosa, but spares the muscular layer. A concentration of 22.5 percent penetrates the whole esophageal wall and into the periesophageal tissues. Cleansing products can contain up to 90 percent NaOH. The strength of esophageal contractions varies according to the level of the esophagus, being weakest at the striated muscle–smooth muscle interface. Consequently, clearance from this area may be somewhat slower, allowing caustic substances to remain in contact with the mucosa longer. This explains why the esophagus is preferentially and more severely affected at this level than in the lower portions.

The lesions caused by lye injury occur in three phases. First is the acute necrotic phase, lasting 1 to 4 days after injury. During this period, coagulation of intracellular proteins results in cell necrosis, and the living tissue surrounding the area of necrosis develops an intense inflammatory reaction. Second is the ulceration and granulation phase, starting 3–5 days after injury. During this period the superficial necrotic tissue sloughs, leaving an ulcerated, acutely inflamed base, and granulation tissue fills the defect left by the sloughed mucosa. This phase lasts 10–12 days, and it is during this period that the esophagus is the weakest. Third is the phase of cicatrization and scarring, which begins the third week following injury. During this period the previously formed connective tissue begins to contract, resulting in narrowing of the esophagus. Adhesions between granulating areas occurs, resulting in pockets and bands. It is during this period that efforts must be made to reduce stricture formation.

TABLE 24-14 Endoscopic Grading of Corrosive Esophageal and Gastric Burns

First degree: Mucosal hyperemia and edema
Second degree: Limited hemorrhage, exudate ulceration, and pseudomembrane formation
Third degree: Sloughing of mucosa, deep ulcers, massive hemorrhage, complete obstruction of lumen by edema, charring, and perforation

Clinical Manifestations

The clinical picture of an esophageal burn is determined by the degree and extent of the lesion. In the initial phase, complaints consist of pain in the mouth and substernal region, hypersalivation, pain on swallowing, and dysphagia. The presence of fever is strongly correlated with the presence of an esophageal lesion. Bleeding can occur, and frequently the patient vomits. These initial complaints disappear during the quiescent period of ulceration and granulation. During the cicatrization and scarring phase, the complaint of dysphagia reappears and is because of fibrosis and retraction, resulting in narrowing of the esophagus. Of the patients who develop strictures, 60 percent do so within 1 month, and 80 percent within 2 months. If dysphagia does not develop within 8 months, it is unlikely that a stricture will occur. Serious systemic reactions such as hypovolemia and acidosis resulting in renal damage can occur in cases in which the burns have been caused by strong acids. Respiratory complications such as laryngospasm, laryngedema, and occasionally pulmonary edema can occur, especially when strong acids are aspirated.

Inspection of the oral cavity and pharynx can indicate that caustic substances were swallowed, but does not reveal that the esophagus has been burned. Conversely, esophageal burns can be present without apparent oral injuries. Because of this poor correlation, early esophagoscopy is advocated to establish the presence of an esophageal injury. To lessen the chance of perforation, the scope should not be introduced beyond the proximal esophageal lesion. Table 24-14 lists criteria by which the degree of injury can be graded. Even if the esophagoscopy is normal, strictures may appear later. Radiographic examination is not a reliable means to identify the presence of early esophageal injury, but is important in later follow-up to identify strictures. Table 24-15 shows the most common locations of caustic injuries.

Treatment

Treatment of a caustic lesion of the esophagus is directed toward management of both the immediate and late consequences of the injury. The immediate

TABLE 24-15 Location of Caustic Injury (n = 62)

Pharynx	10%
Esophagus	70%
Upper	15%
Middle	65%
Lower	2%
Whole	18%
Stomach	20%
Antral	91%
Whole	9%
Both stomach and esophagus	14%

treatment consists of limiting the burn by administering neutralizing agents. To be effective, this must be done within the first hour. Lye or other alkali can be neutralized with half-strength vinegar, lemon juice, or orange juice. Acid can be neutralized with milk, egg white, or antacids. Sodium bicarbonate is not used because it generates CO_2 , which might increase the danger of perforation. Emetics are contraindicated, because vomiting renews the contact of the caustic substance with the esophagus and can contribute to perforation if too forceful. Hypovolemia is corrected and broad-spectrum antibiotics are administered to lessen the inflammatory reaction and prevent infectious complications. If necessary a feeding jejunostomy tube is inserted to provide nutrition. Oral feeding can be started when the dysphagia of the initial phase has regressed.

In the past, surgeons waited until the appearance of a stricture before starting treatment. Currently, dilations are started the first day after the injury, with the aim of preserving the esophageal lumen by removing the adhesions that occurred in the injured segments. However, this approach is controversial in that dilations can traumatize the esophagus, causing bleeding and perforation, and there are data indicating that excessive dilations cause increased fibrosis secondary to the added trauma. The use of steroids to limit fibrosis has been shown to be effective in animals, but their effectiveness in human beings is debatable.

Extensive necrosis of the esophagus frequently leads to perforation, and is best managed by resection. When there is extensive gastric involvement, the esophagus is nearly always necrotic or severely burned, and total gastrectomy and near-total esophagectomy are necessary. The presence of air in the esophageal wall is a sign of muscle necrosis and impending perforation and is a strong indication for esophagectomy.

Some authors have advocated the use of an intraluminal esophageal stent in patients who are operated on and found to have no evidence of extensive esophagogastric necrosis. In these patients, a biopsy of the posterior gastric wall should be performed to exclude occult injury. If histologically there is a question of viability, a second-look operation should be done within 36 h. If a stent is inserted it should be kept in position for 21 days, and removed after a satisfactory barium esophagogram. Esophagoscopy should be done and if strictures are present, dilations initiated.

Once the acute phase has passed, attention is turned to the prevention and management of strictures. The length of time the surgeon should persist with dilation before consideration of esophageal resection is problematic. An adequate lumen should be re-established within 6 months to 1 year, with progressively longer intervals between dilations. If during the course of treatment an adequate lumen cannot be established or maintained (i.e., smaller bougies must be used), operative intervention should be considered. Surgical intervention is indicated when there is (1) complete stenosis in which all attempts from above and below have failed to establish a lumen, (2) marked irregularity and pocketing on barium swallow, (3) the development of a severe periesophageal reaction or mediastinitis with dilatation, (4) a fistula, (5) the inability to dilate or maintain the lumen above a 40F bougie, or (6) a patient who is unwilling or unable to undergo prolonged periods of dilation.

DIAPHRAGMATIC HERNIAS

With the advent of clinical radiology, it became evident that a diaphragmatic hernia was a relatively common abnormality and was not always accompanied by symptoms. Three types of esophageal hiatal hernia were identified: (1) the

sliding hernia, type I, characterized by an upward dislocation of the cardia in the posterior mediastinum; (2) the rolling or paraesophageal hernia, type II, characterized by an upward dislocation of the gastric fundus alongside a normally positioned cardia; and (3) the combined sliding-rolling or mixed hernia, type III, characterized by an upward dislocation of both the cardia and the gastric fundus. The end stage of type I and type II hernias occurs when the whole stomach migrates up into the chest by rotating 180 degrees around its longitudinal axis, with the cardia and pylorus as fixed points. In this situation the abnormality is usually referred to as an intrathoracic stomach.

Clinical Manifestations

The clinical presentation of a paraesophageal hiatal hernia differs from that of a sliding hernia. There is usually a higher prevalence of symptoms of dysphagia and postprandial fullness with paraesophageal hernias, but the typical symptoms of heartburn and regurgitation present in sliding hiatal hernias can also occur. Both are caused by gastroesophageal reflux secondary to an underlying mechanical deficiency of the cardia. The symptoms of dysphagia and postprandial fullness in patients with a paraesophageal hernia are explained by the compression of the adjacent esophagus by a distended cardia, or twisting of the gastroesophageal junction by the torsion of the stomach that occurs as it becomes progressively displaced in the chest.

Approximately one-third of patients with a paraesophageal hernia are found to be anemic, which is because of recurrent bleeding from ulceration of the gastric mucosa in the herniated portion of the stomach. Respiratory complications are frequently associated with a paraesophageal hernia, and consist of dyspnea from mechanical compression and recurrent pneumonia from aspiration. With time the stomach migrates into the chest and can cause intermittent obstruction because of the rotation that has occurred. In contrast, many patients with paraesophageal hiatal hernia are asymptomatic or complain of minor symptoms. However, the presence of a paraesophageal hernia can be life-threatening in that the hernia can lead to sudden catastrophic events, such as excessive bleeding or volvulus with acute gastric obstruction or infarction. With mild dilatation of the stomach, the gastric blood supply can be markedly reduced, causing gastric ischemia, ulceration, perforation, and sepsis. The probability of incarceration is not well known, although recent analysis using mathematical modeling suggests the risk is small.

The symptoms of sliding hiatal hernias are usually because of functional abnormalities associated with gastroesophageal reflux and include heartburn, regurgitation, and dysphagia. These patients have a mechanically defective LES, giving rise to the reflux of gastric juice into the esophagus and the symptoms of heartburn and regurgitation. The symptom of dysphagia occurs from the presence of mucosal edema, Schatzki ring, stricture, or the inability to organize peristaltic activity in the body of the esophagus as a consequence of the disease.

Diagnosis

A radiogram of the chest with the patient in the upright position can diagnose a hiatal hernia if it shows an air-fluid level behind the cardiac shadow. This is usually caused by a paraesophageal hernia or an intrathoracic stomach. The accuracy of the upper GI barium study in detecting a paraesophageal hiatal hernia is greater than for a sliding hernia, because the latter can often

spontaneously reduce. The paraesophageal hiatal hernia is a permanent herniation of the stomach into the thoracic cavity, so a barium swallow provides the diagnosis in virtually every case. Attention should be focused on the position of the gastroesophageal junction, when seen, to differentiate it from a type II hernia. Fiberoptic esophagoscopy is useful in the diagnosis and classification of a hiatal hernia because the scope can be retroflexed. In this position, a sliding hiatal hernia can be identified by noting a gastric pouch lined with rugal folds extending above the impression caused by the crura of the diaphragm, or measuring at least 2 cm between the crura, identified by having the patient sniff, and the squamocolumnar junction on withdrawal of the scope. A paraesophageal hernia is identified on retroversion of the scope by noting a separate orifice adjacent to the gastroesophageal junction into that which gastric rugal folds ascend. A sliding-rolling or mixed hernia can be identified by noting a gastric pouch lined with rugal folds above the diaphragm, with the gastroesophageal junction entering about midway up the side of the pouch.

Treatment

The treatment of paraesophageal hiatal hernia is largely surgical. Controversial aspects include (1) indications for repair, (2) surgical approach, and (3) role of fundoplication.

Indications

The presence of a paraesophageal hiatus hernia has traditionally been considered an indication for surgical repair. This recommendation is largely based on two clinical observations. First, retrospective studies have shown a significant incidence of catastrophic, life-threatening complications of bleeding, infarction, and perforation in patients being followed with known paraesophageal herniation. Second, emergency repair carries a high mortality. In the classic report of Skinner and Belsey, 6 of 21 patients with a paraesophageal hernia, treated medically because of minimal symptoms, died from the complications of strangulation, perforation, exsanguinating hemorrhage, or acute dilatation of the herniated intrathoracic stomach. These catastrophes occurred for the most part without warning. Others have reported similar findings.

Recent studies suggest that catastrophic complications may be somewhat less common. Allen and colleagues followed 23 patients for a median of 78 months with only four patients progressively worsening. There was a single mortality secondary to aspiration that occurred during a barium swallow examination to investigate progressive symptoms. Although emergency repairs had a median hospital stay of 48 days compared to a stay of 9 days in those having elective repair, there were only three cases of gastric strangulation in 735 patient-years of follow-up.

If surgery is delayed and repair is done on an emergency basis, operative mortality is high, compared to less than 1 percent for an elective repair. With this in mind, patients with a paraesophageal hernia are generally counseled to have elective repair of their hernia, particularly if they are symptomatic. Watchful waiting of asymptomatic paraesophageal hernias may be an acceptable option.

Surgical Approach

The surgical approach to repair of a paraesophageal hiatal hernia may be either transabdominal (laparoscopic or open) or transthoracic. Each has its advantages

and disadvantages. A transthoracic approach facilitates complete esophageal mobilization and removal of the hernia sac. Thoracotomy also allows for the occasional gastroplasty, which may be required for esophageal lengthening to achieve a tension-free repair.

The transabdominal approach facilitates reduction of the volvulus that is often associated with paraesophageal hernias. Although some degree of esophageal mobilization can be accomplished transhiatally, complete mobilization to the aortic arch is difficult or impossible without risk of injury to the vagal nerves.

Several authors have reported the successful repair of paraesophageal hernias using a laparoscopic approach. Laparoscopic repair of a pure type II, or mixed type III paraesophageal hernia is an order of magnitude more difficult than a standard laparoscopic Nissen fundoplication. Most would recommend that these procedures are best avoided until the surgeon has accumulated considerable experience with laparoscopic antireflux surgery. There are several reasons for this. First, the vertical and horizontal volvulus of the stomach often associated with paraesophageal hernias makes identification of the anatomy, in particular the location of the esophagus, difficult. Second, dissection of a large paraesophageal hernia sac usually results in significant bleeding, obscuring the operative field. Finally, redundant tissue present at the gastroesophageal junction following dissection of the sac frustrates the creation of a fundoplication, which these authors believe should accompany the repair of all paraesophageal hernias. Mindful of these difficulties, and given appropriate experience, patients with paraesophageal hernia may be approached laparoscopically, with expectation of success in the majority.

Results

Most outcome studies report relief of symptoms following surgical repair of paraesophageal hernias in over 90 percent of patients. The current literature suggests that laparoscopic repair of a paraesophageal hiatal hernia can be successful. Most authors report symptomatic improvement in 80–90 percent of patients, and less than 10–15 percent prevalence of recurrent hernia. However, the problem of recurrent hernia following laparoscopic repair of any hiatal hernia is becoming increasingly appreciated. Recurrent hernia is now the most common cause of anatomic failure following laparoscopic Nissen fundoplication done for GERD. The problem of recurrent hernia following repair of large type III hiatal hernias has received less attention. Outcome following repair of these hernias is usually based on symptomatic assessment alone. Although recurrence rates of 6–13 percent have been reported, they have largely been based on the need for reoperation or investigations that are performed on a selective basis. Recent reports have shown some degree of anatomic recurrence in up to 45 percent of patients who underwent laparoscopic repair of their hernia.

The principles of laparoscopic repair of a large intrathoracic hernia are analogous to those for an open procedure, namely reduction of the hernia, excision of the peritoneal sac, crural repair, and fundoplication. However, there are several factors that make the laparoscopic repair of these large hernias complex. First, the hiatal opening in a patient with a large hernia is wide, with the right and left muscular crura often separated by 4 cm or more. This can make closure problematic because of the tension required to bring the crura together. Second, the right crus may be devoid of stout tissue and sutures may pull through

it easily. Finally, redundant tissue present at the gastroesophageal junction following dissection of the sac retards the creation of the fundoplication.

The use of prosthetic mesh as an adjunct to repair has been advocated for both open and laparoscopic repair of large hiatal hernias. Whether its use is beneficial or not remains controversial, but most prefer to avoid prosthetic material if possible. In contrast to groin hernias, the esophageal hiatus is a dynamic area with constant movement of the diaphragm, esophagus, stomach, and pericardium. Erosion of prosthetic material placed in this area into the GI tract will occur, the only question is how often. The short-term follow-up of most studies is insufficient to provide insight into this problem.

The stomach is a remarkable organ with important digestive, nutritional, and endocrine functions. It stores and facilitates the digestion and absorption of ingested food, and it helps regulate appetite. Treatable diseases of the stomach are common and the stomach is accessible and relatively forgiving. It is thus a favorite therapeutic target. To provide intelligent diagnosis and treatment, the physician and surgeon must understand gastric anatomy, physiology, and pathophysiology. This includes a sound understanding of the mechanical, secretory, and endocrine processes through which the stomach accomplishes its important functions. It also includes a familiarity with the common benign and malignant gastric disorders of clinical significance, especially peptic ulcer and gastric cancer.

Gross Anatomy

The stomach is readily recognizable as the asymmetrical pear-shaped most proximal abdominal organ of the digestive tract. The superior-most part of the stomach is the distensible floppy fundus, bounded superiorly by the diaphragm and laterally by the spleen. The angle of His is where the fundus meets the left side of the gastroesophageal (GE) junction. The inferior extent of the fundus generally is considered to be the horizontal plane of the GE junction, in which the body (corpus) of the stomach begins. The body of the stomach contains most of the parietal (oxyntic) cells. The gastrin secreting antrum comprises the distal 25–30 percent of the stomach.

The stomach is the most richly vascularized portion of the alimentary canal. Most of the gastric blood supply is from the celiac axis via four named arteries. The left and right gastric arteries form an anastomotic arcade along the lesser curvature, and the right and left gastroepiploic arteries form an arcade along the greater gastric curvature. About 15 percent of the time the left gastric artery supplies an aberrant vessel to the left side of the liver which travels in the gastrohepatic ligament (lesser omentum), but rarely is this the only arterial blood supply to this part of the liver. The second largest artery to the stomach is usually the right gastroepiploic artery which arises fairly consistently from the gastroduodenal artery behind the first portion of the duodenum. The left gastroepiploic artery arises from the splenic artery and together with the right gastroepiploic artery forms the rich gastroepiploic arcade along the greater curvature. The right gastric artery usually arises from the hepatic artery near the pylorus and hepatoduodenal ligament, and runs proximally along the distal stomach. In the fundus along the proximal greater curvature, the short gastric arteries and veins arise from the splenic circulation. There may also be vascular branches to the proximal stomach from the phrenic circulation. The veins draining the stomach generally parallel the arteries. The left gastric (coronary vein) and right gastric veins usually drain into the portal vein, although occasionally the coronary vein drains into the splenic vein. The right gastroepiploic vein drains into the superior mesenteric vein near the inferior border of the pancreatic neck, and the left gastroepiploic vein drains into the splenic vein.

Regions of the stomach usually drain lymph to the closest nodal basins. However, within the gastric wall there is a rich anastomotic network of lymphatics which may drain the stomach in a somewhat unpredictable fashion. Thus a tumor arising in the distal stomach could give rise to positive lymph nodes in the splenic hilum. Sentinel node mapping and lymphoscintigraphy are investigational techniques that may evolve as clinically useful methods for staging gastric cancer. Surgeons and pathologists have numbered the primary and secondary lymph node groups to which the stomach drains.

Both the extrinsic and intrinsic innervation of the stomach play an important role in gastric secretory and motor function. The vagus nerves provide the extrinsic parasympathetic innervation to the stomach and acetylcholine is the most important neurotransmitter. Near the gastroesophageal junction the anterior (left) vagus sends a branch (or branches) to the liver in the gastrohepatic ligament and continues along the lesser curvature as the anterior nerve of Latarjet. Similarly, the posterior (right) vagus sends branches to the celiac plexus and continues along the posterior lesser curvature. The nerves of Latarjet send segmental branches to the body of the stomach before they terminate near the angularis incisura as the "crow's foot," sending branches to the antro-pyloric region. In 50 percent of patients there are more than two vagal nerves at the esophageal hiatus. The branch which the posterior vagus sends to the posterior fundus is termed the criminal nerve of Grassi. This branch typically arises above the esophageal hiatus and is easily missed during truncal or highly selective vagotomy. Most (>75 percent) of the axons contained in the vagal trunks are afferent (i.e., carrying stimuli from the viscera to the brain). The extrinsic sympathetic nerve supply to the stomach originates at spinal levels T5–T10 and travels in the splanchnic nerves to the celiac ganglion. Postganglionic sympathetic nerves then travel from the celiac ganglion to the stomach along the blood vessels. Neurons in the myenteric and submucosal plexuses constitute the intrinsic nervous system of the stomach. The extrinsic (parasympathetic and sympathetic) and intrinsic gastric nervous system have various and diverse neurotransmitters including cholinergic, adrenergic, and peptidergic (e.g., substance P, somatostatin).

Histology

There are four distinct layers of the gastric wall: mucosa, submucosa, muscularis propria, and serosa. The epithelium, lamina propria, and muscularis mucosa constitute the "mucosa." The epithelium of the gastric mucosa is columnar glandular. A scanning electron micrograph shows a smooth mucosal carpet punctuated by the openings of the gastric glands. The gastric glands are lined with different types of epithelial cells depending on the location of the stomach (Table 25-1). There are also endocrine cells (such as histamine-secreting enterochromaffin-like [ECL] cells and somatostatin secreting D cells) present in the gastric glands. Progenitor cells at the base of the glands differentiate and replenish sloughed cells on a regular basis. Throughout the stomach, the "carpet" consists primarily of mucous secreting surface epithelial cells which extend down into the gland pits for a variable distance. These cells also secrete bicarbonate and play an important role in protecting the stomach from injury because of acid, pepsin, and/or ingested irritants.

Parietal cells secrete acid and intrinsic factor into the gastric lumen, and bicarbonate into the intercellular space. Chief cells (also called zymogenic cells) secrete pepsinogen which is activated at pH below 2.5. They tend to be

TABLE 25-1 Epithelial Cells of the Stomach

Cell type	Distinctive ultrastructural features	Major functions
Surface-foveolar mucous cells	Apical stippled granules up to 1 μm in diameter	Production of neutral glycoprotein and bicarbonate to form a gel on the gastric luminal surface; neutralization of hydrochloric acid ^a ;
Mucous neck cell	Heterogeneous granules 1–2 μm in diameter dispersed throughout the cytoplasm	Progenitor cell for all other gastric epithelial cells; glycoprotein production; production of pepsinogens I and II
Oxyntic (parietal) cell	Surface membrane invaginations (canaliculi); tubulovesicle structures; numerous mitochondria;	Production of hydrochloric acid production of intrinsic factor production of bicarbonate
Chief cell	Moderately dense apical granules up to 2 μm in diameter; prominent supranuclear Golgi apparatus; extensive basolateral granular endoplasmic reticulum	Production of pepsinogens I and II, and of lipase
Cardiopyloric mucous cell	Mixture of granules like those in mucous neck and chief cells; extensive basolateral granular endoplasmic reticulum	Production of glycoprotein Production of pepsinogen II
Endocrine cells		

^aBicarbonate is probably produced by other gastric epithelial cells in addition to surface-foveolar mucous cells.

clustered toward the base of the gastric glands and have a low columnar shape. In the antrum, the gastric glands are more branched and shallow, parietal cells are rare, and gastrin-secreting G cells and somatostatin-secreting D cells are present. A variety of hormone secreting cells are present in various proportions throughout the gastric mucosal. Histologic analysis suggests that in the normal stomach, 13 percent of the epithelial cells are oxyntic (parietal) cells, 44 percent chief (zymogenic cells), 40 percent mucous cells, and 3 percent endocrine cells.

Deep to the mucosa is the submucosa that is rich in branching blood vessels, lymphatics, collagen, various inflammatory cells, autonomic nerve fibers, and ganglion cells of Meissner autonomic submucosal plexus. The collagen rich submucosa gives strength to gastrointestinal anastomosis. The mucosa and submucosa are folded into the grossly visible gastric rugae which tend to flatten out as the stomach becomes distended.

Below the submucosa is the thick muscularis propria (also referred to as the muscularis externa) which consists of an incomplete inner oblique layer, a complete middle circular layer (continuous with the esophageal circular muscle and the circular muscle of the pylorus), and a complete outer longitudinal layer (continuous with the longitudinal layer of the esophagus and duodenum). Within the muscularis propria is the rich network of autonomic ganglia and nerves which make up Auerbach myenteric plexus. The outer layer of the stomach is the serosa, which is synonymous with the visceral peritoneum.

PHYSIOLOGY

The stomach stores food and facilitates digestion through a variety of secretory and motor functions. Important secretory functions include the production of acid and intrinsic factor from parietal cells, pepsin from chief cells, mucous from mucous secreting epithelial cells, and a variety of gastrointestinal (GI) hormones from gastric endocrine cells. Important motor functions include food storage (receptive relaxation and accommodation), grinding and mixing, controlled emptying of ingested food, and periodic interprandial “housekeeping.”

Acid Secretion

The parietal cell is stimulated to secrete acid when one or more of three membrane receptor types is stimulated by acetylcholine (from vagal nerve fibers), gastrin (from mucosal G cells) or histamine (from mucosal ECL cells). The enzyme H/K-ATPase is the proton pump. The normal human stomach contains about a billion parietal cells, and total gastric acid production is proportional to parietal cell mass. The potent acid suppressing proton pump inhibitor drugs irreversibly interfere with the function of the H/K-ATPase molecule. They must be incorporated into the activated enzyme to be effective and thus work best when taken before or during a meal (when the parietal cell is stimulated). When proton pump inhibitor therapy is stopped, acid secretory capability returns as new hydrogen/potassium-adenosine triphosphatase (H/K-ATPase) is synthesized.

Gastrin, acetylcholine and histamine stimulate the parietal cell to secrete hydrochloric acid. Gastrin binds to type B CCK receptors and acetylcholine binds to M₃ muscarinic receptors. Both stimulate phospholipase C via a G-protein linked mechanism leading to increased production of inositol triphosphate (IP₃) from membrane bound phospholipids. IP₃ stimulates the release of calcium from intracellular stores which leads to activation of protein kinases and activation of H/K-ATPase. Histamine binds to the histamine 2 (H₂) receptor that stimulates adenylate cyclase, also via a G protein linked mechanism. Activation

of adenylate cyclase results in an increase in intracellular cyclic AMP that activates protein kinases leading to increased levels of phosphoproteins and activation of the proton pump. Somatostatin from mucosal D cells binds to membrane receptors and inhibits the activation of adenylate cyclase through an inhibitory G protein.

The acid secretory response that occurs after a meal is traditionally described in three phases: cephalic, gastric, and intestinal. The cephalic or vagal phase begins with the thought, sight, smell, and/or taste of food. These stimuli activate several cortical and hypothalamic sites and signals are transmitted to the stomach by the vagal nerves. Acetylcholine is released leading to stimulation of ECL cells and parietal cells. Although the acid secreted per unit time in the cephalic phase is greater than in the other two phases, the duration of the cephalic phase is briefer. Thus the cephalic phase accounts for no more than 30 percent of total acid secretion in response to a meal. Sham feeding (chew and spit) stimulates gastric acid secretion only via the cephalic phase.

When food reaches the stomach, the gastric phase of acid secretion begins. This phase lasts until the stomach is empty, and accounts for about 60 percent of the total acid secretion in response to a meal. The gastric phase of acid secretion has several components. Amino acids and small peptide directly stimulate antral G cells to secrete gastrin which is carried in the bloodstream to the parietal cells and stimulates acid secretion in an endocrine fashion. Additionally, proximal gastric distention stimulates acid secretion via a vagovagal reflex arc, which is abolished by truncal or highly selective vagotomy. Antral distention also stimulates antral gastrin secretion. Acetylcholine also stimulates gastrin release; and gastrin stimulates histamine release from ECL cells.

The intestinal phase of gastric secretion is poorly understood. It is thought to be mediated by a yet to be discovered hormone released from the proximal small bowel mucosa in response to luminal chyme. This phase starts when gastric emptying of ingested food begins, and continues as long as nutrients remain in the proximal small intestine. It accounts for about 10 percent of meal-induced acid secretion.

ECL cells play a pivotal role in the regulation of gastric acid secretion. A large part of the acid stimulatory effects of both acetylcholine and gastrin are mediated by histamine released from mucosal ECL cells. This explains why the histamine 2 receptor antagonists (H_2 RAs) are such effective inhibitors of acid secretion, even though histamine is only one of three parietal cell stimulants. The mucosal D cell, which releases somatostatin, is also an important regulator of acid secretion. Somatostatin inhibits histamine release from ECL cells and gastrin release from D cells. The function of D cells is inhibited by *H. pylori* infection, and this leads to an exaggerated acid secretory response.

Gastric Mucosal Barrier

The stomach's durable resistance to autodigestion by caustic hydrochloric acid and active pepsin is intriguing. Table 25-2 lists some of the important components of gastric barrier function and cytoprotection. When these defenses break down, ulceration occurs. A variety of factors are important in maintaining an intact gastric mucosal layer. The mucous and bicarbonate secreted by surface epithelial cells forms an unstirred mucous gel with a favorable pH gradient. Cell membranes and tight junctions prevent hydrogen ions from gaining access to the interstitial space. Hydrogen ions that do break through are buffered by the alkaline tide created by basolateral bicarbonate secretion from stimulated

TABLE 25-2 Important Components and Mediators of Mucosal Defenses in the Stomach

Components

Mucous barrier
 Bicarbonate secretion
 Epithelial barrier
 Hydrophobic phospholipids
 Tight junctions
 Restitution
 Microcirculation (reactive hyperemia)
 Afferent sensory neurons

Mediators

Prostaglandins
 Nitric oxide
 Epidermal growth factor
 Calcitonin gene-related peptide
 Hepatocyte growth factor
 Histamine

parietal cells. Any sloughed or denuded surface epithelial cells are rapidly replaced by migration of adjacent cells, a process known as restitution. Mucosal blood flow plays a crucial role in maintaining a healthy mucosa, providing nutrients and oxygen for the cellular functions involved in cytoprotection. “Back diffused” hydrogen is buffered and rapidly removed by the rich blood supply. When “barrier breakers” such as bile or aspirin lead to increased back diffusion of hydrogen ions from the lumen into the lamina propria and submucosa, there is a protective increase in mucosal blood flow. If this protective response is blocked, gross ulceration can occur. Important mediators of these protective mechanisms include prostaglandins, nitric oxide, intrinsic nerves, and peptides (e.g., calcitonin gene related peptide, gastrin). Misoprostol is a commercially available prostaglandin E analogue that has been shown to prevent gastric mucosal damage in chronic nonsteroidal antiinflammatory drug (NSAID) users. Some protective reflexes involve afferent sensory neurons, and can be blocked by the application of topical anesthetics to the gastric mucosa, or the experimental destruction of the afferent sensory nerves. In addition to these local defenses, there are important protective factors in swallowed saliva, duodenal secretions, and pancreatic or biliary secretions.

Gastric Hormones

Gastrin (mostly little gastrin, G-17) is produced by antral G cells and is the major hormonal stimulant of the acid secretion during the gastric phase. The biologically active pentapeptide sequence at the C-terminal end of gastrin is identical to that of CCK. Luminal peptides and amino acids are the most potent stimulants of gastrin release, and luminal acid is the most potent inhibitor of gastrin secretion. The latter effect is predominantly mediated in a paracrine fashion by somatostatin released from antral D cells. Gastrin stimulated acid secretion is significantly blocked by H_2 antagonists, suggesting that the principle mediator of gastrin stimulated acid production is histamine from mucosal ECL cells. Important causes of hypergastrinemia include pernicious anemia, acid suppressive medication, gastrinoma, retained antrum following distal gastrectomy and Billroth II, and vagotomy.

Somatostatin (predominantly somatostatin 14) is produced by D cells located throughout the gastric mucosa. The major stimulus for somatostatin release is antral acidification, and acetylcholine from vagal nerve fibers inhibits its release. Somatostatin inhibits acid secretion from parietal cells, and gastrin release from G cells. It also decreases histamine release from ECL cells. The proximity of the D cells to these target cells suggests that the primary effect of somatostatin is mediated in a paracrine fashion, but an endocrine effect is also possible.

Gastrin-releasing peptide (GRP), the mammalian equivalent of bombesin, stimulates both gastrin and somatostatin release by binding to receptors on the G and D cells. There are nerve terminals ending near the mucosa in the gastric body and antrum which are rich in GRP immunoreactivity. When GRP is given peripherally it stimulates acid secretion, but when it is given centrally into the cerebral ventricles of animals, it inhibits acid secretion apparently via a pathway involving the sympathetic nervous system.

Ghrelin, a small peptide produced primarily in the stomach, is a potent secretagogue of pituitary growth hormone and appears to be an orexigenic regulator of appetite. When ghrelin is elevated, appetite is stimulated and when it is suppressed, appetite is suppressed. The gastric bypass operation, a very effective treatment for morbid obesity, is associated with suppression of plasma ghrelin levels (and appetite) in humans. Resection of the primary source of this hormone, the stomach, may partly account for the anorexia and weight loss seen in some patients following gastrectomy.

Gastric Motility/Emptying

Gastric motor function has several purposes. Interprandial motor activity clears the stomach of undigested debris, sloughed cells, and mucus. When feeding begins, the stomach relaxes to accommodate the meal. Regulated motor activity then breaks down the food into small particles, and controls the output into the duodenum. The stomach accomplishes these functions by coordinated smooth muscle relaxation and contraction of the various gastric segments (proximal, distal, pylorus). Smooth muscle myoelectric potentials are translated into muscular activity which is modulated by extrinsic and intrinsic innervation, and hormones. There are a variety of neurotransmitters, which are generally grouped as excitatory (augment muscular activity) and inhibitory (decrease muscular activity). Important excitatory neurotransmitters include acetylcholine and the tachykinins substance P and neurokinin A. Important inhibitory neurotransmitters include nitric oxide (NO) and vasoactive intestinal peptide (VIP). Serotonin has been shown to modulate both contraction and relaxation. A variety of other molecules affect motility including GRP, histamine, neuropeptide Y, norepinephrine, and endogenous opioids. Specialized cells in the muscularis propria are also important modulators of gastrointestinal motility. These cells, called interstitial cells of Cajal, are distinguishable histologically from neurons and myocytes, and appear to amplify both cholinergic excitatory and neuregic inhibitory input to the smooth muscle of the stomach and intestine.

When food is ingested, intragastric pressure falls as the proximal stomach relaxes. This proximal relaxation is mediated by two important vagovagal reflexes, receptive relaxation (reduction in proximal gastric tone associated with food swallowing) and gastric accommodation (proximal gastric relaxation when food enters the stomach). Because both of these reflexes are mediated by

afferent and efferent vagal fibers, they are significantly altered by truncal and highly selective vagotomy which tend to increase basal intragastric pressure and may increase the rate of liquid emptying. In addition to receptive relaxation and accommodation, proximal gastric tone is decreased by duodenal distention, colonic distention, and ileal perfusion with glucose (the ileal brake).

The distal stomach breaks up solid food and is the main determinant of gastric emptying of solids. Slow waves of myoelectric depolarization sweep down the distal stomach at a rate of about 3 per min. These waves originate from the proximal gastric pacemaker, high on the greater curvature. The pacing cells may be the interstitial cells of Cajal, which have been shown to have a similar function in the small intestine and colon. Most of these myoelectric waves are below the threshold for smooth muscle contraction in the quiescent state, and thus are associated with negligible changes in pressure. Neural and/or hormonal input which increases the plateau phase of the action potential can trigger muscle contraction, resulting in a peristaltic wave associated with the electrical slow wave and of the same frequency (3 per min).

During fasting, distal gastric motor activity is controlled by the migrating motor complex (MMC), the "gastrointestinal housekeeper." The teleologic function of the MMC is to sweep along any undigested food, debris, sloughed cells, and mucous after the fed phase of digestion is complete. The MMC lasts about 100 min (longer at night, shorter during daytime) and is divided into four phases. Neurohormonal control of the MMC is poorly understood, but it appears that different phases are regulated by different mechanisms. For example, vagotomy abolishes phase II of the gastric MMC, but has little influence on phase III. In fact, phase III persists in the autotransplanted stomach, totally devoid of extrinsic neural input. This suggests that phase III is regulated by intrinsic nerves and/or hormones. Indeed, the initiation of phase III of the MMC in the distal stomach corresponds temporally to elevation in serum levels of motilin, a hormone produced in the duodenal mucosa. Resection of the duodenum abolishes distal gastric phase III in dogs. There are clearly motilin receptors on antral smooth muscle and nerves. Other modulators of gastric MMC activity include NO, endogenous opioids, intrinsic cholinergic and adrenergic nerves, duodenal pH (MMC phase III does not occur if the duodenal pH is below 7).

Feeding abolishes the MMC and leads to the fed motor pattern. The fed motor pattern of gastric activity starts within 10 min of food ingestion and persists until all the food has left the stomach. Gastric motility during the fed pattern resembles phase II of the MMC, with irregular but continuous phasic contractions of the distal stomach. Some contractions are prograde and some are retrograde, serving to mix and grind the solid components of the meal. The magnitude of gastric contractions and the duration of the pattern is influenced by the consistency and composition of the meal.

The pylorus functions as a very effective regulator of gastric emptying, preventing large particles and large boluses of liquid from entering the duodenum in which they could overwhelm normal digestive and homeostatic mechanisms. It also is an effective barrier to duodenogastric reflux. Dysfunction, bypass, transection, or resection of the pylorus may lead to uncontrolled gastric emptying of food and the dumping syndrome, or uncontrolled entry of duodenal contents into the stomach, leading to bile reflux gastritis.

Although an oversimplification, liquid emptying has been attributed to the activity of the proximal stomach, and solid emptying to the activity of the distal stomach. Clearly receptive relaxation and gastric accommodation play a role

TABLE 25-3 Promotility Agents That Accelerate Gastric Emptying

Drug	Mechanism
Metoclopramide	Dopamine antagonist
Domperidone	Dopamine antagonist
Erythromycin	Motilin agonist
Bethanecol	Cholinergic agonist
Neostigmine	Cholinergic agonist

in gastric emptying of liquids. Patients with a denervated (e.g., vagotomy), resected, or plicated (e.g., fundoplication) proximal stomach have decreased gastric compliance and may show accelerated gastric emptying of liquids. Normally, the T1/2 of solid gastric emptying is about 2 h. Unlike liquids which display an initial rapid phase followed by a slower linear phase of emptying, solids have an initial lag phase during which very little emptying of solids occurs. It is during this phase that much of the grinding and mixing occurs. A linear emptying phase follows during which the smaller particles are metered out to the duodenum. Solid gastric emptying is a function of meal particle size, caloric content and composition (especially fat). When liquids and solids are ingested together, the liquids empty first. Solids are stored in the fundus and delivered to the distal stomach at constant rates for trituration. Liquids are also sequestered in the fundus but they appear to be readily delivered to the distal stomach for early emptying. The larger the solid component of the meal, the slower the liquid emptying. Patients bothered by dumping syndrome are advised to limit the amount of liquid consumed with the solid meal, taking advantage of this effect. A variety of prokinetic agents have been shown to be clinically useful in increasing gastric emptying. Table 25-3 shows the commonly used agents, mechanisms, and side effects.

EVALUATION OF GASTRIC DISEASE

The most common symptoms of gastric disease are pain, weight loss, early satiety, and anorexia. Nausea, vomiting, bloating and anemia are also frequent complaints. Patients with one or more of the alarm symptoms listed in Table 25-4 should undergo expeditious upper endoscopy (esophagogastroduodenoscopy = EGD). EGD is a very safe and accurate outpatient procedure performed under conscious sedation. To rule out cancer with a high degree of accuracy, all patients with gastric ulcer should have multiple biopsies of the base and rim of the lesion, and brush cytology should be considered. Gastritis is biopsied for histology and to rule out *Helicobacter*. The most serious complications of EGD are rare and include perforation, pulmonary aspiration,

TABLE 25-4 Alarm Symptoms That Indicate the Need for Esophagogastroduodenoscopy

Weight loss
Recurrent vomiting
Dysphagia
Bleeding
Anemia

and respiratory depression from excessive sedation. Generally EGD is a more sensitive test than double contrast upper GI series, but these modalities should be considered complementary rather than competitive. Some anatomic abnormalities are more easily demonstrable or quantifiable on barium study than EGD (e.g., diverticula, fistula, tortuosity or stricture location, and size of hiatal hernia). Computed tomography (CT) scan or magnetic resonance imaging (MRI) should be part of the routine staging workup for most patients with a malignant gastric tumor. MRI may prove clinically useful as a quantitative test for gastric emptying, and may even hold some promise for the analysis of myoelectric derangements in patients with gastroparesis. Arteriography is rarely necessary or useful in the diagnosis of gastric disease. It may be helpful in the occasional poor risk patient with exsanguinating gastric hemorrhage, or in the patient with hard to diagnose occult gastric bleeding. Extravasation of contrast indicates the bleeding vessel, and embolization or selective infusion of vasopressin may be therapeutic. Occasionally empiric embolization of the suspected but unproven bleeding vessel helps. Arteriovenous malformations have a characteristic angiographic appearance.

Endoscopic ultrasound (EUS) is useful in the evaluation of some gastric lesions. Local/regional staging of gastric tumors is best accomplished with EUS. Enlarged nodes can be sampled with EUS guided endoscopic needle biopsy. Malignant tumors that are confined to the mucosa on EUS may be amenable to endoscopic resection, although locally advanced tumors may merit neoadjuvant treatment. EUS can also be used to assess the response of gastric lymphoma to chemotherapy.

Analysis of gastric acid output requires gastric intubation. This somewhat uncomfortable test may be useful in the evaluation of patients for Zollinger-Ellison syndrome, patients with refractory ulcer or GERD, and patients with recurrent ulcer after operation. Historically gastric analysis was performed most commonly to test for the adequacy of vagotomy in postoperative patients with recurrent or persistent ulcer. However this can also be done by assessing peripheral pancreatic polypeptide levels in response to sham feeding. A 50 percent increase of PP within 30 min of sham feeding suggests vagal integrity. Nuclear medicine tests can be helpful in the evaluation of gastric emptying and duodenogastric reflux. The standard scintigraphic evaluation of gastric emptying involves the ingestion of a test meal with one or two isotopes and scanning of the patient under a gamma camera. A curve for liquid and solid emptying is plotted and the T1/2 calculated. Normal standards exist for each facility. Duodenogastric reflux can be quantitated by the intravenous administration of dimethyl iminodiacetic acid (HIDA), which is concentrated and excreted by the liver into the duodenum. Software allows a semiquantitative assessment of how much of the isotope refluxes into the stomach. Lymphoscintigraphy may evolve as a useful staging test for gastric cancer.

A variety of tests can help determine whether or not the patient has active *Helicobacter* infection (Table 25-5). The predictive value (positive and negative) of any of the tests used as a screening tool depends on the prevalence of *Helicobacter* infection in the screened population. A positive test is quite accurate in predicting *Helicobacter* infection, but a negative test is characteristically unreliable. Thus in the appropriate clinical setting, treatment for *Helicobacter* should be initiated on the basis of a positive test, but not necessarily withheld if the test is negative. Antroduodenal motility testing and electrogastrography (EGG)

TABLE 25-5 Tests for *Helicobacter pylori*

Test	When to use	Why	Why not
Serologic test	Test of choice when endoscopy is not indicated and is not an option and when the patient has not received antimicrobial therapy for <i>H. pylori</i> infection	Noninvasive; sensitivity of >80%, specificity of about 90%	Does not confirm eradication, because serologic "scar" remains for indefinite period after microbiologic cure
Urea breath test	Preferred for confirming cure of <i>H. pylori</i> infection, but no sooner than 4 wk after completion of therapy	Simple; sensitivity and specificity of 90 to 99%	False-negatives possible if testing is done too soon after treatment with proton pump inhibitors, antimicrobials, or bismuth compounds; small radiation exposure with ¹⁴ C method; expensive
Histologic test	To directly ascertain presence of <i>H. pylori</i> when endoscopy is being used; also used when determination of neoplastic status of lesion is necessary	Sensitivity of 80–100%, specificity of >95%; hematoxylin-eosin and Diff-Quik stains are simplest; Genta stain has sensitivity of >95% and specificity of 99%	Requires laboratory facilities and experience; when hematoxylin-eosin stain is nondiagnostic, second staining method is required
Rapid urease test	Simplest method when endoscopy is necessary	Simple; rapid (once biopsy specimen has been obtained); sensitivity of 80 to 95%, specificity of 95 to 100%	Invasive; false-negatives possible if testing is done too soon after treatment with proton pump inhibitors, antimicrobials, or bismuth compounds
Culture	After repeated failure of appropriate combination antibiotic therapy; when antimicrobial resistance is suspected or high level of resistance exists in the population	Allows determination of antibiotic susceptibility	Time-consuming; expensive; usually not necessary unless resistance is suspected

are performed in specialized centers and may be useful in the evaluation of the patient with poorly explained epigastric symptoms. Electrogastrography consists of the transcutaneous recording of gastric myoelectric activity. Antroduodenal motility testing is done with a tube placed transnasally or transorally into distal duodenum. There are pressure recording points extending from the stomach to the distal duodenum. The combination of these two tests together with scintigraphy provides a thorough assessment of gastric motility.

PEPTIC ULCER DISEASE

Peptic ulcer remains a common outpatient diagnosis, but the number of physician visits, hospital admissions, and elective operations for peptic ulcer disease have decreased steadily and dramatically over the past three decades. These trends all predated the advent of fiberoptic endoscopy, highly selective vagotomy, and H_2 blockers. The incidence of emergency operation and the death rate for peptic ulcer are fairly stable however. These epidemiologic trends probably represent the net effect of several factors including decreased prevalence of *Helicobacter* infection, better medical therapy, increase in outpatient management, and NSAID/aspirin use (with and without ulcer prophylaxis).

Pathophysiology

A variety of factors may contribute to the development of peptic ulcer. Although it is now recognized that the large majority of duodenal and gastric ulcers are "caused by" *Helicobacter* infestation and/or nonsteroidal antiinflammatory drug use, the final common pathway to ulcer formation is acid-peptic injury of the gastroduodenal mucosal barrier. Thus the adage, "no acid, no ulcer," is as true today as it ever was. Acid suppression either with medication or surgery remains a mainstay in healing both duodenal and gastric ulcers and in preventing recurrence. It is generally thought that *Helicobacter* predisposes to ulceration both by acid hypersecretion and by compromise of mucosal defense mechanisms. NSAIDs are thought to lead to peptic ulcer predominantly by compromise of mucosal defenses. Duodenal ulcer has typically been thought of as a disease of increased acid peptic aggression on the duodenal mucosa, whereas gastric ulcer has been viewed as a disease of weakened mucosal defenses in the face of relatively normal acid peptic aggression. However increased understanding of the pathophysiology of peptic ulcer has blurred this distinction. Clearly weakened mucosal defenses play a role in many duodenal and most gastric ulcers (e.g., duodenal ulcer in *Helicobacter* negative patient on NSAIDs; or typical type I gastric ulcer with acid hyposecretion); whereas acid peptic aggression may result in a duodenal or gastric ulcer in the setting of normal mucosal defenses (e.g., duodenal ulcer in patient with Zollinger-Ellison syndrome; gastric ulcer in patient with gastric outlet obstruction, antral stasis, and acid hypersecretion).

Elimination of *H. pylori* infection or NSAID use is important for optimal ulcer healing and perhaps even more important in preventing recurrence and/or complications. A variety of other diseases are known to cause peptic ulcer, including Zollinger-Ellison Syndrome (gastrinoma), antral G-cell hyperfunction and/or hyperplasia, systemic mastocytosis, trauma, burns, and major physiological stress. Other "causative agents" are drugs (all NSAIDs, aspirin, cocaine), smoking, alcohol and psychological stress. Probably in the United

States, over 90 percent of serious peptic ulcer complications can be attributed to *Helicobacter* infection, NSAID use, and cigarette smoking.

The *H. pylori* bacteria are uniquely equipped for survival in the hostile environment of the stomach. It possesses the urease enzyme which converts urea into ammonia and bicarbonate creating an environment around the bacteria which buffers the acid secreted by the stomach. *H. pylori* infection is associated with decreased levels of gastric mucosal somatostatin production, hypergastrinemia and acid hypersecretion. The acid hypersecretion and the antral gastritis are thought to lead to antral epithelial metaplasia in the post-pyloric duodenum. This duodenal metaplasia allows *H. pylori* to colonize the duodenal mucosa and in these patients the risk of developing a duodenal ulcer increases 50-fold. When *H. pylori* colonizes the duodenum, there is a significant decrease in acid-stimulated duodenal bicarbonate release. Likewise, *Helicobacter* predisposes to gastric ulcer at least in part by weakening mucosal defenses. It is clear from multiple randomized prospective studies that curing *H. pylori* infection dramatically decreases the risk of recurrent ulcer.

As a rule duodenal ulcer patients secrete more acid than patients with gastric ulcer. It has long been recognized that duodenal ulcer patients as a group have a higher mean basal acid output (BAO) and also a higher mean maximal acid output (MAO) than normal controls. However many duodenal ulcer patients have basal and peak acid outputs in the normal range and there is no correlation between acid secretion and the severity of the ulcer disease. Some patients with duodenal ulcer also have increased rates of gastric emptying which delivers an increased acid load per unit of time to the duodenum. Finally the buffering capacity of the duodenum in many patients with duodenal ulcer is compromised because of decreased duodenal bicarbonate secretion.

In patients with gastric ulcer, acid secretion is variable. Generally, four types of gastric ulcer are described. The most common Johnson type I gastric ulcer is typically located near the angularis incisura on the lesser curvature, close to the border between the antrum and the body of the stomach. Usually these patients have normal or decreased acid secretion. Type II gastric ulcer is associated with active or quiescent duodenal ulcer disease, and type III gastric ulcer is prepyloric. Both type II and type III gastric ulcers are associated with normal or increased gastric acid secretion. Type IV gastric ulcer occurs near the gastroesophageal junction and acid secretion is normal or below normal. Patients with Type I or IV gastric ulcer may have weak mucosal defenses which permit an abnormal amount of injurious acid back-diffusion into the mucosa. Duodenogastric reflux may play a role in weakening the gastric mucosal defenses in patients with gastric ulcer. A variety of components in duodenal juice, including bile, lysolecithin, and pancreatic juice, has been shown to cause injury and inflammation in the gastric mucosa. NSAIDs and aspirin have similar effects.

NSAIDs (including aspirin) are inextricably linked to peptic ulcer disease. Patients with rheumatoid arthritis and osteoarthritis who take NSAIDs have a 15–20 percent annual incidence of peptic ulcer, and the prevalence of peptic ulcer in chronic NSAID users is about 25 percent (15 percent gastric and 10 percent duodenal). Complications of peptic ulcer disease (specifically hemorrhage and perforation) are much more common in patients taking NSAIDs. More than half of patients who present with peptic ulcer hemorrhage or perforation report the recent use of nonsteroidal antiinflammatory drugs, including aspirin. Many of these patients remain asymptomatic up until the time they develop these life threatening complications. This problem is put into prospective

when one realizes that approximately 20 million patients in the United States take NSAIDs on a regular basis; perhaps as many regularly take aspirin.

Factors which clearly put patients at increased risk for NSAID-induced GI complications include age older than 60, prior GI event, high NSAID dose, concurrent steroid intake, and concurrent anticoagulant intake. Any patient taking NSAIDs or aspirin who has one or more of these risk factors should receive concomitant acid suppressive medication or misoprostol at a therapeutic dose or should be considered for alternative treatment with cyclooxygenase-2 (COX-2) inhibitors.

Epidemiologic studies suggest that smokers are about twice as likely to develop peptic ulcer disease as nonsmokers. Smoking increases gastric acid secretion and duodenogastric reflux. Smoking decreases both gastroduodenal prostaglandin production and pancreaticoduodenal bicarbonate production. These observations may be related, and any or all could explain the observed association between smoking and peptic ulcer disease. Although difficult to measure, both physiological and psychological stress undoubtedly play a role in the development of peptic ulcer in some patients. In 1842, Curling described duodenal ulcer and/or duodenitis in burn patients. Decades later, Cushing described the appearance of acute peptic ulceration in patients with head trauma (Cushing ulcer). Recently, the use of crack cocaine has been linked to juxta-pyloric peptic ulcers with a propensity to perforate. Alcohol is commonly mentioned as a risk factor for peptic ulcer disease, but confirmatory data are lacking.

Clinical Manifestations and Diagnosis

Over 90 percent of patients with peptic ulcer complain of abdominal pain. The pain is typically nonradiating, burning in quality and located in the epigastrium. Other signs and symptoms include nausea, bloating, weight loss, positive stool for occult blood, and anemia. In the young patient with dyspepsia and/or epigastric pain, it may be appropriate to initiate empiric therapy for peptic ulcer disease without confirmatory testing. All patients with the above symptoms over 45 should have an upper endoscopy, and all patients regardless of age should have this study if any alarm symptoms (see Table 25-4) are present. A good double contrast upper GI radiograph study may be useful. All gastric ulcers should be adequately biopsied, and any sites of gastritis should be biopsied to rule out *Helicobacter*, and for histologic evaluation. Additional testing for *Helicobacter* may be indicated. Although somewhat controversial, it is not unreasonable to test all peptic ulcer patients for *Helicobacter*. A baseline serum gastrin is appropriate to rule out gastrinoma.

The three complications of peptic ulcer disease, in decreasing order of frequency, are bleeding, perforation, and obstruction now account for the large majority of operations performed for peptic ulcer disease, and essentially all of the deaths (most of which are because of bleeding).

Medical Treatment of Peptic Ulcer

Patients with peptic ulcer should stop smoking, and avoid alcohol and NSAIDs (including aspirin). If *Helicobacter* infection is documented, it should be treated with one of numerous acceptable regimens (Table 25-6). If initial *Helicobacter* testing is negative, the ulcer patient may be treated with H₂ receptor blockers or proton pump inhibitors. Sucralfate or misoprostol may also be effective. If ulcer symptoms persist, an empiric trial of anti-*Helicobacter* therapy is reasonable.

(false negative *Helicobacter* tests are not uncommon). Generally antisecretory therapy can be stopped after 3 months if the ulcerogenic stimulus (*Helicobacter* or NSAIDs or aspirin) has been removed. However long-term maintenance therapy for peptic ulcer should be considered in all patients admitted to hospital with an ulcer complication, all high-risk patients on NSAIDs or aspirin (the older adult or debilitated), and all patients with a history of recurrent ulcer or bleeding. Consideration should be given to maintenance therapy in persistent smokers with a history of peptic ulcer. Misoprostol, sucralfate, and acid suppression may be quite comparable in many of these groups, but misoprostol may cause diarrhea and cramps, and cannot be used in women of child-bearing age because of its abortifacient properties.

Surgical Treatment of Peptic Ulcer

Fundamentally, the vast majority of peptic ulcers requiring operation are adequately treated by a variant of one of three basic procedures: highly selective vagotomy; vagotomy and drainage; vagotomy and distal gastrectomy (Table 25-7).

Highly selective vagotomy (HSV), also called parietal cell vagotomy or proximal gastric vagotomy, is safe (mortality risk <0.5 percent) and causes minimal side effects. The operation severs the vagal supply to the proximal two thirds of the stomach, in which essentially all the parietal cells are located. It preserves the vagal innervation to the antrum and pylorus, and the remaining abdominal viscera. HSV decreases total gastric acid secretion by about 65–75 percent, which is quite comparable to truncal vagotomy or acid suppressive medication. Gastric emptying of solids is typically normal in patients

TABLE 25-7 Clinical Results of Surgery for Duodenal Ulcer

	Parietal cell vagotomy	Truncal vagotomy and pyloroplasty	Truncal vagotomy and antrectomy
Operative mortality rate (%)	0	<1	1
Ulcer recurrence rate (%)	5–15	5–15	< 2
Dumping (%)			
Mild	< 5	10	10–15
Severe	0	1	1–2
Diarrhea (%)			
Mild	< 5	25	20
Severe	0	2	1–2

after parietal cell vagotomy; liquid emptying may be normal or increased because of decreased compliance associated with loss of receptive relaxation and accommodation. When applied to uncomplicated duodenal ulcer, the recurrent ulcer rate is higher with HSV than with vagotomy and antrectomy. However our increased understanding of the pathophysiologic role of *Helicobacter* and NSAIDs in the development of recurrent ulcer may mitigate this concern. HSV has not performed particularly well as a treatment for type II (gastric and duodenal) and III (prepyloric) gastric ulcer, perhaps because of hypergastrinemia caused by gastric outlet obstruction and persistent antral stasis.

Truncal vagotomy and pyloroplasty, and truncal vagotomy and gastrojejunostomy are the paradigmatic vagotomy and drainage procedures (TV and D), although total gastric vagotomy (selective vagotomy [SV]) and drainage, and HSV and gastrojejunostomy have also been shown to be effective ulcer operations in selected patients. The advantage of TV and D is that it can be performed safely and quickly by the experienced surgeon. The main disadvantage is the side effect profile (10 percent with significant dumping and/or diarrhea), and a 10 percent recurrent ulcer rate. Whether the incidence of these postoperative problems (heretofore determined in studies predominantly involving patients with intractable uncomplicated duodenal ulcer) will be different in the current era of complicated ulcer, *Helicobacter*, and NSAIDs is unknown.

Truncal vagotomy denervates the antropylic mechanism and therefore some sort of procedure is necessary to ablate or bypass the pylorus, otherwise gastric stasis often results. Gastrojejunostomy or pyloroplasty are the classic drainage procedures.

The advantage of vagotomy and antrectomy (V and A) is the extremely low ulcer recurrence rate and the applicability of the operation to many patients with complicated peptic ulcer (e.g., bleeding duodenal and gastric ulcer; obstructing peptic ulcer; nonhealing gastric ulcer; recurrent ulcer). When applied to gastric ulcer, the resection is usually extended far enough proximally to include the ulcer. The disadvantage of V and A is the somewhat higher operative mortality rate when compared with HSV, or V and D. Following antrectomy, gastrointestinal continuity may be re-established either as a Billroth I gastroduodenostomy or a Billroth II loop gastrojejunostomy. Because antrectomy routinely leaves a 60–70 percent gastric remnant, reconstruction as a Roux gastrojejunostomy should be avoided. The Roux operation is an excellent procedure for keeping duodenal contents out of the stomach and esophagus. But

TABLE 25-8 Surgical Options in the Treatment of Duodenal and Gastric Ulcer Disease

Indication	Duodenal	Gastric

in the presence of a large gastric remnant, this reconstruction will predispose to marginal ulceration and/or gastric stasis.

Distal gastrectomy without vagotomy (usually approximately 50 percent gastrectomy to include the ulcer) has traditionally been the procedure of choice for type I gastric ulcer. Reconstruction may be done as a Billroth I (preferable) or II. Truncal vagotomy is added for Type 2 and 3 gastric ulcers, or if the patient is believed to be at increased risk for recurrent ulcer, and should be considered if Billroth II reconstruction is contemplated. Although not routinely used nowadays in the surgical treatment of peptic ulcer, subtotal gastrectomy (75 percent distal gastrectomy) without vagotomy may be an appealing operation for an occasional ulcer patient.

The choice of operation for the individual patient with peptic ulcer disease depends on a variety of factors including (inter alia) the type of ulcer (duodenal, gastric, recurrent or marginal), the indication for operation, and the condition of the patient. Other important considerations are intraabdominal factors (duodenal scarring/inflammation; adhesions; difficult exposure), the virulence of the ulcer diathesis, the surgeon's experience and personal preference, the *Helicobacter* status, the need for continued NSAID therapy, previous treatment, and the likelihood of future compliance with treatment. Table 25-8 shows the surgical options for managing various aspects of peptic ulcer disease. In general, resective procedures have a lower ulcer recurrence rate, but a higher operative morbidity and mortality (see Table 25-7) when compared to nonresective ulcer operations. We now know that ulcer recurrence is often related to *Helicobacter* and/or NSAIDs, and usually is managed adequately without reoperation. Thus gastric resection to minimize recurrence in duodenal ulcer disease is often not justified today; resection for gastric ulcer remains the standard because of the risk of cancer.

Bleeding

Patients coming to operation for bleeding peptic ulcer today are more selected toward a poor surgical result than ever before. The surgical options for treating

bleeding peptic ulcer are three: suture ligation of the bleeder (and biopsy for gastric ulcer); suture ligation and definitive nonresective ulcer operation (HSV or V and D); and gastric resection (usually including vagotomy and ulcer excision). Indications for operation in bleeding ulcer are: (1) massive hemorrhage unresponsive to endoscopic control, (2) transfusion requirement of greater than 4 to 6 units of blood despite attempts at endoscopic control. Unavailability of therapeutic endoscopist, recurrent hemorrhage after one or more attempts at endoscopic control, unavailability of blood for transfusion, repeat hospitalization for bleeding duodenal ulcer and concurrent indication for surgery such as perforation or obstruction are also indications for operation. Early operation should be considered in patients over 60, those presenting in shock, those requiring more than four units of blood in 24 h or eight units of blood in 48 h, those with rebleeding, and those with ulcers greater than 2 cm in diameter or strategically located as described above.

The two operations most commonly used for bleeding duodenal ulcer are: vagotomy and drainage combined with oversewing of the ulcer, or vagotomy and antrectomy. The trade-off appears to be an increased risk of rebleeding with the vagotomy and drainage procedure versus the increased operative mortality of vagotomy and antrectomy. When the mortality for reoperation for rebleeding is considered, the overall mortality is probably comparable for the two approaches. Patients who are in shock or medically unstable should not have gastric resection.

Bleeding gastric ulcer tends to occur in older and/or medically complicated patients that tend to increase the operative risk. Although this has been used by some as an excuse not to operate early on these patients, experience shows that planned operation in a resuscitated patient results in a better operative mortality than emergent operation in a patient who has rebled and is in shock. Those patients with gastric ulcer bleeding likely to require operation have bled more than six units and have presented in shock. Endoscopically their ulcers tend to be on the lesser curvature with the usual stigmata of recent hemorrhage. Distal gastric resection to include the bleeding ulcer is the operation of choice for bleeding gastric ulcer. Second best is vagotomy and drainage, with oversewing and biopsy of the ulcer. Oversewing of the bleeder followed by long-term acid suppression is a reasonable alternative in extremely high risk patients. The specter of cancer is ever present in the patient with gastric ulcer whether it is bleeding or not.

Perforation

Perforation is the second most common complication of peptic ulcer. As with bleeding peptic ulcer, NSAIDS also have been inextricably linked with perforated peptic ulcer disease especially in the older adult population. Well over 20 percent of patients older than the age of 60 presenting with a perforated ulcer are taking NSAIDS at the time of perforation. Operation is almost always indicated although occasionally nonoperative treatment can be used in the stable patient without peritonitis and in whom radiologic studies document a sealed perforation. The options for surgical treatment of perforated duodenal ulcer are simple patch closure, patch closure and HSV, or patch closure and TV/D. Simple patch closure alone should be done in patients with hemodynamic instability and/or exudative peritonitis signifying a perforation over 24 h old. In all other patients the addition of a definitive ulcer operation (HSV or V and D) should be considered. Numerous studies have reported a negligible

mortality with this approach. Early data now suggest that simple closure of perforated duodenal ulcer may achieve satisfactory long term results when *H. pylori* infection (present in 50–75 percent with perforated duodenal ulcer) is eliminated. On the other hand it is sometimes difficult to determine the *H. pylori* status of the patient having emergent operation for perforated ulcer. Furthermore it is doubtful whether many of these patients will comply with the medication regimen required to eradicate *Helicobacter*. Thus using possible *H. pylori* infection as an excuse not to do a definitive ulcer operation in any patients with perforated duodenal ulcer is irrational. Perforated gastric ulcer carries a higher mortality rate than perforated duodenal ulcer (10–40 percent). This is generally thought to represent the gastric ulcer patients' higher age, increased medical comorbidities, delay in seeking medical attention and large size of gastric ulcers. Perforated gastric ulcers are associated with NSAIDs and tobacco use, and often present without prior symptoms. All perforated gastric ulcers are best treated by gastric resection (to include the ulcer) with or without truncal vagotomy depending on ulcer type. Vagotomy is usually performed for type II and III gastric ulcers. Patch closure with biopsy; or local excision and closure; or biopsy, closure, truncal vagotomy and drainage are alternative operations. All perforated gastric ulcers even those in the pre pyloric position should be biopsied if they are not removed at surgery.

Obstruction

Gastric outlet obstruction is the least common ulcer complication requiring operative treatment. Endoscopic balloon dilation can often transiently improve obstructive symptoms, but many of these patients ultimately fail and come to operation. The most common operations for obstructing peptic ulcer disease are vagotomy and antrectomy, and vagotomy and drainage. HSV and gastrojejunostomy is an appealing operation for obstruction, both because it can be done as a laparoscopic assisted procedure, and because it does not complicate future resection should this be needed. All gastric ulcers associated with obstruction should be adequately biopsied if not resected.

Intractability/Nonhealing

This should indeed be a rare indication for operation nowadays. Arguably, the patient referred for surgical evaluation because of intractable peptic ulcer disease should raise red flags with the surgeon. Acid secretion can be totally blocked and *Helicobacter* eradicated with modern medication, so why does the patient have a persistent ulcer diathesis? The surgeon should review the differential diagnosis of nonhealing ulcer (Table 25-9) prior to any consideration of operative treatment. Surgical treatment should be considered in patients with nonhealing or intractable peptic ulcer who have multiple recurrences, large ulcers (>2 cm), complications (obstruction, perforation or hemorrhage), or suspected gastric cancer. Operation should be considered most cautiously in the thin or marginally nourished individual.

If operation is necessary for intractability, less is often better. Our preferred operations for this group of patients is HSV. In patients with nonhealing gastric ulcer, wedge resection either with HSV or TV and D should be considered in thin or frail patients, and in patients with inconveniently situated ulcers (biopsy alone is sometimes appropriate). Otherwise distal gastrectomy (to include the ulcer) is recommended. It is unnecessary to add a vagotomy to distal gastrectomy in all patients with Type I gastric ulcer.

TABLE 25-9 Differential Diagnosis of Intractability or Nonhealing Peptic Ulcer Disease

Cancer
Gastric
Pancreatic
Duodenal
Persistent <i>H. pylori</i> infection
Tests may be false-negative
Consider empiric treatment
Noncompliant patient
Failure to take prescribed medication
Surreptitious use of nonsteroidal anti-inflammatory drugs
Motility disorder
Zollinger-Ellison syndrome

Zollinger-Ellison Syndrome

Zollinger-Ellison syndrome (ZES) is caused by the uncontrolled secretion of abnormal amounts of gastrin by a pancreatic or duodenal neuroendocrine tumor, i.e., gastrinoma. The inherited or familial form of gastrinoma (20 percent of cases) is associated with multiple endocrine neoplasia type I (MEN I) which consists of parathyroid, pituitary, and pancreatic (or duodenal) tumors. Patients with MEN I usually have multiple gastrinoma tumors and surgical cure is unusual. Sporadic gastrinomas are more often solitary and amenable to surgical cure. Nowadays about 50 percent of gastrinomas are malignant, with lymph node, liver, or other distant metastases at presentation. Five-year survival in patients presenting with metastatic disease is around 40 percent.

The most common symptoms of ZES are epigastric pain, GERD, and diarrhea. The average age of presentation is 50 years, and over 90 percent of patients with gastrinoma have peptic ulcer. Most ulcers are in the typical location (proximal duodenum), but atypical ulcer location (distal duodenum, jejunum, multiple ulcers) should prompt an evaluation for gastrinoma. Gastrinoma should also be considered in the differential diagnosis of recurrent or refractory peptic ulcer, secretory diarrhea, gastric rugal hypertrophy, esophagitis with stricture, bleeding or perforated ulcer, familial ulcer, and ulcer in the setting of hypercalcemia. Causes of hypergastrinemia can be divided into those associated with hyperacidity and those associated with hypoacidity (Table 25-10). The diagnosis of ZES is confirmed by the secretin stimulation test.

TABLE 25-10 Differential Diagnosis of Hypergastrinemia

Pernicious anemia
Atrophic gastritis
Renal failure
Postvagotomy
Short gut syndrome (after significant intestinal resection)

Eighty percent of primary tumors are found in the gastrinoma triangle and many tumors are small (<1 cm) making preoperative localization difficult. Transabdominal ultrasound is quite specific, but not very sensitive. CT scan will detect most lesions over 2 cm and MRI is comparable. Endoscopic ultrasound is more sensitive than these other noninvasive imaging tests, but it still misses many of the smaller lesions, and may confuse normal lymph nodes for gastrinoma. Currently, the imaging study of choice for gastrinoma is somatostatin receptor scintigraphy (SRS, the octreotide scan). Arteriography with selective visceral arterial infusion of secretin, and simultaneous hepatic venous gastrin sampling, may help localize the tumor as inside or outside the gastrinoma triangle.

All patients with sporadic (nonfamilial) gastrinoma should be considered for surgical resection and possible cure. Thorough exploration by an experienced surgeon is important. The lesion should be found in 90 percent of patients and 60 percent are cured. Acid hypersecretion in patients with gastrinoma can always be managed with high dose proton pump inhibitors. Highly selective vagotomy may make management easier in some patients and should be considered in patients with surgically untreatable or unresectable gastrinoma.

MALIGNANT NEOPLASMS OF THE STOMACH

The three most common primary malignant gastric neoplasms are adenocarcinoma (95 percent), lymphoma (4 percent), and malignant gastrointestinal stromal tumor (GIST) (1 percent).

Adenocarcinoma (Gastric Cancer)

Gastric cancer is more common in patients with atrophic gastritis, pernicious anemia, blood group A, or a family history of gastric cancer. Other commonly accepted risk factors for gastric cancer include diet (nitrates, salt, fat), gastric adenomas, familial polyposis, hereditary nonpolyposis colorectal cancer, smoking, and Menetrier disease. A variety of genetic abnormalities have been described in gastric cancer (Table 25-11).

Premalignant Conditions of the Stomach

Polyps. There are five types of gastric epithelial polyps: inflammatory, hamartomatous, heterotopic, hyperplastic, and adenoma. The first three types have negligible malignant potential. Adenomas can lead to carcinoma, just like in the colon, and they should be removed when diagnosed. Occasionally, hyperplastic polyps can lead to carcinoma (<2 percent). Patients with familial adenomatous polyposis (FAP) have a high prevalence of gastric adenomatous polyps (about 50 percent), and are 10 times more likely to develop adenocarcinoma of the stomach than the general population.

Atrophic gastritis. Chronic atrophic gastritis is by far the most common precursor for gastric cancer, particularly the intestinal subtype. In many patients, it is likely that *Helicobacter* is involved in the pathogenesis of atrophic gastritis. An individual's risk of gastric cancer is proportional to the extent of intestinal metaplasia of the gastric mucosa, suggesting that intestinal metaplasia is a precursor lesion to gastric cancer. There is evidence that eradication of *Helicobacter* infection leads to significant regression of intestinal metaplasia and improvement in atrophic gastritis. Thus *Helicobacter* treatment is a

TABLE 25-11 Genetic Abnormalities in Gastric Cancer

reasonable recommendation for patients with atrophic gastritis and *Helicobacter* infection.

Gastric remnant cancer. It has long been recognized that stomach cancer can develop in the gastric remnant, usually years following distal gastrectomy for peptic ulcer disease. The risk is controversial, but the phenomenon is real. Most tumors develop more than 10 years following the initial operation, and they usually arise in an area of chronic gastritis, metaplasia, and dysplasia.

Other premalignant states. Up to 10 percent of gastric cancer cases appear “to run in families”, even without a clear cut genetic diagnosis such as familial polyposis. First degree relatives of patients with gastric cancer have an increased risk of 2 to 3 fold. Patients with hereditary nonpolyposis colorectal cancer (HNPCC) have a 10 percent risk of developing gastric cancer, predominantly the intestinal subtype. The mucous cell hyperplasia of Menetrier disease is generally considered to carry a 5–10 percent risk of adenocarcinoma, but the glandular hyperplasia associated with gastrinoma is not premalignant.

Pathology of Stomach Cancer

It is generally accepted that gastric dysplasia is the universal precursor to gastric adenocarcinoma. Clearly, patients with severe dysplasia require some sort of ablative treatment, usually gastric resection. Patients with mild dysplasia should be followed carefully with endoscopic biopsy surveillance.

Early gastric cancer is defined as adenocarcinoma limited to mucosa and submucosa of the stomach, regardless of lymph node status. About 10 percent of patients with early gastric cancer will have lymph node metastases. About 70 percent of early gastric cancers are well differentiated, and 30 percent are poorly differentiated. The overall cure rate with adequate gastric resection and lymphadenectomy in early gastric cancer is 95 percent. In some Japanese

centers, 50 percent of gastric cancers treated are early gastric cancer. In the United States, less than 20 percent of resected gastric adenocarcinomas are early.

There are four gross forms of gastric cancer: polypoid, fungating, ulcerative, and scirrhous. In the first two, the bulk of the tumor mass is intraluminal. In the latter two gross subtypes, the bulk of the tumor mass is in the wall of the stomach. Scirrhous tumors (linitis plastica) have a particularly poor prognosis, and not uncommonly involve the entire stomach. Although these latter lesions may be technically resectable with total gastrectomy, not uncommonly both the esophageal and duodenal margin of resection will show microscopic evidence of tumor infiltration. Death from recurrent disease within 6 months is the rule. The location of the primary tumor in the stomach is important in planning operation. Several decades ago, the large majority of gastric cancers were in the distal stomach. Recently there is a proximal migration of tumors in the stomach so that currently the distribution is closer to 40 percent for distal, 30 percent for mid, and 30 percent for proximal.

Histology

The most important prognostic indicators in gastric cancer are both histologic: lymph node involvement and depth of tumor invasion. Tumor grade (degree of differentiation: well, moderate, poor) is also important prognostically. The most widespread system for staging of gastric cancer is the TNM staging system based on depth of tumor invasion (T), extent of lymph node metastases (N), and presence of distant metastases (M).

Clinical Manifestations (History and Physical Examination)

Most patients who are diagnosed with gastric cancer in the United States have advanced stage III or IV disease at the time of diagnosis (Table 25-12). The most common symptoms are weight loss and decreased food intake because of anorexia and early satiety. Abdominal pain (usually not severe and often ignored) is also common. Other symptoms include nausea, vomiting and bloating. Acute GI bleeding is somewhat unusual (5 percent), but chronic occult blood loss is common and manifests as iron deficiency anemia and heme positive stool. Dysphagia is common if the tumor involves the cardia of the stomach. Physical examination is usually normal. Other than weight loss, specific physical findings usually indicate incurability. It is important to check for these findings: cervical, supraclavicular (on the left referred to as Virchow node) and axillary lymphadenopathy; metastatic pleural effusion or aspiration pneumonitis; abdominal mass (large primary tumor, liver metastases, or carcinomatosis); palpable umbilical metastasis (Sister Joseph nodule); ascites; "drop metastases" or rectal shelf of Blumer in the pouch of Douglas.

Diagnostic Evaluation

Distinguishing between peptic ulcer and gastric cancer on clinical grounds alone is often impossible. Essentially all patients in whom gastric cancer is on the differential diagnosis should have endoscopy and biopsy. If suspicion for cancer is high and the biopsy is negative, the patient should be re-endoscoped and more aggressively biopsied. Preoperative staging of gastric cancer is best accomplished with abdominal/pelvic CT scan with intravenous and oral

TABLE 25-12 TNM Staging of Gastric Cancer by the International Union Against Cancer and American Joint Committee on Cancer

T: Primary tumor

Tis	Carcinoma in situ; Intraepithelial tumor without invasion of lamina propria
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria or subserosa
T3	Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures
T4	Tumor invades adjacent structures

N: Regional lymph node

N0	No regional lymph node metastasis
N1	Metastasis in 1 to 6 regional lymph nodes
N2	Metastasis in 7 to 15 lymph nodes
N3	Metastasis in more than 15 regional lymph nodes

M: Distant metastasis

M0	No distant metastasis
M1	Distant metastasis

contrast. MRI is probably comparable. The best way to stage the tumor locally is endoscopic ultrasound which gives accurate information about the depth of tumor penetration into the gastric wall and can usually show enlarged perigastric and celiac lymph nodes. In some centers, if the tumor is transmural (T3) or involves lymph nodes (enlarged nodes can usually be needled under ultrasound guidance), preoperative (neoadjuvant) cancer therapy is given. EUS is quite accurate in distinguishing early gastric cancer (T1) from more advanced tumors. PET scan should be considered prior to major operation in patients with particularly high risk tumors, or multiple medical comorbidities. The usefulness of staging laparoscopy and/or peritoneal cytology in gastric cancer depends on the individual patient's situation and the treatment philosophy of the cancer team.

Treatment

Surgery is the only curative treatment for gastric cancer. It is also the best palliation, and provides the most accurate staging. The goal of curative surgical treatment is resection of all tumor (i.e., R0 resection). Thus all margins (proximal, distal, radial) should be negative and an adequate lymphadenectomy performed. Generally, the surgeon strives for a grossly negative proximal and distal margin of at least 5 cm, with frozen section confirmation of histologically negative margins. Patients with positive lymph nodes may be cured by adequate operation, and often nodes thought to be grossly positive at operation turn out to be histologically negative. Thus therapeutic nihilism should be avoided, and in the good risk patient an aggressive attempt to resect all tumor should be made.

Extent of Gastrectomy

The standard operation for gastric cancer is radical subtotal gastrectomy. Reconstruction is usually by Billroth II gastrojejunostomy, but if a small gastric remnant is left (<20 percent) a Roux reconstruction is considered. The operative mortality is around 5 percent. Radical subtotal gastrectomy is generally deemed to be an adequate cancer operation in most Western countries, provided that all gross tumor is resected with negative margins. In the absence of involvement by direct extension, the spleen and pancreatic tail are not removed. Total gastrectomy is not performed unless it is necessary to obtain an R0 resection. There have been several large studies comparing subtotal gastrectomy to total gastrectomy for gastric cancer and the survival results in the two groups have been the same. But the complication rate in the total gastrectomy group is higher. Total gastrectomy with jejunal pouch/esophageal anastomosis may be the best operation for patients with proximal gastric adenocarcinoma.

Extent of Lymphadenectomy

The Japanese have labeled all the lymph node stations which potentially drain the stomach. Generally these are grouped into level N1 (e.g., stations 1–6), level N2 (e.g., stations 7–11), and level N3 (e.g., stations 12–16) nodes. The nodal stations defined as level N1, N2, and N3 varies depending on the location of the tumor. In general, N1 nodes are within 3 cm of the tumor; N2 nodes are along the celiac branches and N3 nodes are the most distant from the tumor (portal triad, retropancreatic, mesenteric root, middle colic, para-aortic). The operation described above, by far the most commonly performed procedure in the United States for gastric cancer, is called a D1 resection because it removes the tumor and the N1 nodes. The standard operation for gastric cancer in the Orient is the D2 gastrectomy, which involves a more extensive lymphadenectomy (removal of N1 and N2 nodes). In addition to the tissue removed in a D1 resection, the standard D2 gastrectomy removes the peritoneal layer over the pancreas and anterior mesocolon, along with nodes along the hepatic and splenic arteries, and the crural nodes. Splenectomy and distal pancreatectomy are not routinely performed, because clearly this has been shown to increase the morbidity of the operation. Randomized prospective trials have not confirmed a survival advantage for the more extensive lymphadenectomy, but the morbidity and mortality in the D2 group was higher (Table 25-13). This was mostly attributable to the splenectomy and distal pancreatectomy which are no longer routinely done as part of the D2 gastrectomy. Some experts have argued that the D2 operation is simply a better staging procedure, and that

TABLE 25-13 Randomized Trials Comparing D1 and D2 Gastrectomy for Gastric Cancer

Authors	Number of patients	Type of surgery	Postoperative complications (%)	Postoperative mortality (%)	5-year survival (%)
Bonenkamp et al.	711	D1	25	4	45
		D2	43	10	47

the apparent improved survival with this more extensive dissection is simply an epiphenomenon of improved pathologic staging. All experts would agree that to avoid understaging of gastric cancer, a minimum of 15 nodes should be resected with the gastrectomy specimen.

Chemotherapy and Radiation for Gastric Cancer

Adjuvant treatment with chemotherapy (5 FU and leucovorin) and radiation (4500 cGy) has demonstrated a survival benefit in resected patients with stage II and III adenocarcinoma of the stomach. There is no indication for the routine use of radiation alone in the adjuvant setting, but in certain patients it can be very effective palliation for bleeding or pain. In patients with gross unresectable, metastatic, or recurrent disease, palliative chemotherapy has not been demonstrated to conclusively prolong survival, but an occasional patient has a dramatic response. These patients should be considered for clinical trials. Agents that have shown activity against gastric cancer include 5 FU, cisplatin, Adriamycin, and methotrexate. Neoadjuvant treatment of gastric adenocarcinoma is being evaluated.

Endoscopic Resection

The Japanese have demonstrated that some patients with early gastric cancer can be adequately treated by an endoscopic mucosal resection. Small tumors (<3 cm) confined to the mucosa have an extremely low chance of lymph node metastasis (3 percent) which approaches the operative mortality rate for gastrectomy. If the resected specimen demonstrates no ulceration, no lymphatic invasion, and size less than 3 cm, the risk of lymph node metastases is less than 1 percent. Thus some patients with early gastric cancer might be better treated with the endoscopic technique. Currently this should be limited to patients with tumors less than 2 cm, which on EUS are node-negative and confined to the mucosa.

Prognosis

The 5 year survival for gastric adenocarcinoma has increased from 15–22 percent in the United States over the past 25 years. Survival is dependent on pathologic stage (TNM stage, see Table 25-12) and degree of tumor differentiation.

Screening for Gastric Cancer

In Japan it has clearly been shown that patients participating in gastric cancer screening programs have a significantly decreased risk of dying from gastric cancer. Thus screening is effective in a high risk population. Certainly screening the general population in the United States (a low-risk country) does not make sense, but patients clearly at risk for gastric cancer should probably have periodic endoscopy and biopsy. This includes patients with FAP, HNPCC, gastric adenomas, Menetrier disease, intestinal metaplasia, dysplasia, and remote gastrectomy or gastrojejunostomy.

Gastric Lymphoma

Gastric lymphomas generally account for about 4 percent of gastric malignancies. Over half of patients with non-Hodgkin lymphoma have involvement of the GI tract. The stomach is the most common site of primary GI lymphoma, and over 95 percent are non-Hodgkin type. Most are B-cell type, thought to arise in mucosa associated lymphoid tissue (MALT). In populations with a high incidence of gastric lymphoma, there is a high incidence of *Helicobacter* infection. And patients with gastric lymphoma usually have *Helicobacter*. Low-grade MALT lymphomas, essentially a monoclonal proliferation of B cells, presumably arise in a background of chronic gastritis associated with *Helicobacter*. Remarkably, when the *Helicobacter* is eradicated and the gastritis improves, the low grade MALT lymphoma often disappears. Thus low-grade MALT lymphoma is not a surgical lesion. Obviously careful follow-up is necessary.

These relatively innocuous "MALTomas" may undergo degeneration to high grade lymphoma, which is the usual variety seen by the surgeon. These patients require aggressive oncologic treatment for cure, and present with many of the same symptoms as gastric cancer patients. However, systemic symptoms such as fever, weight loss, and night sweats occur in about 50 percent of patients with gastric lymphoma. The tumors may bleed and/or obstruct. Lymphadenopathy and/or organomegaly suggest systemic disease. Diagnosis is by endoscopy and biopsy. Much of the tumor may be submucosal and an assiduous attempt at biopsy is necessary. A diligent search for extragastric disease is necessary before the diagnosis of localized primary gastric lymphoma is made. This includes endoscopic ultrasound, CT scan of the chest, abdomen and pelvis, and bone marrow biopsy.

For gastric lymphoma limited to the stomach and regional nodes, radical subtotal gastrectomy may be performed, especially for bulky tumors with bleeding and/or obstruction. Palliative gastrectomy for tumor complications also has a role. Recently, patients have been treated with primary chemotherapy and radiation without operation, and the results have been quite good. Perforation and bleeding especially from thick tumors is a recognized complication of this approach. Certainly, a multidisciplinary team should be involved with the treatment plan for patients with primary gastric lymphoma.

Malignant Gastrointestinal Stromal Tumor

GI stromal tumors arise in mesenchymal tissue from an indistinct (probably multipotential) cell line of origin. There are varying patterns of differentiation including smooth muscle type, formerly called leiomyosarcoma, and epithelioid type. Two-thirds of all gut GISTs occur in the stomach. GISTs

are submucosal tumors, which are slow growing. Smaller lesions are usually found incidentally, although they occasionally may ulcerate and cause impressive bleeding. Larger lesions generally produce symptoms of weight loss, abdominal pain, fullness, early satiety, and bleeding. An abdominal mass may be palpable. Spread is by the hematogenous route often to liver and/or lung, although positive lymph nodes are occasionally seen in resected specimens. Diagnosis is by endoscopy and biopsy, although the interpretation of the latter may be problematic. Endoscopic ultrasound may be helpful, but symptomatic tumors and tumors over 2 cm should be removed. Metastatic workup entails CT of chest, abdomen and pelvis (chest radiograph may suffice in lieu of CT of chest). Wedge resection with clear margins is adequate treatment, and prognosis depends on tumor size and mitotic count. Most patients with low grade lesions are cured (80 percent 5-year survival), but most patients with high-grade lesions are not (30 percent 5-year survival). GIST are usually positive for the proto-oncogene, c-kit. Gleevec, a chemotherapeutic agent which blocks the activity of the tyrosine kinase product of c-kit, shows promising activity in patients with this tumor.

Gastric Carcinoid Tumors

Gastric carcinoids comprise about 3 percent of GI carcinoids, and they clearly have malignant potential. Patients with pernicious anemia or atrophic gastritis are at risk for gastric carcinoid tumors, but thus far chronic pharmacologic suppression of acid has not been recognized as a risk factor. The tumors are submucosal and may be quite small. They are often confused with heterotopic pancreas or small leiomyomas. Biopsy may be difficult because of the submucosal location, and EUS can be helpful in defining the size and depth of the lesion. Gastric carcinoids should be resected. Small lesions confined to the mucosa may be removed endoscopically. Larger lesions should be removed by D1 gastrectomy. Survival is excellent for node negative patients (>90 percent 5-year survival); node positive patients have a 50 percent 5-year survival.

BENIGN GASTRIC NEOPLASMS

The most common gastric polyp (about 75 percent in most series) is the hyperplastic or regenerative polyp which frequently occurs in the setting of gastritis and has a low but real malignant potential. Adenomatous polyps may undergo malignant transformation, similar to adenomas in the colon. They constitute about 10–15 percent of gastric polyps. Hamartomatous, inflammatory, and heterotopic polyps have negligible malignant potential. Polyps which are symptomatic, larger than 2 cm, or adenomatous should be removed, usually by endoscopic snare polypectomy. Consideration should also be given to removing hyperplastic polyps, especially if large. Repeat esophagogastroduodenoscopy (EGD) for surveillance should be done following removal of adenomatous polyps, and perhaps after removal of hyperplastic polyps as well.

What used to be called leiomyoma is now termed GI stromal tumor. The typical leiomyoma is submucosal and firm. If ulcerated it has an umbilicated appearance, and it may bleed. Histologically these lesions appear to be of smooth muscle origin. Lesions less than 2 cm are usually asymptomatic and benign. Larger lesions have greater malignant potential, and a greater likelihood to cause symptoms such as bleeding, obstruction, or pain. Asymptomatic lesions less than 2 cm may be observed; larger lesions and symptomatic lesions should be removed by wedge resection (often possible laparoscopically). When these

lesions are observed rather than resected, the patient should be made aware of their presence and the small possibility for malignancy.

Lipomas are benign submucosal fatty tumors which are usually asymptomatic, found incidentally on upper GI series or EGD. Endoscopically, they have a characteristic appearance; there is also a characteristic appearance on endoscopic ultrasound. Excision is unnecessary unless the patient is symptomatic.

GASTRIC MOTILITY DISORDERS

Most patients with primary gastroparesis present with nausea and vomiting. Bloating, early satiety, and abdominal pain are common. Eighty percent of patients are women. Some are diabetic. The gastroparesis and vomiting significantly complicates the management of the diabetes; frequently the patient takes parenteral insulin, eats, then vomits, then becomes dangerously hypoglycemic. In patients with gastroparesis, it is important to rule out mechanical gastric outlet obstruction, and small bowel obstruction. Upper GI series may suggest slow gastric emptying and relative atony or it may be normal. EGD may show bezoars but is frequently normal. Gastric emptying scintigraphy shows delayed solid emptying, and often delayed liquid emptying. Gastroparesis can be a manifestation of a variety of problems (Table 25-14). Medical treatment includes promotility agents, antiemetics, and perhaps botulinum injection into the pylorus. If appropriate, the patient with severe diabetic gastroparesis should be evaluated for pancreas transplant prior to any invasive abdominal procedure because some patients improve substantially after pancreas transplant. Gastrostomy (for decompression) and jejunostomy (for feeding and prevention of hypoglycemia) may be effective. Other surgical options include implantation of gastric pacemaker, and gastric resection but the latter should be done infrequently, if at all for primary gastroparesis.

MISCELLANEOUS LESIONS OF THE STOMACH

Menetrier disease (hypertrophic gastropathy) is characterized by epithelial hyperplasia and giant gastric folds, associated with protein losing gastropathy and hypochlorhydria. There are large rugal folds in the proximal stomach, and the antrum is usually spared. Mucosal biopsy shows diffuse hyperplasia of the surface mucous secreting cells. The etiology is unclear, and there may be an increased risk of gastric cancer. Most patients with Menetrier disease are middle aged men who present with epigastric pain, weight loss, diarrhea, and hypoproteinemia. Sometimes the disease regresses spontaneously. Gastric resection may be indicated for bleeding, severe hypoproteinemia, or cancer in some patients with this rare problem.

The parallel red stripes atop the mucosal folds of the distal stomach give this rare entity its sobriquet, watermelon stomach (gastric antral vascular ectasia). Histologically gastric antral vascular ectasia is characterized by dilated mucosal blood vessels in the lamina propria, often containing thrombi. Mucosal fibromuscular hyperplasia and hyalinization are often present. The histologic appearance can resemble portal gastropathy, but the latter usually affects the proximal stomach, whereas watermelon stomach predominantly affects the distal stomach. Patients with gastric antral vascular ectasia are usually older adult women with transfusion requiring chronic GI blood loss. Most have an associated autoimmune connective tissue disorder, and at least 25 percent have chronic liver disease. Antrectomy may be required to control blood loss, but

in patients with portal hypertension, transvenous intrahepatic portasystemic shunt (TIPS) should be considered first.

Bezoars are concretions of undigestible matter that accumulate in the stomach. Trichobezoars, composed of hair, occur most commonly in young women who swallow their hair. Phytobezoars are composed of vegetable matter and in this country are usually seen in association with gastroparesis or gastric outlet obstruction. Most commonly, bezoars produce obstructive symptoms, but they may cause ulceration and bleeding. Diagnosis is suggested by upper GI series and confirmed by endoscopy. Treatment options include enzyme therapy (papain, cellulase, acetylcysteine), endoscopic disruption and removal, or surgical removal.

Dieulafoy's lesion is a congenital arteriovenous malformation characterized by an unusually large tortuous submucosal artery. If this artery is eroded, impressive bleeding may occur. To the operating surgeon, this appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. The lesion typically occurs in middle-age or older adult men. Patients present with upper GI bleeding, which may be intermittent, and endoscopy can miss the lesion if not actively bleeding. Treatment options include endoscopic hemostatic therapy (usually injection), angiographic embolization, or operation. At surgery, the lesion may be oversewn or resected.

Gastric diverticula are usually solitary and may be congenital or acquired. Congenital diverticula are true diverticula and contain a full coat of muscularis propria, whereas acquired diverticula (perhaps caused by pulsion) usually have a negligible outer muscle layer. Most gastric diverticula occur in the posterior cardia or fundus and are asymptomatic. However if they can become inflamed, they may produce pain or bleeding. Perforation is rare. Asymptomatic diverticula do not require treatment, but symptomatic lesions should be removed. This can often be done laparoscopically.

Ingested foreign bodies are usually asymptomatic. Removal of sharp or large objects should be considered. This can usually be done endoscopically, with an overtube technique. Recognized dangers include aspiration of the foreign body during removal, and rupture of drug containing bags in "body packers." Both complications can be fatal. Surgical removal is recommended in body packers, and in patients with large jagged objects.

The Mallory-Weiss lesion is a longitudinal tear in the mucosa of the GE junction. It is presumably caused by forceful vomiting and/or retching, and is commonly seen in alcoholics. It typically presents with impressive upper GI bleeding, often with hematemesis. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90 percent of patients stop bleeding spontaneously. Other options to control the bleeding include balloon tamponade, angiographic embolization or selective infusion of vasopressin, systemic vasopressin, and operation. Surgical treatment consists of oversewing the bleeding lesion through a long gastrotomy.

Gastric volvulus is a twist of the stomach, which usually occurs in association with a large hiatal hernia. It can also occur in patients with an unusually mobile stomach without hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), with the greater curvature "flipping up". If the stomach twists around the transverse axis, it is called mesenteroaxial rotation. Usually, volvulus is a chronic condition which can be surprisingly asymptomatic. In these instances, expectant nonoperative management is usually advised, especially in the older adult. The risk of strangulation and infarction has been overestimated in asymptomatic patients. Symptomatic patients should be considered for operation, especially if the symptoms are severe and/or progressive.

GASTROSTOMY

A gastrostomy is performed either for alimentation or for gastric drainage/decompression. Gastrostomy may be done percutaneously, laparoscopically, or via open technique. Currently, percutaneous endoscopic gastrostomy is the most common method used, usually with the Ponsky technique. In this procedure, the insufflated stomach is accessed percutaneously with a thin trocar needle under direct endoscopic vision. A long braided wire is passed through the needle into the stomach, snared endoscopically, and pulled out the mouth where it is attached to the outside end of a special gastrostomy tube. The wire and attached tube are then pulled down the esophagus, into the stomach and out the dilated trocar needle track and is secured. By far the most common open technique is the Stamm gastrostomy, which can be done open or laparoscopically. Complications of gastrostomy include infection, dislodgement, and aspiration pneumonia. Although gastrostomy tubes usually do prevent tense gastric dilatation, they may not adequately drain the stomach, especially when the patient is bedridden.

POSTGASTRECTOMY PROBLEMS

A variety of abnormalities affect some patients after a gastric operation that usually has been performed because of ulcer or tumor. Some of the more common disorders result from disturbance of the normal anatomic and physiologic mechanisms that control gastric motor function, and a discussion of these follows.

Dumping syndrome is a phenomenon caused by the destruction or bypass of the pyloric sphincter. Clinically significant dumping occurs in 5–10 percent of patients after pyloroplasty, pyloromyotomy, or distal gastrectomy, and consists of a constellation of postprandial symptoms ranging in severity from annoying to disabling. The symptoms are thought to be the result of the abrupt delivery of a hyperosmolar load into the small bowel. Rapid fluid influx into the bowel lumen and wall results, along with an incompletely understood neuroendocrine response. There is peripheral and splanchnic vasodilatation. About 15–30 min after a meal, the patient becomes diaphoretic, weak, lightheaded, and tachycardic. These symptoms may be ameliorated by recumbence or saline infusion. Diarrhea often follows. This is referred to as early dumping, and should be distinguished from postprandial (reactive) hypoglycemia, also called “late dumping” which usually occurs later (2–3 h following a meal), and is relieved by the administration of sugar. A variety of hormonal aberrations have been observed in early dumping, including increased vasoactive intestinal peptide (VIP), CCK, neurotensin, PYY, renin/angiotensin/aldosterone and decreased atrial natriuretic peptide. Late dumping is associated with hypoglycemia and hyperinsulinemia.

The medical therapy for the dumping syndrome consists of dietary management and somatostatin analogue (octreotide). Octreotide ameliorates the abnormal hormonal pattern seen in patients with dumping symptoms. It also promotes restoration of a “fasting” motility pattern in the small intestine (i.e., restoration of the MMC). The α -glucosidase inhibitor acarbose may be particularly helpful in ameliorating the symptoms of late dumping. Only a small percentage of patients with dumping symptoms ultimately require operation. The results of remedial operation for dumping are variable and unpredictable. Patients with disabling dumping after loop gastrojejunostomy can be considered for simple takedown of this anastomosis provided that (1) there is some vagal innervation to the antrum and (2) the pyloric channel is open endoscopically. Taking advantage of the disordered motility of the Roux limb, surgeons have used conversion of Billroth I or II to Roux gastrojejunostomy in the management of the dumping syndrome. Although this is probably the procedure of choice in the small group of patients requiring operation for severe dumping following gastric resection, gastric stasis and/or marginal ulceration may result, particularly if a large gastric remnant is left.

Truncal vagotomy is associated with clinically significant diarrhea in 5–10 percent of patients. It occurs soon after operation, tends to improve over time (months and years), and is usually not associated with other symptoms, a fact that helps to distinguish it from dumping. The cause of postvagotomy diarrhea is unclear. Possible mechanisms include intestinal dysmotility and accelerated transit, bile acid malabsorption, rapid gastric emptying, and bacterial overgrowth. Although bacterial overgrowth can be confirmed with the hydrogen breath test, a simpler test is an empirical trial of oral antibiotics. Some patients with postvagotomy diarrhea respond to cholestyramine, although in others codeine or loperamide may be useful. Another theoretical cause of diarrhea

following gastric operation is fat malabsorption because of acid inactivation of pancreatic enzymes or poorly coordinated mixing of food and digestive juices. In the rare patient who is debilitated by postvagotomy diarrhea that is unresponsive to medical management, the operation of choice is a 10 cm reversed jejunal interposition placed in continuity 100 cm distal to the ligament of Treitz. Another option is the onlay antiperistaltic distal ileal graft. Both operations can cause obstructive symptoms and/or bacterial overgrowth.

Gastric stasis following operation on the stomach may be because of a problem with gastric motor function or an obstruction. The gastric motility abnormality may have been preexisting and unrecognized by the operating surgeon. Alternatively, it may be secondary to deliberate or unintentional vagotomy or resection of the dominant gastric pacemaker. An obstruction may be mechanical (e.g., anastomotic stricture, efferent limb kink from adhesions or constricting mesocolon, or a proximal small bowel obstruction), or functional (e.g., retrograde peristalsis in a Roux limb). Gastric stasis presents with vomiting (often of undigested food), bloating, epigastric pain, and weight loss. The evaluation of a patient with suspected postoperative gastric stasis includes EGD, upper GI, gastric emptying scan, and gastric motor testing. Once mechanical obstruction has been ruled out, medical treatment is successful in most cases of motor dysfunction following previous gastric surgery. This consists of dietary modification and promotility agents. Intermittent oral antibiotic therapy may be helpful in treating bacterial overgrowth with its attendant symptoms of bloating, flatulence, and diarrhea. Gastroparesis following vagotomy and drainage may be treated with subtotal (75 percent) gastrectomy. Billroth-II anastomosis with Braun enteroenterostomy may be preferable to Roux-en-Y reconstruction. This latter option may be associated with persistent emptying problems which will subsequently require near-total or total gastrectomy, a nutritionally unattractive option. Gastric pacing is promising, but it has not achieved widespread clinical usefulness in the treatment of postoperative gastric atony.

Bile reflux gastritis. Most patients who have undergone ablation or resection of the pylorus have bile in the stomach on endoscopic examination, along with some degree of gross or microscopic gastric inflammation. Therefore attributing postoperative symptoms to bile reflux is problematic, because most asymptomatic patients have bile reflux too. However it is generally accepted that a small subset of patients have bile reflux gastritis, and present with nausea, bilious vomiting, and epigastric pain and quantitative evidence of excess enterogastric reflux. Curiously, symptoms often develop months or years after the index operation. The differential diagnosis includes afferent or efferent loop obstruction, gastric stasis, and small bowel obstruction. Bile reflux may be quantitated with gastric analysis, or more commonly scintigraphy (bile reflux scan). Remedial operation will eliminate the bile from the vomitus and may improve the epigastric pain, but it is quite unusual to render these patients completely asymptomatic, especially if they are narcotic dependent. Bile reflux gastritis after distal gastric resection may be treated by one of the following options: Roux-en-Y gastrojejunostomy; interposition of a 40-cm isoperistaltic jejunal loop between the gastric remnant and the duodenum (Henley loop); Billroth-II gastrojejunostomy with Braun enteroenterostomy. To avoid bile reflux into the stomach the Roux limb should be at least 45 cm long. The Braun enteroenterostomy should be placed a similar distance from the stomach. Primary bile reflux gastritis (i.e. no previous operation) is rare, and may be treated with the duodenal switch operation, essentially an end-to-end Roux-en-Y to

the proximal duodenum. The Achilles heel of this operation is, not surprisingly, marginal ulceration. Thus it should be combined with highly selective vagotomy, and perhaps H_2 blockers.

Roux syndrome. A subset of patients who have had distal gastrectomy and Roux-en-Y gastrojejunostomy will have great difficulty with gastric emptying in the absence of mechanical obstruction. These patients present with vomiting, epigastric pain, and weight loss. This clinical scenario has been labeled the Roux syndrome. Endoscopy may show bezoar formation, dilation of the gastric remnant, and/or dilation of the Roux limb. Upper GI confirms these findings and may show delayed gastric emptying. This is better quantitated by a gastric emptying scan which always shows delayed solid emptying, and may show delayed liquid emptying as well.

GI motility testing shows abnormal motility in the Roux limb, with propulsive activity toward rather than away from the stomach. Gastric motility may also be abnormal. The disorder seems to be more common in patients with a generous gastric remnant. Truncal vagotomy has also been implicated. Medical treatment consists of promotility agents. Surgical treatment consists of paring down the gastric remnant. If gastric motility is severely disordered, 95 percent gastrectomy should be done. The Roux limb should be resected if it is dilated and flaccid, and doing so does not put the patient at risk for short bowel problems. Gastrointestinal continuity may be re-established with another Roux, a Billroth II with Braun enteroenterostomy, or an isoperistaltic jejunal interposition between the stomach and the duodenum (Henley loop). Truncal vagotomy should probably not be done. Long term acid suppression may be necessary.

Weight loss is common in patients who have had a vagotomy and/or gastric resection. The degree of weight loss tends to parallel the magnitude of the operation. It may be insignificant in the large person, or devastating in the asthenic female. The surgeon should always reconsider before performing a gastric resection for benign disease in a thin female. The causes of weight loss after gastric surgery generally fall into one of two categories: altered dietary intake or malabsorption. If a stool stain for fecal fat is negative, it is likely that decreased caloric intake is the cause. This is the most common cause of weight loss after gastric surgery and may be because of small stomach syndrome, postoperative gastroparesis, or self-imposed dietary modification because of dumping and/or diarrhea. Specific problems may be treated as outlined above. Consultation with an experienced dietitian may prove invaluable.

Anemia. Iron absorption takes place primarily in the proximal gastrointestinal tract, and is facilitated by an acidic environment. Intrinsic factor, essential for the enteric absorption of vitamin B12, is made by the parietal cells of the stomach. Vitamin B12 bioavailability is also facilitated by an acidic environment. Patients with small gastric pouch, decreased compliance or anastomotic stricture may avoid bulky green vegetables, a rich source of folate. Patients who have had gastric surgery should be monitored for anemia, and for iron, folate, and B12 deficiency. Prophylactic vitamin and iron supplementation may be prudent, with therapeutic supplementation required to correct any documented deficiency. Of course, patients who have had a total gastrectomy will all develop B12 deficiency without parenteral vitamin B12 supplementation.

Bone disease. Gastric surgery not uncommonly disturbs calcium and vitamin D metabolism. Calcium absorption occurs primarily in the duodenum, which is bypassed with gastrojejunostomy. Fat malabsorption may occur because of blind loop syndrome and bacterial overgrowth, or because of inefficient mixing of food and digestive enzymes. This can significantly affect the absorption of vitamin D, a fat-soluble vitamin. Both abnormalities of calcium and vitamin D metabolism can contribute to metabolic bone disease in patients following gastric surgery. The problems usually manifest as pain and/or fractures years after the index operation. Musculoskeletal symptoms should prompt a study of bone density. Dietary supplementation of calcium and vitamin D may be useful in preventing these complications. Routine skeletal monitoring of patients at high risk (e.g., older adult male and female; postmenopausal females) may prove useful in identifying skeletal deterioration that with appropriate treatment may be arrested.

THE DISEASE OF OBESITY

Obesity is a serious disease that carries substantial morbidity and mortality. The degrees of obesity are defined by body mass index [BMI = weight (kg)/height (m)²], which correlates body weight with height. Patients are classified as overweight, obese, or severely obese (sometimes referred to as morbidly obese) (Table 26-1). Morbidly obese individuals generally exceed ideal body weight by 100 lb or more, or are 100 percent over ideal body weight, but more uniformly have a BMI of more than 40 kg/m². Superobesity is a term sometimes used to define individuals who have a body weight exceeding a BMI of 50 kg/m² or greater.

Prevalence and Contributing Factors

Morbid obesity is reaching epidemic proportions in the United States. Since 1960, surveys of the prevalence of obesity have been conducted every decade by the National Center for Health Statistics. Twenty-five percent of adult Americans were overweight in 1980 compared to 34 percent in 1990. This trend has even increased in the past decade. In 1990, conservative estimates put the number of Americans with a BMI between 35 and 40 kg/m² at 4 million, with an additional 4 million having a BMI exceeding 40 kg/m². Current estimates put that patient population at over 20 million. Despite the expenditure of over \$30 billion annually on weight loss products, the prevalence of obesity is increasing. Obesity is most common in minorities, low-income groups, and women.

The increase in obesity is multifactorial. Genetics play an important role in the development of obesity. Although children of parents of normal weight have a 10 percent chance of becoming obese, the children of two obese parents have an 80–90 percent chance of developing obesity by adulthood. The weight of adopted children correlates strongly with the weight of their birth parents. Furthermore, concordance rates for obesity in monozygotic twins are doubled compared to others.

Diet and culture are important factors as well; these environmental factors contribute significantly to the epidemic of obesity in the United States because the rapid increase in obesity during the past two decades cannot be explained by any genetic etiology.

Clinical Presentation

The morbidly obese patient often presents with chronic weight-related problems, detailed below. The morbidly obese almost uniformly endure discrimination, prejudice, ridicule, and inappropriately disrespectful treatment from the public. Consequently, the stigma of morbid obesity has a major impact on social function and emotional well-being.

Significant comorbidities, defined as medical problems associated with or caused by obesity, are numerous. The most prevalent and acknowledged of

TABLE 26-1 Assessing Disease Risk Using Body Mass Index and Waist Size

Category	BMI	Men (< 40 in.) women (< 35 in.)	Men (> 40 in.) women (> 35 in.)
Underweight	< 18.5	—	—
Normal	18.5–24.9	—	—
Overweight	25.0–29.9	+	+
Obesity	³ 30		
Class I	30.0–34.9	+	++
Class II	35.0–39.9	++	++
Class III (extreme obesity)	³ 40	+++	

these include degenerative joint disease, low back pain, hypertension, obstructive sleep apnea, gastroesophageal reflux disease (GERD), cholelithiasis, type 2 diabetes, hyperlipidemia, hypercholesterolemia, asthma, hypoventilation syndrome of obesity, fatal cardiac arrhythmias, right sided heart failure, migraine headaches, pseudotumor cerebri, venous stasis ulcers, deep venous thrombosis, fungal skin rashes, skin abscesses, stress urinary incontinence, infertility, dysmenorrhea, depression, abdominal wall hernias, and an increased incidence of various cancers such as those of the uterus, breast, colon, and prostate.

Prognosis

Obesity has a profound effect on overall health and life expectancy, largely secondary to weight-related comorbidities. Obesity is now considered to be the second leading cause of preventable death behind cigarette smoking. The incidence of morbidity and mortality is directly related to the degree of obesity. In a study with 12-year follow-up, mortality rates for those weighing 50 percent over average weight were doubled. A study carried out by the Veterans Administration demonstrated a 12-fold increase in mortality among morbidly obese men aged 25–34 years, and a 6-fold increase among morbidly obese men aged 35–44 years.

Medical Management

Treatment of morbid obesity should begin with simple lifestyle changes, including moderation of diet and initiation of regular exercise such as walking. The treatment of associated comorbidities should be addressed expeditiously. However, because the only effective treatment for morbid obesity is bariatric surgery, these are the initial steps to be taken in preparation for the more definitive, albeit invasive, treatment.

Pharmacotherapy is a second tier therapy usually used in heavier patients (BMI > 27) or when lifestyle changes alone have failed. Sibutramine and orlistat are the only current Food and Drug Administration (FDA)–approved drugs for weight loss treatment. Orlistat is a potent and selective inhibitor of gastric and pancreatic lipases that reduces lipid intestinal absorption, although sibutramine is a noradrenaline and 5-hydroxytryptamine reuptake inhibitor that works as an appetite suppressant. Despite their different mechanisms of action, they effectively produce weight loss of 6–10 percent of initial body weight at 1 year, but much of this weight is regained once the drug is stopped.

OVERVIEW OF BARIATRIC SURGERY

The goal of bariatric surgery is to improve health in morbidly obese patients by achieving long-term, durable weight loss. It involves reducing caloric intake and/or absorption of calories from food, and may modify eating behavior by promoting slow ingestion of small boluses of food.

Restrictive operations restrict the amount of food intake by reducing the quantity of food that can be consumed at one time, which results in a reduction in caloric intake. Malabsorptive procedures limit the absorption of nutrients and calories from ingested food by bypassing the duodenum and predetermined lengths of small intestine.

The operations currently in use for the management of morbid obesity involve gastric restriction with or without intestinal malabsorption. Purely gastric restrictive procedures include vertical banded gastroplasty (VBG) and laparoscopic adjustable gastric banding (LAGB). Primarily malabsorptive procedures include biliopancreatic diversion (BPD), and biliopancreatic diversion with duodenal switch (BPD-DS). Roux-en-Y gastric bypass (RYGB) has features of primary restriction with some malabsorption. The advent of laparoscopic techniques allowed surgeons to offer minimally invasive approaches to these bariatric procedures.

Indications

Patients that have a BMI of 35 kg/m^2 or more with comorbidity, or those with a BMI of 40 kg/m^2 or greater regardless of comorbidity, are eligible for bariatric surgery. Candidates should have attempted weight loss in the past by medically supervised diet regimens, exercise, or medications, but this is not mandatory. They must be motivated to comply with postoperative dietary and exercise regimens and follow up. Traditionally, surgeons have offered bariatric surgery to patients aged 18–60 years. However, bariatric surgery is now offered to carefully selected older adults at some institutions with no reported increase in morbidity or mortality. Adolescent patients with morbid obesity may be considered for bariatric surgery under selected circumstances. A summary of appropriate indications for bariatric surgery and approved bariatric operations was recently published after a consensus conference held by the American Association for Bariatric Surgery (ASBS).

Contraindications

Patients who are unable to undergo general anesthesia because of cardiac, pulmonary, or hepatic disease, or those who are unwilling or unable to comply with postoperative lifestyle changes, diet, supplementation, or follow up should not undergo these procedures. Patients with ongoing substance abuse, unstable psychiatric illness, or inadequate ability to understand the consequences of surgery are also considered to be poor surgical candidates.

Preparation for Surgery

Comorbidities are identified during the medical and surgical history taking and physical examination of the patient. Preoperative testing should be performed and additional studies should be considered, depending on the patient's comorbidities. A preoperative electrocardiogram should be obtained for all patients. Patients with cardiovascular disease should have preoperative evaluation

by a cardiologist. Echocardiography, stress testing, and cardiac catheterization may be indicated.

Symptoms of loud snoring or daytime sleepiness in a morbidly obese patient should prompt a work-up for obstructive sleep apnea. The diagnosis is established by polysomnography at a sleep center. Patients with significant sleep apnea are treated with nasal continuous positive airway pressure. Obesity hypoventilation syndrome is characterized by hypoxemia (partial pressure of arterial oxygen [P_{aO_2} < 55 mmHg]) and hypercarbia (partial pressure of carbon dioxide [P_{aCO_2} > 47 mmHg]), with severe pulmonary hypertension and polycythemia. These patients require preoperative evaluation by a pulmonologist, and consideration of intensive care monitoring postoperatively. They also are possibly at increase risk for venous thromboembolic complications.

Patients with severe gastroesophageal reflux should undergo upper endoscopy with possible biopsy to rule out esophagitis or Barrett esophagus. Because of the high incidence of gallstones in the obese population, many surgeons advocate routine preoperative sonography, and cholecystectomy when stones are present.

Nutritional evaluation and education is invaluable in the preoperative period. The dietitian may help determine whether the patient is able to understand the necessary changes in postoperative eating habits and food choices.

The objective of psychologic screening for obesity surgery is to determine whether a patient has realistic expectations about the results of the procedure, and a fundamental understanding of the impact that it will have on his or her life. It may also help to identify patients suffering from depression, history of abusive relationships, or psychotic disorders that were previously unrecognized and that may require intervention.

Assessment of Results

Weight loss has traditionally been used as the main outcome measure in bariatric surgery. Although an easily measured objective parameter, weight loss alone is insufficient as a single outcome goal in bariatric surgery outcomes.

The National Institute of Health (NIH) Conference recommended statistical reporting of surgical results, including quality of life, to provide a clearer assessment of outcomes. It underlines the fact weight loss should be considered the main postoperative outcome, but improvement of medical conditions associated with obesity is also desirable. The Bariatric Analysis and Reporting Outcome System (BAROS) has been developed to standardize and compare outcomes of bariatric surgical series.

Follow-up

A bariatric electronic database is very useful for outcomes reporting and further analyses. All bariatric surgeons should record such data so as to be aware of their outcomes.

The ASBS recommends visits during the immediate postoperative period, and then at variable intervals for life, with additional visits as needed, depending on the patient's condition. A typical schedule for visits is 1–2 weeks, 4–6 weeks, 3 months, 6 months, 1 year, then annually after surgery. Patients are encouraged to comply with lifelong follow-up, exercise, and vitamin supplementation after undergoing bariatric surgery. Follow-up includes assessment of weight loss trends and regular monitoring of metabolic and nutritional parameters.

Efficacy

Past randomized controlled trials have established the superiority of surgical weight loss procedures over nonsurgical approaches in achieving durable weight loss. The Swedish Obese Subjects (SOS) matched pair cohort study compared surgery with nonsurgical treatment. Weight loss at 2 years was 28 ± 15 kg among the operated patients and 0.5 ± 8.9 kg among the obese controls. At 8 years weight loss remained significantly different. There was also a reduction in the incidence of diabetes and hypertension at 2 years, which remained for diabetes at 8 years. The SOS trial also provides evidence for improvement in quality of life.

Gastric bypass produces weight loss of 68 percent to 62 percent of excess weight at one to three years postoperatively. Long-term (5 to 14 years) excess weight loss has been 49–62 percent. Laparoscopic and open approaches to RYGB appear to result in similar weight loss. Studies reporting gastric banding results collectively demonstrate a 40–60 percent mean estimated weight loss (EWL) at 3–5 years. Patients with malabsorption procedures had up to 78 percent EWL at 18 years.

BARIATRIC SURGICAL PROCEDURES

Vertical Banded Gastroplasty

The VBG is listed and described here as much for historic reasons as for practical applicability today. It represents the procedure least commonly done in the United States over the past several years. Its abandonment has been largely because of the poor overall long-term weight loss observed in many studies.

The VBG is purely restrictive in nature. A proximal gastric pouch empties through a calibrated stoma, which is reinforced by a strip of mesh or a Silastic ring.

Technique

Mason first described the VBG in 1982. A 32F Ewald tube is passed orally into the stomach and positioned against the lesser curvature. A circular stapler is positioned against it and used to create a 2.5-cm window through the stomach 8–9 cm below the angle of His. A line of four rows of 90-mm staples leads from the circular opening to the angle of His to create a pouch 50 mL in size or smaller. Using a linear stapler to divide this tissue prevents staple line breakdown. A 7×1.5 cm. strip of polypropylene mesh is placed around the lesser curvature channel and is sewn to itself to create a 5.0–5.5-cm collar. The laparoscopic technique follows the same steps.

Another technique involves use of a linear cutting stapler to excise a wedge of fundus, thereby creating a 20-mL pouch without the use of a circular stapler. A polypropylene mesh or polytetrafluoroethylene band is sutured around the distal end of the gastroplasty.

Efficacy

VBG achieves acceptable short- to medium-term weight loss. In a series of 305 patients followed for a minimum of 2 years, a mean excess weight loss of 61 percent was reported. Studies have shown excess weight loss of 63 percent after 7 years.

A significant number of patients have required reoperation following VBG. In a study from Spain, 25 percent of patients required reoperation for complications related to the technique. A prospective study of 71 patients who underwent VBG with a 99 percent 10-year follow up reported that only 26 percent had maintained a loss of at least 50 percent of their excess weight, and 17 percent had a bariatric reoperation. In a study of 60 patients followed for a median of 9.6 years, only 40 percent maintained their original weight loss, although 60 percent regained a significant amount of weight and 31 percent returned to preoperative weight. Patients who regain weight were found to change eating patterns to adopt a diet high in high-calorie soft and liquid foods.

Complications

The overall operative morbidity rate with VBG is under 10 percent and the mortality rate is 0–0.38 percent. Late complications include stomal stenosis, which may occur in 15–20 percent, and staple line dehiscence, which occurs in up to 48 percent if the linear staple line is not a divided one. In a series from MacLean and associates, 30 percent of all patients required reoperations for this problem. Reflux esophagitis may occur in 16–38 percent of patients, and some patients may require conversion to Roux-en-Y gastric bypass for severe symptoms. Intractable vomiting one or more times a week was seen in as many as 30–50 percent of patients.

Advantages and Disadvantages

Weight loss following VBG can significantly improve comorbidities. VBG is associated with minimal long-term metabolic or nutritional deficiencies. It is technically easier to perform than RYGB, and requires less operative time. These relative advantages of VBG, however, are more than overshadowed by the disadvantages of poor long-term weight loss and the high incidence of long-term complications listed above.

Laparoscopic Adjustable Gastric Banding

Technique

The patient is placed in reverse Trendelenburg position. Six laparoscopic ports are placed. A 5-mm liver retractor is used to elevate the left hepatic lobe. A 15-mL gastric calibration balloon is used to identify the location for the initial dissection. A retrogastric tunnel is created starting at the base of the right diaphragmatic crus, using the pars flaccida technique. The silicone band is passed through the tunnel so that it encircles the cardia of the stomach about 1 cm below the gastroesophageal junction. The tail of the silicone band is passed through the buckle of the band and locked into place. A calibration tube is reinserted to determine the stoma diameter. Interrupted sutures are placed to imbricate the anterior stomach over the band in all but the buckle area. The end of the silicone tube is brought out through the abdominal wall and connected to the access port. The port, which will subsequently be used for injection or withdrawal of saline postoperatively for band volume adjustment, is secured to the anterior rectus sheath.

Postoperative Care

Patients are given clear liquids a few h after the procedure. A Gastrografin swallow is obtained on the first postoperative day to confirm band position and

patency. Patients can generally be discharged 1–2 days after surgery with a liquid diet for 4 weeks.

Band adjustment may be performed with fluoroscopic guidance initially at 8–12 weeks. Patients are assessed monthly for weight loss and tolerance of oral intake. Band adjustments are made accordingly and as needed every 4–8 weeks during the first year, with the band progressively tightened as needed to provide slow but steady weight loss of 1–2 kg per week.

Efficacy

Suter et al observed mean excess weight loss after LAGB at 1 and 2 years was 55 and 56 percent, respectively. O'Brien and associates reported a series of over 700 patients undergoing LAGB and observed steady progression of weight loss, with 52 ± 19 percent EWL at 24 months ($n = 333$), 52 ± 24 percent EWL at 48 months ($n = 108$), 54 ± 24 percent EWL at 60 months ($n = 30$). Major improvements occurred in diabetes, asthma, GERD, dyslipidemia, sleep apnea, and depression. Quality of life showed highly significant improvement.

Data on 1893 patients who underwent LAGB were reported by the Italian Collaborative Study Group for the Lap-Band System. Weight loss was evaluated at 24, 36, 48, 60, and 72 months, with a BMI of 34.8, 34.1, 32.7, 34.8, and 32 kg/m², respectively.

Complications

During LAGB, intraoperative complications include splenic injury, esophageal or gastric injury (0–1 percent), conversion to an open procedure (1–2 percent), and bleeding (0–1 percent). Early postoperative complications include bleeding (0.5 percent), wound infection (0–1 percent), and food intolerance (0–11 percent). Late complications include slippage of the band (7.3–21 percent), band erosion (1.9–7.5 percent), tubing-related problems (4.2 percent), leakage of the reservoir, persistent vomiting (13 percent), pouch dilatation (5.2 percent) and gastroesophageal reflux.

In O'Brien's report, there were no deaths perioperatively or during follow up in 700 patients. Postoperative complications occurred in 1.2 percent of patients. Reoperation was needed for prolapse (slippage) in 12.5 percent, erosion of the band into the stomach in 2.8 percent, and for tubing breaks in 3.6 percent of patients. Among the patients requiring reoperation, 12 (1.7 percent) had the device removed.

The Italian Cooperative Group reported a postoperative mortality of 0.53 percent, a conversion to open rate of 3.1 percent, and a postoperative complication rate of 10.2 percent. Complications included tube port failure 4.1 percent, gastric pouch dilation (4.9 percent), and gastric erosion (1.1 percent).

Advantages and Disadvantages

LAGB is a relatively simple procedure that takes less operative time than the more complex procedures such as laparoscopic RYGB or laparoscopic BPD. The mortality rate is very low (0.06 percent), as are conversion rates (0–4 percent). No staple lines or anastomoses are required. Recovery is rapid and hospital stay is short. Performance as an outpatient has been reported. The adjustable nature of the laparoscopic band allows the degree of restriction to be optimized.

Disadvantages include the potential for port site complications and the need for frequent postoperative visits for band adjustment. Some patients

(5–10 percent) experience band slipping or gastric prolapse, which usually requires reoperation. Other potential problems include band erosion, GERD, alterations in esophageal motility, and esophageal dilatation.

Open Roux-en-Y Gastric Bypass

Technique

The peritoneum between the angle of His and the tip of the superior pole of the spleen is opened. The gastrohepatic ligament is opened, and the mesentery between the first and second branches of the left gastric artery is divided. Blunt dissection is carried out between the opening in the gastrohepatic omentum and the angle of His. An appropriate size (28F–36F) red rubber tube or Mallekot catheter is placed behind the stomach, and the open end of the tube is then brought through the opening in the mesentery and used to guide a linear stapler across the stomach. The stomach is completely divided using the linear stapler, creating the proximal gastric pouch.

The ligament of Treitz is identified and a point 15–45 cm distally is identified. The jejunum is divided with a linear stapling device. The mesentery is divided between clamps to mobilize the Roux limb, and a side-to-side jejuno-jejunostomy is created with a linear stapler to create a 50–75-cm Roux limb for a standard gastric bypass, or a 150-cm limb for a long-limb modification in the superobese. The enterotomy is closed as is the mesenteric defect.

The Roux limb is most commonly brought through the transverse mesocolon and behind the stomach, but may also be brought anterior to the colon or anterior to the stomach. A gastrojejunal anastomosis is created between the gastric pouch and the proximal end of the Roux limb, using either a linear stapler, circular stapler or a hand-sewn technique. The integrity of the anastomosis is tested by injecting methylene blue or air under pressure (to distend the pouch). All mesenteric defects are closed.

Postoperative Care

Early ambulation postoperatively is important to help prevent deep venous thrombosis. Pain control must be adequate to allow coughing and use of incentive spirometry. Although controversial, we obtain a Gastrografin swallow on postoperative day 1 to document pouch size, proximal and distal anastomotic patency, lack of obstruction, and reconfirm the absence of leakage (although clinical criteria outweigh the results of such testing for determining reoperation for suspected leak). Liquids are started after this study, if all appears well. Patients are generally discharged 2–4 days after surgery.

Efficacy

RYGB results in weight loss that is slightly superior to that of purely restrictive operations. Five-year weight loss results have ranged from 48–74 percent excess weight loss. One series of 608 patients followed over 14 years with less than 3 percent of patients lost to follow up has demonstrated a 49 percent excess weight loss.

RYGB has been demonstrated not only to prevent the progression of non-insulin-dependent diabetes mellitus, but also to reduce the mortality from diabetes mellitus, primarily because of a reduction in the number of deaths from cardiovascular disease. Durable control of diabetes mellitus is achieved following RYGB, along with amelioration or resolution of other comorbidities such as hypertension, sleep apnea, GERD, and cardiopulmonary failure. Other

obesity-related medical illnesses that have shown improvement or resolution following RYGB include hyperlipidemia, hypertension, asthma, osteoarthritis, angina, venous stasis, and obesity-hypoventilation syndrome.

Complications

Early complications include anastomotic leak with peritonitis (1.2 percent), acute distal gastric dilatation, Roux limb obstruction, severe wound infection (4.4 percent), and minor wound infection or seroma (11.4 percent). Late complications include stomal stenosis (15 percent), marginal ulcer (13 percent), intestinal obstruction (2 percent), internal hernia (1 percent), staple line disruption (0 to 1 percent), incisional hernia (16.9 percent), cholecystitis (10 percent). Mortality in the best of series is as low as 0.4 percent, and more commonly at 1–2 percent in general practice. Metabolic complications include deficiencies of vitamin B12 (26–40 percent), iron (20–49 percent), and anemia (18–35 percent).

A few postoperative complications are specific to RYGB, including distal gastric distention and internal hernia. Distal gastric distention, usually because of obstruction at or distal to the enteroenterostomy, is an emergency requiring percutaneous or operative decompression of the distal stomach. Internal hernias, at times difficult to diagnose, may present with vague periumbilical pain, nausea, and vomiting. A radiographic upper gastrointestinal study or computed tomography (CT) scan may be helpful in diagnosis, but may not be diagnostic. Operative exploration and repair is indicated if this diagnosis is being entertained.

Advantages and Disadvantages

The RYGB is more effective than VBG in terms of weight loss, as is detailed above. This is true even if diet preferences are selected for preoperatively. Overall resolution of comorbidities, especially those of diabetes, GERD, and perhaps hyperlipidemias appear better after RYGB than after any of the restrictive operations. RYGB has become the most popular bariatric operation in the United States, because of its overall effectiveness and relatively low need for reoperation.

Dumping syndrome occurs in a variable number of patients following gastric bypass. Patients may experience bloating, nausea, diarrhea, and abdominal pain after ingesting sweets or milk products. Vasomotor symptoms such as palpitations, diaphoresis, and lightheadedness also may occur. Dumping syndrome may provide a beneficial effect in promoting weight loss by causing patients to avoid sweets.

Laparoscopic Roux-en-Y Gastric Bypass

Technique

Laparoscopic RYGB was first described by Wittgrove, Clark, and Tremblay in 1994. After pneumoperitoneum is established, five or six access ports are inserted. A vertically oriented proximal gastric pouch measuring 15–30 mL is created from the proximal lesser curvature portion of the stomach using sequential applications of a linear endoscopic stapler.

The ligament of Treitz is identified, and the jejunum is divided 20–50 cm distally with a linear stapler. More distal division is needed if an antecolic route of the Roux limb is planned. A 75–150-cm Roux limb (once again based on patient's preoperative weight) is constructed and a side-to-side jejunojejunostomy

is created with linear endoscopic staplers. Some groups use an elongated Roux limb of 150–250 cm for superobesity.

The gastrojejunal anastomosis may be stapled or hand-sewn. Several stapling techniques have been described. For a circular stapled anastomosis with transoral passage of the anvil, upper endoscopy is performed and a looped wire is used to pass the anvil of a circular stapler into and through the wall of the pouch. An incision is made near the end of the Roux limb to admit the circular stapler, which is mated with the anvil to create the stapled anastomosis.

To create a circular stapled anastomosis with transgastric anvil insertion, a gastrotomy is created on the anterior stomach and the anvil is introduced into the stomach. The tip is brought through the gastric wall; the pouch is then created using sequential firings of the linear stapler.

For a linear-stapled anastomosis, a posterior layer of sutures is placed to approximate the Roux limb to the pouch. A 45-mm linear stapler is used to create the gastrojejunostomy. Closure of the stapler defect is performed with two layers of sutures.

The gastrojejunal anastomosis may also be completely hand-sewn in two layers using absorbable suture.

Insufflation of the gastric pouch with air by endoscopy or orogastric tube or with methylene blue is performed to test the integrity of the anastomosis. Port sites larger than 5 mm are closed at the fascial level.

Postoperative Care

Some surgeons place a Jackson-Pratt or Blake drain at the anastomosis, which is left in place for a varying length of time, depending on surgeon preference. Nasogastric tubes are not used routinely. Early postoperative mobilization is emphasized. Parameters used for open RYGB are similarly used for LRYGB.

Efficacy

Mean excess weight loss after LRYGB ranges from 69–82 percent with follow-up of 24 months or less. Wittgrove and associates demonstrated a mean excess weight loss of 73 percent with follow up of 60 months. Schauer and associates showed the mean excess weight loss was 83 and 77 percent at 24 and 30 months, respectively. Most comorbidities were improved or eradicated, including diabetes mellitus, hypertension, sleep apnea, and GERD. Quality of life was improved significantly.

Complications

Postoperative complications observed after LRYGB include pulmonary embolism (0–1.5 percent), anastomotic leak (1.5–5.8 percent), bleeding (0–3.3 percent), and pulmonary complications (0–5.8 percent). Stenosis of the gastrojejunostomy is observed in 1.6–6.3 percent. Other complications include internal hernia (2.5–5 percent), gallstones (1.4 percent), marginal ulcer (1.4 percent), and staple-line failure (1 percent). Conversion to an open procedure occurs in 3–9 percent. The mortality rate is 0–1.5 percent.

Advantages and Disadvantages

LRYGB offers the advantages over open RYGB of better cosmesis, less postoperative pain, and attenuation of the postoperative stress response. Patients recover rapidly and have a shorter hospital stay. There is an improvement in postoperative pulmonary function with the laparoscopic procedure. The principal advantage of the laparoscopic approach has been in reducing perioperative

morbidity, in particular the marked reduction in wound-related complications, including incisional hernias.

LRYGB, although safe and feasible, is a technically challenging, advanced laparoscopic procedure with a steep learning curve. This approach may be more difficult in superobese patients, those with large livers, and those who have a preponderance of fat in the abdominal area.

Biliopancreatic Diversion

Indications

BPD is primarily indicated for the superobese, for those who have failed restrictive bariatric procedures, or for those patients wishing to have less restriction on their ability to eat after surgery but willing to accept the consequences of increased bowel frequency and diarrhea.

Contraindications

Patients with anemia, hypocalcemia, and osteoporosis, and those who are not motivated to comply with stringent postoperative supplementation regimens may not be appropriate for this procedure. Patients whose social situation and geographic location suggest they may be noncompliant with follow up also are not good candidates. The laparoscopic approach may be especially challenging in patients who have undergone multiple previous abdominal surgeries, previous weight loss surgery, patients with an enlarged fatty liver, and in those with a large amount of intraabdominal fat.

Technique

The BPD was developed by Nicola Scopinaro of Italy. The procedure combines mild to moderate gastric restriction with an intestinal malabsorptive procedure.

A subtotal distal gastrectomy is performed, leaving a proximal 200-mL gastric pouch for the superobese patient, or up to a 400-mL pouch for the others. The terminal ileum is measured, and the intestine divided 250 cm proximal to the ileocecal valve. The distal end of this divided bowel is anastomosed to the gastric pouch with a 2–3-cm stoma. An enteroenterostomy is created 50–100 cm proximal to the ileocecal valve to incorporate the distal end of the biliopancreatic limb into the alimentary stream. A concomitant cholecystectomy is performed.

Biliopancreatic Diversion with Duodenal Switch

A modification of this technique is called the biliopancreatic diversion with BPD-DS. This involves performing a greater curvature sleeve gastrectomy, with maintenance of the continuity of the antrum, pylorus, and first portion of the duodenum. The distal bowel division and connections are the same, except the anastomosis to the stomach is instead performed to the distal stump of the retained first portion of the duodenum. This may be an end to side or end to end anastomosis, and is often performed using a circular stapler.

The BPD-DS allows for a lower marginal ulcer rate (0–1 percent) and a lower incidence of dumping syndrome. For the laparoscopic approach, six to eight laparoscopic ports are inserted. A sleeve gastrectomy is performed to create a gastric reservoir of 150–200 mL. As in the open procedure, the ileum is divided 250 cm proximal to the ileocecal valve and is anastomosed to the first

portion of the duodenum. An enteroenterostomy is created laparoscopically, leaving a 100 cm common channel.

Postoperative Care

The patient must be on lifelong vitamin, calcium, and iron supplementation, and must comply with lifelong follow up because of the risk of malnutrition. Fat soluble vitamin supplementation is indicated, and this must often be done using the parenteral route. Careful follow-up is necessary to be on alert for the potential for protein-calorie malnutrition, which is important to recognize and treat aggressively with parenteral nutrition or even, if persistent, revision and lengthening of the common channel.

Efficacy

Weight loss results with BPD are excellent and durable. At 8 years, patients weighing up to 120 percent of ideal body weight, and those weighing more than 120 percent of ideal body weight maintained 72 and 77 percent mean excess weight loss, respectively. A group of 40 patients had a mean excess weight loss of 70 percent for a 15-year period.

The results of laparoscopic BPD-DS in 40 patients were reported. Median preoperative BMI was 60 kg/m². There was one conversion to an open procedure (2.5 percent). Median length of stay was 4 days. Mean excess weight loss at 6 and 9 months was 46 ± 2 percent and 58 ± 3 percent, respectively, with a median follow up of 6 months.

Complications

The incidence of postoperative complications, including nutritional ones, is substantial following BPD. The most common morbidities include anemia (30 percent), protein-calorie malnutrition (20 percent), dumping syndrome, and marginal ulceration (10 percent). The duodenal switch modification is associated with a lower ulceration rate (1 percent) and a lower incidence of dumping syndrome. Other complications include vitamin B12 deficiency, hypocalcemia, fat-soluble vitamin deficiencies, osteoporosis, night blindness, and prolongation of prothrombin time. The postoperative mortality rate ranges from 0.4–2.5 percent.

From Scopinaro's series, early surgical complications included wound infection and dehiscence (1.2 percent). Late complications included incisional hernia (8.7 percent), intestinal obstruction (1.2 percent), protein malnutrition (7 percent), iron deficiency anemia (< 5 percent), stomal ulcer (2.8 percent), and acute biliopancreatic limb obstruction. Bone demineralization was seen in 25 percent preoperatively; at 1–2 years, it was observed in 29 percent. At 3–5 years, it was present in 53 percent, and in 14 percent at 6–10 years.

In a laparoscopic series from Ren and colleagues, there was one death (2.5 percent). The major morbidity rate was 15 percent, including anastomotic leak (2.5 percent), venous thrombosis (2.5 percent), staple-line hemorrhage (10 percent), and subphrenic abscess (2.5 percent).

Advantages and Disadvantages

Even if patients consume a great quantity of food, the malabsorptive component of the BPD allows for excellent results in terms of weight loss. This operation may be more effective than RYGB or LAGB in the patients with BMI greater than 70 kg/m², or in those who have failed to maintain weight loss following those operations. Patients are not as restricted in terms of types of food that

they may eat. Of the BPD or BPD-DS options, the BPD is generally felt to be technically easier to perform, as the duodenoileostomy anastomosis is challenging. On the other hand, the BPD-DS does offer a lower incidence of dumping and marginal ulcer postoperatively. The laparoscopic versions of the BPD or BPD-DS procedures have the same advantages as the open approach versions.

The disadvantages of BPD include the fact it is technically more complex than any restrictive procedure. Protein malnutrition with anemia, hypoalbuminemia, edema, and alopecia are among the serious adverse sequelae of this operation. Severe iron and fat-soluble vitamin deficiencies may occur, leading to anemia, osteoporosis and night-blindness. Treatment requires prolonged supplementation, often parenteral. Routine replacement of fat-soluble vitamins is needed for patients following BPD or BPD-DS. Patients typically have four to six foul-smelling stools per day and may also experience bloating and heartburn.

Protein calorie malnutrition is a potentially life-threatening complication, which occurs in 3–20 percent of patients. It requires total parenteral nutrition to correct its acute phase, then improved diet intake and modification. If recurrent hypoalbuminemia persists, the common channel must be lengthened at reoperation.

The laparoscopic approaches to the BPD or BPD-DS are both especially challenging procedures technically, and are generally felt to be the most technically difficult laparoscopic bariatric operations to perform.

SPECIAL ISSUES RELATING TO THE BARIATRIC PATIENT

Bariatric Procedures in the Adolescent Patient

Bariatric surgery in morbidly obese adolescents is controversial. An estimated 25 percent of children in the United States are obese, a number that has doubled over a 30-year period. Although very little information has been published on the subject of obesity surgery in adolescents, review of the available literature shows that bariatric surgery in adolescents is safe and is associated with significant weight loss, correction of obesity-related comorbidities, and improved self-image and socialization.

Surgery may be indicated in this population because of the dismal failure of conservative methods of weight control. All patients should meet NIH criteria for bariatric surgery. Issues of preoperative consent and compliance with follow up suggest that patients who do undergo such procedures must have a more intensive multidiscipline team approach to preparation for and follow up after surgery.

The reports in the literature report small numbers of patients at any institution. Sugerman and associates described 33 adolescents who underwent gastroplasty ($n = 3$) or RYGB ($n = 30$). There were two late sudden deaths (2 and 6 years postoperatively), unrelated to the bariatric procedure. Significant weight loss was maintained in the majority of patients for up to 14 years after surgery. Most of comorbidities resolved at 1 year. Self-image was greatly enhanced, resulting in successful marriages and educational achievements. Capella and colleagues reported 19 adolescent patients undergoing banded RYGB who experienced an 80 percent excess weight loss at 5.5-year follow-up. Abu-Abeid reported 11 patients who underwent LAGB. Their mean BMI dropped from 46.6 down to 32.1 kg/m², with marked improvement in medical conditions.

Bariatric Surgery in Older Adult Patients

Information about the association between body weight and mortality at higher ages is sparse. Indices of visceral obesity may be better indicators of risk than BMI in these age groups. Not only actual weight, but also weight development over the last decades of life may predict outcome. Little is known about the benefits of diets or drugs that induce weight loss in this age group. Osteoarthritis and static respiratory complications seem to improve with weight loss, even at higher ages. Recent studies suggest that bariatric surgery, previously considered contraindicated in obese patients above age 60, can be safely performed even in patients above age 70, with the same benefits as those seen in younger patients.

Some surgeons have considered age 50 years or older as a relative contraindication to bariatric surgery. Gonzales et al demonstrated safety and efficacy in a group of patients aged 50 years or older undergoing RYGB. Macgregor and Rand reported that patients aged 55 years and older undergoing gastric restrictive surgery had an average loss of 57 percent excess body weight and 20–48 percent reduction of comorbidities. Nehoda and colleagues reported patients over age 50 who underwent LAGB experienced the same clinical outcome as younger patients.

The Female Patient: Pregnancy and Gynecologic Issues in the Bariatric Surgery Patient

Pregnancy in morbidly obese women carries increased risks, and should be managed as a high-risk pregnancy. The incidence of gestational diabetes and hypertension is increased, and macrosomia is common. Following the pregnancy is difficult because of limitations of the physical examinations. More costly, more frequent ultrasound examinations are needed. There is a 2–3-fold increase in the rate of cesarean sections, with more complications. However, fetal morbidity does not appear to be changed when maternal weight gain is limited.

Bariatric surgery reduces both a woman's weight and the incidence of obesity-related comorbidities, and appears to confer decreased risk to pregnancy. Dixon and associates suggest that morbidly obese women have higher obstetric risks and poorer neonatal outcomes. However, weight loss reduced obstetric risk. They noticed decreased maternal weight gain during pregnancy for women who underwent LAGB. No difference in birth weights was noted for women before and after LAGB. Obstetric complications were minimal, and there were no premature or low birth weight infants.

Wittgrove's group evaluated the rate of complications in patients becoming pregnant following RYGB or LRYGB. They found a lower risk of gestational diabetes, macrosomia, and cesarean section in postsurgical patients than in those who were obese and had not had bariatric surgery. Another study showed medical complications that were frequent during pregnancy whereas individuals were severely obese (hypertension 26.7 percent, preeclampsia 12.8 percent, diabetes 7.0 percent, and deep vein thrombosis 7.0 percent) did not occur after weight loss and weight stabilization. Because surgical patients after RYGB have had an operation that restricts food intake, some dietary precautions should be taken when they become pregnant. They are at risk for developing severe iron deficiency anemia because of poor absorption of iron.

The incidence of infertility is increased in morbidly obese women. Obesity-induced hormonal disorders contribute to biologic imbalance, and thus favor

the development of dysfunctional ovulation. An abnormal menstrual history is common. In one study, infertility problems were present preoperatively in 29.3 percent of female patients. Bariatric surgery results in normalization of many gynecologic and obstetric risks and problems from obesity. Menstrual irregularities decreased from 40.4–4.6 percent after bariatric surgery in one report.

The polycystic ovary syndrome results from a systemic hormonal dysfunction. Women with polycystic ovaries are frequently obese and have a higher risk of infertility, anovulation, hyperandrogenism, dyslipidemia, insulin resistance, and abnormal menses. Improvement of these problems may occur after surgically induced weight loss.

Obesity has a major impact on stress urinary incontinence. Women suffering from obesity manifest increased intraabdominal pressures, which adversely stress the pelvic floor and may contribute to the development of urinary incontinence. Additionally, obesity may affect the neuromuscular function of the genitourinary tract, thereby also contributing to incontinence. Dwyer and colleagues reported on incontinent women who underwent urodynamic assessment: 63 percent were diagnosed as having genuine stress incontinence and 27 percent as having detrusor instability. Obesity was significantly more common in women with genuine stress incontinence and detrusor instability than in the normal population. Weight reduction after bariatric surgery improves urinary incontinence in obese women. In one study, the incidence decreased from 61.2–11.6 percent.

Gallbladder Disease in the Bariatric Surgery Patient

Rapid weight loss after diets or bariatric surgery is known to be associated with increased gallstone formation. After RYGB, this incidence has been quantified as being as high as 38–53 percent of patients who preoperatively did not have stones. The incidence of cholecystectomy in such at-risk patients after RYGB is described as being from 10–27 percent within 3 years after surgery. Most bariatric surgeons recommend simultaneous cholecystectomy when stones are known to be present at the time of the bariatric operation. This is especially true for open procedures and malabsorptive procedures.

Routine cholecystectomy concomitant with a LRYGB remains controversial. The safety of combining laparoscopic cholecystectomy and LRYGB has been established, but performing both in one procedure may increase the length of hospital stay and adds 30–60 min to the operative time. If cholecystectomy is not performed, excellent data exist that the prophylactic use of oral ursodiol after RYGB is indicated. It has been shown that ursodiol, if taken in doses of 300 mg twice daily for the first 6 months postoperatively, decreases the incidence of postoperative gallstones formation to 2 percent.

Choledocholithiasis after RYGB or BPD becomes a difficult clinical problem because of a loss of endoscopic access to the duodenum. Anchoring the remnant stomach to the anterior abdominal wall, preferably with a radiologic marker, may provide a safe point for percutaneous access for endoscopic retrograde cholangiopancreatography, especially if known gallstones are left in situ.

Diabetes in the Bariatric Surgery Patient

Paralleling the rise in incidence of morbid obesity is the incidence of type II diabetes, often as a component of the metabolic syndrome (syndrome X) comprising central obesity, glucose intolerance, dyslipidemia, and hypertension.

Several recently published outcome studies demonstrate the value of bariatric operations in improving diabetes in the morbidly obese. LAGB resulted in complete resolution or definite improvement of diabetes in 97 percent of patients. In a study by Schauer and associates, 21 percent of 1160 patients undergoing laparoscopic LRYGB demonstrated impaired fasting glucose or type II diabetes mellitus. After surgery, fasting plasma glucose and glycosylated hemoglobin concentrations returned to normal levels (83 percent) or were markedly improved (17 percent) in all patients. A significant reduction in the use of oral antidiabetic agents (80 percent) and insulin (79 percent) was also observed. Patients with the shortest duration (<5 years), the mildest form of diabetes (diet-controlled), and the greatest weight loss after surgery, were most likely to achieve complete resolution of diabetes.

Plastic Surgery Following Weight Loss

Most patients who lose massive amounts of weight are troubled by hanging skin and rolls of skin and fat. Although smaller in size, their clothes fit poorly. Skin macerates under an abdominal pannus, hanging inner thighs, and ptotic breasts. Body aroma is unpleasant. Heavy flaps of skin burden the back and inhibit vigorous exercise. Intimate relations may be untenable. Plastic surgery can substantially improve or correct the skin changes resulting from weight loss.

Body contouring surgery advanced considerably during the 1990s, and these procedures have been modified for this new post-bariatric surgery population. The massive weight loss patient has a deflated shape that is related to genetically defined fat deposition patterns. The most susceptible regions are the anterior neck, upper arms, breasts, lower back, flanks, abdomen, mons pubis, and thighs. Problematic areas for women include the subcutaneous abdomen and hips and thighs; in men, they are the flanks, abdomen, and breasts. The deformity reflects the initial BMI and its change. Because the etiology of the skin laxity is not understood, there is no medical therapy. The widest possible areas of skin are excised and closed. Operative planning is based on the deformity and patient priorities. Most have excess tissue of the lower torso and thighs removed through a circumferential abdominoplasty and lower body lift. Starting prone and then turning supine, the operation removes a wide swath of skin and fat along the bikini line. A panniculectomy that corrects the overhanging pannus is included. The circumferential abdominoplasty removes the redundant skin of the lower abdomen, flattens the abdomen, and incorporates the lower body lift. A medial high transverse thighplasty usually accompanies the lower body lift in massive weight loss patients. Unwanted skin redundancy distal to the mid-thighs requires long vertical medial excision of skin.

Mid-back and epigastric rolls and sagging breasts are corrected with an upper body lift. The upper body lift is a reverse abdominoplasty, removal of mid-torso excess skin, and reshaping of the breasts. For highly selected individuals, and with a well organized team, a single-stage total body lift, which includes a circumferential abdominoplasty, lower body lift, medial thighplasty, an upper body lift, and breast reshaping, can be performed safely in under 8 h.

The opportunity that these large numbers of massive weight loss patients provide for plastic surgery innovation, treatment, and professional satisfaction is extraordinary. Patients are uniformly pleased with their improvements. Research in adipocyte physiology, skin biomechanics, and alternative surgical technique should lead to improved care.

GROSS ANATOMY

The small intestine is a tubular structure that consists of three segments lying in series: the duodenum, the jejunum, and the ileum. The duodenum, the most proximal segment, lies in the retroperitoneum immediately adjacent to the head and inferior border of the body of the pancreas. The duodenum is demarcated from the jejunum by the ligament of Treitz. The jejunum and ileum lie within the peritoneal cavity and are tethered to the retroperitoneum by a broad-based mesentery. No distinct anatomic landmark demarcates the jejunum from the ileum; the proximal 40 percent of the jejunoileal segment is arbitrarily defined as the jejunum and the distal 60 percent as the ileum.

The small intestine contains mucosal folds known as plicae circulares or valvulae conniventes that are visible on gross inspection. These folds are also visible radiographically and help to distinguish between small intestine and colon (which does not contain them) on abdominal radiographs. Gross examination of the small-intestinal mucosa also reveals aggregates of lymphoid follicles. Those follicles are most prominent in the ileum, in which they are designated Peyer patches.

Most of the duodenum derives its arterial blood from branches of both the celiac and the superior mesenteric arteries. The distal duodenum, the jejunum, and the ileum derive their arterial blood from the superior mesenteric artery. Their venous drainage occurs via the superior mesenteric vein. Lymph drainage occurs through lymphatic vessels coursing parallel to corresponding arteries. This lymph drains through mesenteric lymph nodes to the cisterna chyli, then through the thoracic duct, and ultimately into the left subclavian vein. The parasympathetic and sympathetic innervation of the small intestine is derived from the vagus and splanchnic nerves, respectively.

HISTOLOGY

The wall of the small intestine consists of four distinct layers: mucosa, submucosa, muscularis propria, and serosa.

The mucosa is the innermost layer, which itself consists of three layers: epithelium, lamina propria, and muscularis mucosae. The epithelium is exposed to the intestinal lumen and is the surface through which absorption from and secretion into the lumen occurs. The lamina propria is located immediately external to the epithelium and consists of connective tissue and a heterogeneous population of cells. It is demarcated from the more external submucosa by the muscularis mucosae, a thin sheet of smooth-muscle cells.

The mucosa is organized into villi and crypts (crypts of Lieberkühn). Villi are finger-like projections of epithelium and underlying lamina propria that contain blood and lymphatic vessels (lacteals) that extend into the intestinal lumen. Epithelial cellular proliferation is confined to the crypts. All epithelial cells in each crypt are derived from yet uncharacterized multipotent stem cells located at or near the crypt's base. Their descendants undergo differentiation along one

of four pathways that ultimately yield enterocyte and goblet, enteroendocrine, and Paneth cells.

Enterocytes are the predominant absorptive cell of the intestinal epithelium. Their apical (lumen-facing) cell membrane contains microvilli and specialized digestive enzymes and transporter mechanisms. Goblet cells produce mucin believed to play a role in mucosal defense against pathogens. Enteroendocrine cells are characterized by secretory granules containing regulatory agents. Paneth cells are located at the base of the crypt and contain secretory granules containing growth factors, digestive enzymes, and antimicrobial peptides. Additionally, the intestinal epithelium contains M cells and intraepithelial lymphocytes, both components of the immune system.

The submucosa consists of dense connective tissue and a heterogeneous population of cells, including leukocytes and fibroblasts. The submucosa also contains an extensive network of vascular and lymphatic vessels, nerve fibers, and ganglion cells of the submucosal (Meissner) plexus.

The muscularis propria consists of an outer, longitudinally oriented layer and an inner, circularly oriented layer of smooth-muscle fibers. Located at the interface between these two layers are ganglion cells of the myenteric (Auerbach) plexus.

The serosa consists of a single layer of mesothelial cells and is a component of the visceral peritoneum.

DEVELOPMENT

The gut tube is formed from the endoderm during the fourth week of gestation. The gut tube initially communicates with the yolk sac; however, the communication between these two structures narrows by the sixth week to form the vitelline duct. Incomplete obliteration of the vitelline duct results in the spectrum of defects associated with Meckel diverticula.

At approximately the fifth week of gestation, the bowel begins to lengthen to an extent greater than that which can be accommodated by the developing abdominal cavity, resulting in the extracoelomic herniation of the developing bowel. The bowel is retracted back into the abdominal cavity during the tenth week of gestation. Coincident with extrusion and retraction, the bowel undergoes a 270-degree counterclockwise rotation relative to the posterior abdominal wall. Errors in this process can result in intestinal malrotation.

During the sixth week of gestation, the lumen of the developing bowel becomes obliterated as bowel epithelial proliferation accelerates. Vacuoles form within the bowel substance during the subsequent weeks and coalesce to form the intestinal lumen by the ninth week of gestation. Errors in this recanalization may account for defects such as intestinal webs and stenoses.

PHYSIOLOGY

Digestion and Absorption

Eight to 9 L of fluid enter the small intestine daily. Most of this volume consists of salivary, gastric, biliary, pancreatic, and intestinal secretions. Under normal conditions, the small intestine absorbs more than 80 percent of this fluid, leaving approximately 1.5 L that enters the colon.

Carbohydrate Digestion and Absorption

Pancreatic amylase is the major enzyme of starch digestion, although salivary amylase initiates the process. The terminal products of amylase-mediated starch digestion are oligosaccharides, maltotriose, maltose, and α -limit dextrans. These products, and the major disaccharides in the diet (sucrose and lactose) undergo hydrolytic cleavage into their constituent monosaccharides, primarily glucose, galactose, and fructose, which are absorbed through specific transmembrane carriers.

Protein Digestion and Absorption

Protein digestion begins in the stomach with the action of pepsins. Digestion continues in the duodenum with the actions of a variety of pancreatic peptidases. The final products of intraluminal protein digestion consist of amino acids and peptides that are two to six amino acids in length. Additional digestion occurs through the actions of peptidases that exist in the enterocyte brush border and cytoplasm. Epithelial absorption occurs for both single amino acids and di- or tripeptides via specific membrane-bound transporters. Absorbed amino acids and peptides then enter the portal venous circulation. Of all amino acids, glutamine appears to be a unique, major source of energy for enterocytes.

Fat Digestion and Absorption

Ingested fat, primarily in the form of triglycerides, is converted into an emulsion by the mechanical actions of mastication and antral peristalsis. Although lipolysis of triglycerides to form fatty acids and monoglycerides is initiated in the stomach by gastric lipase, its principal site is the proximal intestine, in which pancreatic lipase is the catalyst.

Bile acids form mixed micelles with the products of lipolysis to aid in their solubilization in water. Most lipids are absorbed in the proximal jejunum, whereas bile salts are absorbed in the distal ileum. Within the enterocytes, triglycerides are resynthesized and incorporated into chylomicrons that are secreted into the intestinal lymphatics and ultimately enter the thoracic duct.

The steps described above are required for the digestion and absorption of triglycerides containing long-chain fatty acids. However, triglycerides containing short- and medium-chain fatty acids are more hydrophilic and are directly absorbed and enter the portal venous circulation rather than the lymphatics.

Vitamin Absorption

Vitamin B12 (cobalamin) malabsorption can result from a variety of surgical manipulations. The vitamin is initially bound by saliva-derived R protein. In the duodenum, R protein is hydrolyzed by pancreatic enzymes, allowing free cobalamin to bind to gastric parietal cell-derived intrinsic factor. The cobalamin-intrinsic factor complex is able to escape hydrolysis by pancreatic enzymes, allowing it to reach the terminal ileum, which expresses specific receptors for intrinsic factor, facilitating cobalamin absorption. Because each of these steps is necessary for cobalamin assimilation, gastric resection, gastric bypass, and ileal resection can each result in vitamin B12 insufficiency.

Barrier and Immune Function

Factors contributing to epithelial defense include immunoglobulin A (IgA), mucins, and the relative impermeability of the brush border membrane and tight junctions to macromolecules and bacteria.

The intestinal component of the immune system is known as the gut-associated lymphoid tissue (GALT). The GALT is conceptually divided into inductive and effector sites. Inductive sites include Peyer's patches, mesenteric lymph nodes, and smaller, isolated lymphoid follicles scattered throughout the small intestine. At inductive sites, naïve lymphocytes become primed following antigen exposure, then exit through the draining lymphatics to enter the mesenteric lymph nodes where they undergo differentiation. These lymphocytes then migrate into the systemic circulation via the thoracic duct, and ultimately accumulate in the intestinal mucosa at effector sites.

Effector lymphocytes are distributed into distinct compartments. T cell subsets are located in the epithelium and lamina propria where they play regulatory and cytotoxic roles. Plasma cells, located in the lamina propria secrete IgA, which is transported through the intestinal epithelial cells into the lumen, in which it exists in the form of a dimer complexed with a secretory component. This configuration renders IgA resistant to proteolysis by digestive enzymes. IgA is believed both to help prevent the entry of microbes through the epithelium and to promote excretion of antigens or microbes that have already penetrated into the laminal propria.

Motility

Contractions of the muscularis propria are responsible for small-intestinal peristalsis. Contractions of the muscularis mucosae contribute to mucosal or villus motility, but not to peristalsis.

The regulatory mechanisms driving small-intestinal motility consist of both pacemakers intrinsic to the small intestine and external neurohumoral modulatory signals. The interstitial cells of Cajal are pleomorphic mesenchymal cells located within the muscularis propria of the intestine that generate the electrical slow wave (basic electrical rhythm or pacesetter potential) that plays a pacemaker role in setting the fundamental rhythmicity of small-intestinal contractions. In general, the sympathetic motor supply is inhibitory to the enteric motor system; therefore, increased sympathetic input into the intestine leads to decreased intestinal smooth-muscle activity. The parasympathetic motor supply is more complex, with projections to both inhibitory and excitatory enteric motor system motor neurons.

Endocrine Function

More than 30 peptide hormone genes have been identified as being expressed in the gastrointestinal tract.

Table 27-1 summarizes examples of regulatory peptides produced by enteroendocrine cells of the small-intestinal epithelium and their most commonly ascribed functions. Some of these peptides, or their analogues, are used in routine clinical practice. For example, therapeutic applications of octreotide, a long-acting analogue of somatostatin, include the amelioration of symptoms associated with neuroendocrine tumors (e.g., carcinoid syndrome), postgastrectomy dumping syndrome, enterocutaneous fistulas, and the initial treatment of acute hemorrhage caused by esophageal varices. The gastrin secretory response to secretin administration forms the basis for the standard test used to establish the diagnosis of Zollinger-Ellison syndrome. Cholecystokinin is used in evaluations of gallbladder ejection fraction, a parameter that may have utility in patients who have symptoms of biliary colic but are not found to have gallstones.

TABLE 27-1 Representative Regulatory Peptides Produced in the Small Intestine

Hormone	Source ^a	Actions
Somatostatin	D cell	Inhibits gastrointestinal secretion, motility, and splanchnic perfusion
Secretin	S cell	Stimulates exocrine pancreatic secretion; stimulates intestinal secretion
Cholecystokinin	I cell	Stimulates pancreatic exocrine secretion; stimulates gallbladder emptying; inhibits sphincter of Oddi contraction
Motilin	M cell	Stimulates intestinal motility
Peptide YY	L cell	Inhibits intestinal motility and secretion
Glucagon-like peptide 2	L cell	Stimulates intestinal epithelial proliferation
Neurotensin	N cell	Stimulates pancreatic and biliary secretion; inhibits small bowel motility; stimulates intestinal mucosal growth

^aThis table indicates which enteroendocrine cell types located in the intestinal epithelium produce these peptides. These peptides are also widely expressed in nonintestinal tissues.

Of the peptides listed in Table 27-1, glucagon-like peptide 2 (GLP-2) is the most recently characterized. This product of the proglucagon gene has potent trophic activity that is specific for the intestinal epithelium. It is currently under clinical evaluation as an intestinotrophic agent in patients suffering from the short bowel syndrome.

SMALL-BOWEL OBSTRUCTION

Epidemiology

Mechanical small-bowel obstruction is the most frequently encountered surgical disorder of the small intestine. Intraabdominal adhesions related to prior abdominal surgery is the etiologic factor in up to 75 percent of cases of small-bowel obstruction. Other common etiologies include hernias and Crohn disease. Although congenital abnormalities capable of causing small-bowel obstruction usually become evident during childhood, they sometimes are diagnosed for the first time in adult patients. For example, intestinal malrotation and mid-gut volvulus should be considered when considering the differential diagnosis of adult patients with acute or chronic symptoms of small-bowel obstruction, especially those without a history of prior abdominal surgery. A rare etiology of obstruction is the superior mesenteric artery syndrome, characterized by compression of the third portion of the duodenum by the superior mesenteric artery as it crosses over this portion of the duodenum. This condition should be considered in young asthenic individuals who have chronic symptoms suggestive of proximal small-bowel obstruction.

Pathophysiology

The obstructing lesion can be conceptualized according to its anatomic relationship to the intestinal wall as (1) intraluminal (e.g., foreign bodies,

TABLE 27-2 Small-Bowel Obstruction: Common Etiologies

Adhesions

gallstones, or meconium), (2) intramural (e.g., tumors, Crohn disease-associated inflammatory strictures, or hematomas), or (3) extrinsic (e.g., adhesions, hernias, or carcinomatosis).

With onset of obstruction, gas and fluid accumulate within the intestinal lumen proximal to the site of obstruction. With ongoing gas and fluid accumulation, the bowel distends and intraluminal and intramural pressures rise. If the intramural pressure becomes high enough, microvascular perfusion to the intestine is impaired, leading to intestinal ischemia, and, ultimately, necrosis. This condition is termed strangulating bowel obstruction.

With partial small-bowel obstruction, only a portion of the intestinal lumen is occluded, allowing passage of some gas and fluid. The progression of pathophysiologic events described above tends to occur more slowly than with complete small-bowel obstruction, and development of strangulation is less likely. In contrast, progression to strangulation occurs especially rapidly with closed loop obstruction in which a segment of intestine is obstructed both proximally and distally (e.g., with volvulus).

Clinical Presentation

The symptoms of small-bowel obstruction are colicky abdominal pain, nausea, vomiting, and obstipation. Continued passage of flatus and/or stool beyond 6–12 h after onset of symptoms is characteristic of partial rather than complete obstruction. The signs of small-bowel obstruction include abdominal distention and hyperactive bowel sounds. Laboratory findings reflect intravascular volume depletion and consist of hemoconcentration and electrolyte abnormalities. Mild leukocytosis is common.

Features of strangulated obstruction include tachycardia, localized abdominal tenderness, fever, marked leukocytosis, and acidosis. It is important to note

that these parameters lack sufficient predictive value to allow for differentiation between simple and strangulated obstruction prior to the onset of irreversible intestinal ischemia.

Diagnosis

The diagnostic evaluation should focus on the following goals: distinguishing mechanical obstruction from ileus; determining the etiology of the obstruction; discriminating partial from complete obstruction; and discriminating simple from strangulating obstruction.

Important elements to obtain on history include prior abdominal operations (suggesting the presence of adhesions) and the presence of abdominal disorders (e.g., intraabdominal cancer or inflammatory bowel disease) that may provide insights into the etiology of obstruction. On examination, a meticulous search for hernias (particularly in the inguinal and femoral regions) should be conducted. The stool should be checked for gross or occult blood, the presence of which is suggestive of intestinal strangulation.

The diagnosis of small-bowel obstruction is usually confirmed with radiographic examination. The abdominal series consists of a radiograph of the abdomen with the patient in a supine position, a radiograph of the abdomen with the patient in an upright position, and a radiograph of the chest with the patient in an upright position. The finding most specific for small-bowel obstruction is the triad of dilated small-bowel loops (>3 cm in diameter), air-fluid levels seen on upright films, and a paucity of air in the colon. False-negative findings on radiographs can result when the site of obstruction is located in the proximal small bowel and when the bowel lumen is filled with fluid but no gas, thereby preventing visualization of air-fluid levels or bowel distention.

Computed tomographic (CT) scan findings of small-bowel obstruction include a discrete transition zone with dilation of bowel proximally, decompression of bowel distally, intraluminal contrast that does not pass beyond the transition zone, and a colon containing little gas or fluid. Strangulation is suggested by thickening of the bowel wall, pneumatosis intestinalis (air in the bowel wall), portal venous gas, mesenteric haziness, and poor uptake of intravenous contrast into the wall of the affected bowel. CT scanning also offers a global evaluation of the abdomen and may therefore reveal the etiology of obstruction.

A limitation of CT scanning is its low sensitivity in the detection of low-grade or partial small-bowel obstruction. In such cases, contrast examinations of the small bowel, either small-bowel series (small-bowel follow-through) or enteroclysis, can be helpful. For standard small-bowel series, contrast is swallowed or instilled into the stomach through a nasogastric tube. Abdominal radiographs are then taken serially as the contrast travels distally in the intestine. Although barium can be used, water-soluble contrast agents, such as Gastrografin, should be used if the possibility of intestinal perforation exists. For enteroclysis, 200–250 mL of barium followed by 1–2 L of a solution of methylcellulose in water is instilled into the proximal jejunum via a long nasoenteric catheter. Enteroclysis is rarely performed in the acute setting, but offers greater sensitivity than small-bowel series in the detection of lesions that may be causing partial small-bowel obstruction.

Therapy

Small-bowel obstruction is usually associated with a marked depletion of intravascular volume caused by decreased oral intake, vomiting, and sequestration of fluid in bowel lumen and wall. Therefore, fluid resuscitation is integral to treatment. An indwelling bladder catheter is placed to monitor urine output. Central venous or pulmonary artery catheter monitoring may be necessary, particularly in patients with underlying cardiac disease. Broad-spectrum antibiotics are commonly administered because of concerns that bacterial translocation may occur in the setting of small-bowel obstruction. The stomach should be continuously evacuated of air and fluid, using a nasogastric (NG) tube, to decrease nausea, distention, and the risk of vomiting and aspiration.

The standard therapy for small-bowel obstruction is expeditious surgery, with the exception of specific situations described below. The operative procedure performed varies according to the etiology of the obstruction. For example, adhesions are lysed, tumors are resected, and hernias are reduced and repaired. Regardless of the etiology, the affected intestine should be examined, and nonviable bowel resected. Criteria suggesting viability are normal color, peristalsis, and marginal arterial pulsations. Usually visual inspection alone is adequate in judging viability. In borderline cases, a Doppler probe may be used to check for pulsatile flow to the bowel, and arterial perfusion can be verified by visualizing intravenously administered fluorescein dye in the bowel wall under ultraviolet illumination. In general, if the patient is hemodynamically stable, short lengths of bowel of questionable viability should be resected and primary anastomosis of the remaining intestine performed. However, if the viability of a large proportion of the intestine is in question, a concerted effort to preserve intestinal tissue should be made. In such situations, the bowel of uncertain viability should be left intact and the patient reexplored in 24–48 h in a “second-look” operation. At that time, definitive resection of nonviable bowel is completed.

Exceptions to the recommendation for expeditious surgery for intestinal obstruction include partial small-bowel obstruction, obstruction occurring in the early postoperative period, intestinal obstruction as a consequence of Crohn disease, and carcinoma-tosis.

Progression to strangulation is less likely to occur with partial small-bowel obstruction, and an attempt at nonoperative resolution is warranted. However, most patients with partial small obstruction whose symptoms do not improve within 48 h after initiation of nonoperative therapy should undergo surgery. Patients undergoing nonoperative therapy should be closely monitored for signs suggestive of peritonitis, the development of which would mandate urgent surgery.

Obstruction that occurs in the early postoperative period is usually partial and only rarely is associated with strangulation. Therefore, a period of extended nonoperative therapy consisting of bowel rest, hydration, and total parenteral nutrition (TPN) administration is usually warranted. However, if complete obstruction is demonstrated or if signs suggestive of peritonitis are detected, expeditious reoperation should be undertaken without delay.

Intestinal obstruction in patients with Crohn disease often responds to medical therapy and is discussed in more detail later under “Crohn Disease.” Twenty-five to 33 percent of patients with a history of cancer who present with small-bowel obstruction have adhesions as the etiology of their obstruction and therefore should not be denied appropriate therapy. Even in cases in

which the obstruction is related to recurrent malignancy, palliative resection or bypass can be considered. Patients with obvious carcinomatosis pose a difficult challenge, given their limited prognosis. Management must be tailored to an individual patient's prognosis and desires.

Outcomes

The perioperative mortality rate associated with surgery for nonstrangulating small-bowel obstruction is less than 5 percent, with most deaths occurring in older adult patients with significant comorbidities. Mortality rates associated with surgery for strangulating obstruction range from 8–25 percent.

ILEUS AND OTHER DISORDERS OF INTESTINAL MOTILITY

Epidemiology

Ileus and intestinal pseudo-obstruction designate clinical syndromes caused by impaired intestinal motility and are characterized by symptoms and signs of intestinal obstruction in the absence of a lesion-causing mechanical obstruction.

Ileus is temporary and generally reversible if the inciting factor can be corrected. In contrast, chronic intestinal pseudo-obstruction comprises a spectrum of specific disorders associated with irreversible intestinal dysmotility.

Pathophysiology

The most frequently encountered factors causing ileus are abdominal operations, infection and inflammation, electrolyte abnormalities, and drugs.

Among the proposed mechanisms responsible for postoperative ileus are surgical stress-induced sympathetic reflexes, inflammatory response-mediator release, and anesthetic/analgesic effects, each of which can inhibit intestinal motility.

Chronic intestinal pseudo-obstruction can be caused by a large number of specific abnormalities affecting intestinal smooth muscle, the myenteric plexus, or the extraintestinal nervous system. Both sporadic and familial forms of visceral myopathies and neuropathies exist. Systemic disorders involving the smooth muscle such as progressive systemic sclerosis and progressive muscular dystrophy, and neurologic diseases such as Parkinson disease also can be complicated by chronic intestinal pseudo-obstruction. Additionally, viral infections, such as those associated with cytomegalovirus and Epstein-Barr virus can cause intestinal pseudo-obstruction.

Clinical Presentation

The clinical presentation of ileus resembles that of small-bowel obstruction. Inability to tolerate liquids and solids by mouth, nausea, and lack of flatus or bowel movements are the most common symptoms. Vomiting and abdominal distention may occur. Bowel sounds are characteristically diminished or absent, in contrast to the hyperactive bowel sounds that usually accompany mechanical small-bowel obstruction. The clinical manifestations of chronic intestinal pseudo-obstruction include variable degrees of nausea, vomiting, abdominal pain, and distention.

Diagnosis

Routine postoperative ileus should be expected and requires no diagnostic evaluation. If ileus persists beyond 3–5 days postoperatively or occurs in the absence of abdominal surgery, diagnostic evaluation to detect specific underlying factors capable of inciting ileus and to rule out the presence of mechanical obstruction is warranted.

Patient medication lists should be reviewed for the presence of drugs known to be associated with impaired intestinal motility. Measurement of serum electrolytes may demonstrate hypokalemia, hypocalcemia, hypomagnesemia, hypermagnesemia, or other electrolyte abnormalities commonly associated with ileus. Abdominal radiographs are often obtained, but the distinction between ileus and mechanical obstruction may be difficult based on this test alone. In the postoperative setting, CT scanning is the test of choice because it can demonstrate the presence of an intraabdominal abscess or other evidence of peritoneal sepsis that may be causing ileus and can exclude the presence of complete mechanical obstruction.

The diagnosis of chronic pseudo-obstruction is suggested by clinical features and confirmed by radiographic and manometric studies. Diagnostic laparotomy or laparoscopy with full-thickness biopsy of the small intestine may be required to establish the specific underlying cause.

Therapy

The management of ileus consists of limiting oral intake and correcting the underlying inciting factor. If vomiting or abdominal distention are prominent, the stomach should be decompressed using a nasogastric tube. Fluid and electrolytes should be administered intravenously until ileus resolves. If the duration of ileus is prolonged, TPN may be required.

The therapy of patients with chronic intestinal pseudo-obstruction focuses on palliation of symptoms and fluid, electrolyte, and nutritional management. Surgery should be avoided if at all possible. Prokinetic agents, such as metoclopramide and erythromycin, are associated with poor efficacy. Cisapride has been associated with palliation of symptoms; however, because of cardiac toxicity and reported deaths, this agent is restricted to compassionate use.

CROHN DISEASE

Epidemiology

Crohn disease is a chronic, idiopathic inflammatory disease with a propensity to affect the distal ileum, although any part of the alimentary tract can be involved. The median age at which patients are diagnosed with Crohn disease is approximately 30 years; however, age of diagnosis can range from early childhood through the entire life span. Both genetic and environmental factors appear to influence the risk for developing Crohn disease. The relative risk among first-degree relatives of patients with Crohn disease is 14–15 times higher than that of the general population.

Pathophysiology

Crohn disease is characterized by sustained inflammation. Various hypotheses on the roles of environmental factors, including infectious agents, and derangements in immune regulation have been proposed. Specific genetic defects

associated with Crohn disease in human patients are beginning to be defined. For example, the presence of a locus on chromosome 16 (the so-called IBD1 locus) has been linked to Crohn disease. The IBD1 locus has been identified as the NOD2 gene. Persons with allelic variants on both chromosomes have a 40-fold relative risk of Crohn disease when compared to those without variant NOD2 genes.

Pathology

The earliest lesion characteristic of Crohn disease is the aphthous ulcer. These superficial ulcers are up to 3 mm in diameter and are surrounded by a halo of erythema. In the small intestine, aphthous ulcers typically arise over lymphoid aggregates. Granulomas are highly characteristic of Crohn disease and are reported to be present in up to 70 percent of intestinal specimens obtained during surgical resection. These granulomas are noncaseating and can be found in both areas of active disease and apparently normal intestine, in any layer of the bowel wall, and in mesenteric lymph nodes.

As disease progresses, aphthae coalesce into larger, stellate-shaped ulcers. Linear or serpiginous ulcers may form when multiple ulcers fuse in a direction parallel to the longitudinal axis of the intestine. With transverse coalescence of ulcers, a cobblestone appearance of the mucosa may arise.

With advanced disease, inflammation can be transmural. Serosal involvement results in adhesion of the inflamed bowel to other loops of bowel or other adjacent organs. Transmural inflammation also can result in fibrosis, with stricture formation, intraabdominal abscesses, fistulas, and, rarely, free perforation. Inflammation in Crohn disease can affect discontinuous portions of intestine: so-called “skip lesions” that are separated by intervening normal-appearing intestine.

A feature of Crohn disease that is grossly evident and helpful in identifying affected segments of intestine during surgery is the presence of fat wrapping (encroachment of mesenteric fat onto the serosal surface of the bowel).

Clinical Presentation

The most common symptoms of Crohn disease are abdominal pain, diarrhea, and weight loss. However, the clinical features are highly variable among individual patients and depend on which segment(s) of the gastrointestinal tract is (are) predominantly affected, the intensity of inflammation, and the presence or absence of specific complications. The onset of symptoms is insidious, and once present, their severity follows a waxing and waning course. Constitutional symptoms, particularly weight loss and fever, or growth retardation in children, may also be prominent and are occasionally the sole presenting features of Crohn disease.

The distal ileum is the single most frequently affected site, being diseased at some time in 75 percent of patients with Crohn disease. The small bowel alone is affected in 15–30 percent of patients, both the ileum and colon are affected in 40–60 percent of patients, and the colon alone is affected in 25–30 percent of patients. Isolated perineal and anorectal disease occurs in 5–10 percent of affected patients.

An estimated 25 percent of all patients with Crohn disease will have an extraintestinal manifestation of their disease. One-fourth of those affected will have more than one manifestation. Table 27-3 lists the most common extraintestinal manifestations.

TABLE 27-3 Extraintestinal Manifestations of Crohn Disease

Osteoporosis
Endocarditis, myocarditis, pleuropericarditis
Interstitial lung disease
Amyloidosis
Pancreatitis

Diagnosis

Clinical situations in which the diagnosis of Crohn disease should be considered include the presence of acute or chronic abdominal pain, especially when localized to the right lower quadrant, chronic diarrhea, evidence of intestinal inflammation on radiography or endoscopy, the discovery of a bowel stricture or fistula arising from the bowel, and evidence of inflammation or granulomas on intestinal histology. Disorders associated with clinical presentations that resemble those of Crohn disease include ulcerative colitis, functional bowel disorders such as irritable bowel syndrome, mesenteric ischemia, collagen vascular diseases, carcinoma and lymphoma, diverticular disease, and infectious enteritides. Infectious enteritides are most frequently diagnosed in immunocompromised patients but also can occur in patients with normal immune function. Acute ileitis caused by *Campylobacter* and *Yersinia* species can be difficult to distinguish from that caused by an acute presentation of Crohn disease. Typhoid enteritis caused by *Salmonella typhosa* can lead to overt intestinal bleeding and perforation, most often affecting the terminal ileum. The distal ileum and cecum are the most common sites of intestinal involvement by infection caused by *Mycobacterium tuberculosis*. This condition can result in intestinal inflammation, strictures, and fistula formation, similar to those seen in Crohn disease. Cytomegalovirus (CMV) can cause intestinal ulcers, bleeding, and perforation.

The diagnosis is based on a complete assessment of the clinical presentation with confirmatory findings derived from radiographic, endoscopic, and, in most cases, pathologic tests. Contrast examinations of the small bowel and

colon may reveal strictures or networks of ulcers and fissures leading to the typical "cobblestone appearance" of the mucosa. CT scanning may reveal intraabdominal abscesses and is useful in acute presentations to rule out the presence of other intraabdominal disorders. Colonoscopy is used to visualize and biopsy disease in the colon; occasionally the distal ileum can be reached as well. Esophagogastroduodenoscopy (EGD) is done for disease of the proximal alimentary tract.

Therapy

Because no curative therapies are available for Crohn disease, the goal of treatment is to palliate symptoms. Medical therapy is used to induce and maintain disease remission. Surgery is reserved for specific indications described below. Additionally, nutritional support in the form of aggressive enteral regimens or, if necessary, parenteral nutrition, is used to manage the malnutrition that is common in patient's with Crohn disease.

Medical Therapy

Pharmacologic agents used to treat Crohn disease include antibiotics, aminosalicylates, corticosteroids, and immunomodulators. Antibiotics have an adjunctive role in the treatment of infectious complications associated with Crohn disease. They are also used to treat patients with perianal disease, enterocutaneous fistulas, and active colonic disease.

Infliximab is a chimeric monoclonal anti-tumor-necrosis-factor antibody that has recently been shown to promote remission and closure of enterocutaneous fistulas. Infliximab is generally well tolerated but should not be used in patients with ongoing sepsis.

Surgical Therapy

Seventy to 80 percent of patients with Crohn disease will ultimately require surgical therapy for their disease. Surgery is generally reserved for patients whose disease is unresponsive to aggressive medical therapy or who develop complications of their disease.

One third of patients with Crohn disease will require surgery for intestinal obstruction. Growth retardation constitutes an indication for surgery in 30 percent of children with Crohn disease. Less-common complications that require surgical intervention are acute gastrointestinal hemorrhage and cancer.

During surgery, thorough examination of the entire intestine should be performed. The presence of active disease is suggested by thickening of the bowel wall, narrowing of the lumen, serosal inflammation and coverage by creeping fat, and thickening of the mesentery. Skip lesions are present in approximately 20 percent of cases and should be sought. The length of uninvolved small intestine should be noted.

Segmental intestinal resection of grossly evident disease followed by primary anastomosis is the usual procedure of choice. Microscopic evidence of Crohn disease at the resection margins does not compromise a safe anastomosis, and frozen-section analysis of resection margins is unnecessary.

An alternative to segmental resection for obstructing lesions is stricturoplasty. This technique allows for preservation of intestinal surface area and is especially well-suited to patients with extensive disease and fibrotic strictures who may have undergone previous resection and are at risk for developing short-bowel syndrome. In this technique, the bowel is opened longitudinally to

expose the lumen. Depending on the length of the stricture, the reconstruction can be fashioned in a manner similar to the Heinecke-Mikulicz pyloroplasty (for strictures less than 12 cm in length) or the Finney pyloroplasty (for longer strictures as much as 25 cm in length). Stricturoplasty is associated with recurrence rates that are no different from those associated with segmental resection. Stricturoplasty is contraindicated in patients with intraabdominal abscesses or intestinal fistulas.

An uncommon, but not rare, scenario is the intraoperative discovery of inflammation limited to the terminal ileum during operations performed for presumed appendicitis. This scenario can result from an acute presentation of Crohn disease or from acute ileitis caused by bacteria such as *Yersinia* or *Campylobacter*. Both conditions should be treated medically; ileal resection is not generally indicated. However, the appendix, even if normal appearing, should be removed (unless the cecum is inflamed, increasing the potential morbidity of this procedure) to eliminate appendicitis from the differential diagnosis of abdominal pain in these patients, particularly those with Crohn disease who may be destined to have recurring symptoms.

Since the 1990s, laparoscopic surgical techniques have been applied to patients with Crohn disease. However, it is important to remember that the inflammatory changes associated with Crohn disease, such as thickened and foreshortened mesentery, obliterated tissue planes, and friable tissues with engorged vasculature, potentially make laparoscopic surgery difficult and dangerous.

Outcomes

Overall complication rates following surgery for Crohn disease range from 15–30 percent. Wound infections, postoperative intraabdominal abscesses, and anastomotic leaks account for most of these complications.

Most patients whose disease is resected eventually develop recurrence. If recurrence is defined endoscopically, 70 percent recur within 1 year of a bowel resection and 85 percent by 3 years. Clinical recurrence, defined as the return of symptoms confirmed as being caused by Crohn disease, affects 60 percent of patients by 5 years and 94 percent by 15 years after intestinal resection. Reoperation becomes necessary in approximately one-third of patients by 5 years after the initial operation.

INTESTINAL FISTULAS

Epidemiology

A fistula is defined as an abnormal communication between two epithelialized surfaces. The communication occurs between two parts of the gastrointestinal tract or adjacent organs in an internal fistula (e.g., enterocolonic fistula or colovesicular fistula). An external fistula (e.g., enterocutaneous fistula or rectovaginal fistula) involves the skin or another external surface epithelium. Enterocutaneous fistulas that drain less than 200 mL of fluid per day are known as low-output fistulas, whereas those that drain more than 500 mL of fluid per day are known as high-output fistulas.

More than 80 percent of enterocutaneous fistulas represent iatrogenic complications that occur as the result of enterotomies or intestinal anastomotic dehiscences. Fistulas that arise spontaneously without antecedent iatrogenic injury are usually manifestations of underlying Crohn disease or cancer.

Pathophysiology

The manifestations of fistulas depend on which structures are involved. Low-resistance enteroenteric fistulas, which allow luminal contents to bypass a significant proportion of the small intestine, may result in clinically significant malabsorption. Enterovesicular fistulas often cause recurrent urinary tract infections. The drainage emanating from enterocutaneous fistulas are irritating to the skin and cause excoriation. The loss of enteric luminal contents, particularly from high-output fistulas originating from the proximal small intestine, results in dehydration, electrolyte abnormalities, and malnutrition.

Clinical Presentation

Iatrogenic enterocutaneous fistulas usually become clinically evident between the fifth and tenth postoperative days. Fever, leukocytosis, prolonged ileus, abdominal tenderness, and wound infection are the initial signs. The diagnosis becomes obvious when drainage of enteric material through the abdominal wound or through existing drains occurs. These fistulas are often associated with intraabdominal abscesses.

Diagnosis

CT scanning is the most useful initial test. Intraabdominal abscesses should be sought and drained percutaneously. If the anatomy of the fistula is not clear on CT scanning, a small-bowel series or enteroclysis examination can be obtained to demonstrate the fistula's site of origin in the bowel. Occasionally, contrast administered into the intestine does not demonstrate the fistula tract. A fistulogram, in which contrast is injected under pressure through a catheter placed percutaneously into the fistula tract, may offer greater sensitivity in localizing the fistula origin.

Therapy

The treatment of enterocutaneous fistulas should proceed through an orderly sequence of steps. Step 1: Stabilization. Fluid and electrolyte resuscitation is begun. Nutrition is provided, usually through the parenteral route initially. Sepsis is controlled with antibiotics and drainage of abscesses. The skin is protected from the fistula effluent with ostomy appliances or fistula drains. Step 2: Investigation. The anatomy of the fistula is defined using the studies described above. Step 3: Rehabilitation. Probability of spontaneous closure is maximized. Nutrition and time are the key components of this phase. Most patients will require TPN; however, a trial of oral or enteral nutrition should be attempted in patients with low-output fistulas originating from the distal intestine. The somatostatin analogue octreotide is a useful adjunct, particularly in patients with high-output fistulas, because its administration reduces the volume of fistula output, thereby facilitating fluid and electrolyte management. Furthermore, octreotide may accelerate the rate at which fistulas close.

If the fistula fails to resolve by 2–3 months, surgery may be required, during which the fistula tract, together with the segment of intestine from which it originates, should be resected. Simple closure of the opening in the intestine from which the fistula originates is associated with high recurrence rates.

Outcomes

Enterocutaneous fistulas are associated with a 10–15 percent mortality rate, mostly related to sepsis or underlying disease. Overall, 50 percent of intestinal fistulas close spontaneously. A useful mnemonic designates factors that inhibit spontaneous closure of intestinal fistulas: FRIEND (foreign body within the fistula tract; radiation enteritis; infection/inflammation at the fistula origin; epithelialization of the fistula tract; neoplasm at the fistula origin; distal obstruction of the intestine). Surgery for fistulas is associated with a greater than 50 percent morbidity rate, including a 10 percent recurrence rate.

SMALL-BOWEL NEOPLASMS

Epidemiology

Adenomas are the most common benign neoplasm of the small intestine. Other benign tumors include fibromas, lipomas, hemangiomas, lymphangiomas, and neurofibromas.

Primary small-bowel cancers are rare, with an estimated incidence of 5300 cases per year in the United States. Among small-bowel cancers, adenocarcinomas comprise 35–50 percent of all cases, carcinoid tumors comprise 20–40 percent, and lymphomas comprise approximately 10–15 percent. Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors arising in the small intestine and comprise up to 15 percent of small-bowel malignancies. The small intestine is frequently affected by metastases from or local invasion by cancers originating at other sites. Melanoma, in particular, is associated with a propensity for metastasis to the small intestine.

Reported risk factors for developing small-intestinal adenocarcinoma include consumption of red meat, ingestion of smoked or cured foods, Crohn disease, celiac sprue, hereditary nonpolyposis colorectal cancer (HNPCC), familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome. Patients with FAP have a nearly 100 percent cumulative lifetime risk of developing duodenal adenomas that have the potential to undergo malignant transformation. The risk of duodenal cancer in these patients is more than 100-fold than in the general population.

Pathogenesis

Small-intestinal adenocarcinomas are believed to arise from preexisting adenomas through a sequential accumulation of genetic abnormalities in a model similar to that described for the pathogenesis of colorectal cancer. Adenomas are histologically classified as tubular, villous, and tubulovillous. Tubular adenomas have the least-aggressive features. Villous adenomas have the most-aggressive features and tend to be large, sessile, and located in the second portion of the duodenum. Malignant degeneration has been reported to be present in up to 45 percent of villous adenomas by the time of diagnosis.

A defining feature of GISTs is their expression of the receptor tyrosine kinase KIT (CD117). The majority of GISTs have activating mutations in the *c-kit* protooncogene, which cause KIT to become constitutively activated, presumably leading to persistence of cellular growth or survival signals. Because the interstitial cells of Cajal normally express KIT, these cells have been implicated as the cell of origin for GISTs.

Clinical Presentation

Most small-intestinal neoplasms are asymptomatic until they become large. Partial small-bowel obstruction, with associated symptoms of crampy abdominal pain and distention, nausea, and vomiting, is the most common mode of presentation. Obstruction can be the result of either luminal narrowing by the tumor itself or intussusception, with the tumor serving as the lead point. Hemorrhage, usually indolent, is the second most common mode of presentation.

Physical examination may reveal an abdominal mass or signs of intestinal obstruction. Fecal occult blood test may be positive. Cachexia or ascites may be present with advanced disease.

Adenocarcinomas, and adenomas (from which most are believed to arise), are most commonly found in the duodenum, except in patients with Crohn disease, in whom most are found in the ileum. Lesions in the periampullary location can cause obstructive jaundice or pancreatitis. Adenocarcinomas located in the duodenum tend to be diagnosed earlier in their progression than those located in the jejunum or ileum, which are rarely diagnosed prior to the onset of locally advanced or metastatic disease.

Carcinoid tumors of the small intestine are also usually diagnosed after the development of metastatic disease. These tumors are associated with a more aggressive behavior than the more common appendiceal carcinoid tumors. Approximately 25–50 percent of patients with carcinoid tumor-derived liver metastases will develop manifestations of the carcinoid syndrome. These manifestations include diarrhea, flushing, hypotension, tachycardia, and fibrosis of the endocardium and valves of the right heart. Candidate tumor-derived mediators of the carcinoid syndrome, such as serotonin, bradykinin, and substance P, undergo nearly complete metabolism during first passage through the liver. As a result, symptoms of carcinoid syndrome are rare in the absence of liver metastases.

Lymphoma may involve the small intestine primarily or as a manifestation of disseminated systemic disease. Primary small-intestinal lymphomas are most commonly located in the ileum, which contains the highest concentration of lymphoid tissue in the intestine. Although partial small-bowel obstruction is the most common mode of presentation, 10 percent of patients with small-intestinal lymphoma present with bowel perforation.

Sixty to 70 percent of GISTs are located in the stomach. The small intestine is the second most common site, containing 25–35 percent of GISTs. There appears to be no regional variation in the prevalence of GISTs within the small intestine. GISTs have a greater propensity to be associated with overt hemorrhage than the other small-intestinal malignancies.

Metastatic tumors involving the small intestine can induce intestinal obstruction and bleeding.

Diagnosis

Because of the absent or nonspecific symptoms associated with most small-intestinal neoplasms, these lesions are rarely diagnosed preoperatively. Laboratory tests are nonspecific, with the exception of elevated serum 5-hydroxyindole acetic acid (5-HIAA) levels in patients with the carcinoid syndrome.

Contrast radiography of the small intestine may demonstrate benign and malignant lesions. Enteroclysis has a sensitivity of greater than 90 percent in the detection of small-bowel tumors and is the test of choice, particularly

for tumors located in the distal small bowel. CT scanning has low sensitivity for detecting mucosal or intramural lesions, but can demonstrate large tumors and is useful in the staging of intestinal malignancies. Tumors associated with significant bleeding can be localized with angiography or radioisotope-tagged red blood cell (RBC) scans. Tumors located in the duodenum can be visualized and biopsied on EGD.

Therapy

Benign neoplasms of the small intestine that are symptomatic should be surgically resected or removed endoscopically, if feasible. Duodenal adenomas occurring in the setting of FAP require an especially aggressive approach to management. Patients with FAP should undergo screening EGD starting sometime during their second or third decade of life. Adenomas detected should be removed endoscopically, if possible, followed by surveillance endoscopy at 6 months and yearly thereafter, in the absence of recurrence. If surgery is required, pancreaticoduodenectomy is generally necessary because adenomas in patients with FAP tend to be multiple and sessile, with a predilection for the periampullary region.

The surgical therapy of small-intestinal malignancies usually consists of wide-local resection of the intestine harboring the lesion. For adenocarcinomas, a wide excision of corresponding mesentery is done to achieve regional lymphadenectomy. For most adenocarcinomas of the duodenum, except those in the distal duodenum, pancreaticoduodenectomy is required. In the presence of locally advanced or metastatic disease, palliative intestinal resection or bypass is performed. Chemotherapy has no proven efficacy in the adjuvant or palliative treatment of small-intestinal adenocarcinomas.

The goal of surgical therapy for carcinoids is resection of all visible disease. Localized small-intestinal carcinoid tumors should be treated with segmental intestinal resection and regional lymphadenectomy. In approximately 30 percent of cases, multiple small-intestinal carcinoid tumors are present. Therefore, the entire small intestine should be examined before planning the extent of resection. In the presence of metastatic disease, tumor debulking should be conducted because it can be associated with long-term survival and amelioration of symptoms of the carcinoid syndrome. Response rates of 30–50 percent have been reported to chemotherapy regimens based on agents such as doxorubicin, 5-fluorouracil, and streptozocin. However, none of these regimens is associated with a clearly demonstrable impact on the natural history of disease. Octreotide is the most effective pharmacologic agent for management of symptoms of carcinoid syndrome.

Localized small-intestinal lymphoma should be treated with segmental resection of the involved intestine and adjacent mesentery. If the small intestine is diffusely affected by lymphoma, chemotherapy, rather than surgical resection, should be the primary therapy. The value to adjuvant chemotherapy after resection of localized lymphoma is controversial.

Small-intestinal GISTs should be treated with segmental intestinal resection. If the diagnosis is known prior to resection, wide lymphadenectomy can be avoided because GISTs are rarely associated with lymph node metastases. GISTs are resistant to conventional chemotherapy agents. Imatinib (Gleevec, formerly known as ST1571) is a tyrosine kinase inhibitor with potent activity against tyrosine kinase KIT. Recent clinical trials show that 80 percent of patients with unresectable or metastatic GISTs derive clinical benefit from the

administration of imatinib, with 50–60 percent having objective evidence of reduction in tumor volume.

Metastatic cancers affecting the small intestine that are symptomatic should be treated with palliative resection or bypass except in the most advanced cases.

Outcomes

Complete resection of duodenal adenocarcinomas is associated with postoperative 5-year survival rates ranging from 50–60 percent. Complete resection of adenocarcinomas located in the jejunum or ileum is associated with 5-year survival rates of only 5–30 percent. Five-year survival rates of 75–95 percent following resection of localized small-intestinal carcinoid tumors have been reported. In the presence of carcinoid tumor-derived liver metastases, 5-year survival rates of 19–54 percent have been reported. The overall 5-year survival rate for patients diagnosed with intestinal lymphoma ranges from 20–40 percent. For patients with localized lymphoma amenable to surgical resection, the 5-year survival rate is 60 percent.

The 5-year survival rate following surgical resection of GISTs ranges from 35–60 percent. Both tumor size and mitotic index are independently correlated with prognosis.

RADIATION ENTERITIS

Epidemiology

Acute radiation enteritis is a transient condition that occurs in approximately 75 percent of patients undergoing radiation therapy for abdominal and pelvic cancers. Chronic radiation enteritis is inexorable and develops in approximately 5–15 percent of these patients.

Pathophysiology

The principal mechanism of radiation-induced cell death is believed to be apoptosis resulting from free radical-induced breaks in double-stranded deoxyribonucleic acid (DNA). Because radiation has its greatest impact on rapidly proliferating cells, the small-intestinal epithelium is acutely susceptible to radiation-induced injury. The intensity of injury is related to the dose of radiation administered, with most cases occurring in patients who have received at least 4500 cGy. Risk factors for acute radiation enteritis include conditions that may limit splanchnic perfusion such as hypertension, diabetes mellitus, coronary artery disease, and restricted motility of the small intestine caused by adhesions. Injury is potentiated by concomitant administration of chemotherapeutic agents that act as radiation-sensitizers such as doxorubicin, 5-fluorouracil, actinomycin D, and methotrexate.

Chronic radiation enteritis is characterized by a progressive occlusive vasculitis that leads to chronic ischemia and fibrosis that affects all layers of the intestinal wall.

Clinical Presentation

The most common manifestations of acute radiation enteritis are nausea, vomiting, diarrhea, and crampy abdominal pain. Symptoms are generally transient and subside after the discontinuation of radiation therapy. Because the diagnosis is usually obvious, given the clinical context, no specific diagnostic tests

are required. However, if patients develop signs suggestive of peritonitis, CT scanning should be performed to rule out the presence of other conditions capable of causing acute abdominal syndromes.

The clinical manifestations of chronic radiation enteritis usually become evident within 2 years of radiation administration, although they can begin as early as several months or as late as decades afterwards. The most common clinical presentation is one of partial small-bowel obstruction with nausea, vomiting, intermittent abdominal distention, crampy abdominal pain, and weight loss being the most common symptoms. The terminal ileum is the most frequently affected segment. Other manifestations of chronic radiation enteritis include complete bowel obstruction, acute or chronic intestinal hemorrhage, and abscess or fistula formation.

Diagnosis

Enteroclysis is the most accurate imaging test for diagnosing chronic radiation enteritis. CT scanning should be obtained to rule out the presence of recurrent cancer because its clinical manifestations may overlap with those of chronic radiation enteritis.

Therapy

Most cases of acute radiation enteritis are self-limited. Supportive therapy, including the administration of antiemetics, is usually sufficient. Patients with diarrhea-induced dehydration may require hospital admission and parenteral fluid administration.

The treatment of chronic radiation enteritis represents a formidable challenge. Surgery for this condition is difficult, is associated with high morbidity rates, and should be avoided in the absence of specific indications such as high-grade obstruction, perforation, hemorrhage, intraabdominal abscesses, and fistulas. The goal of surgery is limited resection of diseased intestine with primary anastomosis between healthy bowel segments. If limited resection is not achievable, an intestinal bypass procedure may be an option, except in cases for which hemorrhage is the surgical indication.

Outcomes

Acute radiation injury to the intestine is self-limited; its severity is not correlated with the probability of chronic radiation enteritis developing. Surgery for chronic radiation enteritis is associated with high morbidity rates and reported mortality rates averaging 10 percent.

MECKEL DIVERTICULUM

Epidemiology

Meckel diverticula are designated true diverticula because their walls contain all of the layers found in normal small intestine. Approximately 60 percent of Meckel diverticula contain heterotopic mucosa, of which more than 60 percent consist of gastric mucosa. A useful mnemonic describing Meckel diverticula is the “rule of twos”: 2 percent prevalence, 2:1 female predominance, location 2 feet proximal to the ileocecal valve in adults, and half of those who are symptomatic are younger than 2 years of age.

Pathophysiology

During the eighth week of gestation, the omphalomesenteric (vitelline) duct normally undergoes obliteration. Failure or incomplete vitelline duct obliteration results in a spectrum of abnormalities, the most common of which is Meckel diverticulum. Other abnormalities include omphalomesenteric fistula, enterocysts, and a fibrous band connecting the intestine to the umbilicus. A remnant of the left vitelline artery can persist to form a mesodiverticular band tethering a Meckel diverticulum to the ileal mesentery.

Bleeding associated with Meckel diverticulum is usually the result of ileal mucosal ulceration that occurs adjacent to acid-producing, heterotopic gastric mucosa located within the diverticulum. Intestinal obstruction associated with Meckel diverticulum can result from several mechanisms: (1) volvulus of the intestine around the fibrous band attaching the diverticulum to the umbilicus; (2) entrapment of intestine by a mesodiverticular band; (3) intussusception with the diverticulum acting as a lead point; or (4) stricture secondary to chronic diverticulitis.

Clinical Presentation

Meckel diverticula are asymptomatic unless associated complications arise. Bleeding is the most common presentation in children with Meckel diverticula, representing more than 50 percent of Meckel diverticulum-related complications among patients who are younger than 18 years of age. Intestinal obstruction is the most common presentation in adults with Meckel diverticula. Diverticulitis, present in 20 percent of patients with symptomatic Meckel diverticula, and is associated with a clinical syndrome that is indistinguishable from acute appendicitis.

Diagnosis

In the absence of bleeding, Meckel diverticula rarely are diagnosed prior to the time of surgical intervention. Enteroclysis is associated with an accuracy of 75 percent, but is usually not applicable during acute presentations of complications related to Meckel diverticula. Radionuclide scans (^{99m}Tc-pertechnetate) suggest the diagnosis of Meckel diverticulum when uptake occurs in associated ectopic gastric mucosa, or when extravasation occurs during active bleeding. Angiography can localize the site of bleeding during acute hemorrhage related to Meckel diverticula.

Therapy

The surgical treatment of symptomatic Meckel diverticula should consist of diverticulectomy with removal of associated bands connecting the diverticulum to the abdominal wall or intestinal mesentery. If the indication for diverticulectomy is bleeding, segmental resection of ileum that includes both the diverticulum and the adjacent ileal peptic ulcer should be performed. Segmental ileal resection may also be necessary if the diverticulum contains a tumor, or if the base of the diverticulum is inflamed or perforated. The management of incidentally found (asymptomatic) Meckel diverticula remains controversial.

ACQUIRED DIVERTICULA

Epidemiology

Acquired diverticula are designated false diverticula because their walls consist of mucosa and submucosa but lack a complete muscularis. Acquired diverticula in the duodenum tend to be located adjacent to the ampulla; such diverticula are known as periampullary, juxtapapillary, or peri-Vaterian diverticula. Acquired diverticula in the jejunum or ileum are known as jejunoileal diverticula.

The prevalence of duodenal diverticula is reported to range from 5–27 percent. The prevalence of jejunoileal diverticula has been estimated to range from 1–5 percent.

Pathophysiology

The pathogenesis of acquired diverticula is hypothesized to be related to acquired abnormalities of intestinal smooth muscle or dysregulated motility, leading to herniation of mucosa and submucosa through weakened areas of muscularis.

Acquired diverticula can be associated with bacterial overgrowth, leading to vitamin B12 deficiency, megaloblastic anemia, malabsorption, and steatorrhea. Periampullary duodenal diverticula have been described to become distended with intraluminal debris and to compress the common bile duct or pancreatic duct, thus causing obstructive jaundice or pancreatitis, respectively. Jejunoileal diverticula can also cause intestinal obstruction through intussusception or compression of adjacent bowel.

Clinical Presentation

Acquired diverticula are asymptomatic unless associated complications arise. Such complications are estimated to occur in 6–10 percent of patients with acquired diverticula and include intestinal obstruction, diverticulitis, hemorrhage, perforation, and malabsorption. Periampullary duodenal diverticula may be associated with choledocholithiasis, cholangitis, recurrent pancreatitis, and sphincter of Oddi dysfunction.

Diagnosis

Most acquired diverticula are discovered incidentally. On ultrasound and CT scanning, duodenal diverticula may be mistaken for pancreatic pseudocysts and fluid collections, biliary cysts, and periampullary neoplasms. These lesions can be missed on endoscopy and are best diagnosed on upper gastrointestinal radiographs. Enteroclysis is the most sensitive test for detecting jejunoileal diverticula.

Therapy

Asymptomatic acquired diverticula should be left alone. Bacterial overgrowth associated with acquired diverticula is treated with antibiotics. Other complications, such as bleeding and diverticulitis, are treated with segmental intestinal resection for diverticula located in the jejunum or ileum. Bleeding and obstruction related to lateral duodenal diverticula are generally treated with diverticulectomy alone. These procedures can be technically difficult for medial duodenal diverticula that penetrate into the substance of the pancreas.

Complications related to these diverticula should be managed nonoperatively if possible.

MESENTERIC ISCHEMIA

Mesenteric ischemia can present as one of two distinct clinical syndromes: acute mesenteric ischemia and chronic mesenteric ischemia.

Pathophysiology

Four distinct pathophysiologic mechanisms can lead to acute mesenteric ischemia: arterial embolus, arterial thrombosis, vasospasm (also known as nonocclusive mesenteric ischemia, or NOMI), and venous thrombosis. Regardless of the pathophysiologic mechanism, acute mesenteric ischemia can lead to intestinal mucosal sloughing within 3 h of onset and full-thickness intestinal infarction by 6 h.

In contrast, chronic mesenteric ischemia develops insidiously, allowing for development of collateral circulation, and, therefore, rarely leads to intestinal infarction. Chronic mesenteric arterial ischemia results from atherosclerotic lesions in the main splanchnic arteries (celiac, superior mesenteric, and inferior mesenteric arteries). In most patients with symptoms attributable to chronic mesenteric ischemia, at least two of these arteries are either occluded or severely stenosed. A chronic form of mesenteric venous thrombosis can involve the portal or splenic veins and may lead to portal hypertension, with resulting esophagogastric varices, splenomegaly, and hypersplenism.

Clinical Presentation

Abdominal pain for which the severity is out of proportion to the degree of tenderness on examination is the hallmark of acute mesenteric ischemia. Associated symptoms can include nausea, vomiting, and diarrhea. Physical findings are characteristically absent early in the course of ischemia. With the onset of bowel infarction, abdominal distention, peritonitis, and passage of bloody stools occur.

With chronic mesenteric ischemia, postprandial abdominal pain is the most prevalent symptom, producing a characteristic aversion to food ("food-fear") and weight loss. Most patients with chronic mesenteric venous thrombosis are asymptomatic because of the presence of extensive collateral venous drainage routes. However, some patients with chronic mesenteric venous thrombosis present with bleeding from esophagogastric varices.

Diagnosis

It is important to consider and pursue the diagnosis of acute mesenteric ischemia in any patient who has the classic early finding of severe abdominal pain out of proportion to physical findings. Laboratory test abnormalities, such as leukocytosis and acidosis are late findings; no laboratory tests have clinically useful sensitivity for the detection of acute mesenteric ischemia prior to the onset of intestinal infarction.

Patients suspected of having acute mesenteric ischemia and who have physical findings suggestive of peritonitis should undergo emergent laparotomy. In the absence of such findings, diagnostic imaging should be performed.

Although angiography is the most reliable method for diagnosing acute mesenteric arterial occlusion, it is invasive, time-consuming, and costly.

Therefore, most patients suspected of having acute mesenteric ischemia should undergo CT scanning as the initial imaging test. CT scans should be evaluated for (1) disorders other than acute mesenteric ischemia that might account for abdominal pain; (2) evidence of ischemia in the intestine and the mesentery; and (3) evidence of occlusion or stenosis of the mesenteric vasculature. CT scanning is also the test of choice for diagnosing acute mesenteric venous thrombosis.

Angiography should be performed if CT scanning reveals no evidence of mesenteric ischemia or other conditions that could account for acute abdominal pain and a high clinical suspicion for the presence of mesenteric ischemia remains. Additionally, because the CT findings of NOMI are nonspecific, patients at risk and suspected of having NOMI should undergo angiography without delay. The angiographic findings of NOMI include diffuse narrowing of mesenteric vessels in the absence of obstructing lesions and reduced opacification of bowel parenchyma.

The gold standard for the diagnosis of chronic arterial mesenteric ischemia is angiography, although CT angiography with three-dimensional reconstruction is noninvasive and offers good resolution. CT findings suggestive of chronic mesenteric ischemia include the presence of atherosclerotic calcified plaques at or near the origins of proximal splanchnic arteries and obvious focal stenosis of proximal mesenteric vessels with prominent collateral development.

Therapy

For embolus or thrombus-induced acute mesenteric ischemia, the standard treatment is surgical revascularization (embolectomy/thrombectomy/mesenteric bypass). These procedures are not indicated if most of the bowel supplied by the affected artery has already become infarcted, or if the patient is too unstable to undergo additional surgery beyond resection of infarcted intestine. For patients diagnosed with embolus or thrombus-induced acute mesenteric ischemia who do not have signs of peritonitis, thrombolysis, using agents such as streptokinase, urokinase, or recombinant tissue plasminogen activator, is an alternative therapeutic option.

The standard treatment of NOMI is selective infusion of a vasodilator, most commonly papaverine hydrochloride, into the superior mesenteric artery. If signs of peritonitis develop, emergent laparotomy should be performed and infarcted intestine resected.

The standard treatment of acute mesenteric venous thrombosis is anticoagulation. Heparin administration is associated with reductions in mortality and recurrence rates, and should be initiated as soon as the diagnosis is made. As for mesenteric ischemia of arterial origin, signs of peritonitis mandate laparotomy, and infarcted bowel should be resected. Most patients should be maintained on warfarin to achieve chronic anticoagulation for 6–12 months.

The standard therapy for chronic arterial mesenteric ischemia is surgical revascularization using aortomesenteric bypass grafting and mesenteric endarterectomy procedures. An alternative therapy is percutaneous transluminal mesenteric angioplasty alone or with stent insertion. The durability of these procedures in inducing relief of symptoms appears to be less than that associated with surgical revascularization.

Patients with chronic venous mesenteric thrombosis who have an underlying thrombophilia identified should be treated with chronic anticoagulation.

Additional therapy is indicated to control or prevent recurrent bleeding caused by esophagogastric varices. Pharmacologic agents such as propranol and endoscopic therapy are the first-line modalities. Surgical portosystemic shunts are indicated in patients whose bleeding cannot be controlled by conservative measures and who have a suitable vein for portosystemic venous anastomosis.

Outcomes

Recently reported mortality rates among patients with acute arterial mesenteric ischemia range from 59–93 percent. Reported mortality rates among patients with acute mesenteric venous thrombosis range from 20–50 percent.

Reported perioperative mortality rates associated with surgical therapy for chronic mesenteric ischemia range from 0–16 percent, with lower mortality rates predominating in recent series.

MISCELLANEOUS CONDITIONS

Obscure GI Bleeding

Obscure GI bleeding refers to gastrointestinal bleeding for which no source has been identified by routine endoscopic studies (EGD and colonoscopy). The small bowel contains most of the lesions responsible for obscure GI bleeding. Small-intestinal angiodysplasias account for approximately 75 percent of cases in adults; neoplasms account for approximately 10 percent. Meckel's diverticulum is the most common etiology of obscure GI bleeding in children. Other etiologies of obscure GI bleeding include Crohn disease, infectious enteritides, nonsteroidal antiinflammatory drug (NSAID)-induced ulcers and erosions, vasculitis, ischemia, varices, diverticula, and intussusception.

Four endoscopic techniques for visualizing the small intestine are available: push enteroscopy, sonde enteroscopy, intraoperative enteroscopy, and wireless capsule enteroscopy.

Push enteroscopy entails advancing a long endoscope (such as a pediatric or adult colonoscope or a specialized instrument) beyond the ligament of Treitz into the proximal jejunum. This procedure can enable visualization of approximately 60 cm of the proximal jejunum. In addition to diagnosis, push enteroscopy enables cauterization of bleeding sites.

In sonde enteroscopy, a long, thin fiberoptic instrument is propelled through the intestine by peristalsis following inflation of a balloon at the instrument's tip. Visualization is done during instrument withdrawal; approximately 50–75 percent of the small intestinal mucosa can be examined. However, this instrument lacks biopsy or therapeutic capability.

Intraoperative enteroscopy can be done during either laparotomy or laparoscopy. An endoscope (usually a colonoscope), is inserted into the small bowel through peroral intubation or through an enterotomy made in the small bowel or cecum. The endoscope is advanced by successively telescoping short segments of intestine onto the end to the instrument. Identified lesions should be marked with a suture placed on the serosal surface of the bowel; these lesions can be resected after completion of endoscopy.

Wireless capsule enteroscopy relies on a radiotelemetry capsule endoscope that is small enough to swallow and has no external wires, fiberoptic bundles, or cables. While the capsule is being propelled through the intestine by peristalsis, video images are transmitted using radiotelemetry to an array of detectors attached to the patient's body. These detectors capture the images and permit

continuous triangulation of the capsule location in the abdomen, facilitating the localization of lesions detected. The entire system is portable, allowing the patient to be ambulatory during the entire examination. Initial comparative studies indicate that the diagnostic yield of wireless capsule enteroscopy in patients with obscure GI bleeding is as good or better than that of push enteroscopy.

For patients in whom bleeding from an obscure GI source has apparently stopped, push and/or sonde enteroscopy or capsule enteroscopy (if available) is a reasonable initial study. If these examinations do not reveal a potential source of bleeding, then enteroclysis should be performed. If still no diagnosis has been made, a watch-and-wait approach is reasonable, although angiography should be considered if the prior episode of bleeding was severe. Angiography can reveal angiodysplasia and vascular tumors in the small intestine, even in the absence of ongoing bleeding.

For persistent mild bleeding from an obscure GI source, push and/or sonde enteroscopy should be used initially, if available. The role of capsule enteroscopy in this setting remains to be defined. If these examinations are non-diagnostic, then ^{99m}Tc -labeled RBC scanning should be performed and, if positive, followed by angiography to localize the source of bleeding. ^{99m}Tc -pertechnetate scintigraphy to diagnose Meckel diverticulum should be considered, although its yield in patients older than 40 years of age is extremely low. Patients who remain undiagnosed but who continue to bleed, and those patients with recurrent episodic bleeding significant enough to require blood transfusions, should then undergo exploration with intraoperative enteroscopy.

Patients with persistent severe bleeding from an obscure source should undergo angiography. Push enteroscopy can be attempted, but sonde and capsule enteroscopy are too slow to be applicable in this setting. If these examinations fail to localize the source of bleeding, exploratory laparoscopy or laparotomy with intraoperative enteroscopy is indicated. If bleeding is massive enough to cause hemodynamic derangements, expeditious exploration avoiding the delays inherent with angiography may be necessary.

Small-Bowel Perforation

Iatrogenic injury incurred during gastrointestinal endoscopy is the most common cause of small-bowel perforation. Other etiologies of small-bowel perforation include infections (especially tuberculosis, typhoid, and cytomegalovirus [CMV]), Crohn disease, ischemia, drugs (e.g., potassium- and NSAID-induced ulcers), radiation-induced injury, Meckel and acquired diverticula, neoplasms (especially lymphoma, adenocarcinoma, and melanoma), and foreign bodies.

Perforation of the jejunum and ileum occurs into the peritoneal cavity and usually causes overt symptoms and signs, such as abdominal pain, tenderness, and distention accompanied by fever and tachycardia. Perforations of the duodenum distal to its bulb, because of its retroperitoneal location, tend to be locally contained and can present insidiously. Manifestations of contained duodenal perforation following ERCP can resemble those of ERCP-induced pancreatitis, including hyperamylasemia.

Plain abdominal radiographs may reveal free intraperitoneal air if intraperitoneal perforation has occurred. If perforation is suspected but not clinically obvious, contrast radiography using a water-soluble contrast agent or CT scanning

should be performed. CT scanning is the most sensitive test for diagnosing duodenal perforations.

Iatrogenic small-bowel perforation incurred during endoscopy, if immediately recognized, can sometimes be repaired using endoscopic techniques. Ampullary injury incurred during ERCP can usually be managed by biliary stent placement. Additionally, contained select cases of retroperitoneal perforations of the duodenum can be managed nonoperatively, in the absence of progression and sepsis. However, intraperitoneal duodenal perforations require surgical repair with pyloric exclusion and gastrojejunostomy or tube duodenostomy. Jejunal and ileal perforations require surgical repair or segmental resection.

Chylous Ascites

Chylous ascites refers to the accumulation of triglyceride-rich peritoneal fluid with a milky or creamy appearance that is caused by the presence of intestinal lymph in the peritoneal cavity.

The most common etiologies of chylous ascites in Western countries are abdominal malignancies and cirrhosis. In Eastern and developing countries, infectious etiologies, such as tuberculosis and filariasis, account for most cases. Chylous ascites can also develop as a complication of abdominal and thoracic operations and trauma. Other etiologies of chylous ascites include congenital lymphatic abnormalities (e.g., primary lymphatic hypoplasia), radiation, pancreatitis, and right-sided heart failure.

Three mechanisms have been postulated to cause chylous ascites: (1) exudation of chyle from dilated lymphatics on the wall of the bowel and in the mesentery caused by obstruction of lymphatic vessels at the base of the mesentery or the cisterna chيلي (e.g., by malignancies); (2) direct leakage of chyle through a lymphoperitoneal fistula (e.g., those which develop as a result of trauma or surgery); and (3) exudation of chyle through the wall of dilated retroperitoneal lymphatic vessels (e.g., in congenital lymphangiectasia or thoracic duct obstruction).

Patients with chylous ascites develop abdominal distention over a period of weeks to months. Postoperative chylous ascites can present acutely during the first postoperative week. Paracentesis is the most important diagnostic test. Fluid triglyceride concentrations above 110 mg/dL are diagnostic. CT scanning may be useful in identifying pathologic intraabdominal lymph nodes and masses and in identifying extent and localization of fluid. Lymphangiography and lymphoscintigraphy may help to localize lymph leaks and obstruction.

Management of patients with chylous ascites should focus on evaluating and treating the underlying causes, especially for patients with infectious, inflammatory, or hemodynamic etiologies for this condition.

Most patients respond to administration of a high-protein and low-fat diet supplemented with medium-chain triglycerides. This regimen is designed to minimize chyle production and flow. Medium-chain triglycerides are absorbed by the intestinal epithelium and are transported to the liver through the portal vein; they do not contribute to chylomicron formation.

Patients who do not respond to this approach should be fasted and placed on TPN. Octreotide can further decrease lymph flow. Paracentesis is indicated for respiratory difficulties related to abdominal distention. Approximately 30 percent of patients will require surgical therapy for chylous ascites. In general, postoperative and trauma-related cases that fail to respond to initial

nonoperative therapy are best managed by surgical repair. Lymphatic leaks are localized and repaired with fine nonabsorbable sutures. If extravasation of chyle is localized to the periphery of the small-bowel mesentery, then a limited small-bowel resection can be performed instead. For patients who are poor surgical candidates and who do not respond to prolonged conservative therapy, peritoneovenous shunting may be an option.

SHORT-BOWEL SYNDROME

Epidemiology

Short-bowel syndrome has been arbitrarily defined as the presence of less than 200 cm of residual small bowel in adult patients. A functional definition, in which insufficient intestinal absorptive capacity results in the clinical manifestations of diarrhea, dehydration, and malnutrition, is more broadly applicable.

In adults, the most common etiologies of short-bowel syndrome are acute mesenteric ischemia, malignancy, and Crohn disease. In pediatric patients, intestinal atresias, volvulus, and necrotizing enterocolitis are the most common etiologies of short-bowel syndrome.

Pathophysiology

Clinically significant malabsorption occurs when greater than 50–80 percent of the small intestine has been resected. Among adult patients who lack a functional colon, lifelong TPN dependence is likely to persist if there is less than 100 cm of residual small intestine. Among adult patients who have an intact and functional colon, lifelong TPN dependence is likely to persist if there is less than 60 cm of residual small intestine. Among infants with short-bowel syndrome, weaning from TPN-dependence has been achieved with as little as 10 cm of residual small intestine.

Residual bowel length is not the only factor predictive of achieving independence from TPN (enteral autonomy), however. First, is the presence or absence of an intact colon because the colon has the capacity to absorb large fluid and electrolyte loads. Additionally, the colon can play an important, albeit small, role in nutrient assimilation by absorbing short-chain fatty acids. Second, an intact ileocecal valve is believed to be associated with decreased malabsorption. The ileocecal valve delays transit of chyme from the small intestine into the colon, thereby prolonging the contact time between nutrients and the small-intestinal absorptive mucosa. Third, a healthy, rather than diseased, residual small intestine is associated with decreased severity of malabsorption. Fourth, resection of jejunum is better tolerated than resection of ileum, because the capacity for bile salt and vitamin B12 absorption is specific to the ileum.

Malabsorption in patients who have undergone massive small-bowel resection is exacerbated by a characteristic hypergastrinemia-associated gastric acid hypersecretion that persists for 1–2 years postoperatively. The increased acid load delivered to the duodenum inhibits absorption by a variety of mechanisms, including the inhibition of digestive enzymes, most of which function optimally under alkaline conditions.

Also during the first 1–2 years following massive small-bowel resection, the remaining intestine undergoes compensatory adaptation. Clinically, the period of adaptation is associated with reductions in volume and frequency of bowel movements, increases in the capacity for enteral nutrient assimilation, and reductions in TPN requirements.

THERAPY

Medical Therapy

For patients having undergone massive small-bowel resection, the initial treatment priorities include management of the primary condition precipitating the intestinal resection and the repletion of fluid and electrolytes lost in the severe diarrhea that characteristically occurs. Most patients will require TPN, at least initially. Enteral nutrition should be gradually introduced, once ileus has resolved. High-dose histamine₂ receptor antagonists or proton pump inhibitors should be administered to reduce gastric acid secretion. Antimotility agents, such as loperamide hydrochloride or di-phenoxylate, may be administered to delay small-intestinal transit. Octreotide can be administered to reduce the volume of gastrointestinal secretions.

During the period of adaptation, generally lasting 1–2 years postoperatively, TPN and enteral nutrition are titrated in an attempt to allow for independence from TPN. Patients who remain dependent on TPN face TPN-associated morbidities, including catheter sepsis, venous thrombosis, liver and kidney failure, and osteoporosis. Because of these problems, alternative therapies for short-bowel syndrome are under investigation.

Nontransplant Surgical Therapy

Among patients with stomas, restoration of intestinal continuity should be performed, whenever possible, to capitalize on the absorptive capacity of all residual intestine.

Operations designed to slow intestinal transit include segmental reversal of the small bowel, interposition of a segment of colon between segments of small bowel, construction of small-intestinal valves, and electrical pacing of the small intestine. Intestinal lengthening procedures include the longitudinal intestinal lengthening and tailoring (LILT) procedure, first described by Bianchi, and the more recently described serial transverse enteroplasty procedure (STEP). These operations are associated with unclear efficacy and/or substantial morbidities, and therefore should not be applied routinely.

Intestinal Transplantation

Approximately 100 intestinal transplants are performed in the United States annually, with most of these procedures applied to patients with short-bowel syndrome. The currently accepted indication for intestinal transplantation is the presence of life-threatening complications attributable to intestinal failure and/or long-term TPN therapy. Specific complications for which intestinal transplantation is indicated include impending or overt liver failure, thrombosis of major central veins, frequent episodes of catheter-related sepsis, and frequent episodes of severe dehydration.

Isolated intestinal transplantation is used for patients with intestinal failure who have no significant liver disease or failure of other organs. Combined intestine/liver transplantation is used for patients with both intestinal and liver failure. Nearly 80 percent of survivors have full intestinal graft function with no need for TPN. However, morbidities associated with intestinal transplantation are substantial and include acute and chronic rejection, CMV infection, and posttransplant lymphoproliferative disease.

Outcomes

Approximately 50–70 percent of patients with short-bowel syndrome who initially require TPN are ultimately able to achieve independence from TPN.

ANATOMY

Anatomic divisions of the large intestine:

1. Colon
2. Rectum
3. Anal canal

Layers of the colon and rectum:

1. Mucosa
2. Submucosa
3. Inner circular muscle – Coalesces distally to create the internal anal sphincter.
4. Outer longitudinal muscle – Separated into three teniae coli in the colon; teniae converge proximally at the appendix and distally at the rectum.
5. Serosa – Covers the intraperitoneal colon and one third of the rectum.

Colorectal and Anorectal Vascular Supply

The arterial supply to the colon is highly variable. In general, the arterial supply to the colon is as follows:

1. Superior mesenteric artery branches
 - a. Ileocolic artery (absent in up to 20 percent of people) supplies blood flow to the terminal ileum and proximal ascending colon.
 - b. Right colic artery supplies the ascending colon.
 - c. Middle colic artery supplies the transverse colon.
2. Inferior mesenteric artery branches
 - a. Left colic artery supplies the descending colon.
 - b. Sigmoidal branches supply the sigmoid colon.
 - c. Superior rectal artery supplies the proximal rectum.

The terminal branches of each artery form anastomoses with the terminal branches of the adjacent artery and communicate via the marginal artery of Drummond (complete in only 15–20 percent of people).
3. Internal iliac artery branches
 - a. Middle rectal artery (variable presence and size).
 - b. Internal pudendal artery branch.
 - i. Inferior rectal artery supplies the lower rectum and anal canal.

A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia.

Except for the inferior mesenteric vein, the veins of the colon, rectum, and anus parallel their corresponding arteries and bear the same terminology. The inferior mesenteric vein ascends in the retroperitoneal plane over the psoas muscle and continues posterior to the pancreas to join the splenic vein. The venous drainage of the rectum parallels the arterial supply. The superior rectal vein drains into the portal system via the inferior mesenteric vein. The middle rectal vein drains into the internal iliac vein. The inferior rectal vein drains

into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the hemorrhoidal plexus and drains into all three veins.

Colorectal and Anorectal Lymphatic Drainage

The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but also can drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

Colorectal and Anorectal Nerve Supply

The nerves to the colon and rectum parallel the course of the arteries.

1. Sympathetic (inhibitory) arise from T6-T12 and L1-L3.
2. Parasympathetic (stimulatory) innervation to the right and transverse colon is from the vagus nerve; parasympathetic nerves to the left colon arise from sacral nerves S2–S4 to form the nervi erigentes. The external anal sphincter and puborectalis muscles are innervated by the inferior rectal branch of the internal pudendal nerve. The levator ani receives innervation from both the internal pudendal nerve and direct branches of S3–S5. Sensory innervation to the anal canal is provided by the inferior rectal branch of the pudendal nerve. Whereas the rectum is relatively insensate, the anal canal below the dentate line is sensate.

CLINICAL EVALUATION

Endoscopy

1. Anoscopy – The anoscope is useful for examination of the anal canal and can generally allow examination of the distal 6–8 cm of the anus. Anoscopy can be diagnostic or therapeutic (e.g., sclerotherapy or rubber band ligation of hemorrhoids).
2. Proctoscopy – The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and is occasionally used therapeutically (e.g., polypectomy, electrocoagulation, or detorsion of a sigmoid volvulus).
3. Flexible Sigmoidoscopy and Colonoscopy – Flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length and may allow visualization as high as the splenic flexure. Partial preparation with enemas is usually adequate for sigmoidoscopy and most patients can tolerate this procedure without sedation.

Colonoscopes measure 100–160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation usually is necessary for colonoscopy and the duration and discomfort of the procedure

usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically.

Imaging

1. Plain radiograph of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intraabdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus.
2. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. Gastrografin is recommended if perforation or leak is suspected. Double-contrast barium enema is more sensitive for the detection of mass lesions greater than 1 cm in diameter.
3. Computed Tomography – Computed tomography (CT) is commonly employed in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intraabdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma. Extravasation of oral or rectal contrast also may confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of intraluminal lesions.
4. Virtual Colonoscopy (CT colography) – Virtual colonoscopy is a technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation are used to maximize sensitivity.
5. Magnetic Resonance Imaging (MRI) – The main use of MRI in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting bony involvement or pelvic sidewall extension of rectal tumors. MRI with an endorectal coil can be helpful in the detection and delineation of complex fistulas in ano.
6. Positron Emission Tomography (PET) – Positron emission tomography is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors. PET has been used as an adjunct to CT in the staging of colorectal cancer and may prove useful in discriminating recurrent cancer from fibrosis.
7. Angiography – Angiography is occasionally used for the detection of brisk bleeding (approximately 0.5–1.0 mL per minute) within the colon or small bowel. If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic.
8. Endorectal and Endoanal Ultrasound – Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. Ultrasound can reliably differentiate most benign polyps from invasive tumors and can differentiate superficial (T1–T2) from deeper (T3–T4) tumors. This modality also can detect enlarged perirectal lymph nodes. Ultrasound may also prove useful for early detection of local recurrence after surgery.

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas.

Physiologic and Pelvic Floor Investigations

Anorectal physiologic testing techniques are useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other disorders of the pelvic floor.

1. **Manometry** – Anorectal manometry measures pressure in the anal canal. The resting pressure in the anal canal reflects the function of the internal anal sphincter (normal: 40–80 mmHg), whereas the squeeze pressure, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal: 40–80 mmHg above resting pressure). The high-pressure zone estimates the length of the anal canal (normal: 2.0–4.0 cm).
2. **Neurophysiology** – Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal: 1.8–2.2 msec); prolonged latency suggests the presence of neuropathy. EMG recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to “squeeze,” and decreases when a patient is instructed to “push.” Inappropriate recruitment is an indication of paradoxical contraction (non-relaxation of the puborectalis).
3. **Rectal Evacuation Studies** – Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient’s ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation.

Evaluation of Common Symptoms

Pain

Abdominal pain. Abdominal pain related to the colon and rectum can result from obstruction, inflammation, perforation, or ischemia. Plain radiographs and judicious use of contrast studies and/or a CT scan can often confirm the diagnosis. Gentle retrograde contrast studies (barium or Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy performed by an experienced endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation or obstruction is suspected, colonoscopy and/or sigmoidoscopy are generally contraindicated.

Pelvic pain. Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass. Cyclical pain associated with menses suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis.

Anorectal pain. Anorectal pain most often is secondary to an anal fissure or perirectal abscess and/or fistula. Physical examination can usually differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions.

Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical examination is critical in evaluating patients with anorectal pain. If a patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI may be helpful in select cases in which the etiology of pain is elusive.

Lower Gastrointestinal Bleeding

The first goal in evaluating and treating a patient with gastrointestinal hemorrhage is adequate resuscitation. The principles of ensuring a patent airway, supporting ventilation, and optimizing hemodynamic parameters apply and coagulopathy and/or thrombocytopenia should be corrected. The second goal is to identify the source of hemorrhage. Because the most common source of gastrointestinal hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or nonbile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy is performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99 (99mTc)-tagged red blood cell (RBC) scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the 99mTc-tagged RBC scan is positive, angiography can then be employed to localize bleeding. Infusion of vasopressin or angioembolization may be therapeutic. Alternatively, a catheter can be left in the bleeding vessel to allow localization at the time of laparotomy. If the patient is hemodynamically stable, a rapid bowel preparation (over 4–6 h) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection of epinephrine into the bleeding site may be used to control hemorrhage. Colectomy may be required if bleeding persists despite these interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. “Blind” subtotal colectomy very rarely may be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, it is crucial to irrigate the rectum and examine the mucosa by proctoscopy to ensure that the source of bleeding is not distal to the resection margin.

Hematochezia is commonly caused by hemorrhoids or fissure. Sharp, knife-like pain and bright-red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright-red rectal bleeding with bowel movements is often secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.

Diarrhea and Irritable Bowel Syndrome

Diarrhea is a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection, inflammatory bowel disease, or ischemia. Stool wet-mount and culture can often diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal

tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn's colitis, infection, malabsorption, and short-gut syndrome can cause chronic diarrhea. Rarely, carcinoid syndrome and islet cell tumors present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy with biopsies can be invaluable.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Work-up reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

Defecation Disorders, Constipation, and Incontinence

Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intraabdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This "sampling reflex" allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (the accommodation response). Defecation proceeds by coordination of increasing intraabdominal pressure via the Valsalva maneuver, increased rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

The maintenance of fecal continence requires adequate rectal wall compliance, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a "sling" around the distal rectum, forming an acute angle that distributes intraabdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. Hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal.

Constipation and Obstructed Defecation

Constipation has a myriad of causes. Underlying metabolic, pharmacologic, endocrine, psychologic, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy or barium enema. After these causes have been excluded, evaluation focuses on differentiating slow-transit constipation from outlet obstruction. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. Anorectal manometry and electromyography can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex suggests Hirschsprung disease and may prompt a rectal mucosal biopsy.

Defecography can identify rectal prolapse, intussusception, rectocele, or enterocele.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from non-relaxation of the puborectalis often responds to biofeedback. Surgery to correct rectocele and rectal prolapse has a variable effect on symptoms of constipation, but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions.

Incontinence

Incontinence ranges in severity from occasional leakage of gas and liquid stool to daily loss of solid stool. The underlying cause of incontinence often is multifactorial and diarrhea often is contributory. In general, causes of incontinence can be classified as neurogenic or anatomic. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia, overflow incontinence secondary to impaction or neoplasm, and trauma. The most common traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

Therapy depends on the underlying abnormality. Diarrhea should be treated medically. Even in the absence of frank diarrhea, the addition of dietary fiber may improve continence. Some patients may respond to biofeedback. Many patients with a sphincter defect are candidates for an overlapping sphincteroplasty. Innovative technologies such as sacral nerve stimulation or artificial bowel sphincter are proving useful in patients who fail other interventions.

GENERAL SURGICAL CONSIDERATIONS

Resections

The extent of colonic resection is determined by the nature of the primary pathology (malignant or benign), the intent of the resection (curative or palliative), the precise location(s) of the primary pathology, and the condition of the mesentery (thin and soft or thickened and indurated). Curative resection of a colorectal cancer is usually best accomplished by performing a proximal mesenteric vessel ligation and radical mesenteric clearance of the lymphatic drainage basin of the tumor site with concomitant resection of the overlying omentum. Resection of a benign process does not require wide mesenteric resection and the omentum can be preserved if desired.

Emergency Resection

Emergency resection may be required because of obstruction, perforation, or hemorrhage. In this setting, the bowel almost always is unprepared and the patient may be unstable. The surgical principles described above apply and an attempt should be made to resect the involved segment along with its lymphovascular supply. If the resection involves the right colon or proximal transverse colon (right or extended right colectomy), a primary ileocolonic anastomosis can usually be performed safely as long as the remaining bowel appears healthy and the patient is stable. For left-sided tumors, the traditional approach has involved resection of the involved bowel and end colostomy, with or without a mucus fistula. However, there is an increasing body of data

to suggest that a primary anastomosis with an on-table lavage, with or without a diverting ileostomy, may be equally safe in this setting. If the proximal colon looks unhealthy (vascular compromise, serosal tears, perforation), a subtotal colectomy can be performed with a small bowel to rectosigmoid anastomosis. Resection and diversion (ileostomy or colostomy) remains safe and appropriate if the bowel looks compromised or if the patient is unstable, malnourished, or immunosuppressed.

Laparoscopic Resection

Many procedures that previously have required laparotomy can now be performed laparoscopically. To date, most studies have demonstrated equivalence between laparoscopic and open resection in terms of extent of resection. However, laparoscopic colon resections are technically demanding and consistently require longer operative time than do open procedures. Return of bowel function and length of hospital stay are highly variable. Long-term outcome has yet to be determined.

Colectomy

A variety of terms are used to describe different types of colectomy. Ileocolic Resection – used to remove disease involving ileum, cecum, and/or appendix. If curable malignancy is suspected, more radical resections (right hemicolectomy) are generally indicated.

Right Colectomy – used to remove lesions or disease in the right colon and is oncologically the most appropriate operation for curative intent resection of proximal colon carcinoma.

Extended Right Colectomy – used for curative intent resection of lesions located at the hepatic flexure or proximal transverse colon.

Transverse Colectomy – may be used to resect lesions in the mid and distal transverse colon (an extended right colectomy may be safer with an equivalent functional result).

Left Colectomy – used to resect lesions confined to the distal transverse colon, splenic flexure, or descending colon.

Extended Left Colectomy – used to resect lesions in the distal transverse colon.

Sigmoid Colectomy – used to resect lesions in the sigmoid colon. In general, the entire sigmoid colon should be resected to the level of the peritoneal reflection and an anastomosis created between the descending colon and upper rectum.

Total and Subtotal Colectomy – may be required for patients with fulminant colitis, attenuated familial adenomatous polyposis, or synchronous colon carcinomas. Total abdominal colectomy refers to resection of the entire colon, including the sigmoid colon, with or without an ileorectal anastomosis. Subtotal colectomy refers to resection of the right, transverse, and left colon with or without an anastomosis between the ileum and sigmoid colon. If an anastomosis is contraindicated, an end-ileostomy is created and the remaining sigmoid or rectum is managed either as a mucus fistula or a Hartmann pouch.

Proctocolectomy

Total Proctocolectomy – removal of the entire colon, rectum, and anus with creation of an ileostomy. Restorative proctocolectomy (total proctocolectomy with ileoanal pouch) refers to removal of the entire colon and rectum, with

preservation of the anal sphincters. Bowel continuity is restored by anastomosis of an ileal reservoir to the anal canal.

Anterior Resection – a general term used to describe resection of the rectum from an abdominal approach.

High Anterior Resection – used to describe resection of the distal sigmoid colon and upper rectum; appropriate for benign lesions at the rectosigmoid junction.

Low Anterior Resection – used to remove lesions in the upper and mid rectum. Circular stapling devices have greatly facilitated the conduct and improved the safety of the colon to extraperitoneal rectal anastomosis.

Extended Low Anterior Resection – used to remove lesions located in the distal rectum, but several centimeters above the sphincter. After resection, a coloanal anastomosis can be created. Because the risk of an anastomotic leak and subsequent sepsis is higher when an anastomosis is created in the distal rectum or anal canal, creation of a temporary ileostomy should be considered in this setting. Although an anastomosis may be technically feasible very low in the rectum or anal canal, it is important to note that postoperative function and continence may be poor.

Hartmann's Procedure and Mucus Fistula – refers to a colon or rectal resection without an anastomosis in which a colostomy or ileostomy is created proximally and the distal colon or rectum is left as a closed off blind pouch (Hartmann pouch). A mucus fistula is an option if the distal colon is long enough to reach the abdominal wall. It can be created by opening the defunctioned bowel and suturing it to the skin.

Abdominoperineal Resection – removal of the entire rectum, anal canal, and anus with construction of a permanent colostomy from the descending or sigmoid colon.

Anastomoses

Anastomoses may be created between two segments of bowel in a multitude of ways. The geometry of the anastomosis may be end-to-end, end-to-side, side-to-end, or side-to-side. The anastomotic technique may be handsewn (single or double layer) or stapled. The choice of anastomosis depends on the operative anatomy and surgeon preference.

Ostomies

Depending on the clinical situation, a stoma may be temporary or permanent. It may be end-on or a loop. However, regardless of the indication for a stoma, placement and construction are crucial for function. A stoma should be located within the rectus muscle to minimize the risk of a postoperative parastomal hernia. It also should be placed where the patient can see it and easily manipulate the appliance. The surrounding abdominal soft tissue should be as flat as possible to ensure a tight seal and prevent leakage. Preoperative evaluation by an enterostomal therapy nurse to identify the ideal stoma site and to counsel and educate the patient is invaluable.

Ileostomy

Temporary Ileostomy. A temporary ileostomy often is used to “protect” an anastomosis that is at risk for leakage (low in the rectum, in an irradiated field, in an immunocompromised or malnourished patient, and in some emergency operations). The stoma often is constructed as a loop ileostomy. The advantage

of a loop ileostomy is that subsequent closure often can be accomplished without a formal laparotomy.

Permanent Ileostomy. A permanent ileostomy is sometimes required after total proctocolectomy or in patients with obstruction. An end ileostomy is the preferred configuration for a permanent ileostomy because a symmetric protruding nipple can be fashioned more easily than with a loop ileostomy.

Complications of Ileostomy

Anatomic

1. Stoma necrosis
2. Stoma retraction
3. Skin irritation
4. Obstruction: intraabdominally or at the site where the stoma exits the fascia
5. Parastomal hernia (less common than after colostomy)
6. Prolapse (rare)

Functional. Dehydration and fluid/electrolyte abnormalities: The creation of an ileostomy bypasses the fluid-absorbing capability of the colon, and dehydration with fluid and electrolyte abnormalities is not uncommon. Ideally, ileostomy output should be maintained at less than 1500 mL/day to avoid this problem. Bulk agents and antidiarrheal agents are useful.

Colostomy

Most colostomies are created as end colostomies. Because a protruding stoma is considerably easier to pouch, colostomies also should be matured in a Brooke fashion. Closure of a colostomy usually requires laparotomy.

Complications of Colostomy

Anatomic.

1. Colostomy necrosis
2. Colostomy retraction (less problematic with a colostomy than with an ileostomy because the stool is less irritating to the skin than succus entericus)
3. Obstruction (intraabdominal or at the site where the bowel exits the fascia)
4. Parastomal hernia is the most common late complication of a colostomy and requires repair if it is symptomatic. Repair usually requires resiting the stoma to the contralateral side of the abdomen.
5. Prolapse (rare)

Bowel Preparation

The rationale for bowel preparation is that decreasing the bacterial load in the colon and rectum will decrease the incidence of postoperative infection. Mechanical bowel preparation uses cathartics to rid the colon of solid stool the night before surgery. The most commonly used regimens include polyethylene glycol (PEG) solutions or sodium phosphate. Antibiotic prophylaxis also is recommended. A combination of three doses of neomycin (1 g) and erythromycin base (1 g) is most commonly used. Some surgeons substitute metronidazole (500 mg) for erythromycin to avoid gastrointestinal upset. Ciprofloxacin also has been used in this setting. A broad-spectrum parenteral antibiotic(s) should

be administered just prior to the skin incision. There is no proven benefit to using antibiotics postoperatively after an uncomplicated colectomy.

INFLAMMATORY BOWEL DISEASE

General Considerations

Epidemiology

Inflammatory bowel disease includes ulcerative colitis, Crohn disease, and indeterminate colitis. Multiple etiologies for inflammatory bowel disease have been proposed, but none are proven. Suggested etiology includes an environmental factor (diet, infection), smoking, alcohol, oral contraceptive use, and/or an autoimmune mechanism. Ten to 30 percent of patients will have a family history of irritable bowel disease (IBD). Regardless of the underlying cause of either ulcerative colitis or Crohn disease, both disorders are characterized by intestinal inflammation and medical therapy is largely based on reducing inflammation.

Pathology and Differential Diagnosis

1. **Ulcerative Colitis:** Ulcerative colitis is a mucosal process in which the colonic mucosa and submucosa are infiltrated with inflammatory cells. The mucosa may be atrophic and crypt abscesses are common. Endoscopically, the mucosa is frequently friable and may possess multiple inflammatory pseudopolyps. In long-standing ulcerative colitis, the colon may be foreshortened and the mucosa replaced by scar. In quiescent ulcerative colitis, the colonic mucosa may appear normal both endoscopically and microscopically. A key feature of ulcerative colitis is the continuous involvement of the rectum and colon; rectal sparing or skip lesions suggests a diagnosis of Crohn disease. Symptoms are related to the degree of mucosal inflammation and the extent of colitis. Patients typically complain of bloody diarrhea and crampy abdominal pain. Severe abdominal pain and fever raises the concern of fulminant colitis or toxic megacolon. Physical findings are nonspecific and range from minimal abdominal tenderness and distention to frank peritonitis. In the nonemergent setting, the diagnosis is typically made by colonoscopy and mucosal biopsy.
2. **Crohn Disease:** Crohn disease is a transmural inflammatory process that can affect any part of the gastrointestinal tract. Mucosal ulcerations, an inflammatory cell infiltrate, and noncaseating granulomas are characteristic pathologic findings. Chronic inflammation may ultimately result in fibrosis, strictures, and fistulas in either the colon or small intestine. The endoscopic appearance of Crohn colitis is characterized by deep serpiginous ulcers and a "cobblestone" appearance. Skip lesions and rectal sparing are common. Symptoms of Crohn disease depend on the severity of inflammation and/or fibrosis and the location of inflammation in the gastrointestinal tract. Acute inflammation may produce diarrhea, crampy abdominal pain, and fever. Strictures may produce symptoms of obstruction. Weight loss is common, both because of obstruction and from protein loss. Perianal Crohn disease may present with pain, swelling, and drainage from fistulas or abscesses. Physical findings also are related to the site and severity of disease.
3. **Indeterminate Colitis:** In 15 percent of patients with colitis from IBD, differentiation of ulcerative colitis from Crohn colitis proves impossible.

Endoscopic and pathologic findings usually include features common to both diseases.

4. **Differential Diagnosis:** Differential diagnoses include infectious colitides, especially *Campylobacter jejuni*, *Entamoeba histolytica*, *C. difficile*, *Neisseria gonococcus*, *Salmonella*, and *Shigella* species.

Extraintestinal Manifestations

1. **Hepatic**
 - A. Fatty infiltration (40–50 percent) – reversible
 - B. Cirrhosis (2–5 percent) – irreversible
 - C. Primary Sclerosing cholangitis – irreversible
 - D. Pericholangitis
 - E. Bile duct carcinoma – rare
2. **Rheumatologic**
 - A. Arthritis – reversible
 - B. Sacroiliitis – irreversible
 - C. Ankylosing spondylitis – irreversible
 - D. Erythema nodosum (5–15 percent)
 - E. Pyoderma gangrenosum (rare)
3. **Ocular (10 percent)**
 - A. Uveitis
 - B. Iritis
 - C. Episcleritis
 - D. Conjunctivitis

Principles of Nonoperative Management

Medical therapy for inflammatory bowel disease focuses on decreasing inflammation and alleviating symptoms, and many of the agents used are the same for both ulcerative colitis and Crohn disease. In general, mild to moderate flares may be treated in the outpatient setting. More severe signs and symptoms mandate hospitalization. Pancolitis generally requires more aggressive therapy than limited disease. Because ulcerative proctitis and proctosigmoiditis are limited to the distal large intestine, topical therapy with salicylate and/or corticosteroid suppositories and enemas can be extremely effective. Systemic therapy rarely is required in these patients.

Salicylates. Sulfasalazine (Azulfidine), 5-ASA, and related compounds are first-line agents in the medical treatment of mild to moderate inflammatory bowel disease. Multiple preparations are available for administration to different sites in the small intestine and colon (sulfasalazine, mesalamine [Pentasa], Asacol, Rowasa).

Antibiotics. Antibiotics are used to decrease the intraluminal bacterial load in Crohn disease. Metronidazole has been reported to improve Crohn colitis and perianal disease, but the evidence is weak. Fluoroquinolones also may be effective in some cases. In the absence of fulminant colitis or toxic megacolon, antibiotics are not used to treat ulcerative colitis.

Corticosteroids. Corticosteroids (oral or parenteral) are a key component of treatment for an acute exacerbation of either ulcerative colitis or Crohn disease. Seventy-five to 90 percent of patients will improve with the administration of these drugs. Corticosteroid enemas provide effective local therapy for proctitis and proctosigmoiditis and have fewer side effects than systemic

corticosteroids. Failure to wean systemic corticosteroids is a relative indication for surgery.

Immunosuppressive Agents

1. Antimetabolites: Azathioprine and 6-mercaptopurine (6-MP) interfere with nucleic acid synthesis and thus decrease proliferation of inflammatory cells. These agents are useful for treating ulcerative colitis and Crohn disease in patients who have failed salicylate therapy or who are dependent on or are refractory to corticosteroids. Onset of action of these drugs takes 6–12 weeks, and concomitant use of corticosteroids almost always is required.
2. Cyclosporine: Cyclosporine interferes with T-cell function. Although cyclosporine is not routinely used to treat inflammatory bowel disease, up to 80 percent of patients with an acute flare of ulcerative colitis will improve with its use. However, the majority of these patients will ultimately require colectomy. Cyclosporine also is occasionally used to treat exacerbations of Crohn's disease and approximately two-thirds of patients will note some improvement.
3. Methotrexate: Methotrexate is a folate antagonist. Although the efficacy of this agent is unproven, there are reports that more than 50 percent of patients will improve with administration of this drug.
4. Infliximab: Infliximab (Remicade) is a monoclonal antibody against tumor necrosis factor alpha (TNF- α). Intravenous infusion of this agent decreases inflammation systemically. More than 50 percent of patients with moderate to severe Crohn disease will improve with infliximab therapy. This agent also has been useful in treating patients with perianal Crohn disease. Recurrence is common, however, and many patients require infusions on a bimonthly basis. Infliximab has not been used as extensively for treatment of ulcerative colitis; however, there are reports of efficacy in this setting.

Nutrition. Patients with inflammatory bowel disease are often malnourished. Parenteral nutrition should be strongly considered early in the course of therapy for either Crohn disease or ulcerative colitis. The nutritional status of the patient also should be considered when planning operative intervention and nutritional parameters such as serum albumin, prealbumin, and transferrin should be assessed. In extremely malnourished patients, especially those who also are being treated with corticosteroids, creation of a stoma often is safer than a primary anastomosis.

Ulcerative Colitis

Ulcerative colitis is a dynamic disease characterized by remissions and exacerbations. The clinical spectrum ranges from an inactive or quiescent phase to low-grade active disease to fulminant disease. The onset of ulcerative colitis may be insidious, with minimal bloody stools, or the onset can be abrupt, with severe diarrhea and bleeding, tenesmus, abdominal pain, and fever. The severity of symptoms depends on the degree and extent of inflammation. Although anemia is common, massive hemorrhage is rare. Physical findings often are nonspecific.

Diagnosis of ulcerative colitis almost always is made endoscopically. Because the rectum is invariably involved, proctoscopy may be adequate to establish the diagnosis. A complete evaluation with colonoscopy or barium enema during an acute flare is contraindicated because of the risk of perforation.

Because the inflammation in ulcerative colitis is purely mucosal, strictures are highly uncommon. Any stricture diagnosed in a patient with ulcerative colitis must be presumed to be malignant until proven otherwise.

Indications for Surgery

Emergency surgery is required for patients with life-threatening hemorrhage, toxic megacolon, or fulminant colitis who fail to respond rapidly to medical therapy. Patients with fulminant colitis should be treated with bowel rest, hydration, broad-spectrum antibiotics, and parenteral corticosteroids. Colonoscopy and barium enema are contraindicated and antidiarrheal agents should be avoided. Clinical deterioration or failure to improve within 24 h mandates surgery.

Indications for elective surgery include intractability despite maximal medical therapy, development of major complications from medical therapy, and risk of developing colorectal carcinoma. Risk of malignancy increases with pancolonic disease and the duration of symptoms; the risk is approximately 2 percent after 10 years, 8 percent after 20 years, and 18 percent after 30 years. Unlike sporadic colorectal cancers, carcinoma developing in the context of ulcerative colitis is more likely to arise from areas of flat dysplasia and may be difficult to diagnose at an early stage. For this reason, it is recommended that patients with long-standing ulcerative colitis undergo colonoscopic surveillance with multiple (40–50), random biopsies to identify dysplasia before invasive malignancy develops. Surveillance is recommended annually after 8 years in patients with pancolitis, and annually after 15 years in patients with left-sided colitis. Although low-grade dysplasia was long thought to represent minimal risk, more recent studies show that invasive cancer may be present in up to 20 percent of patients with low-grade dysplasia. For this reason, any patient with dysplasia should be advised to undergo proctocolectomy. Controversy exists over whether prophylactic proctocolectomy should be recommended for patients who have had chronic ulcerative colitis for greater than 10 years in the absence of dysplasia.

Operative Management

Emergency operation. In a patient with fulminant colitis or toxic megacolon, total abdominal colectomy with end ileostomy is recommended. Although the rectum is invariably diseased, most patients improve dramatically after an abdominal colectomy, and this operation avoids a difficult and time-consuming pelvic dissection in a critically ill patient. Rarely, a loop ileostomy and decompressing colostomy may be necessary if the patient is too unstable to withstand colectomy.

Elective operation. Total proctocolectomy with end ileostomy has been the “gold standard” for patients with chronic ulcerative colitis. This operation removes the entire affected intestine, but leaves the patient with a permanent ileostomy. Total proctocolectomy with continent ileostomy (Kock pouch) was developed to improve function and quality of life after total proctocolectomy, but morbidity is significant and restorative proctocolectomy is generally preferred today. Restorative proctocolectomy with ileal pouch–anal anastomosis has become the procedure of choice for most patients who require total proctocolectomy but wish to avoid a permanent ileostomy.

Crohn Disease

Crohn disease is characterized by exacerbations and remissions and may affect any portion of the intestinal tract, from mouth to anus. Diagnosis may be made by colonoscopy or esophagogastroduodenoscopy, or by barium small bowel study or enema, depending on which part of the intestine is most affected. Skip lesions are key in differentiating Crohn colitis from ulcerative colitis, and rectal sparing occurs in approximately 40 percent of patients. The most common site of involvement in Crohn disease is the terminal ileum and cecum, followed by the small bowel, and then by the colon and rectum. Crohn disease may affect the distal rectum and anal canal and may present as complex perianal/perirectal fistulas and/or abscesses.

Indications for Surgery

Because Crohn disease can affect any part of the gastrointestinal tract, the therapeutic rationale is fundamentally different from that of ulcerative colitis. In Crohn disease, it is impossible to remove all of the at-risk intestine; therefore surgical therapy is reserved for complications of the disease.

Crohn disease may present as an acute inflammatory process or as a chronic fibrotic process. During the acute inflammatory phase, patients may present with intestinal inflammation complicated by fistulas and/or intraabdominal abscesses. Maximal medical therapy should be instituted, including antiinflammatory medications, bowel rest, and antibiotics. Parenteral nutrition should be considered if the patient is malnourished. Most intraabdominal abscesses can be drained percutaneously with the use of CT scan guidance. Although the majority of these patients will ultimately require surgery to remove the diseased segment of bowel, these interventions allow the patient's condition to stabilize, nutrition to be optimized, and inflammation to decrease prior to embarking on a surgical resection.

Chronic fibrosis may result in strictures in any part of the gastrointestinal tract. Chronic strictures rarely improve with medical therapy. Optimal timing for surgery should take into account the patient's underlying medical and nutritional status. Strictures may be treated with resection or stricturoplasty. Associated fistulas generally require resection of the segment of bowel with active Crohn disease; the secondary sites of the fistula are often otherwise normal and do not generally require resection after division of the fistula. Simple closure of the secondary fistula site usually suffices.

Ileocolic and Small-Bowel Crohn Disease

The terminal ileum and cecum are involved in Crohn disease in up to 41 percent of patients; the small intestine is involved in up to 35 percent of patients. The most common indications for surgery are internal fistula or abscess (30–38 percent) and obstruction (35–37 percent). Psoas abscess may result from ileocolic Crohn disease. Sepsis should be controlled with percutaneous drainage of abscess(es) and antibiotics, if possible. The extent of resection depends on the amount of involved intestine. Because many patients with Crohn disease will require multiple operations, the length of bowel removed should be minimized. Short segments of inflamed small intestine and right colon, and isolated chronic strictures should be resected. Bowel should be resected to an area with grossly normal margins. In patients with multiple fibrotic strictures that would require extensive small-bowel resection, stricturoplasty is a safe and effective alternative to resection. A primary anastomosis may be safely created if the

patient is medically stable, nutritionally replete, and taking few immunosuppressive medications. Creation of a stoma should be strongly considered in any patient who is hemodynamically unstable, septic, malnourished, or receiving high-dose immunosuppressive therapy and in patients with extensive intraabdominal contamination. Risk of recurrence after resection for ileocolic and small-bowel Crohn disease is high. More than 50 percent of patients will experience a recurrence within 10 years and the majority of these will require a second operation.

Crohn Colitis

Crohn disease of the large intestine may present as fulminant colitis or toxic megacolon. In this setting, treatment is identical to treatment of fulminant colitis and toxic megacolon secondary to ulcerative colitis. Other indications for surgery in chronic Crohn colitis are intractability, complications of medical therapy, and risk of or development of malignancy. Unlike ulcerative colitis, Crohn colitis may be segmental and rectal sparing often is observed. A segmental colectomy may be appropriate if the remaining colon and/or rectum appear normal. An isolated colonic stricture also may be treated by segmental colectomy. Crohn colitis (especially pancolitis) carries nearly the same risk for cancer as ulcerative colitis and similar surveillance and treatment are recommended. Ileal pouch–anal reconstruction is not recommended because of the risk for development of Crohn disease within the pouch and the high risk of complications and pouch failure.

Anal and Perianal Crohn Disease

Anal or perianal disease occurs in 35 percent of all patients with Crohn disease. Isolated anal Crohn disease is uncommon, affecting only 3 to 4 percent of patients. Detection of anal Crohn disease, therefore, should prompt evaluation of the remainder of the gastrointestinal tract. The most common perianal lesions in Crohn disease are skin tags. Fissures also are common and tend to occur in unusual locations. Perianal abscess and fistulas are common and can be particularly challenging. Fistulas tend to be complex and often have multiple tracts. Treatment of anal and perianal Crohn disease focuses on alleviation of symptoms. In general, skin tags and hemorrhoids should not be excised unless they are extremely symptomatic because of the risk of creating chronic, nonhealing wounds. Fissures may respond to local or systemic therapy; sphincterotomy is relatively contraindicated because of the risk of creating a chronic, nonhealing wound, and because of the increased risk of incontinence in a patient with diarrhea from underlying colitis or small bowel disease. Examination under anesthesia often is necessary to exclude an underlying abscess or fistula and to assess the rectal mucosa in patients with severe anal pain.

Recurrent abscess(es) or complex anal fistulas should raise the possibility of Crohn disease. Treatment focuses on control of sepsis, delineation of complex anatomy, treatment of underlying mucosal disease, and sphincter preservation. Abscesses often can be drained locally, and mushroom catheters are useful for maintaining drainage. Endoanal ultrasound and pelvic MRI are useful for mapping complex fistulous tracts. Liberal use of setons can control many fistulas and avoid division of the sphincter. Many patients with anal Crohn disease function well with multiple setons left in place for years. Endoanal advancement flaps may be considered for definitive therapy if the rectal mucosa is uninvolved. In 10–15 percent of cases, intractable perianal sepsis requires proctectomy.

Medical treatment of underlying proctitis with salicylate and/or corticosteroid enemas may be helpful; however, control of sepsis is the primary goal of therapy. Metronidazole also has been used with some success in this setting. Infliximab has shown some efficacy in healing chronic fistulas secondary to Crohn disease. However, it is of paramount importance to drain any and all abscesses before initiating immunosuppressive therapy such as corticosteroids or infliximab.

Indeterminate Colitis

Approximately 15 percent of patients with inflammatory bowel disease manifest clinical and pathologic characteristics of both ulcerative colitis and Crohn disease. The indications for surgery are the same as those for ulcerative colitis. In the setting of indeterminate colitis in a patient who prefers a sphincter-sparing operation, a total abdominal colectomy with end ileostomy may be the best initial procedure. Pathologic examination of the entire colon may then allow a more accurate diagnosis. Elective proctectomy with or without reconstruction can be undertaken once the final pathologic diagnosis is known.

DIVERTICULAR DISEASE

Diverticulosis

Diverticulosis refers to the presence of diverticula without inflammation. It is estimated that half of the population older than age 50 years has colonic diverticula. The sigmoid colon is the most common site of diverticulosis. The majority of colonic diverticula are false diverticula in which the mucosa and muscularis mucosa have herniated through the colonic wall. These diverticula occur between the teniae coli, at points where the main blood vessels penetrate the colonic wall (presumably creating an area of relative weakness in the colonic muscle). They are thought to be pulsion diverticula resulting from high intraluminal pressure. Although diverticulosis is common, most cases are asymptomatic and complications occur in the minority of people with this condition.

Inflammatory Complications (Diverticulitis)

Diverticulitis refers to inflammation and infection associated with a diverticulum and is estimated to occur in 10–25 percent of people with diverticulosis. Infection results from a perforation (macroscopic or microscopic) of a diverticulum, which leads to contamination, inflammation, and infection.

Uncomplicated diverticulitis is characterized by left lower quadrant pain and tenderness. CT findings include pericolic soft-tissue stranding, colonic wall thickening, and/or phlegmon. Some patients with uncomplicated diverticulitis will respond to outpatient therapy with broad-spectrum oral antibiotics and a low-residue diet. Patients with more severe pain, tenderness, fever, and leukocytosis should be treated in the hospital with parenteral antibiotics and bowel rest. Most patients improve within 48–72 h. Failure to improve may suggest abscess formation. CT can be extremely useful in this setting and many pericolic abscesses can be drained percutaneously. Deterioration in clinical condition and/or the development of peritonitis are indications for laparotomy.

Most patients with uncomplicated diverticulitis will recover without surgery and 50–70 percent will have no further episodes. However, the risk of complications increases with recurrent disease. For this reason, elective sigmoid

colectomy often is recommended after the second episode of diverticulitis. Resection may be indicated after the first episode in young patients and in immunosuppressed patients, and often is recommended after the first episode of complicated diverticulitis. In the elective setting, a sigmoid colectomy with a primary anastomosis is the procedure of choice. The resection should always be extended to the rectum distally because the risk of recurrence is high if a segment of sigmoid colon is retained. The proximal extent of the resection should include all thickened or inflamed bowel; however, resection of all diverticula is unnecessary.

Complicated diverticulitis includes diverticulitis with abscess, obstruction, diffuse peritonitis (free perforation), or fistulas between the colon and adjacent structures. The Hinchey staging system often is used to describe the severity of complicated diverticulitis:

Stage I – colonic inflammation with a pericolic abscess

Stage II – colonic inflammation with a retroperitoneal or pelvic abscess

Stage III – purulent peritonitis

Stage IV – fecal peritonitis

Treatment depends on the patient's overall clinical condition and the degree of peritoneal contamination and infection. Small abscesses (< 2 cm diameter) may be treated with parenteral antibiotics. Larger abscesses are best treated with CT-guided percutaneous drainage. The majority of these patients will ultimately require resection, but percutaneous drainage may allow a one-stage, elective procedure. Urgent or emergent laparotomy may be required if an abscess is inaccessible to percutaneous drainage, if the patient's condition deteriorates or fails to improve, or if the patient presents with free intraabdominal air or peritonitis. In almost all cases, an attempt should be made to resect the affected segment of bowel. Patients with small, localized pericolic or pelvic abscesses (Hinchey stages I and II) may be candidates for a sigmoid colectomy with a primary anastomosis (a one-stage operation). In patients with larger abscesses, peritoneal soiling, or peritonitis, sigmoid colectomy with end colostomy and Hartmann pouch is the most commonly used procedure. Success also has been reported after sigmoid colectomy, primary anastomosis, \pm on-table lavage, and proximal diversion (loop ileostomy). The presence of inflammation and phlegmon may increase the risk of ureteral damage during mobilization of the sigmoid colon, and preoperative placement of ureteral catheters can be invaluable. In extremely unstable patients, or in the presence of such severe inflammation that resection would harm adjacent organs, proximal diversion and local drainage have been employed. However, this approach is generally avoided because of high morbidity and mortality rates, along with the requirement for multiple operations.

Obstructive symptoms occur in approximately 67 percent of patients with acute diverticulitis, and complete obstruction occurs in 10 percent. Patients with incomplete obstruction often respond to fluid resuscitation, nasogastric suction, and gentle, low-volume water or Gastrografin enemas. Relief of obstruction allows full bowel preparation and elective resection. A high-volume oral bowel preparation is contraindicated in the presence of obstructive symptoms. Obstruction that does not rapidly respond to medical management mandates laparotomy and sigmoid colectomy.

Approximately 5 percent of patients with complicated diverticulitis develop fistulas between the colon and an adjacent organ. Colovesical fistulas are most common, followed by colovaginal and coloenteric fistulas. Two key points in the evaluation of fistulas are to define the anatomy of the fistula and

exclude other diagnoses. Contrast enema and/or small bowel studies are useful in defining the course of the fistula. CT scan can identify associated abscesses or masses. The differential diagnosis includes malignancy, Crohn disease, and radiation-induced fistulas. Once the anatomy of the fistula has been defined and other diagnoses excluded, operative management should include resection of the affected segment of the colon (usually with a primary anastomosis) and simple repair of the secondarily involved organ. Suspicion of carcinoma may mandate a wider, en bloc resection.

Because colon carcinoma may have an identical clinical presentation to diverticulitis, all patients must be evaluated for malignancy after resolution of the acute episode. Sigmoidoscopy or colonoscopy is recommended 4–6 weeks after recovery. Inability to exclude malignancy is an indication for resection.

Hemorrhage

Bleeding from a diverticulum results from erosion of the peridiverticular arteriole and may result in massive hemorrhage. Most significant lower gastrointestinal hemorrhage occurs in older adult patients in whom both diverticulosis and angiodysplasia are common. Consequently, the exact bleeding source may be difficult to identify. Fortunately, in 80 percent of patients, bleeding stops spontaneously. Clinical management should focus on resuscitation and localization of the bleeding site as described for lower gastrointestinal hemorrhage. Colonoscopy may occasionally identify a bleeding diverticulum that may then be treated with epinephrine injection or cautery. Angiography may be diagnostic and therapeutic in this setting. In the rare instance in which diverticular hemorrhage persists or recurs, laparotomy and segmental colectomy may be required.

ADENOCARCINOMA AND POLYPS

Epidemiology (Risk Factors)

Colorectal carcinoma is the most common malignancy of the gastrointestinal tract. Risk factors include the following:

1. Aging – Aging is the dominant risk factor for colorectal cancer, with incidence rising steadily after age 50. However, individuals of any age can develop colorectal cancer, so symptoms such as a significant change in bowel habits, rectal bleeding, melena, unexplained anemia, or weight loss require a thorough evaluation.
2. Hereditary Risk Factors – Approximately 80 percent of colorectal cancers occur sporadically, whereas 20 percent arise in patients with a known family history of colorectal cancer. Assays currently exist to detect the most common genetic abnormalities.
3. Environmental and Dietary Factors – A diet high in saturated or polyunsaturated fats increases risk of colorectal cancer, whereas a diet high in oleic acid (olive oil, coconut oil, fish oil) does not increase risk. In contrast, a diet high in vegetable fiber appears to be protective. A correlation between alcohol intake and incidence of colorectal carcinoma also has been suggested. Ingestion of calcium; selenium; vitamins A, C, and E; carotenoids; and plant phenols may decrease the risk of developing colorectal cancer. Obesity and sedentary lifestyle dramatically increase cancer-related mortality in a number of malignancies, including colorectal carcinoma.

4. Inflammatory Bowel Disease – Patients with long-standing colitis from inflammatory bowel disease are at increased risk for the development of colorectal cancer.
5. Other Risk Factors – Cigarette smoking is associated with an increased risk of colonic adenomas, especially after more than 35 years of use. Patients with ureterosigmoidostomy are at increased risk for both adenoma and carcinoma formation. Acromegaly, which is associated with increased levels of circulating human growth hormone and insulin-like growth factor-1, increases risk as well. Pelvic irradiation may increase the risk of developing rectal carcinoma.

Pathogenesis of Colorectal Cancer

Genetic Pathways

Two major pathways for tumor initiation and progression have been described: the loss of heterozygosity (LOH) pathway and the replication error (RER) pathway. The LOH pathway is characterized by chromosomal deletions and tumor aneuploidy. Eighty percent of colorectal carcinomas appear to arise from mutations in the LOH pathway. The remaining 20 percent of colorectal carcinomas are thought to arise from mutations in the RER pathway, which is characterized by errors in mismatch repair during DNA replication.

LOH Pathway

1. APC gene defects – Defects in the APC gene were first described in patients with Familial Adenomatous Polyposis (FAP). By investigating these families, characteristic mutations in the APC gene were identified. They are now known to be present in 80 percent of sporadic colorectal cancers as well. The APC gene is a tumor-suppressor gene. Mutations in both alleles are necessary to initiate polyp formation. In FAP, the site of mutation correlates with the clinical severity of the disease. APC inactivation alone does not result in a carcinoma. Instead, this mutation sets the stage for the accumulation of genetic damage that results in malignancy via mutations accumulated in the loss of heterozygosity (LOH) pathway.
2. K-ras: K-ras is classified as a proto-oncogene because mutation of only one allele will perturb the cell cycle. The K-ras gene product is a G-protein involved in intracellular signal transduction. When active, K-ras binds guanosine triphosphate (GTP); hydrolysis of GTP to guanosine diphosphate (GDP) then inactivates the G-protein. Mutation of K-ras results in an inability to hydrolyze GTP, thus leaving the G-protein permanently in the active form. It is thought that this then leads to uncontrolled cell division.
3. DCC – DCC is a tumor-suppressor gene and loss of both alleles is required for malignant degeneration. The role of the DCC gene product is poorly understood, but it might be involved in cellular differentiation. DCC mutations are present in more than 70 percent of colorectal carcinomas and may negatively impact prognosis.
4. p53 – The p53 protein, a tumor suppressor, appears to be crucial for initiating apoptosis in cells with irreparable genetic damage and has been characterized in a large number of malignancies. Mutations in p53 are present in 75 percent of colorectal cancers.

The Replication Error Repair (RER) Pathway

A number of genes have been identified that appear to be crucial for recognizing and repairing DNA replication errors. These mismatch repair genes include hMSH2, hMLH1, hPMS1, hPMS2, and hMSH6/GTBP. A mutation in one of these genes predisposes a cell to mutations and accumulation of these errors, then leads to genomic instability and ultimately to carcinogenesis.

The RER pathway is associated with microsatellite instability. Microsatellites are regions of the genome in which short base-pair segments are repeated several times. These areas are particularly prone to replication error. Consequently, a mutation in a mismatch repair gene produces variable lengths of these repetitive sequences, a finding that has been described as microsatellite instability (MSI).

Tumors with MSI are more likely to be right sided, possess diploid DNA, and are associated with a better prognosis than tumors that arise from the LOH pathway that are microsatellite stable (MSS).

Polyps

It is now well accepted that the majority of colorectal carcinomas evolve from adenomatous polyps; this sequence of events is the adenoma–carcinoma sequence. Colorectal polyps may be classified as neoplastic (tubular adenoma, villous adenoma, tubulovillous adenomas), hamartomatous (juvenile, Peutz-Jeghers, Cronkite-Canada), inflammatory (pseudopolyp, benign lymphoid polyp), or hyperplastic.

Neoplastic Polyps

Adenomatous polyps are common, occurring in up to 25 percent of the population older than 50 years of age in the United States. By definition, these lesions are dysplastic. The risk of malignant degeneration is related to both the size and type of polyp. Tubular adenomas are associated with malignancy in only 5 percent of cases, whereas villous adenomas may harbor cancer in up to 40 percent. Tubulovillous adenomas are at intermediate risk (22 percent). Invasive carcinomas are rare in polyps smaller than 1 cm; the incidence increases with size. The risk of carcinoma in a polyp larger than 2 cm is 35–50 percent. Although most neoplastic polyps do not evolve to cancer, most colorectal cancers originate as a polyp.

Polyps may be pedunculated or sessile. Most pedunculated polyps are amenable to colonoscopic snare excision. Removal of sessile polyps often is more challenging. Special colonoscopic techniques, including saline lift and piecemeal snare excision, facilitate successful removal of many sessile polyps. For rectal sessile polyps, transanal operative excision is preferred because it produces an intact, single pathology specimen that can be used to determine the need for further therapy. Interpretation of the precise depth of invasion of a cancer arising in a sessile polyp after piecemeal excision often is impossible. The site of sessile polypectomies should be marked by injection of methylene blue or India ink to guide follow-up colonoscopy sessions to ensure that the polyp has been completely removed, and to facilitate identification of the involved bowel segment should operative resection be necessary. Colectomy is reserved for cases in which colonoscopic removal is impossible, such as large, flat lesions or if a focus of invasive cancer is confirmed in the specimen. These patients may be ideal candidates for laparoscopic colectomy.

Complications of polypectomy include perforation and bleeding. A small perforation (microperforation) in a fully prepared, stable patient may be managed with bowel rest, broad-spectrum antibiotics, and close observation. Signs of sepsis, peritonitis, or deterioration in clinical condition are indications for laparotomy. Bleeding may occur immediately after polypectomy or may be delayed. The bleeding will usually stop spontaneously, but colonoscopy may be required to re-snare a bleeding stalk, cauterize the lesion, or inject epinephrine around the bleeding vessel. Occasionally angiography and infusion of vasopressin may be necessary. Rarely, colectomy is required.

Hamartomatous Polyps (Juvenile Polyps)

Hamartomatous polyps (juvenile polyps) are not usually premalignant. These lesions are the characteristic polyps of childhood but may occur at any age. Bleeding is a common symptom and intussusception and/or obstruction may occur. Because the gross appearance of these polyps is identical to adenomatous polyps, these lesions also should be treated by polypectomy.

Familial juvenile polyposis is an autosomal dominant disorder in which patients develop hundreds of polyps in the colon and rectum. Unlike solitary juvenile polyps, these lesions may degenerate into adenomas, and eventually carcinoma. Annual screening should begin between the ages of 10 and 12 years. Treatment is surgical and depends in part on the degree of rectal involvement.

Peutz-Jeghers syndrome is characterized by polyposis of the small intestine, and to a lesser extent, polyposis of the colon and rectum. Characteristic melanin spots often are noted on the buccal mucosa and lips of these patients. The polyps of Peutz-Jeghers syndrome are generally considered to be hamartomas and are not thought to be at significant risk for malignant degeneration. However, carcinoma may occasionally develop. Because the entire length of the gastrointestinal tract may be affected, surgery is reserved for symptoms such as obstruction or bleeding or for patients in whom polyps develop adenomatous features. Screening consists of a baseline colonoscopy and upper endoscopy at age 20 years, followed by annual flexible sigmoidoscopy thereafter.

Cronkite-Canada syndrome is a disorder in which patients develop gastrointestinal polyposis in association with alopecia, cutaneous pigmentation, and atrophy of the fingernails and toenails. Diarrhea is a prominent symptom, and vomiting, malabsorption, and protein-losing enteropathy may occur. Most patients die of this disease despite maximal medical therapy, and surgery is reserved for complications of polyposis such as obstruction.

Cowden syndrome is an autosomal dominant disorder with hamartomas of all three embryonal cell layers. Facial trichilemmomas, breast cancer, thyroid disease, and gastrointestinal polyps are typical of the syndrome. Patients should be screened for cancers. Treatment is otherwise based on symptoms.

Inflammatory Polyps (Pseudopolyps)

Inflammatory polyps occur most commonly in the context of inflammatory bowel disease, but also may occur after amebic colitis, ischemic colitis, and schistosomal colitis. These lesions are not premalignant, but they cannot be distinguished from adenomatous polyps based on gross appearance and therefore should be removed.

Hyperplastic Polyps

Hyperplastic polyps are extremely common in the colon. These polyps are usually small (< 5 mm) and show histologic characteristics of hyperplasia without any dysplasia. They are not considered premalignant, but cannot be distinguished from adenomatous polyps colonoscopically and are therefore often removed. In contrast, large hyperplastic polyps (> 2 cm) may have a slight risk of malignant degeneration. Moreover, large polyps may harbor foci of adenomatous tissue and dysplasia. Hyperplastic polyposis is a rare disorder in which multiple large hyperplastic polyps occur in young adults.

Inherited Colorectal Carcinoma

Familial Adenomatous Polyposis

This rare autosomal dominant condition accounts for only approximately 1 percent of all colorectal adenocarcinomas. The genetic abnormality in FAP is a mutation in the APC gene, located on chromosome 5q. Of patients with FAP, APC mutation testing is positive in 75 percent of cases. Although most patients with FAP will have a known family history of the disease, up to 25 percent present without other affected family members. Clinically, patients develop hundreds to thousands of adenomatous polyps shortly after puberty. The lifetime risk of colorectal cancer in FAP patients approaches 100 percent by age 50 years.

Flexible sigmoidoscopy of first-degree relatives of FAP patients beginning at age 10–15 years has been the traditional mainstay of screening. Today, following genetic counseling, APC gene testing may be used to screen family members, providing an APC mutation has been identified in a family member. If APC testing is positive in a relative of a patient with a known APC mutation, annual flexible sigmoidoscopy beginning at age 10–15 years is done until polyps are identified. If APC testing is negative, the relative can be screened starting at age 50 years per average-risk guidelines.

FAP patients also are at risk for the development of adenomas anywhere in the gastrointestinal tract, particularly in the duodenum. Periampullary carcinoma is a particular concern. Upper endoscopy is therefore recommended for surveillance every 1–3 years beginning at age 25–30 years.

Once the diagnosis of FAP has been made and polyps are developing, treatment is surgical. Four factors affect the choice of operation: age of the patient; presence and severity of symptoms; extent of rectal polyposis; and presence and location of cancer or desmoid tumors. Three operative procedures can be considered: total proctocolectomy with either an end (Brooke) ileostomy or continent (Kock) ileostomy; total abdominal colectomy with ileorectal anastomosis; and restorative proctocolectomy with ileal pouch–anal anastomosis with or without a temporary ileostomy. Most patients elect to have an ileal pouch–anal anastomosis in the absence of a distal rectal cancer, a mesenteric desmoid tumor that prevents the ileum from reaching the anus or poor sphincter function. Total abdominal colectomy with an ileorectal anastomosis is also an option in these patients, but requires vigilant surveillance of the retained rectum for development of rectal cancer. There is increasing data suggesting that the administration of COX-2 inhibitors (celecoxib, sulindac) may slow or prevent the development of polyps.

FAP may be associated with extraintestinal manifestations such as congenital hypertrophy of the retinal pigmented epithelium, desmoid tumors,

epidermoid cysts, mandibular osteomas (Gardner syndrome), and central nervous system tumors (Turcot syndrome).

Attenuated FAP

Patients with attenuated FAP present later in life with fewer polyps (usually 10 to 100) dominantly located in the right colon. Colorectal carcinoma develops in more than 50 percent of these patients, but occurs later (average age 50 years). Patients also are at risk for duodenal polyposis. APC mutation testing is positive in approximately 60 percent of patients. If the family mutation is unknown, screening colonoscopy is recommended beginning at age 13–15 years, then every 4 years to age 28 years, and then every 3 years. These patients often are candidates for a total abdominal colectomy with ileorectal anastomosis because the limited polyposis in the rectum can usually be treated by colonoscopic snare excision. Prophylaxis with COX-2 inhibitors also may be appropriate.

Hereditary Nonpolyposis Colon Cancer (Lynch Syndrome)

Hereditary nonpolyposis colon cancer (HNPCC or Lynch syndrome) is more common than FAP, but is still extremely rare (1–3 percent). The genetic defects associated with HNPCC arise from errors in mismatch repair genes. HNPCC is inherited in an autosomal dominant pattern and is characterized by the development of colorectal carcinoma at an early age (average age: 40–45 years). Approximately 70 percent of affected individuals will develop colorectal cancer. Cancers appear in the proximal colon more often than in sporadic colorectal cancer and have a better prognosis regardless of stage. The risk of synchronous or metachronous colorectal carcinoma is 40 percent. HNPCC also may be associated with extracolonic malignancies, including endometrial, ovarian, pancreas, stomach, small bowel, biliary, and urinary tract carcinomas. The diagnosis of HNPCC is made based on family history. The Amsterdam criteria for clinical diagnosis of HNPCC are three affected relatives with histologically verified adenocarcinoma of the large bowel (one must be a first-degree relative of one of the others) in two successive generations of a family with one patient diagnosed before age 50 years. The presence of other HNPCC-related carcinomas should raise the suspicion of this syndrome.

Screening colonoscopy is recommended annually for at-risk patients beginning at either age 20–25 years or 10 years younger than the youngest age at diagnosis in the family, whichever comes first. Because of the high risk of endometrial carcinoma, transvaginal ultrasound or endometrial aspiration biopsy also is recommended annually after age 25–35 years. Because there is a 40 percent risk of developing a second colon cancer, total colectomy with ileorectal anastomosis is recommended once adenomas or a colon carcinoma is diagnosed, or if prophylactic colectomy is decided on. Annual proctoscopy is necessary because the risk of developing rectal cancer remains high. Similarly, prophylactic hysterectomy and bilateral salpingo-oophorectomy should be considered in women who have completed childbearing.

Familial Colorectal Cancer

Nonsyndromic familial colorectal cancer accounts for 10–15 percent of patients with colorectal cancer. The lifetime risk of developing colorectal cancer increases with a family history of the disease. The lifetime risk of colorectal cancer in a patient with no family history of this disease (average-risk

population) is approximately 6 percent, but rises to 12 percent if one first-degree relative is affected and to 35 percent if two first-degree relatives are affected. Age of onset also impacts risk and a diagnosis before the age of 50 years is associated with a higher incidence in family members. Screening colonoscopy is recommended every 5 years beginning at age 40 years or beginning 10 years before the age of the earliest diagnosed patient in the pedigree.

Prevention: Screening and Surveillance

Because the majority of colorectal cancers are thought to arise from adenomatous polyps, preventive measures focus on identification and removal of these premalignant lesions. Additionally, many cancers are asymptomatic and screening may detect these tumors at an early and curable stage (Table 28-1). Screening guidelines are meant for asymptomatic patients. Any patient with a gastrointestinal complaint (bleeding, change in bowel habits, pain, etc) requires a complete evaluation, usually by colonoscopy.

1. **Fecal Occult Blood Testing (FOBT)** – FOBT is used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based on serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any gastrointestinal source will produce a positive result. Nonetheless, the direct evidence that FOBT screening is efficacious and decreases both the incidence and mortality of colorectal cancer is so strong that national guidelines recommend annual FOBT screening for asymptomatic, average-risk Americans older than 50 years of age as one of several accepted strategies. Newer immunohistochemical methods for detecting human globin may prove to be more sensitive and specific. A positive FOBT test should be followed by colonoscopy.
2. **Flexible Sigmoidoscopy** – Screening by flexible sigmoidoscopy every 5 years may lead to a 60–70 percent reduction in mortality from colorectal cancer, chiefly by identifying high-risk individuals with adenomas. Patients found to have a polyp, cancer, or other lesion on flexible sigmoidoscopy will require colonoscopy. The combination of FOBT plus sigmoidoscopy is more sensitive for detection of polyps and/or cancer than either test alone, therefore the combination of the two tests has been suggested as a reasonable screening strategy. American Cancer Society recommendations for average-risk Americans include the combination of FOBT annually and flexible sigmoidoscopy every 5 years.
3. **Colonoscopy** – Colonoscopy is currently the most accurate and most complete method for examining the large bowel. This procedure is highly sensitive for detecting even small polyps (<1 cm) and allows biopsy, polypectomy, control of hemorrhage, and dilation of strictures. However, colonoscopy does require mechanical bowel preparation and the discomfort associated with the procedure requires conscious sedation in most patients. Additionally, the risk of complications, although low, is greater than with other screening modalities.
4. **Air-Contrast Barium Enema (ACBE)** – ACBE also is highly sensitive for detecting polyps greater than 1 cm in diameter (90 percent sensitivity). Accuracy is greatest in the proximal colon but may be compromised in the sigmoid colon if there is significant diverticulosis. For this reason, barium

TABLE 28-1 Advantages and Disadvantages of Screening Modalities for Asymptomatic Individuals

	Advantages	Disadvantages
Fecal occult blood testing	Ease of use and noninvasive Low cost Good sensitivity with repeat testing	May not detect most polyps Low specificity Colonoscopy required for positive result Poor compliance with serial testing
Sigmoidoscopy	Examines colon most at risk Very sensitive for polyp detection in left colon Does not require full bowel preparation (enemas only)	Invasive Uncomfortable Slight risk of perforation or bleeding May miss proximal lesions Colonoscopy required if polyp identified
Colonoscopy	Examines entire colon Highly sensitive and specific Therapeutic	Most invasive Uncomfortable and requires sedation Requires bowel preparation Risk of perforation or bleeding Costly
Double-contrast barium enema	Examines entire colon Good sensitivity for polyps >1 cm	Requires bowel preparation Less sensitivity for polyps <1 cm May miss lesions in the sigmoid colon Colonoscopy required for positive result
CT Colonography (virtual colonoscopy)	Examines entire colon Noninvasive Sensitivity may be as good as colonoscopy	Requires bowel preparation Insensitive for small polyps Minimal experience and data Colonoscopy required for positive result Costly

CT = Computed tomography

enema is often combined with flexible sigmoidoscopy for screening purposes. The major disadvantages of barium enema are the need for mechanical bowel preparation and the requirement for colonoscopy if a lesion is discovered.

5. **CT Colonography (Virtual Colonoscopy)** – CT colonography makes use of helical CT technology and three-dimensional reconstruction to image the intraluminal colon. Patients require a mechanical bowel preparation. The colon is then insufflated with air, a spiral CT is performed, and both two-dimensional and three-dimensional images are generated. In the hands

of a qualified radiologist, sensitivity appears to be as good as colonoscopy for colorectal cancers and polyps greater than 1 cm in size. Colonoscopy is required if a lesion is identified.

Guidelines for Screening

Current American Cancer Society guidelines advocate screening for the average-risk population (asymptomatic, no family history of colorectal carcinoma, no personal history of polyps or colorectal carcinoma, no familial syndrome) beginning at age 50 years. Recommended procedures include yearly FOBT, flexible sigmoidoscopy every 5 years, FOBT and flexible sigmoidoscopy in combination, air-contrast barium enema every 5 years, or colonoscopy every 10 years. Patients with other risk factors should be screened earlier and more frequently (Table 28-2).

Routes of Spread and Natural History

Carcinoma of the colon and rectum arises in the mucosa. The tumor subsequently invades the bowel wall and eventually adjacent tissues and other viscera. Tumors may become bulky and circumferential, leading to colon obstruction. Local extension (especially in the rectum) may occasionally cause obstruction of other organs such as the ureter.

Regional lymph node involvement is the most common form of spread of colorectal carcinoma and usually precedes distant metastasis or the development of carcinomatosis. The likelihood of nodal metastasis increases with tumor size, poorly differentiated histology, lymphovascular invasion, and depth of invasion. The T stage (depth of invasion) is the single most significant predictor of lymph node spread. Carcinoma in situ (Tis) in which there is no penetration of the muscularis mucosa (basement membrane) also has been called high-grade dysplasia and should carry no risk of lymph node metastasis. Small lesions confined to the bowel wall (T1 and T2) are associated with lymph node metastasis in 5–20 percent of cases, whereas larger tumors that invade through the bowel wall or into adjacent organs (T3 and T4) are likely to have lymph node metastasis in more than 50 percent of cases. The number of lymph nodes with metastases correlates with the presence of distant disease and inversely with survival. Four or more involved lymph nodes predict a poor prognosis. Lymphatic spread usually follows the major venous outflow from the involved segment of the colon or rectum.

The most common site of distant metastasis from colorectal cancer is the liver. These metastases arise from hematogenous spread via the portal venous system. The risk of hepatic metastasis increases with tumor size and grade. However, even small tumors may produce distant metastasis. The lung is also a site of hematogenous spread for colorectal carcinoma. Pulmonary metastases rarely occur in isolation. Carcinomatosis (diffuse peritoneal metastases) occurs by peritoneal seeding and has a dismal prognosis.

Staging and Preoperative Evaluation

Clinical Presentation

Symptoms of colon and rectal cancers are nonspecific and generally develop when the cancer is locally advanced. The classic first symptoms are a change in bowel habits and rectal bleeding. Abdominal pain, bloating, and other signs of obstruction typically occur with larger tumors and suggest more advanced disease. Left-sided tumors are more likely to cause obstruction than are right-sided

TABLE 28-2 Screening Guidelines for Colorectal Cancer

Population	Initial age	Recommended screening test
Average risk	50 years	Annual FOBT <i>or</i> Flexible sigmoidoscopy every 5 years <i>or</i> Annual FOBT and flexible sigmoidoscopy every 5 years <i>or</i> Air contrast barium enema every 5 years <i>or</i> Colonoscopy every 10 years
Adenomatous polyps	50 years	Colonoscopy at first detection; then colonoscopy in 3 years If no further polyps, colonoscopy every 5 years If polyps, colonoscopy every 3 years Annual colonoscopy for > 5 adenomas
Colorectal cancer	At diagnosis	Pretreatment colonoscopy; then at 12 months after curative resection; then colonoscopy after 3 years; then colonoscopy every 5 years, if no new lesions
Ulcerative colitis Crohn colitis	At diagnosis; then after 8 years for pancolitis, after 15 years for left-sided colitis	Colonoscopy with multiple biopsies every 1–2 years
FAP	10–12 years	Annual flexible sigmoidoscopy Upper endoscopy every 1–3 years after polyps appear
Attenuated FAP	20 years	Annual flexible sigmoidoscopy Upper endoscopy every 1–3 years after polyps appear
HNPCC	20–25 years	Colonoscopy every 1–2 years Endometrial aspiration biopsy every 1–2 years
Familial colorectal cancer 1st degree relative	40 years or 10 years before the age of the youngest affected relative	Colonoscopy every 5 years Increase frequency if multiple family members are affected, especially before 50 years

FAP = familial adenomatous polyposis

FOBT = fecal occult blood test

HNPCC = hereditary nonpolyposis colorectal cancer

tumors. Rectal tumors may cause bleeding, tenesmus, and pain. Alternatively, patients may be asymptomatic and/or present with unexplained anemia or weight loss.

Staging

Colorectal cancer staging is based on tumor depth and the presence or absence of nodal or distant metastases. Older staging systems, such as the Dukes Classification and its Astler-Coller modification, have been largely replaced by

TABLE 28-3 TNM Staging of Colorectal Carcinoma

Tumor stage (T)		Definition
Tx		Cannot be assessed
T0		No evidence of cancer
Tis		Carcinoma in situ
T1		Tumor invades submucosa
T2		Tumor invades muscularis propria
T3		Tumor invades through muscularis propria into subserosa or into nonperitonealized pericolic or perirectal tissues
T4		Tumor directly invades other organs or tissues or perforates the visceral peritoneum of specimen
Nodal stage (N)		
NX		Regional lymph nodes cannot be assessed
N0		No lymph node metastasis
N1		Metastasis to one to three pericolic or perirectal lymph nodes
N2		Metastasis to four or more pericolic or perirectal lymph nodes
N3		Metastasis to any lymph node along a major named vascular trunk
Distant metastasis (M)		
MX		Presence of distant metastasis cannot be assessed
M0		No distant metastasis
M1		Distant metastasis present

the TNM staging system (Table 28-3). In colon cancer, differentiating stages I, II, and III depends on examination of the resected specimen. In rectal cancer, endorectal ultrasound may predict the stage (ultrasound stage, uTxNx) preoperatively, but the final determination depends on pathology examination of the resected tumor and adjacent lymph nodes (pathologic stage, pTxNx). Disease stage correlates with 5-year survival (Table 28-4). Although nodal involvement is the single most important prognostic factor in colorectal carcinoma, tumor characteristics, such as degree of differentiation, mucinous or signet-ring cell histology, vascular invasion, and DNA aneuploidy, also affect prognosis.

Preoperative Evaluation

Once a colon or rectal carcinoma has been diagnosed, a staging evaluation should be undertaken. The colon must be evaluated for synchronous tumors, usually by colonoscopy. Synchronous disease will be present in up to 5 percent

TABLE 28-4 TNM Staging of Colorectal Carcinoma and 5-Year Survival

Stage	TNM	5-Year Survival
I	T1–2, N0, M0	70–95%
II	T3–4, N0, M0	54–65%
III	Tany, N1–3, M0	39–60%
IV	Tany, Nany, M1	0–16%

of patients. For rectal cancers, digital rectal examination and rigid proctoscopy with biopsy should be done to assess tumor size, location, morphology, histology, and fixation. Endorectal ultrasound can be invaluable in staging rectal cancer and is used to classify the ultrasound T and N stage of rectal cancers. A chest radiograph and abdominal/pelvic CT scan should be obtained to evaluate for distant metastases. CT scan of the chest is only necessary if the chest radiograph is abnormal. Pelvic CT scan, and sometimes MRI, can be invaluable in large rectal tumors and in recurrent disease to determine the extent of local invasion. In patients with obstructive symptoms, a water-soluble contrast study (Gastrografin enema) may be useful for delineating the degree of obstruction. It is important to avoid mechanical bowel preparation (for either colonoscopy or surgery) in a patient who appears to be obstructed. PET scan may be useful in evaluating lesions seen on CT scan, and in patients in whom a risky or highly morbid operation is planned (pelvic exenteration, sacrectomy). Preoperative CEA often is obtained, and may be useful for postoperative follow up.

THERAPY FOR COLONIC CARCINOMA

Principles of Resection

The objective in treatment of carcinoma of the colon is to remove the primary tumor along with its lymphovascular supply. Because the lymphatics of the colon accompany the main arterial supply, the length of bowel resected depends on which vessels are supplying the segment involved with the cancer. Any adjacent organ or tissue, such as the omentum that has been invaded, should be resected en bloc with the tumor. If all of the tumor cannot be removed, a palliative procedure should be considered.

The presence of synchronous cancers or adenomas or a strong family history of colorectal neoplasms suggests that the entire colon is at risk for carcinoma (a field defect) and a subtotal or total colectomy should be considered. Metachronous tumors (a second primary colon cancer) identified during follow-up studies should be treated similarly. If unexpected metastatic disease is encountered at the time of a laparotomy, the primary tumor should be resected, if technically feasible and safe. In the rare instance in which the primary tumor is not resectable, a palliative procedure can be performed and usually involves a proximal stoma or bypass. Hemorrhage in an unresectable tumor can sometimes be controlled with angiographic embolization.

Stage-Specific Therapy

Stage 0 (Tis, N0, M0). Polyps containing carcinoma in situ (high-grade dysplasia) carry no risk of lymph node metastasis. However, the presence of high-grade dysplasia increases the risk of finding an invasive carcinoma within the polyp. For this reason, these polyps should be excised completely and pathologic margins should be free of dysplasia.

Stage I: The malignant polyp (T1, N0, M0). Treatment of a malignant polyp is based on the risk of local recurrence and the risk of lymph node metastasis. The risk of lymph node metastases depends primarily on the depth of invasion. Invasive carcinoma in the head of a pedunculated polyp with no stalk involvement carries a low risk of metastasis (< 1 percent) and may be completely resected endoscopically. However, lymphovascular invasion, poorly differentiated histology, or tumor within 1 mm of the resection margin greatly increases the risk of local recurrence and metastatic spread. Segmental colectomy

is then indicated. Invasive carcinoma arising in a sessile polyp extends into the submucosa and is usually best treated with segmental colectomy.

Stages I and II: Localized colon carcinoma (T1–3, N0, M0). The majority of patients with stages I and II colon cancer will be cured with surgical resection. However, up to 46 percent of patients with completely resected stage II disease will ultimately die from colon cancer. For this reason, adjuvant chemotherapy has been suggested for selected patients with stage II disease (young patients, tumors with “high-risk” histologic findings).

Stage III: Lymph Node Metastasis (T any, N1, M0). Patients with lymph node involvement are at significant risk for both local and distant recurrence, and adjuvant chemotherapy has been recommended routinely in these patients. 5-Fluorouracil-based regimens (with levamisole or leucovorin) reduce recurrences and improve survival in this patient population. Newer chemotherapeutic agents such as capecitabine, irinotecan, oxaliplatin, angiogenesis inhibitors, and immunotherapy also show promise.

Stage IV: Distant metastasis (T any, N any, M1). Survival is extremely limited in stage IV colon carcinoma. Of patients with systemic disease, approximately 15 percent will have metastases limited to the liver. Of these, 20 percent are potentially resectable for cure. Survival is improved in these patients (20–40 percent 5-year survival) when compared to patients who do not undergo resection. Hepatic resection of synchronous metastases from colorectal carcinoma may be performed as a combined procedure or in two stages. All patients require adjuvant chemotherapy.

The remainder of patients with stage IV disease cannot be cured surgically and therefore the focus of treatment should be palliation.

Therapy for Rectal Carcinoma

Principles of Resection

The biology of rectal adenocarcinoma is presumed to be identical to the biology of colonic adenocarcinoma, and the operative principles of complete resection of the primary tumor, its lymphatic bed, and any other involved organ apply to surgical resection of rectal carcinoma. However, the anatomy of the pelvis and proximity of other structures (ureters, bladder, prostate, vagina, iliac vessels, and sacrum) make resection more challenging and often require a different approach than for colonic adenocarcinoma. Moreover, it is more difficult to achieve negative radial margins in rectal cancers that extend through the bowel wall because of the anatomic limitations of the pelvis. Therefore, local recurrence is higher than with similar stage colon cancers. However, unlike the intraperitoneal colon, the relative paucity of small bowel and other radiation-sensitive structures in the pelvis makes it easier to treat rectal tumors with radiation. Therapeutic decisions, therefore, are based on the location and depth of the tumor and its relationship to other structures in the pelvis.

Local Therapy

The distal 10 cm of the rectum are accessible transanally. For this reason, several local approaches have been proposed for treating rectal neoplasms. Transanal excision (full thickness or mucosal) is an excellent approach for noncircumferential, benign, villous adenomas of the rectum. Although this technique can be used for selected T1, and possibly some T2, carcinomas,

local excision does not allow pathologic examination of the lymph nodes and might therefore understage patients. Local recurrence rates are high without the addition of adjuvant chemoradiation therapy. Transanal endoscopic microsurgery (TEM) makes use of a specially designed proctoscope, magnifying system, and instruments similar to those used in laparoscopy to allow local excision of lesions higher in the rectum (up to 15 cm). Local excision of any rectal neoplasm should be considered an excisional biopsy because final pathologic examination of the specimen may reveal a more deeply invasive carcinoma than suggested by preoperative staging. More radical therapy may be indicated.

Ablative techniques, such as electrocautery or endocavitary radiation, also have been used. The disadvantage of these techniques is that no pathologic specimen is retrieved to confirm the tumor stage. Fulguration is generally reserved for extremely high-risk patients with a limited life span who cannot tolerate more radical surgery.

Radical Resection

Radical resection is preferred to local therapy for most rectal carcinomas. Radical resection involves removal of the involved segment of the rectum along with its lymphovascular supply. A 2-cm, distal mural margin is sought for curative resections.

Total mesorectal excision (TME) is a technique that uses sharp dissection along anatomic planes to ensure complete resection of the rectal mesentery during low and extended low anterior resections. For upper rectal or rectosigmoid resections, a partial mesorectal excision of at least 5 cm distal to the tumor appears adequate. Total mesorectal excision both decreases local recurrence rates and improves long-term survival rates. Moreover, this technique is associated with less blood loss and less risk to the pelvic nerves and presacral plexus than is blunt dissection. The principles of total mesorectal excision should be applied to all radical resections for rectal cancer.

Extensive involvement of other pelvic organs (often in the presence of recurrent cancer) may require a pelvic exenteration. The rectal and perineal portions of this operation are similar to an abdominoperineal resection but en bloc resection of the ureters, bladder, and prostate or uterus and vagina also are performed. A permanent colostomy and an ileal conduit to drain the urinary tract may be necessary. The sacrum also may be resected if necessary (sacrectomy) up to the level of the S2–S3 junction.

Pretreatment staging of rectal carcinoma often relies on endorectal ultrasound to determine the T and N status of a rectal cancer. Ultrasound evaluation can guide choice of therapy in most patients.

Stage 0 (Tis, N0, M0). Villous adenomas harboring carcinoma in situ (high-grade dysplasia) are ideally treated with local excision. A 1-cm margin should be obtained. Rarely, radical resection will be necessary if transanal excision is not technically possible (large circumferential lesions).

Stage I: Localized rectal carcinoma (T1–2, N0, M0). Invasive carcinoma confined to the head of a pedunculated polyp carries a very low risk of metastasis (< 1 percent). Polypectomy with clear margins is appropriate therapy. Although local excision has been used for small, favorable sessile uT1N0 and uT2N0 rectal cancers, local recurrence rates may be as high as 20 and 40 percent, respectively. For this reason, radical resection is strongly recommended in all good-risk patients. Lesions with unfavorable histologic characteristics and those located in the distal third of the rectum, in particular, are prone to

recurrence. In high-risk patients and in those patients who refuse radical surgery because of the risk of need for a permanent colostomy, local excision may be adequate, but strong consideration should be given to adjuvant chemoradiation to improve local control.

Stage II: Localized rectal carcinoma (T3–4, N0, M0). Larger rectal tumors are more likely to recur locally. There are two schools of thought, each differing in their approach to control local recurrences. Advocates of total mesorectal resection suggest that optimization of operative technique will obviate the need for any adjuvant chemoradiation to control local recurrence after resection. The opposing school suggests that stages II and III rectal cancers will benefit from chemoradiation. Both preoperative chemoradiation (neoadjuvant therapy) and postoperative chemoradiation (adjuvant therapy) have been recommended. Recent evidence favors neoadjuvant therapy.

Stage III: Lymph node metastasis (T any, N1, M0). Because of the risk of either local or systemic recurrence, adjuvant or neoadjuvant chemoradiation is routinely recommended for patients with rectal cancer and nodal metastases. Both preoperative chemoradiation (neoadjuvant therapy) and postoperative chemoradiation (adjuvant therapy) have been shown to decrease local recurrence and prolong survival in locally advanced rectal cancer.

Stage IV: Distant metastasis (T any, N any, M1). Like stage IV colon carcinoma, survival is limited in patients with distant metastasis from rectal carcinoma. Isolated hepatic metastases are rare, but when present may be resected for cure in selected patients. Most patients will require palliative procedures. Local therapy using cautery, endocavitary radiation, or laser ablation may be adequate to control bleeding or prevent obstruction. Intraluminal stents may be useful in the uppermost rectum, but often cause pain and tenesmus lower in the rectum. Occasionally, a proximal diverting colostomy will be required to alleviate obstruction. A mucus fistula should be created if possible to vent the distal colon.

Follow-Up and Surveillance

Patients who have been treated for one colorectal cancer are at risk for the development of recurrent disease (either locally or systemically) or metachronous disease (a second primary tumor). In theory, metachronous cancers should be preventable by using surveillance colonoscopy to detect and remove polyps before they progress to invasive cancer. For most patients, a colonoscopy should be performed within 12 months after the diagnosis of the original cancer (or sooner if the colon was not examined in its entirety prior to the original resection). If that study is normal, colonoscopy should be repeated every 3–5 years thereafter.

The optimal method of following patients for recurrent cancer remains controversial. The goal of close follow-up observation is to detect resectable recurrence and to improve survival. Re-resection of local recurrence and resection of distant metastasis to liver, lung, or other sites is often technically challenging and highly morbid, with only a limited chance of achieving long-term survival. Thus, only selected patients who would tolerate such an approach should be followed intensively. Because most recurrences occur within 2 years of the original diagnosis, surveillance focuses on this time period. CEA often is followed every 2–3 months for 2 years. CT scans are not routinely employed, but may be useful if CEA is elevated. More intensive surveillance is appropriate

in high-risk patients such as those with possible HNPCC syndrome or T3 N+ cancers. Although intensive surveillance improves detection of resectable recurrences, it is important to note that a survival benefit has never been proven.

Treatment of Recurrent Colorectal Carcinoma

Between 20 and 40 percent of patients who have undergone curative intent surgery for colorectal carcinoma will eventually develop recurrent disease. Most recurrences occur within the first 2 years after the initial diagnosis, but preoperative chemoradiation therapy may delay recurrence. Although most of these patients will present with distant metastases, a small proportion will have isolated local recurrence and may be considered for salvage surgery. Recurrence after colon cancer resection usually occurs at the local site within the abdomen or in the liver or lungs. Resection of other involved organs may be necessary. Recurrence of rectal cancer can be considerably more difficult to manage because of the proximity of other pelvic structures. If the patient has not received chemotherapy and radiation, then adjuvant therapy should be administered prior to salvage surgery. Radical resection may require extensive resection of pelvic organs (pelvic exenteration with or without sacrectomy). Pelvic MRI is useful for identifying tumor extension that would prevent successful resection (extension of tumor into the pelvic sidewall, involvement of the iliac vessels or bilateral sacral nerves, and sacral invasion above the S2–S3 junction). Patients also should undergo a thorough preoperative evaluation to identify distant metastases (CT of chest, abdomen, and pelvis, and PET scan) before undergoing such an extensive procedure.

OTHER NEOPLASMS

Rare Colorectal Tumors

Carcinoid Tumors

Carcinoid tumors occur most commonly in the gastrointestinal tract and up to 25 percent of these tumors are found in the rectum. Most small rectal carcinoids are benign, and overall survival is greater than 80 percent. However, the risk of malignancy increases with size, and more than 60 percent of tumors greater than 2 cm in diameter are associated with distant metastases. Rectal carcinoids appear to be less likely to secrete vasoactive substances than carcinoids in other locations, and carcinoid syndrome is uncommon in the absence of hepatic metastases. Small carcinoids can be locally resected, either transanally or using transanal endoscopic microsurgery. Larger tumors or tumors with obvious invasion into the muscularis require more radical surgery. Carcinoid tumors in the proximal colon are less common and are more likely to be malignant. Size also correlates with risk of malignancy, and tumors less than 2 cm in diameter rarely metastasize. However, the majority of carcinoid tumors in the proximal colon present as bulky lesions and up to two-thirds will have metastatic spread at the time of diagnosis. These tumors should usually be treated with radical resection. Because carcinoid tumors are typically slow growing, patients with distant metastases may expect reasonably long survival. Symptoms of carcinoid syndrome often can be alleviated with somatostatin analogues (octreotide) and/or interferon- α . Tumor debulking can offer effective palliation in selected patients.

Carcinoid Carcinomas

Composite carcinoid carcinomas (adenocarcinoids) have histologic features of both carcinoid tumors and adenocarcinomas. The natural history of these tumors more closely parallels that of adenocarcinomas.

Lipomas

Lipomas occur most commonly in the submucosa of the colon and rectum. They are benign lesions, but rarely may cause bleeding, obstruction, or intussusception, especially when greater than 2 cm in diameter. Small asymptomatic lesions do not require resection. Larger lipomas should be resected by colonoscopic techniques or by a colotomy and enucleation or limited colectomy.

Lymphoma

Lymphoma involving the colon and rectum is rare, but accounts for about 10 percent of all gastrointestinal lymphomas. The cecum most often is involved. Symptoms include bleeding and obstruction, and these tumors may be clinically indistinguishable from adenocarcinomas. Bowel resection is the treatment of choice. Adjuvant therapy may be given based on the stage of disease.

Leiomyoma and Leiomyosarcoma

Leiomyomas are benign tumors of the smooth muscle of the bowel wall and occur most commonly in the upper gastrointestinal tract. Most patients are asymptomatic, but large lesions can cause bleeding or obstruction. Because it is difficult to differentiate a benign leiomyoma from a malignant leiomyosarcoma, these lesions should be resected. Recurrence is common after local resection, but most small leiomyomas can be adequately treated with limited resection. Lesions larger than 5 cm should be treated with radical resection because the risk of malignancy is high.

Leiomyosarcoma is rare in the gastrointestinal tract. When this malignancy occurs in the large intestine, the rectum is the most common site. Symptoms include bleeding and obstruction. A radical resection is indicated for these tumors.

Retrorectal Tumors

Tumors occurring in the retrorectal space are rare. The retrorectal space contains multiple embryologic remnants derived from a variety of tissues (neuroectoderm, notochord, and hindgut). Tumors that develop in this space often are heterogeneous.

Congenital lesions are most common (67 percent). The remainder are classified as neurogenic, osseous, inflammatory, or miscellaneous lesions. Malignancy is more common in the pediatric population than in adults, and solid lesions are more likely to be malignant than are cystic lesions. Inflammatory lesions may be solid or cystic (abscess) and usually represent extensions of infection either in the perirectal space or in the abdomen.

Patients may present with pain (lower back, pelvic, or lower extremity), gastrointestinal symptoms, or urinary tract symptoms. Most lesions are palpable on digital rectal examination. Although plain radiograph and CT scans often are used to evaluate these lesions, pelvic MRI is the most sensitive and specific imaging study. Myelogram occasionally is necessary if there is central nervous system involvement. Biopsy is not indicated, especially if the lesion

appears to be resectable, because of the risk of infection and/or tumor seeding. Treatment almost always is surgical resection. The approach depends in part on the nature of the lesion and its location. High lesions may be approached via a transabdominal route, whereas low lesions may be resected transsacally. Intermediate lesions may require a combined abdominal and sacral operation.

Anal Canal and Perianal Tumors

Cancers of the anal canal are uncommon and account for approximately 2 percent of all colorectal malignancies. Neoplasms of the anal canal can be divided into those affecting the anal margin (distal to the dentate line) and those affecting the anal canal (proximal to the dentate line). In many cases, therapy depends on whether the tumor is located in the anal canal or at the anal margin.

Anal Intraepithelial Neoplasia (Bowen Disease)

Bowen disease refers to squamous cell carcinoma in situ of the anus. Pathologically, carcinomas in situ and high-grade squamous intraepithelial dysplasia appear identical, and the term anal intraepithelial neoplasia (AIN) recently has been used to describe these lesions. AIN is a precursor to an invasive squamous cell carcinoma (epidermoid carcinoma) and is associated with infection with the human papilloma virus, especially HPV types 16 and 18. Treatment of AIN is aimed at either resection or ablation. Because of a high recurrence and/or reinfection rate, these patients require extremely close surveillance. High-risk, immunosuppressed patients should be followed with frequent anal Papanicolaou (Pap) smears every 3–6 months. An abnormal Pap smear should be followed by an examination under anesthesia and anal mapping using high-resolution anoscopy, biopsy, and ablation of dysplastic lesions.

Epidermoid Carcinoma

Epidermoid carcinoma of the anus includes squamous cell carcinoma, cloacogenic carcinoma, transitional carcinoma, and basaloid carcinoma. Epidermoid carcinoma is a slow-growing tumor, and usually presents as an anal or perianal mass. Epidermoid carcinoma of the anal margin may be treated in a similar fashion as squamous cell carcinoma of the skin in other locations (wide local excision) because adequate surgical margins can usually be achieved without resecting the anal sphincter. Epidermoid carcinoma occurring in the anal canal or invading the sphincter cannot be excised locally, and first-line therapy relies on chemotherapy and radiation (the Nigro protocol). More than 80 percent of these tumors can be cured by using this regimen. Recurrence usually requires radical resection (abdominoperineal resection).

Verrucous Carcinoma (Buschke-Lowenstein Tumor, Giant Condyloma Acuminata)

Verrucous carcinoma is a locally aggressive form of condyloma acuminata. Although these lesions do not metastasize, they can cause extensive local tissue destruction and may be grossly indistinguishable from epidermoid carcinoma. Wide local excision is the treatment of choice when possible.

Basal Cell Carcinoma

Basal cell carcinoma of the anus is rare and resembles basal cell carcinoma elsewhere on the skin. This is a slow-growing tumor that rarely metastasizes.

Wide local excision is the treatment of choice, but recurrence occurs in up to 30 percent of patients.

Adenocarcinoma

Adenocarcinoma of the anus is extremely rare, and usually represents downward spread of a low rectal adenocarcinoma. Adenocarcinoma may occasionally arise from the anal glands or may develop in a chronic fistula. Radical resection with or without adjuvant chemoradiation is usually required.

Extramammary perianal Paget disease is adenocarcinoma in situ arising from the apocrine glands of the perianal area. These tumors are often associated with a synchronous gastrointestinal adenocarcinoma, so a complete evaluation of the intestinal tract should be performed. Wide local excision is usually adequate treatment for perianal Paget disease.

Melanoma

Anorectal melanoma is extremely rare. Overall 5-year survival is less than 10 percent, and many patients present with systemic metastasis and/or deeply invasive tumors at the time of diagnosis. A few patients with anorectal melanoma, however, present with isolated local or locoregional disease that is potentially resectable for cure. In these patients, wide local excision with a 1–2 cm margin is recommended if technically feasible. Radical resection (APR) may be necessary for circumferential lesions or tumors invading the anal sphincter.

OTHER BENIGN COLORECTAL CONDITIONS

Rectal Prolapse and Solitary Rectal Ulcer Syndrome

Rectal Prolapse

Rectal prolapse refers to a circumferential, full-thickness protrusion of the rectum through the anus and also has been called “first-degree” prolapse, “complete” prolapse, or procidentia. Internal prolapse occurs when the rectal wall intussuscepts but does not protrude (internal intussusception). Mucosal prolapse is a partial-thickness protrusion often associated with hemorrhoidal disease and usually is treated with banding or hemorrhoidectomy.

In adults, this condition is far more common among women, with a female-to-male ratio of 6:1. Prolapse becomes more prevalent with age in women and peaks in the seventh decade of life. In men, prevalence is unrelated to age. Symptoms include tenesmus, a sensation of tissue protruding from the anus that may or may not spontaneously reduce, and a sensation of incomplete evacuation. Mucus discharge and leakage may accompany the protrusion. Patients also present with a myriad of functional complaints, from incontinence and diarrhea to constipation and outlet obstruction.

A thorough preoperative evaluation, including colonic transit studies, anorectal manometry, tests of pudendal nerve terminal motor latency, electromyography, and cinedefecography, may be useful. The colon should be evaluated by colonoscopy or air-contrast barium enema to exclude neoplasms or diverticular disease. Cardiopulmonary condition should be thoroughly evaluated because comorbidities may influence the choice of surgical procedure.

Surgical therapy for rectal prolapse: The primary therapy for rectal prolapse is surgery.

1. Abdominal procedures
 - A. Reduction of the perineal hernia and closure of the cul-de-sac (Moschowitz repair)
 - B. Fixation of the rectum, either with a prosthetic sling (Ripstein and Wells rectopexy) or by suture rectopexy
 - C. Resection of redundant sigmoid colon
 - D. Resection combined with rectal fixation (resection rectopexy)
2. Perineal procedures
 - A. Tightening the anus with a variety of prosthetic materials
 - B. Reefing the rectal mucosa (Delorme procedure)
 - C. Resection of the prolapsed bowel from the perineum (perineal rectosigmoidectomy or Altemeier procedure)

Because rectal prolapse occurs most commonly in older adult women, the choice of operation depends in part on the patient's overall medical condition. Abdominal rectopexy (with or without sigmoid resection) offers the most durable repair, with recurrence occurring in fewer than 10 percent of patients. Perineal rectosigmoidectomy avoids an abdominal operation and may be preferable in high-risk patients, but is associated with a higher recurrence rate. Reefing the rectal mucosa is effective for patients with limited prolapse. Anal encirclement procedures generally have been abandoned.

Solitary Rectal Ulcer Syndrome

Solitary rectal ulcer syndrome and colitis cystica profunda commonly are associated with internal intussusception. Patients may complain of pain, bleeding, mucus discharge, or outlet obstruction. In solitary rectal ulcer syndrome, one or more ulcers are present in the distal rectum, usually on the anterior wall. In colitis cystica profunda, nodules or a mass may be found in a similar location. Evaluation should include anorectal manometry, defecography, and either colonoscopy or barium enema to exclude other diagnoses. Biopsy of an ulcer or mass is mandatory to exclude malignancy. Nonoperative therapy (high-fiber diet, defecation training to avoid straining, and laxatives or enemas) is effective in the majority of patients. Surgery (either abdominal or perineal repair of prolapse as described above) is reserved for highly symptomatic patients who have failed all medical interventions.

Volvulus

Volvulus occurs when an air-filled segment of the colon twists about its mesentery. A volvulus may reduce spontaneously, but more commonly produces bowel obstruction, which can progress to strangulation, gangrene, and perforation. Chronic constipation may produce a large, redundant colon (chronic megacolon) that predisposes to volvulus.

1. Sigmoid Volvulus (80 percent) – Sigmoid volvulus produces a characteristic bent inner tube or coffee bean appearance on abdominal radiographs, with the convexity of the loop lying in the right upper quadrant (opposite the site of obstruction). Gastrografin enema shows a narrowing at the site of the volvulus and a pathognomonic bird's beak. Unless there are obvious signs of gangrene or peritonitis, the initial management of sigmoid volvulus is resuscitation followed by endoscopic detorsion. A rectal tube may be inserted to maintain decompression. Although these techniques are successful in reducing sigmoid volvulus in the majority of patients, the risk of recurrence

is high (40 percent). For this reason, an elective sigmoid colectomy should be performed after the patient has been stabilized and undergone an adequate bowel preparation. Clinical evidence of gangrene or perforation mandates immediate surgical exploration without an attempt at endoscopic decompression.

2. **Cecal Volvulus (<20 percent)** – Cecal volvulus results from nonfixation of the right colon. Rotation occurs around the ileocolic blood vessels and vascular impairment occurs early. Abdominal radiographs show a characteristic kidney-shaped, air-filled structure in the left upper quadrant (opposite the site of obstruction), and a Gastrografin enema confirms obstruction at the level of the volvulus.

Unlike sigmoid volvulus, cecal volvulus can almost never be detorsed endoscopically. Moreover, because vascular compromise occurs early in the course of cecal volvulus, surgical exploration is necessary when the diagnosis is made. Right hemicolectomy with a primary ileocolic anastomosis can usually be performed safely and prevents recurrence. Simple detorsion or detorsion and cecopexy are associated with a high rate of recurrence.

3. **Transverse Colon Volvulus (rare)** – Nonfixation of the colon and chronic constipation with megacolon may predispose to transverse colon volvulus. The radiographic appearance resembles sigmoid volvulus, but Gastrografin enema will reveal a more proximal obstruction. Although colonoscopic detorsion is occasionally successful in this setting, most patients require emergent exploration and resection.

Megacolon

Megacolon describes a chronically dilated, elongated, hypertrophied large bowel. Megacolon may be congenital or acquired and usually is related to chronic mechanical or functional obstruction. In general, the degree of megacolon is related to the duration of obstruction. Evaluation must always include examination of the colon and rectum (either endoscopically or radiographically) to exclude a surgically correctable mechanical obstruction.

Congenital megacolon caused by Hirschsprung disease results from the failure of migration of neural crest cells to the distal large intestine. Surgical resection of the aganglionic segment is curative. Although Hirschsprung disease is primarily a disease of infants and children, it occasionally presents later in adulthood, especially if an extremely short segment of the bowel is affected (ultrashort-segment Hirschsprung disease).

Acquired megacolon may result from infection or chronic constipation. Infection with the protozoan *Trypanosoma cruzi* (Chagas disease) destroys ganglion cells and produces both megacolon and megaesophagus. Chronic constipation from slow transit or secondary to medications (especially anticholinergic medications) or neurologic disorders (paraplegia, poliomyelitis, amyotrophic lateral sclerosis, multiple sclerosis) may produce progressive colonic dilatation. Diverting ileostomy or subtotal colectomy with an ileorectal anastomosis is occasionally necessary in these patients.

Colonic Pseudo-Obstruction (Ogilvie Syndrome)

Colonic pseudo-obstruction (Ogilvie syndrome) is a functional disorder in which the colon becomes massively dilated in the absence of mechanical obstruction. Pseudo-obstruction most commonly occurs in hospitalized patients and is associated with the use of narcotics, bedrest, and comorbid disease.

Pseudo-obstruction is thought to result from autonomic dysfunction and severe adynamic ileus. The diagnosis is made based on the presence of massive dilatation of the colon (usually predominantly the right and transverse colon) in the absence of a mechanical obstruction. Initial treatment consists of cessation of narcotics, anticholinergics, or other medications that may contribute to ileus. Strict bowel rest and intravenous hydration are crucial. Most patients will respond to these measures. In patients who fail to improve, colonoscopic decompression often is effective. Recurrence occurs in up to 40 percent of patients. Intravenous neostigmine (an acetylcholinesterase inhibitor) also is extremely effective in decompressing the dilated colon and is associated with a low rate of recurrence (20 percent). However, neostigmine may produce transient but profound bradycardia and may be inappropriate in patients with cardiopulmonary disease. Because the colonic dilatation is typically greatest in the proximal colon, placement of a rectal tube is rarely effective. It is crucial to exclude mechanical obstruction (usually with a Gastrografin or barium enema) prior to medical or endoscopic treatment.

Ischemic Colitis

Intestinal ischemia occurs most commonly in the colon. Unlike small-bowel ischemia, colonic ischemia is rarely associated with major arterial or venous occlusion. Instead, most colonic ischemia appears to result from low flow and/or small-vessel occlusion. Risk factors include vascular disease, diabetes mellitus, vasculitis, and hypotension. Additionally, ligation of the inferior mesenteric artery during aortic surgery predisposes to colonic ischemia. Occasionally, thrombosis or embolism may cause ischemia. Although the splenic flexure is the most common site of ischemic colitis, any segment of the colon may be affected. The rectum is relatively spared because of its rich collateral circulation.

Signs and symptoms of ischemic colitis reflect the extent of bowel ischemia. In mild cases, patients may have diarrhea (usually bloody) without abdominal pain. With more severe ischemia, intense abdominal pain (often out of proportion to the clinical examination), tenderness, fever, and leukocytosis are present. Peritonitis and/or systemic toxicity are signs of full-thickness necrosis and perforation.

The diagnosis of ischemic colitis often is based on the clinical history and physical examination. Plain films may reveal thumb printing, which results from mucosal edema and submucosal hemorrhage. CT often shows nonspecific colonic wall thickening and pericolic fat stranding. Angiography usually is not helpful because major arterial occlusion is rare. Although sigmoidoscopy may reveal characteristic dark, hemorrhagic mucosa, the risk of precipitating perforation is high. For this reason, sigmoidoscopy is relatively contraindicated in any patient with significant abdominal tenderness. Contrast studies (Gastrografin or barium enema) are similarly contraindicated during the acute phase of ischemic colitis.

Treatment of ischemic colitis depends on clinical severity. Unlike ischemia of the small bowel, the majority of patients with ischemic colitis can be treated medically. Bowel rest and broad-spectrum antibiotics are the mainstay of therapy and 80 percent of patients will recover with this regimen. Hemodynamic parameters should be optimized, especially if hypotension and low flow appear to be the inciting cause. Long-term sequelae include stricture (10–15 percent) and chronic segmental ischemia (15–20 percent). Colonoscopy should be

performed after recovery to evaluate strictures and to rule out other diagnoses such as inflammatory bowel disease or malignancy. Failure to improve after 2–3 days of medical management, progression of symptoms, or deterioration in clinical condition is indication for surgery. In this setting, all necrotic bowel should be resected. Primary anastomosis should be avoided. Occasionally, repeated exploration (a second-look operation) may be necessary.

Infectious Colitis

Pseudomembranous Colitis (*Clostridium difficile* Colitis)

C. difficile colitis is extremely common and is the leading cause of nosocomially acquired diarrhea. The spectrum of disease ranges from watery diarrhea to fulminant, life-threatening colitis. Colitis is thought to result from overgrowth of *C. difficile* after depletion of the normal commensal flora of the gut with the use of antibiotics, and almost any antibiotic may cause this disease. Immunosuppression, medical comorbidities, prolonged hospitalization or nursing home residence, and bowel surgery increase the risk. *C. difficile* colitis usually is diagnosed based on the presence of toxins in the stool (toxin A, an enterotoxin, and toxin B, a cytotoxin). The diagnosis also may be made endoscopically by detection of characteristic ulcers, plaques, and pseudomembranes. Management should include immediate cessation of the offending antimicrobial agent. Patients with mild disease (diarrhea but no fever or abdominal pain) may be treated as outpatients with oral metronidazole or oral vancomycin (second-line agent). More severe diarrhea associated with dehydration and/or fever and abdominal pain is best treated with bowel rest, intravenous hydration, and oral metronidazole or vancomycin. Proctosigmoiditis may respond to vancomycin enemas. Recurrent colitis occurs in up to 20 percent of patients and may be treated by a longer course of oral metronidazole or vancomycin (up to 1 month). Reintroduction of normal flora by ingestion of probiotics has been suggested as a possible treatment for recurrent or refractory disease. Fulminant colitis, characterized by septicemia and/or evidence of perforation, requires emergent laparotomy. A total abdominal colectomy with end ileostomy may be lifesaving.

Other Infectious Colitides

1. Bacterial

- A. Common: enterotoxigenic *E. coli*, *Campylobacter jejuni*, *Yersinia enterocolitica*, *Salmonella typhi*, *Shigella*, *Neisseria gonorrhoeae*
- B. Less common – *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Actinomyces israelii*, *Treponema pallidum* (syphilis)

2. Parasitic – amebiasis, cryptosporidiosis, giardiasis

3. Fungal (rare) – *Candida* species, histoplasmosis

4. Viral – HIV, herpes simplex viruses, cytomegalovirus

Most symptoms of infection are nonspecific and consist of diarrhea (with or without bleeding), crampy abdominal pain, and malaise. A thorough history may offer clues to the etiology (other medical conditions, especially immunosuppression; recent travel or exposures; and ingestions). Diagnosis usually is made by identification of a pathogen in the stool, either by microscopy or culture. Serum immunoassays also may be useful (amebiasis, HIV, CMV). Occasionally, endoscopy with biopsy may be required. Treatment is tailored to the infection.

ANORECTAL DISEASES

Hemorrhoids

Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth-muscle fibers that are located in the anal canal. Three hemorrhoidal cushions are found in the left lateral, right anterior, and right posterior positions and are thought to function as part of the continence mechanism. Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic.

1. External hemorrhoids are located distal to the dentate line and are covered with anoderm. Thrombosis of an external hemorrhoid may cause significant pain. Treatment of external hemorrhoids and skin tags are only indicated for symptomatic relief.
2. Internal hemorrhoids are located proximal to the dentate line and covered by insensate anorectal mucosa. Internal hemorrhoids may prolapse or bleed, but rarely become painful unless they develop thrombosis and necrosis. Internal hemorrhoids are graded according to the extent of prolapse:
First-degree hemorrhoids—bulge into the anal canal
Second-degree hemorrhoids—prolapse through the anus but reduce spontaneously
Third-degree hemorrhoids—prolapse through the anal canal and require manual reduction
Fourth-degree hemorrhoids—prolapse but cannot be reduced and are at risk for strangulation
3. Combined internal and external hemorrhoids straddle the dentate line and have characteristics of both internal and external hemorrhoids.
4. Postpartum hemorrhoids result from straining during labor, which results in edema, thrombosis, and/or strangulation.
5. Rectal varices may result from portal hypertension. Despite the anastomoses between the portal venous system (middle and upper hemorrhoidal plexuses) and the systemic venous system (inferior rectal plexuses), hemorrhoidal disease is no more common in patients with portal hypertension than in the normal population. Rectal varices, however, may cause significant hemorrhage. In general, rectal varices are best treated by lowering portal venous pressure. Surgical hemorrhoidectomy should be avoided in these patients because of the risk of massive, difficult-to-control variceal bleeding.

Treatment

Medical Therapy (dietary fiber, stool softeners, increased fluid intake, and avoidance of straining) – appropriate for bleeding first- and second-degree hemorrhoids.

Rubber Band Ligation, sclerotherapy, infrared photocoagulation – appropriate for bleeding first-, second-, and selected third-degree hemorrhoids.

Excision of Thrombosed External Hemorrhoids. Acutely thrombosed external hemorrhoids generally cause intense pain and a palpable perianal mass during the first 24–72 h after thrombosis. The thrombosis can be effectively treated with an elliptical excision performed in the office under local anesthesia. Because the clot is usually loculated, simple incision and drainage is

rarely effective. After 72 h, the clot begins to resorb, and the pain resolves spontaneously. Sitz baths and analgesics often are helpful.

Operative hemorrhoidectomy. A number of surgical procedures have been described for elective resection of symptomatic hemorrhoids. All are based on decreasing blood flow to the hemorrhoidal plexuses and excising redundant anoderm and mucosa:

1. Closed Submucosal Hemorrhoidectomy
2. Open Hemorrhoidectomy
3. Whitehead Hemorrhoidectomy
4. Stapled Hemorrhoidectomy

Complications of hemorrhoidectomy

1. Postoperative pain – Pain can be significant following excisional hemorrhoidectomy, and requires analgesia with oral narcotics, nonsteroidal anti-inflammatory drugs, muscle relaxants, topical analgesics, and sitz baths.
2. Urinary retention – Urinary retention occurs in 10–50 percent of patients after hemorrhoidectomy. The risk of urinary retention can be minimized by limiting intraoperative and perioperative intravenous fluids, and by providing adequate analgesia.
3. Fecal impaction – Risk of impaction may be decreased by preoperative enemas or a limited mechanical bowel preparation, liberal use of laxatives postoperatively, and adequate pain control.
4. Bleeding – Massive hemorrhage can occur after hemorrhoidectomy. Bleeding may occur in the immediate postoperative period (often in the recovery room) as a result of inadequate ligation of the vascular pedicle, and mandates an urgent return to the operating room. Bleeding may also occur 7–10 days after hemorrhoidectomy when the necrotic mucosa overlying the vascular pedicle sloughs. Although some of these patients may be safely observed, others will require an exam under anesthesia to ligate the bleeding vessel or to oversee the wounds if no specific site of bleeding is identified.
5. Infection – Infection is uncommon after hemorrhoidectomy; however, necrotizing soft-tissue infection can occur with devastating consequences. Severe pain, fever, and urinary retention may be early signs of serious infection. If this is suspected, an emergent examination under anesthesia, drainage of abscess, and/or débridement of all necrotic tissue are required.
6. Long-term sequelae
 - A. incontinence (usually transient)
 - B. anal stenosis
 - C. ectropion (Whitehead deformity)

Anal Fissure

A fissure in ano is a tear in the anoderm distal to the dentate line. Most anal fissures occur in the posterior midline. Ten to 15 percent occur in the anterior midline. Less than 1 percent of fissures occur off midline.

Symptoms and Findings: Characteristic symptoms include tearing pain with defecation and hematochezia. On physical examination, the fissure can often be seen in the anoderm by gently separating the buttocks. Patients are often too tender to tolerate digital rectal examination, anoscopy, or proctoscopy. An acute fissure is a superficial tear of the distal anoderm and almost always heals with medical management. Chronic fissures develop ulceration and heaped-up

edges with the white fibers of the internal anal sphincter visible at the base of the ulcer. There is often an associated external skin tag and/or a hypertrophied anal papilla internally. These fissures are more challenging to treat and may require surgery. A lateral location of a chronic anal fissure may be evidence of an underlying disease such as Crohn disease, human immunodeficiency virus, syphilis, tuberculosis, or leukemia.

Treatment

Therapy focuses on breaking the cycle of pain, spasm, and ischemia:

1. Dietary changes – bulk agents, stool softeners, and warm sitz baths.
2. Topical agents – Lidocaine jelly or other analgesic creams, nitroglycerin ointment, oral and topical diltiazem, and topical nifedipine (effective in most acute fissures, but will heal only approximately 50–60 percent of chronic fissures).
3. Botulinum toxin – Botulinum toxin causes temporary muscle paralysis by preventing acetylcholine release from presynaptic nerve terminals, and has been proposed as an alternative to surgical sphincterotomy for chronic fissure. Although there is limited experience with this approach, results appear to be superior to other medical therapy, and complications such as incontinence are rare.
4. Surgical sphincterotomy – Surgical therapy has been recommended for chronic fissures that have failed medical therapy, and lateral internal sphincterotomy is the procedure of choice for most surgeons. Approximately 30 percent of the internal sphincter fibers are divided. Healing is achieved in more than 95 percent of patients by using this technique and most patients experience immediate pain relief. Recurrence is rare (less than 10 percent), but the risk of minor incontinence ranges from 5–15 percent.

Anorectal Sepsis and Cryptoglandular Abscess

Relevant Anatomy

Infection of an anal gland in the intersphincteric space results in the formation of an abscess that enlarges and spreads along one of several planes in the perianal and perirectal spaces. The anatomy of these spaces influences the location and spread of infection.

1. Perianal space – surrounds the anus and laterally becomes continuous with the fat of the buttocks
2. Intersphincteric space – separates the internal and external anal sphincters.
3. Ischiorectal space (ischiorectal fossa) – located lateral and posterior to the anus and bounded medially by the external sphincter, laterally by the ischium, superiorly by the levator ani, and inferiorly by the transverse septum. The two ischiorectal spaces connect posteriorly above the anococcygeal ligament but below the levator ani muscle, forming the deep postanal space.
4. Supralelevator spaces – above the levator ani on either side of the rectum (communicate posteriorly).

Diagnosis

Pain is the most common presenting complaint. A palpable mass often is detected by inspection of the perianal area or by digital rectal examination. Occasionally, patients will present with fever, urinary retention, or life-threatening sepsis. The diagnosis of a perianal or ischiorectal abscess can usually be made

with physical exam alone. However, complex or atypical presentations may require imaging studies (CT or MRI) to fully delineate the anatomy of the abscess.

Treatment

Anorectal abscesses should be treated by drainage as soon as the diagnosis is established. If the diagnosis is in question, an examination under anesthesia is often the most expeditious way both to confirm the diagnosis and to treat the problem. Antibiotics are only indicated if there is extensive cellulitis or if the patient is immunocompromised, has diabetes mellitus, or has valvular heart disease. Surgical treatment is based in part on the location of the abscess:

Perianal Abscess – painful swelling at the anal verge. Most can be drained under local anesthesia. Larger, more complicated abscesses may require drainage in the operating room.

Ischiorectal Abscesses – may become extremely large and may involve one or both sides, forming a “horseshoe” abscess. Simple ischiorectal abscesses are drained through an incision in the overlying skin. Horseshoe abscesses require drainage of the deep postanal space and often require counterincisions over one or both ischiorectal spaces.

Intersphincteric Abscess – occur in the intersphincteric space and are notoriously difficult to diagnose. The diagnosis is made based on a high index of suspicion and usually requires an examination under anesthesia. Once identified, an intersphincteric abscess can be drained through a limited, usually posterior, internal sphincterotomy.

Supralelevator Abscess – is uncommon and may result from extension of an intersphincteric or ischiorectal abscess upward, or extension of an intraperitoneal abscess downward. It is essential to identify the origin of a supralelevator abscess prior to treatment. If the abscess is secondary to an upward extension of an intersphincteric abscess, it should be drained through the rectum. If a supralelevator abscess arises from the upward extension of an ischiorectal abscess, it should be drained through the ischiorectal fossa. If the abscess is secondary to intraabdominal disease, the primary process requires treatment and the abscess is drained via the most direct route.

Perianal sepsis in the immunocompromised patient. Because of leukopenia, immunocompromised patients may develop serious perianal infection without any of the cardinal signs of inflammation. Although broad-spectrum antibiotics may cure some of these patients, an exam under anesthesia should not be delayed because of neutropenia. An increase in pain or fever, and/or clinical deterioration mandates an exam under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

Necrotizing soft-tissue infection of the perineum. Necrotizing soft-tissue infection of the perineum is a rare, but lethal, condition. Most of these infections are polymicrobial and synergistic. The source of sepsis is commonly an undrained or inadequately drained cryptoglandular abscess or a urogenital infection. Immunocompromised patients and diabetic patients are at increased risk. Surgical débridement of all nonviable tissue is required to treat all necrotizing soft-tissue infections. Multiple operations may be necessary to ensure that all necrotic tissue has been resected. Broad-spectrum antibiotics are frequently employed, but adequate surgical débridement remains the mainstay of therapy. Despite early recognition and adequate surgical therapy, the

mortality of necrotizing perineal soft-tissue infections remains approximately 50 percent.

Fistula in Ano

Drainage of an anorectal abscess results in cure for about 50 percent of patients. The remaining 50 percent develop a persistent fistula in ano. The fistula usually originates in the infected crypt (internal opening) and tracks to the external opening. The course of the fistula often can be predicted by the anatomy of the previous abscess.

Diagnosis

Patients present with persistent drainage from the internal and/or external openings. In general, fistulas with an external opening anteriorly connect to the internal opening by a short, radial tract. Fistulas with an external opening posteriorly track in a curvilinear fashion to the posterior midline (Goodsall rule). However, exceptions to this rule often occur. Fistulas are categorized based on their relationship to the anal sphincter complex and treatment options are based on these classifications. The goal of treatment of fistula in ano is eradication of sepsis without sacrificing continence. Because fistulous tracks encircle variable amounts of the sphincter complex, surgical treatment is dictated by the location of the internal and external openings and the course of the fistula.

1. Intersphincteric fistula – tracks through the distal internal sphincter to an external opening near the anal verge; often treated by fistulotomy (opening the fistulous tract), curettage, and healing by secondary intention.
2. Transsphincteric fistula – results from an ischiorectal abscess and extends through both the internal and external sphincters. “Horseshoe” fistulas usually have an internal opening in the posterior midline and extend anteriorly and laterally to one or both ischiorectal spaces by way of the deep postanal space. Fistulas that include less than 30 percent of the sphincter muscles often can be treated by sphincterotomy. High transsphincteric fistulas, which encircle a greater amount of muscle, are more safely treated by initial placement of a seton.
3. Suprasphincteric fistula – originates in the intersphincteric plane and tracks up and around the entire external sphincter and is usually treated with a seton.
4. Extrasphincteric fistula – originates in the rectal wall and tracks around both sphincters to exit laterally, usually in the ischiorectal fossa. Treatment depends on both the anatomy of the fistula and its etiology. In general, the portion of the fistula outside the sphincter should be opened and drained. A primary tract at the level of the dentate line also may be opened if present. Complex fistulas with multiple tracts may require numerous procedures to control sepsis and facilitate healing. Liberal use of drains and setons is helpful.
5. Complex, nonhealing fistula – Complex and/or nonhealing fistulas may result from Crohn disease, malignancy, radiation proctitis, or unusual infection. Proctoscopy should be performed in all cases of complex and/or nonhealing fistulas to assess the health of the rectal mucosa. Biopsies of the fistula tract should be taken to rule out malignancy.

A seton is a drain placed through a fistula to maintain drainage and/or induce fibrosis. Cutting setons consist of a suture or a rubber band that is placed

through the fistula and intermittently tightened. Tightening the seton results in fibrosis and gradual division of the sphincter, thus eliminating the fistula while maintaining continuity of the sphincter. A noncutting seton is a soft plastic drain (often a vessel loop) placed in the fistula to maintain drainage. The fistula tract may subsequently be laid open with less risk of incontinence because scarring prevents retraction of the sphincter. Alternatively, the seton may be left in place for chronic drainage. Higher fistulas may be treated by an endorectal advancement flap. Fibrin glue also has been used to treat persistent fistulas with variable results.

Rectovaginal Fistula

A rectovaginal fistula is a connection between the vagina and the rectum or anal canal proximal to the dentate line and is classified based on location.

1. Low – rectal opening close to the dentate line and vaginal opening in the fourchette; commonly caused by obstetric injuries or trauma from a foreign body.
2. Middle – vaginal opening between the fourchette and cervix; may result from more severe obstetric injury, but also occur after surgical resection of a mid-rectal neoplasm, radiation injury, or extension of an undrained abscess.
3. High – vaginal opening near the cervix; result from operative or radiation injury, complicated diverticulitis, or Crohn disease.

Diagnosis

Patients describe symptoms varying from the sensation of passing flatus from the vagina to the passage of solid stool from the vagina. Contamination may result in vaginitis. Large fistulas may be obvious on anoscopic and/or vaginal speculum examination, but smaller fistulas may be difficult to locate. Occasionally, a barium enema or vaginogram may identify these fistulas. Endorectal ultrasound also may be useful. With the patient in the prone position, installation of methylene blue into the rectum while a tampon is in the vagina may confirm the presence of a small fistula.

Treatment

The treatment of rectovaginal fistula depends on the size, location, etiology, and condition of surrounding tissues. Because up to 50 percent of fistulas caused by obstetric injury heal spontaneously, it is prudent to wait 3–6 months before embarking on surgical repair in these patients. If the fistula was caused by a cryptoglandular abscess, drainage of the abscess may allow spontaneous closure.

Low and mid-rectovaginal fistulas are usually best treated with an endorectal advancement flap. If a sphincter injury is present, an overlapping sphincteroplasty should be performed concurrently. High rectovaginal, colovaginal, and enterovaginal fistulas are usually best treated via a transabdominal approach. The diseased tissue, which caused the fistula (upper rectum, sigmoid colon, or small bowel), is resected and the hole in the vagina closed. Rectovaginal fistulas caused by Crohn disease, radiation injury, or malignancy almost never heal spontaneously. Because differentiating radiation damage from malignancy can be extremely difficult, all fistulas resulting from radiation should be biopsied to rule out cancer.

Perianal Dermatitis

Pruritus Ani

1. Anatomic causes – prolapsing hemorrhoids, ectropion, fissure, fistula, and neoplasms.
2. Infectious causes – fungus (*Candida* species, *Monilia*, and *Epidermophyton* organisms), parasites (*Enterobius vermicularis* [pinworms], *Pediculus pubis* [a louse], and *Sarcoptes scabiei* [scabies]), bacteria (*Corynebacterium minutissimum* [erythrasma] and *Treponema pallidum* [syphilis]), or viruses (human papilloma virus [*condyloma acuminata*]).
3. Noninfectious/dermatologic causes – seborrhea, psoriasis, contact dermatitis.
4. Systemic diseases – jaundice, diabetes.
5. Idiopathic causes – The majority of pruritus ani is idiopathic and probably related to local hygiene, neurogenic, or psychogenic causes.

Treatment focuses on removal of irritants, improving perianal hygiene, dietary adjustments, and avoiding scratching. Biopsy and/or culture may be required to rule out an infectious or dermatologic cause. Hydrocortisone ointment 0.5–1.0 percent can provide symptomatic relief but should not be used for prolonged periods of time because of dermal atrophy. Skin barriers such as Calmoseptine also can provide relief. Systemic antihistamines or tricyclic antidepressants also have been used with some success.

Nonpruritic Lesions

Leprosy, amebiasis, actinomycosis, and lymphogranuloma venereum produce characteristic perianal lesions. Neoplasms such as Bowen disease, Paget disease, and invasive carcinomas also may appear first in the perianal skin. Biopsy usually can distinguish these diagnoses.

Sexually Transmitted Diseases

1. Bacterial Infections
 - A. Proctitis – *N. gonorrhoeae*, *C. trachomatis*, *T. pallidum* (syphilis), *Haemophilus ducreyi* (chancroid), *Donovania* (*granuloma inguinale*).
 - B. Diarrhea – *Campylobacter*, *Shigella*, other.
2. Parasitic Infections – *Entamoeba histolytica*, *Giardia lamblia*
3. Viral Infections
 - A. Herpes Simplex Virus – may cause extremely painful proctitis.
 - B. Human Papilloma Virus – may cause condyloma acuminata (anogenital warts), anal intraepithelial neoplasia, squamous cell carcinoma. HPV serotypes 16 and 18 appear to predispose to malignancy and often cause flat dysplasia in skin unaffected by warts. HPV types 6 and 11 commonly cause warts, but do not appear to cause malignant degeneration. Treatment of anal condyloma includes topical application of bichloroacetic acid or podophyllin (small warts), Imiquimod (Aldara), and surgical excision/fulguration (larger or more extensive warts).

Pilonidal Disease

Pilonidal disease (cyst, infection) consists of a hair-containing sinus or abscess occurring in the intergluteal cleft. These ingrown hairs may then become infected and present acutely as an abscess in the sacrococcygeal region. An

acute abscess should be incised and drained as soon as the diagnosis is made. Once an acute episode has resolved, recurrence is common. Definitive surgical treatment may include:

1. Unroofing the tract, curetting the base, and marsupializing the wound
2. Small lateral incision and pit excision
3. Flap closure, Z-plasty, advancement flap, or rotational flap (extensive and/or recurrent pilonidal disease)

Hidradenitis Suppurativa

Hidradenitis suppurativa is an infection of the cutaneous apocrine sweat glands. The infection may mimic complex anal fistula disease, but stops at the anal verge because there are no apocrine glands in the anal canal. Treatment involves incision and drainage of acute abscesses and unroofing and débridement of all chronically inflamed fistulas.

TRAUMA

Penetrating Colorectal Injury

Management of colonic injury depends on the mechanism of injury, the delay between the injury and surgery, the overall condition and stability of the patient, the degree of peritoneal contamination, and the condition of the injured colon. A primary repair may be considered in hemodynamically stable patients with few additional injuries and minimal contamination if the colon appears otherwise healthy. Contraindications to primary repair include shock, injury to more than two other organs, mesenteric vascular damage, and extensive fecal contamination. A delay of greater than 6 h between the injury and the operation is a relative contraindication to primary repair. Injuries caused by high-velocity gunshot wounds or blast injuries are usually treated by fecal diversion after débridement of all nonviable tissue.

Primary repair of the rectum is more difficult than primary repair of the colon and most rectal injuries are associated with significant contamination. The majority of penetrating rectal injuries should be treated with proximal fecal diversion and copious irrigation of the rectum (distal rectal washout). If there is extensive fecal contamination, presacral drains may be useful. Small, clean rectal injuries may be closed primarily without fecal diversion in an otherwise stable patient.

Blunt Colorectal Injury

Blunt trauma can cause colon perforation and shear injury to the mesentery can devascularize the intestine. Management of these injuries should follow the same principles outlined for management of penetrating injuries. Blunt injury to the rectum may result from significant trauma, such as a pelvic crush injury, or may result from local trauma caused by an enema or foreign body. Crush injuries, especially with an associated pelvic fracture, often are associated with significant rectal damage and contamination. These patients require débridement of all nonviable tissue, proximal fecal diversion, and a distal rectal washout, with or without drain placement. Blunt trauma from an enema or foreign body may produce a mucosal hematoma, which requires no surgical treatment if the mucosa is intact. Small mucosal tears may be closed primarily if the bowel is relatively clean and there is little contamination.

Iatrogenic Injury

Intraoperative Injury

The key to managing these injuries is early recognition. The vast majority of iatrogenic colorectal injuries may be closed primarily if there is little contamination and if the patient is otherwise stable. Delayed recognition of colorectal injuries may result in significant peritonitis and life-threatening sepsis. In these cases, fecal diversion almost always is required and the patient may need repeated exploration for drainage of abscesses.

Injury from Barium Enema

Colorectal injury from a barium enema is an extremely rare complication associated with a high rate of morbidity and mortality. Perforation with spillage of barium, especially above the peritoneal reflection, may result in profound peritonitis, sepsis, and a systemic inflammatory response. If the perforation is recognized early, it may be closed primarily and the abdomen irrigated to remove stool and barium. However, if the patient has developed sepsis, fecal diversion (with or without bowel resection) is almost always required.

Colonoscopic Perforation

Colonoscopic perforation occurs in less than 1 percent of patients. Management of colonoscopic perforation depends on the size of the perforation, the duration of time since the injury, and the overall condition of the patient. A large perforation recognized during the procedure requires surgical exploration; most can be repaired primarily. If there is significant contamination, if there has been a delay in diagnosis with resulting peritonitis, or if the patient is hemodynamically unstable, proximal diversion with or without resection is the safest approach. Polypectomy using electrocautery may produce a full-thickness burn, resulting in postpolypectomy syndrome in which a patient develops abdominal pain, fever, and leukocytosis without evidence of diffuse peritonitis. Many of these patients will have a "microperforation" which will resolve with bowel rest, broad-spectrum antibiotics, and close observation. Evidence of peritonitis or any deterioration in clinical condition mandates exploration. Free retroperitoneal or intraperitoneal air may be discovered incidentally after colonoscopy. In a completely asymptomatic patient, this finding is thought to result from barotrauma and dissection of air through tissue planes without a free perforation. Many of these patients can be successfully treated with bowel rest and broad-spectrum antibiotics. Surgical exploration is indicated for any clinical deterioration.

Anal Sphincter Injury and Incontinence

The most common cause of anal sphincter injury is obstetric trauma during vaginal delivery. Sphincter damage also may result from hemorrhoidectomy, sphincterotomy, abscess drainage, or fistulotomy. Patients with incontinence and a suspected sphincter injury can be evaluated with anal manometry, electromyography (EMG), and endoanal ultrasound. Mild incontinence, even in the presence of a sphincter defect, may respond to dietary changes and/or biofeedback. More severe incontinence may require surgical repair.

Surgical Repairs

The most common method of repair of the anal sphincter is a wrap-around sphincteroplasty. In cases in which there has been significant loss of sphincter muscle, or in which prior repairs have failed, more complex techniques, such as gracilis muscle transposition or artificial anal sphincter may be indicated. Sacral nerve stimulation via an implanted pulse generator is a new technique used for neurogenic incontinence when the sphincter is intact.

Foreign Body

Depending on the level of entrapment, a foreign body may cause damage to the rectum, rectosigmoid, or descending colon. Generalized abdominal pain suggests intraperitoneal perforation. Evaluation of the patient includes inspection of the perineum and a careful abdominal examination to detect any evidence of perforation. Plain films of the abdomen are mandatory to detect free intraabdominal air. Foreign bodies lodged low in the rectum often may be removed under conscious sedation with or without a local anesthetic block. Objects impacted higher in the rectum may require regional or general anesthesia for removal. Only rarely will a laparotomy be required to remove the object. After removal of the foreign body, proctoscopy and/or flexible sigmoidoscopy should be performed to evaluate the rectum and sigmoid colon for injury.

THE IMMUNOCOMPROMISED PATIENT (HUMAN IMMUNODEFICIENCY VIRUS OR IMMUNOSUPPRESSION FOR TRANSPLANTATION)

1. Diarrhea
 - A. Bacteria – *C. difficile*, Salmonella, Shigella, Campylobacter, Chlamydia, and Mycobacterium species
 - B. Fungi – Histoplasmosis, Coccidiosis, Cryptococcus
 - C. Protozoa – Toxoplasmosis, Cryptosporidiosis, Isosporiasis
 - D. Viruses – CMV, HSV colitis
2. Malignancy
 - A. Kaposi sarcoma (most common malignancy in AIDS patients)
 - B. Gastrointestinal lymphoma (usually non-Hodgkin lymphoma)
 - C. Posttransplant lymphoproliferative disease
 - D. Anal squamous cell carcinoma (associated with HPV infection)
3. Perianal disease
 - A. Sexually transmitted diseases (more common in HIV disease)
 - B. Abscesses and fistulas (may be complex and/or difficult to recognize)
4. Diverticulitis (may be more common in some populations of transplant patients and may have a more virulent course)
5. Graft-versus-host disease (unique to transplant patients)

The Neutropenic Patient

Neutropenic enterocolitis (typhlitis) is a life-threatening problem with a mortality rate of greater than 50 percent. This syndrome is characterized by abdominal pain and distention, fever, diarrhea (often bloody), nausea, and vomiting in a patient with fewer than 1000 neutrophils from any cause (bone marrow transplantation, solid-organ transplantation, or chemotherapy). CT scan of the abdomen often shows a dilated cecum with pericolic stranding. However, a normal-appearing CT scan does not exclude the diagnosis. Some patients will

respond to bowel rest, broad-spectrum antibiotics, parenteral nutrition, and granulocyte infusion or colony-stimulating factors. Evidence of perforation, generalized peritonitis, or deterioration in clinical condition are indications for operation.

ANATOMY AND FUNCTION

The appendix first becomes visible in the eighth week of development as a protuberance off the cecum. During development the growth rate of the cecum exceeds that of the appendix, displacing the appendix medially toward the ileocecal valve. The relationship of the base of the appendix to the cecum remains constant, whereas the tip can be found in a retrocecal, pelvic, subcecal, preileal, or right pericolic position. The three taenia coli converge at the junction of the cecum with the appendix. The appendix can vary in length from less than 1 cm to greater than 30 cm; most appendices are 6–9 cm in length.

The appendix is an immunologic organ that participates in the secretion of immunoglobulins, particularly immunoglobulin A (IgA). Although the appendix is an integral component of the gut-associated lymphoid tissue (GALT) system, its function is not essential and appendectomy is not associated with any manifestation of immune compromise. Lymphoid tissue first appears in the appendix approximately 2 weeks after birth. The amount of lymphoid tissue increases throughout puberty, remains steady for the next decade, and then begins a steady decrease with age.

ACUTE APPENDICITIS

Historical Background

The greatest contributor to the treatment of appendicitis is Charles McBurney. In 1889, he published his landmark paper in the *New York Medical Journal* describing the indications for early laparotomy for the treatment of appendicitis. It is in this paper that he described McBurney's point as the point of "maximum tenderness, when one examines with the fingertips is, in adults, one-half to two inches inside the right anterior spinous process of the ilium on a line drawn to the umbilicus." McBurney subsequently published a paper describing the incision that bears his name in 1894. Semm is widely credited with performing the first successful laparoscopic appendectomy in 1982.

Incidence

The lifetime rate of appendectomy is 12 percent for men and 25 percent for women, with approximately 7 percent of all people undergoing appendectomy for acute appendicitis. Over a 10-year period from 1987 to 1997, the overall appendectomy rate decreased parallel to a decrease in incidental appendectomy. However, the rate of appendectomy for appendicitis has remained constant at 10 per 10,000 patients per year. Appendicitis is most frequently seen in patients in their second through fourth decades of life, with a mean age of 31.3 years and a median age of 22 years. There is a slight male to female predominance (M:F 1.2–1.3:1). Despite increased use of ultrasonography, computed tomography (CT) scanning, and laparoscopy between 1987 and 1997, the rate of misdiagnosis of appendicitis has remained constant (15.3 percent), as has the rate of appendiceal rupture. The percentage of misdiagnosis of appendicitis is significantly higher among women than men (22.2 vs. 9.3 percent). The

negative appendectomy rate for women of reproductive age is 23.2 percent, with the highest rates identified in women age 40–49 years. The highest negative appendectomy rate is reported for women older than 80 years of age.

Etiology and Pathogenesis

There is a predictable sequence of events leading to appendiceal rupture. Proximal obstruction of the appendiceal lumen produces a closed-loop obstruction, and continuing secretion by the appendiceal mucosa produces distention. Distention of the appendix stimulates nerve endings of visceral afferent stretch fibers, producing vague, dull, diffuse pain in the mid-abdomen or lower epigastrium. Peristalsis is also stimulated by the sudden distention, so that some cramping may be superimposed on the visceral pain early in the course of appendicitis. Distention continues from continued mucosal secretion and from multiplication of the resident bacteria of the appendix. Distention of this magnitude causes reflex nausea and vomiting, and the diffuse visceral pain becomes more severe. As pressure in the organ increases, venous pressure is exceeded. Capillaries and venules are occluded, but arteriolar inflow continues, resulting in engorgement and vascular congestion. The inflammatory process soon involves the serosa of the appendix and in turn parietal peritoneum in the region, producing the characteristic shift in pain to the right lower quadrant.

The mucosa of the appendix is susceptible to impairment of blood supply, thus its integrity is compromised early in the process, allowing bacterial invasion. As progressive distention encroaches on first the venous return and subsequently the arteriolar inflow, the area with the poorest blood supply suffers most. As distention, bacterial invasion, compromise of vascular supply, and infarction progress, perforation occurs, usually through one of the infarcted areas on the antimesenteric border. Perforation generally occurs just beyond the point of obstruction rather than at the tip. This sequence is not inevitable, however, and some episodes of acute appendicitis apparently subside spontaneously.

Bacteriology

The bacteriology of the normal appendix is similar to that of the normal colon. The bacteria cultured in cases of appendicitis are therefore similar to those seen in other colonic infections such as diverticulitis. The principal organisms seen in the normal appendix, in acute appendicitis, and in perforated appendicitis are *Escherichia coli* and *Bacteroides fragilis*. However, a wide variety of both facultative and anaerobic bacteria and mycobacteria may be present (Table 29-1). Appendicitis is a polymicrobial infection, with some series reporting up to 14 different organisms cultured in patients with perforation.

TABLE 29-1 Common Organisms Seen in Patients with Acute Appendicitis

Aerobic and facultative	Anaerobic
Gram-negative bacilli	Gram-negative bacilli
<i>E. coli</i>	<i>Bacteroides fragilis</i>
<i>Pseudomonas aeruginosa</i>	<i>Bacteroides</i> species
<i>Klebsiella</i> species	<i>Fusobacterium</i> species
Gram-positive cocci	Gram-positive cocci
<i>Streptococcus anginosus</i>	<i>Peptostreptococcus</i> species
<i>Streptococcus</i> species	Gram-positive bacilli
<i>Enterococcus</i> species	<i>Clostridium</i> species

The routine use of intraperitoneal cultures in patients with either perforated or nonperforated appendicitis is questionable. As discussed above, the flora is known and therefore broad-spectrum antibiotics are indicated. By the time culture results are available, the patient often has recovered from the illness. Additionally, the number of organisms cultured and the ability of a specific lab to culture anaerobic organisms vary greatly. Peritoneal culture should be reserved for patients who are immunosuppressed, and for patients who develop an abscess after the treatment of appendicitis. Antibiotic coverage is limited to 24–48 h in cases of nonperforated appendicitis. For perforated appendicitis, 7–10 days is recommended. Intravenous antibiotics are usually given until the white blood cell count is normal and the patient is afebrile for 24 h.

Clinical Manifestations

Symptoms

Abdominal pain is the prime symptom of acute appendicitis. Classically, pain is initially diffusely centered in the lower epigastrium or umbilical area, is moderately severe, and is steady, sometimes with intermittent cramping superimposed. After a period varying from 1–12 h, the pain localizes to the right lower quadrant. This classic pain sequence, although usual, is not invariable. In some patients, the pain of appendicitis begins in the right lower quadrant and remains there. Variations in the anatomic location of the appendix account for many of the variations in the principal locus of the somatic phase of the pain. Anorexia nearly always accompanies appendicitis. It is so constant that the diagnosis should be questioned if the patient is not anorectic. Although vomiting occurs in 75 percent of patients, it is neither prominent nor prolonged.

Most patients give a history of obstipation beginning prior to the onset of abdominal pain, and many feel that defecation would relieve their abdominal pain. However, diarrhea occurs in some patients, particularly children, so that the pattern of bowel function is of little differential diagnostic value.

The sequence of symptom appearance has great differential diagnostic significance. In more than 95 percent of patients with acute appendicitis, anorexia is the first symptom, followed by abdominal pain, which is followed, in turn, by vomiting. If vomiting precedes the onset of pain, the diagnosis of appendicitis should be questioned.

Signs

Physical findings are determined principally by the anatomic position of the inflamed appendix, and by whether the organ has already ruptured when the patient is first examined.

Vital signs are minimally changed by uncomplicated appendicitis. Temperature elevation is rarely more than 1°C (33.8°F) and the pulse rate is normal or slightly elevated. Changes of greater magnitude usually indicate that a complication has occurred or that another diagnosis should be considered.

Patients with appendicitis usually prefer to lie supine, with the thighs, drawn up, because any motion increases pain. The classic right lower quadrant physical signs are present when the inflamed appendix lies in the anterior position. Tenderness is often maximal at or near the McBurney point. Direct rebound tenderness is usually present. Additionally, referred or indirect rebound tenderness is present. This referred tenderness is felt maximally in the right lower quadrant, indicating localized peritoneal irritation. The Rovsing sign—pain in the right lower quadrant when palpatory pressure is exerted in the left lower

quadrant—also indicates the site of peritoneal irritation. Cutaneous hyperesthesia in the area supplied by the spinal nerves on the right at T10, T11, and T12 frequently accompanies acute appendicitis. Muscular resistance to palpation of the abdominal wall parallels the severity of the inflammatory process.

Anatomic variations in the position of the inflamed appendix lead to deviations in the usual physical findings. The psoas sign indicates an irritative focus in proximity to that muscle. The test is performed by having patients lay on their left side as the examiner slowly extends the right thigh, thus stretching the iliopsoas muscle. The test is positive if extension produces pain. Similarly, a positive obturator sign of hypogastric pain on stretching the obturator internus indicates irritation in the pelvis. The test is performed by passive internal rotation of the flexed right thigh with the patient supine.

Laboratory Findings

Mild leukocytosis, ranging from 10,000–18,000/mm³, is usually present in patients with acute, uncomplicated appendicitis and is often accompanied by a moderate polymorphonuclear predominance. However, white blood cell counts are variable. It is unusual for the white blood cell count to be greater than 18,000/mm³ in uncomplicated appendicitis. White blood cell counts above this level raise the possibility of a perforated appendix. Urinalysis is useful to rule out the urinary tract as the source of infection. Although several white or red blood cells can be present from ureteral or bladder irritation as a result of an inflamed appendix, bacteriuria in a catheterized urine specimen is not seen with acute appendicitis.

Imaging Studies

Plain films of the abdomen, although frequently obtained as part of the general evaluation of a patient with an acute abdomen, are rarely helpful in diagnosing acute appendicitis. However, plain radiographs can be of significant benefit in ruling out other pathology. In patients with acute appendicitis, one often sees an abnormal bowel gas pattern, which is a nonspecific finding. The presence of a fecalith is rarely noted on plain films, but if present, is highly suggestive of the diagnosis.

Graded compression sonography has been suggested as an accurate way to establish the diagnosis of appendicitis. The technique is inexpensive, can be performed rapidly, does not require contrast, and can be used in pregnant patients. Sonographically, the appendix is identified as a blind-ending, non-peristaltic bowel loop originating from the cecum. With maximal compression, the diameter of the appendix is measured in the anteroposterior dimension. A scan is considered positive if a noncompressible appendix 6 mm or greater in the anteroposterior direction is demonstrated. The presence of an appendicolith establishes the diagnosis. The presence of thickening of the appendiceal wall and periappendiceal fluid is highly suggestive. Sonographic demonstration of a normal appendix excludes the diagnosis of acute appendicitis. The study is considered inconclusive if the appendix is not visualized and there is no pericecal fluid or mass. When the diagnosis of acute appendicitis is excluded by sonography, a brief survey of the remainder of the abdominal cavity should be performed to establish an alternative diagnosis. In females of child-bearing age, the pelvic organs must be adequately visualized. The sonographic diagnosis of acute appendicitis has a reported sensitivity of 55–96 percent and a specificity of 85–98 percent.

Some studies have reported that graded compression sonography improved the diagnosis of appendicitis over clinical exam, specifically decreasing the percentage of negative explorations for appendectomies from 37 down to 13 percent. Sonography also decreases the time before operation. Sonography identified appendicitis in 10 percent of patients who were believed to have a low likelihood of the disease on physical examination. The positive and negative predictive values of ultrasonography have been reported as 91 or 92 percent, respectively. However, in a recent prospective multicenter study, routine ultrasonography did not improve the diagnostic accuracy or rates of negative appendectomy or perforation when compared to clinical assessment.

High-resolution, helical, computer tomography also has been used to diagnose appendicitis. On CT scan, the inflamed appendix appears dilated and the wall is thickened. There is usually evidence of inflammation, with "dirty fat," thickened mesoappendix, and even an obvious phlegmon. Fecaliths can be easily visualized, but their presence is not necessarily pathognomonic of appendicitis. An important suggestive abnormality is the arrowhead sign. This is caused by thickening of the cecum, which funnels contrast toward the orifice of the inflamed appendix. CT scanning is also an excellent technique for identifying other inflammatory processes masquerading as appendicitis.

Several CT techniques have been used, including focused and nonfocused CT scans and enhanced and nonenhanced helical CT scanning. Surprisingly, all these techniques have yielded similar rates of diagnostic accuracy, i.e., 92–97 percent sensitivity, 85–94 percent specificity, 90–98 percent accuracy, and 75–95 percent positive and 95–99 percent negative predictive values. A number of studies have documented improvement in diagnostic accuracy with the liberal use of CT scanning in the workup of suspected appendicitis. Computed tomography lowered the rate of negative appendectomies from 19 down to 12 percent in one study, and the incidence of negative appendectomies in women from 24 down to 5 percent in another. The use of this imaging study altered the care of 24 percent of patients studied and provided alternative diagnoses in half of the patients with normal appendices on CT scan.

Problems exist with routine CT scanning for suspected appendicitis. CT scanning is expensive, exposes the patients to significant radiation, and cannot be used during pregnancy. Allergy contraindicates the application of intravenous contrast in some patients, and others cannot tolerate the oral ingestion of luminal dye, particularly in the presence of nausea and vomiting. Finally, not all studies have documented the utility of CT scanning in all patients with right lower quadrant pain.

Studies comparing the effectiveness of ultrasound to helical CT in establishing the diagnosis of appendicitis have demonstrated CT scanning superior. In one study, 600 ultrasounds and 317 CT scans revealed sensitivities of 80 and 97 percent, specificities of 93 and 94 percent, diagnostic accuracies of 89 and 95 percent, positive predictive values of 91 and 92 percent, and negative predictive values of 88 and 98 percent, respectively. In another study, ultrasound positively impacted the management of 19 percent of patients, as compared to 73 percent of patients for CT. Finally, in a third study, patients studied by ultrasonography had a 17 percent negative appendix rate compared to a 2 percent negative appendix rate in patients who underwent helical CT scanning.

One issue that has not been resolved is which patients are candidates for imaging studies. The concept that all patients with right lower quadrant pain should undergo CT scanning has been strongly supported by two reports by

TABLE 29-2 Alvarado Scale for the Diagnosis of Appendicitis

Rao and his colleagues at the Massachusetts General Hospital. In one, this group documented a fall in the negative appendectomy rate from 20 down to 7 percent, and a decline in the perforation rate from 22 down to 14 percent, and establishing an alternative diagnosis in 50 percent of patients. In the second study, published in the *New England Journal of Medicine*, they documented that CT scanning prevented 13 unnecessary appendectomies, saved 50 inpatient hospital days, and lowered the per patient cost by \$447. In contrast, several studies failed to prove an advantage of routine CT scanning, documenting that surgeon accuracy approached that of the imaging study and expressing concern that the imaging studies could adversely delay appendectomy in affected patients.

The rational approach is the selective use of CT scanning. This has been documented by several studies in which imaging was performed based on an algorithm or protocol. The likelihood of appendicitis can be ascertained using the Alvarado scale (Table 29-2). This scoring system was designed to improve the diagnosis of appendicitis and was devised by giving relative weight to specific clinical manifestation.

Laparoscopy can serve as both a diagnostic and therapeutic maneuver for patients with acute abdominal pain and suspected acute appendicitis. Laparoscopy is most useful in the evaluation of females with lower abdominal complaints because appendectomy is performed on a normal appendix in as many as 30–40 percent of these patients. Differentiating acute gynecologic pathology from acute appendicitis can be effectively accomplished by using the laparoscope.

Appendiceal Rupture

Immediate appendectomy has long been the recommended treatment of acute appendicitis because of the risk of rupture. The overall rate of perforated appendicitis is 25.8 percent. Children younger than age 5 years and patients older than age 65 years have the highest rate of perforation (45 and 51 percent, respectively). It has been suggested that delays in presentation are responsible for the majority of perforated appendices. There is no accurate way of determining when and if an appendix will rupture prior to resolution of the inflammatory process. Although it has been suggested that observation and antibiotic therapy alone may be an appropriate treatment for acute appendicitis, nonoperative treatment exposes the patient to the increased morbidity and mortality associated with a ruptured appendix.

Appendiceal rupture should be suspected in the presence of fever greater than 39°C (102°F) and a white blood cell count greater than 18,000/mm³. In the majority of cases, rupture is contained and patients display localized rebound tenderness. Generalized peritonitis will be present if the walling-off process is ineffective in containing the rupture.

In 2–6 percent of cases, an ill-defined mass will be detected on physical examination. This could represent a phlegmon or a periappendiceal abscess. Patients who present with a mass have a longer duration of symptoms, usually at least 5–7 days. The ability to distinguish acute, uncomplicated appendicitis from acute appendicitis with perforation on the basis of clinical findings is often difficult, but it is important to make the distinction because their treatment differs. CT scan may be beneficial in guiding therapy. Phlegmons and small abscesses can be treated conservatively with intravenous antibiotics; well-localized abscesses can be managed with percutaneous drainage; complex abscesses should be considered for surgical drainage. If operative drainage is required, it should be performed by using an extraperitoneal approach, with appendectomy reserved for cases in which the appendix is easily accessible. Interval appendectomy performed at least 6 weeks following the acute event has classically been recommended for all patients treated either nonoperatively or with simple drainage of an abscess.

Differential Diagnosis

The differential diagnosis of acute appendicitis is essentially the diagnosis of the “acute abdomen” (see Chapter 34). This is because clinical manifestations are not specific for a given disease, but are specific for disturbance of a physiologic function or functions. Thus, an essentially identical clinical picture can result from a wide variety of acute processes within or near the peritoneal cavity.

The accuracy of preoperative diagnosis should be approximately 85 percent. If it is consistently less, it is likely that some unnecessary operations are being performed, and a more rigorous preoperative differential diagnosis is in order. A diagnostic accuracy rate consistently greater than 90 percent should also cause concern, because this may mean that some patients with atypical, but bona fide cases of, acute appendicitis are being “observed” when they should have prompt surgical intervention. The Haller group has shown, however, that this is not invariably true. Before the group’s study, the perforation rate at the hospital in which the study took place was 26.7 percent, and acute appendicitis was found in 80 percent of the operations. By a policy of intensive in-hospital observation when the diagnosis of appendicitis was unclear, the group raised the rate of acute appendicitis found at operation to 94 percent, although the perforation rate remained unchanged at 27.5 percent.

There are a few conditions in which operation is contraindicated. Other disease processes that are confused with appendicitis are also surgical problems, or, if not, are not made worse by surgical intervention. A common error is to make a preoperative diagnosis of acute appendicitis only to find some other condition (or nothing) at operation; much less frequently, acute appendicitis is found after a preoperative diagnosis of another condition. The most common erroneous preoperative diagnoses—accounting for more than 75 percent—in descending order of frequency are acute mesenteric lymphadenitis, no organic pathologic conditions, acute pelvic inflammatory disease, twisted ovarian cyst or ruptured graafian follicle, and acute gastroenteritis.

The differential diagnosis of acute appendicitis depends on four major factors: the anatomic location of the inflamed appendix; the stage of the process (i.e., simple or ruptured); the patient's age; and the patient's sex.

Acute Appendicitis in the Young

The establishment of a diagnosis of acute appendicitis in young children is more difficult than in the adult. The more rapid progression to rupture and the inability of the underdeveloped greater omentum to contain a rupture lead to significant morbidity rates in children. Children younger than 5 years of age have a negative appendectomy rate of 25 percent and an appendiceal perforation rate of 45 percent. This is compared to a negative appendectomy rate of less than 10 percent and a perforated appendix rate of 20 percent for children 5–12 years of age. The incidence of major complications after appendectomy in children is correlated with appendiceal rupture. The wound infection rate after the treatment of nonperforated appendicitis in children is 2.8 percent as compared to a rate of 11 percent after the treatment of perforated appendicitis. The incidence of intraabdominal abscess is also higher after the treatment of perforated appendicitis as compared to nonperforated cases (6 percent vs. 3 percent). The treatment regimen for perforated appendicitis generally includes immediate appendectomy and irrigation of the peritoneal cavity. Antibiotic coverage is limited to 24–48 h in cases of nonperforated appendicitis. For perforated appendicitis, 7–10 days of antibiotics is recommended. Intravenous antibiotics are usually given until the white blood cell count is normal and the patient is afebrile for 24 h. Laparoscopic appendectomy has been shown to be safe and effective for the treatment of appendicitis in children.

Acute Appendicitis in Older Adults

Although the incidence of appendicitis in older adults is lower than in younger patients, the morbidity and mortality are significantly increased in this patient population. Delays in diagnosis, a more rapid progression to perforation, and comorbid disease are all contributing factors. The diagnosis of appendicitis may be subtler and less typical than in younger individuals, and a high index of suspicion should be maintained. In patients older than age 80 years, perforation rates of 49 percent and mortality rates of 21 percent have been reported.

Acute Appendicitis During Pregnancy

Appendicitis is the most frequently encountered extrauterine disease requiring surgical treatment during pregnancy. The incidence is approximately 1 in 2000 pregnancies. Acute appendicitis can occur at any time during pregnancy, but is more frequent during the first two trimesters. As fetal gestation progresses, the diagnosis of appendicitis becomes more difficult as the appendix is displaced laterally and superiorly. Nausea and vomiting after the first trimester or new-onset nausea and vomiting should raise the consideration of appendicitis. Abdominal pain and tenderness will be present, although rebound and guarding are less frequent because of laxity of the abdominal wall. Elevation of the white blood cell count above the normal pregnancy levels of 15,000–20,000/ μ L, with a predominance of polymorphonuclear cells, is usually present. When the diagnosis is in doubt, abdominal ultrasound may be beneficial. Laparoscopy may be indicated in equivocal cases, especially early in pregnancy. The performance of any operation during pregnancy carries a risk of premature labor of

10–15 percent. The most significant factor associated with both fetal and maternal death is appendiceal perforation. Fetal mortality increases from 3–5 percent in early appendicitis to 20 percent with perforation. The suspicion of appendicitis during pregnancy should prompt rapid diagnosis and surgical intervention.

Appendicitis in Patients with AIDS or HIV Infection

The incidence of acute appendicitis in HIV-infected patients is reported to be 0.5 percent. This is higher than the 0.1–0.2 percent incidence reported for the general population. The presentation of acute appendicitis in HIV-infected patients is similar to that of noninfected patients. The majority of HIV-infected patients with appendicitis will have fever, periumbilical pain radiating to the right lower quadrant (91 percent), right lower quadrant tenderness (91 percent), and rebound tenderness (74 percent). HIV-infected patients will not manifest an absolute leukocytosis; however, if a baseline leukocyte count is available, nearly all HIV-infected patients with appendicitis will demonstrate a relative leukocytosis.

There appears to be an increased risk of appendiceal rupture in HIV-infected patients. In one large series of HIV-infected patients who underwent appendectomy for presumed appendicitis, 43 percent of patients were found to have perforated appendicitis at laparotomy. The increased risk of appendiceal rupture may be related to the delay in presentation seen in this patient population. The mean duration of symptoms prior to arrival in the emergency room has been reported to be increased in HIV-infected patients, with more than 60 percent of patients reporting the duration of symptoms to be longer than 24 h. A low CD4 count is also associated with an increase in appendiceal rupture.

The differential diagnosis of right lower quadrant pain in HIV-infected patients should include the possibility of an opportunistic infection. These opportunistic infections include cytomegalovirus (CMV), Kaposi sarcoma, tuberculosis, lymphoma, and other causes of infectious colitis. In the HIV-infected patient with classic signs and symptoms of appendicitis, immediate appendectomy is indicated. In those patients with diarrhea as a prominent symptom, colonoscopy may be warranted. In patients with equivocal findings, CT scan is usually helpful. The majority of pathologic findings identified in HIV-infected patients who undergo appendectomy for presumed appendicitis are typical. The negative appendectomy rate is 5–10 percent. However, up to 25 percent of patients will have AIDS-related entities in the operative specimens, including CMV, Kaposi sarcoma, and *Mycobacterium aviumintracellulare*.

In a report of 77 human immunodeficiency virus (HIV)-infected patients from 1988–1995, the 30-day mortality rate for patients undergoing appendectomy was reported to be 9.1 percent. More recent series report 0 percent mortality in this group of patients. Morbidity rates for HIV-infected patients with nonperforated appendicitis are similar to those seen in the general population. Postoperative morbidity rates appear to be higher in HIV-infected patients with perforated appendicitis. Additionally, the length of hospital stay for HIV-infected patients undergoing appendectomy is twice that of the general population.

Treatment

Once the decision to operate for presumed acute appendicitis has been made, the patient should be prepared for the operating room. Adequate hydration

should be ensured; electrolyte abnormalities corrected; and preexisting cardiac, pulmonary, and renal conditions should be addressed. Many trials have demonstrated the efficacy of preoperative antibiotics in lowering the infectious complications in appendicitis. For intraabdominal infections of gastrointestinal tract origin of mild to moderate severity, the Surgical Infection Society has recommended single-agent therapy with cefoxitin, cefotetan, or ticarcillin-clavulanic acid. For more severe infections, single-agent therapy with carbapenems or combination therapy with a third-generation cephalosporin, monobactam, or aminoglycoside plus anaerobic coverage with clindamycin or metronidazole is indicated.

Open Appendectomy

Most surgeons employ either a McBurney (oblique) or Rocky-Davis (transverse) right lower quadrant muscle-splitting incision in patients with suspected appendicitis. The incision should be centered over either the point of maximal tenderness or a palpable mass. If an abscess is suspected, a laterally placed incision is imperative to allow retroperitoneal drainage and to avoid generalized contamination of the peritoneal cavity. If the diagnosis is in doubt, a lower midline incision is recommended to allow a more extensive examination of the peritoneal cavity. This is especially relevant in older patients with possible malignancy or diverticulitis.

Several techniques can be used to locate the appendix. Because the cecum is usually visible within the incision, the convergence of the taeniae can be followed to the base of the appendix. A sweeping lateral to medial motion can aid in delivering the appendiceal tip into the operative field. Occasionally, limited mobilization of the cecum is needed to aid in adequate visualization. Once identified, the appendix is mobilized by dividing the mesoappendix, taking care to ligate the appendiceal artery securely.

The appendiceal stump can be managed by simple ligation or by ligation and inversion with either a purse-string or Z stitch. As long as the stump is clearly viable and the base of the cecum not involved with the inflammatory process, the stump can be safely ligated with a nonabsorbable suture. The mucosa is frequently obliterated to avoid the development of mucocoele. The peritoneal cavity is irrigated and the wound closed in layers. If perforation or gangrene is found in adults, the skin and subcutaneous tissue should be left open and allowed to heal by secondary intent or closed in 4–5 days as a delayed primary closure. In children, who generally have little subcutaneous fat, primary wound closure has not led to an increased incidence of wound infection. If appendicitis is not found, a methodical search for an alternative diagnosis must be performed.

Laparoscopy

Laparoscopic appendectomy is performed under general anesthesia. A nasogastric tube and a urinary catheter are placed prior to obtaining a pneumoperitoneum. Laparoscopic appendectomy usually requires the use of three ports. Four ports may occasionally be necessary to mobilize a retrocecal appendix. The surgeon usually stands to the patient's left. One assistant is required to operate the camera. One trocar is placed in the umbilicus (10 mm), with a second trocar placed in the suprapubic position. Some surgeons will place this second port in the left lower quadrant. The suprapubic trocar is either 10 or 12 mm, depending on whether a linear stapler will be used. The placement of the third trocar (5 mm) is variable and is usually either in the left lower

quadrant, epigastrium, or right upper quadrant. Placement is based on location of the appendix and surgeon preference. Initially, the abdomen is thoroughly explored to exclude other pathology. The appendix is identified by following the anterior taeniae to its base. Dissection at the base of the appendix enables the surgeon to create a window between the mesentery and base of the appendix. The mesentery and base of the appendix are then secured and divided separately. When the mesoappendix is involved with the inflammatory process, it is often best to divide the appendix first with a linear stapler, and then to divide the mesoappendix immediately adjacent to the appendix. The base of the appendix is not inverted. The appendix is removed from the abdominal cavity through a trocar site or within a retrieval bag. The base of the appendix and the mesoappendix should be evaluated for hemostasis. The right lower quadrant should be irrigated. Trocars are removed under direct vision.

The largest meta-analysis comparing open to laparoscopic appendectomy included 47 studies, 39 of which were studies of adult patients. This analysis demonstrated that the duration of surgery and operation costs were higher for laparoscopic appendectomy than for open appendectomy. Wound infections were approximately half as likely after laparoscopic appendectomy than after open appendectomy. However, intraabdominal abscess was three times greater after laparoscopic appendectomy than after open appendectomy. Patient-reported pain on the first postoperative day is significantly less after laparoscopic appendectomy. However, the difference has been calculated to be only 8 on a 100-point visual analogue scale. Hospital length of stay also is statistically significantly less after laparoscopic appendectomy. In most studies this difference is less than 1 day. The more important determinant of length of stay after appendectomy is the pathology at operation; specifically whether a patient has perforated or nonperforated appendicitis. In nearly all studies, laparoscopic appendectomy is associated with a shorter return to normal activity, return to work, and return to sports. Although the majority of studies have been performed in adults, similar data has been obtained in children.

There appears to be little benefit to laparoscopic appendectomy over open appendectomy in thin males between the ages of 15 and 45 years. In these patients, the diagnosis is usually straightforward. Open appendectomy has been associated with outstanding results for several decades. Laparoscopic appendectomy should be considered an option in these patients, based on surgeon and patient preference. Laparoscopic appendectomy may be beneficial in obese patients in whom it may be difficult to gain adequate access through a small right lower quadrant incision. Additionally, there may be a decreased risk of postoperative wound infection after laparoscopic appendectomy in obese patients.

Diagnostic laparoscopy has been advocated as a potential tool to decrease the number of negative appendectomies performed. However, the morbidity associated with laparoscopy and general anesthesia is acceptable only if pathology requiring surgical treatment is present and is amenable to laparoscopic techniques. The question of leaving a normal appendix *in situ* is a controversial one. Seventeen to 26 percent of normal-appearing appendices at exploration have a pathologic histologic finding. The availability of diagnostic laparoscopy may lower the threshold for exploration, thus impacting the negative appendectomy rate adversely. Fertile women with presumed appendicitis constitute the group of patients most likely to benefit from diagnostic laparoscopy. Up to one third of these patients will not have appendicitis at exploration. Most of these patients without appendicitis will have gynecologic pathology identified.

A meta-analysis demonstrated that in fertile women in whom appendectomy was deemed necessary, diagnostic laparoscopy reduced the number of unnecessary appendectomies. Additionally, the number of women without a final diagnosis was smaller. It appears that leaving a normal-appearing appendix in fertile women with identifiable gynecologic pathology is safe.

In summary, it has not been resolved whether laparoscopic appendectomy is more effective at treating acute appendicitis than the time-proven method of open appendectomy. It does appear that laparoscopic appendectomy is effective in the management of acute appendicitis. Laparoscopic appendectomy should be considered part of the surgical armamentarium available to treat acute appendicitis. The decision regarding how to treat any single patient with appendicitis should be based on surgical skill, patient characteristics, clinical scenario, and patient preference.

Interval Appendectomy

The accepted algorithm for the treatment of appendicitis associated with a palpable or radiographically documented mass (abscess or phlegmon) is conservative therapy with interval appendectomy 6–10 weeks later. This technique has been quite successful and provides much lower morbidity and mortality rates than immediate appendectomy. This treatment is associated with added expense and longer hospitalization. The initial treatment consists of intravenous antibiotics and bowel rest. Although generally effective, there is a 9–15 percent failure rate, with operative intervention required at 3–5 days after presentation. Percutaneous or operative drainage of abscesses is not considered a failure of conservative therapy.

The data support the need for interval appendectomy. In a prospective series, 19 of 48 (40 percent) patients who were successfully treated conservatively needed appendectomy earlier (4.3 weeks) than the 10 weeks planned because of bouts of appendicitis. Overall, the rate of late failure as a consequence of acute disease averages 20 percent. An additional 14 percent of patients either continue to have, or redevelop, right lower quadrant pain. Although the appendix may occasionally be pathologically normal, persistent periappendiceal abscesses and adhesions are found in 80 percent of patients. Additionally, almost 50 percent have histologic evidence of inflammation in the organ itself. Several neoplasms also have been detected in the resected appendix.

The timing of interval appendectomy is controversial. Appendectomy may be required as early as 3 weeks following conservative therapy. Two thirds of the cases of recurrent appendicitis occur within 2 years, and this is the outside limit.

Interval appendectomy is associated with a morbidity rate of 3 percent or less and a hospitalization of 1–3 days in length. The laparoscopic approach has been used recently and has been successful in 68 percent of procedures.

Prognosis

The mortality from appendicitis in the United States has steadily decreased from a rate of 9.9 per 100,000 in 1939, to 0.2 per 100,000 as of 1986. Principal factors in mortality are whether rupture occurs before surgical treatment and the age of the patient. The overall mortality rate for a general anesthetic is 0.06 percent. The overall mortality rate in ruptured acute appendicitis is about 3 percent—a 50-fold increase. The mortality rate of ruptured appendicitis in

older adults is approximately 15 percent—a 5-fold increase from the overall rate.

Morbidity rates parallel mortality rates, being significantly increased by rupture of the appendix and to a lesser extent by old age. Complications occur in 3 percent of patients with nonperforated appendicitis and in 47 percent of patients with perforations. Most of the serious early complications are septic and include abscess and wound infection. Wound infection is common, but is nearly always confined to the subcutaneous tissues and promptly responds to wound drainage. Wound infection predisposes the patient to wound dehiscence. The type of incision is relevant; complete dehiscence rarely occurs in a McBurney incision.

The incidence of intraabdominal abscesses secondary to peritoneal contamination from gangrenous or perforated appendicitis has decreased markedly because the introduction of potent antibiotics. The sites of predilection for abscesses are the appendiceal fossa, pouch of Douglas, subhepatic space, and between loops of intestine. The latter are usually multiple. Transrectal drainage is preferred for an abscess that bulges into the rectum.

Fecal fistula is an annoying, but not particularly dangerous, complication of appendectomy that may be caused by sloughing of that portion of the cecum inside a constricting purse-string suture; by the ligature's slipping off an appendiceal stump; or by necrosis from an abscess encroaching on the cecum.

CHRONIC APPENDICITIS

The existence of chronic appendicitis as a clinical entity has been questioned for many years. Recent clinical data document the existence of this uncommon disease. Histologic criteria have been established. The pain lasts longer and is less intense than that of acute appendicitis, but is in the same location. There is a much lower incidence of vomiting, but anorexia and occasionally nausea, pain with motion, and malaise are characteristic. Leukocyte counts are predictably normal and CT scans are generally nondiagnostic.

At operation, surgeons can establish the diagnosis with 94 percent specificity and 78 percent sensitivity. There is an excellent correlation between clinical symptomatology, intraoperative findings, and histologic abnormalities. Laparoscopy can be effectively used in the management of this clinical entity. Appendectomy is curative. Symptoms resolve postoperatively in 82–93 percent of patients. Many of those whose symptoms are not cured or recur are ultimately diagnosed with Crohn disease.

APPENDICEAL PARASITES

A number of intestinal parasites cause appendicitis. Although *Ascaris lumbricoides* is the most common, a wide spectrum of helminths have been implicated, including *Enterobius vermicularis*, *Strongyloides stercoralis*, and *Echinococcus granulosus*. The live parasites occlude the appendiceal lumen, causing obstruction. The presence of parasites in the appendix at operation makes ligation and stapling of the appendix technically difficult. Once appendectomy has been performed and the patient recovered, therapy with helminthicide is necessary to clear the remainder of the gastrointestinal tract.

Amebiasis can also cause appendicitis. Invasion of the mucosa by trophozoites of *Entamoeba histolytica* incites a marked inflammatory process. Appendiceal involvement is a component of more generalized intestinal amebiasis.

Appendectomy must be followed by appropriate antibiotic therapy (metronidazole).

INCIDENTAL APPENDECTOMY

The decisions regarding the efficacy of incidental appendectomy should be based on the epidemiology of appendicitis. The best data were published by the Centers for Disease Control and Prevention (CDC) based on the period from 1979–1984. During this period, there was an average of 250,000 cases of appendicitis in the United States. The highest annual incidence of appendicitis was in patients 9–19 years of age (23.3 per 10,000 population). Males were more likely to develop appendicitis than females. Accordingly, the incidence during teenage years was 27.6 in males and 20.5 in females per 10,000 population per year. Beyond age 19 years, the annual incidence fell. After 45 years of age, the annual incidence was 6 in 10,000 males and 4 in 10,000 females. Using the life table technique, the data identified a lifetime risk of appendicitis of 8.6 percent in men and 6.7 percent in women. Although men were more likely to develop appendicitis, the preoperative diagnosis was correct in 91.2 percent of men and 78.6 percent of women. Similarly, perforation occurred more commonly in men (19.2 vs. 17.8 percent in women). In contrast to the cases of appendicitis, 310,000 incidental appendectomies were performed between 1979 and 1984, 62 percent of the total appendectomies in men and 17.7 percent in women. Based on these data, 36 incidental appendectomies had to be performed to prevent 1 patient from developing appendicitis.

Indications to consider incidental appendectomy include children about to undergo chemotherapy, the disabled who cannot describe symptoms or react normally to abdominal pain, Crohn disease patients in whom the cecum is free of macroscopic disease, and individuals who are about to travel to remote places in which there is no access to medical/surgical care.

TUMORS

Appendiceal malignancies are extremely rare. Primary appendiceal cancer is diagnosed in 0.9–1.4 percent of appendectomy specimens. These tumors are only rarely suspected preoperatively. Additionally, less than 50 percent of cases are diagnosed at operation. Most series report that carcinoid is the most common appendiceal malignancy, representing more than 50 percent of the primary lesions of the appendix. However, a recent review from The National Cancer Institute's (NCI) Surveillance, Epidemiology, and End Results (SEER) program found the age-adjusted incidence of appendiceal malignancies to be 0.12 cases per 1,000,000 people per year, and identified mucinous adenocarcinoma as the most frequent histologic diagnosis with 37 percent of total reported cases. Carcinoid was the second most frequent histologic diagnosis, comprising 33 percent of total cases.

Carcinoid

The appendix is the most common site of gastrointestinal carcinoid, followed by the small bowel and then rectum. Carcinoid syndrome is rarely associated with appendiceal carcinoid unless widespread metastases are present, which occur in 2.9 percent of cases. Symptoms attributable directly to the carcinoid are rare, although the tumor can occasionally obstruct the appendiceal lumen much like a fecalith and result in acute appendicitis.

The majority of carcinoids are located in the tip of the appendix. Malignant potential is related to size, with tumors less than 1 cm rarely resulting in extension outside of the appendix or adjacent to the mass. In one report, 78 percent of appendiceal carcinoids were less than 1 cm, 17 percent were 1–2 cm, and only 5 percent were greater than 2 cm. Treatment rarely requires more than simple appendectomy. For tumors smaller than 1 cm with extension into the mesoappendix, and for all tumors larger than 1.5 cm, a right hemicolectomy should be performed.

Adenocarcinoma

Primary adenocarcinoma of the appendix is a rare neoplasm of three major histologic subtypes: mucinous adenocarcinoma, colonic adenocarcinoma, and adenocarcinoid. The most common mode of presentation for appendiceal carcinoma is that of acute appendicitis. Patients may also present with ascites or a palpable mass, or the neoplasm may be discovered during an operative procedure for an unrelated cause. The recommended treatment for all patients with adenocarcinoma of the appendix is a formal right hemicolectomy. Appendiceal adenocarcinomas have a propensity for early perforation, although they are not clearly associated with a worsened prognosis. Overall 5-year survival is 55 percent and varies with stage and grade. Patients with appendiceal adenocarcinoma are at significant risk for both synchronous and metachronous neoplasms, approximately half of which will originate from the gastrointestinal tract.

Mucocele

An appendiceal mucocele leads to progressive enlargement of the appendix from the intraluminal accumulation of a mucoid substance. Mucoceles are of four histologic types, and the type dictates the course of the disease and prognosis: retention cysts, mucosal hyperplasia, cystadenomas, and cystadenocarcinomas. A mucocele of benign etiology is adequately treated by a simple appendectomy.

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a rare condition in which diffuse collections of gelatinous fluid are associated with mucinous implants on peritoneal surfaces and omentum. Pseudomyxoma is two to three times more common in females than males. There is controversy in the literature regarding whether pseudomyxoma arises from the appendix or the ovary in female patients. Recent immunocytologic and molecular studies suggest that the appendix is the site of origin for most cases of pseudomyxoma. Pseudomyxoma is invariably caused by neoplastic mucous-secreting cells within the peritoneum. These cells may be difficult to classify as malignant because they may be sparse, widely scattered, and have a low-grade cytologic appearance. Patients with pseudomyxoma usually present with abdominal pain, distention, or a mass. Primary pseudomyxoma usually does not cause abdominal organ dysfunction. However, ureteral obstruction and obstruction of venous return can be seen.

The use of imaging before surgery is advantageous to plan surgery. CT scanning is the preferred imaging modality. At surgery a variable volume of mucinous ascites is found together with tumor deposits involving the right hemidiaphragm, right retrohepatic space, left paracolic gutter, ligament of Treitz, and the ovaries in women. Peritoneal surfaces of the bowel are usually free of tumor. Thorough surgical debulking is the mainstay of treatment. All

gross disease should be removed. Appendectomy is routinely performed. Hysterectomy with bilateral salpingo-oophorectomy is performed in women. Ultraradical surgery has not been shown to be of significant benefit. Additionally, adjuvant intraperitoneal chemotherapy (with or without hyperthermia) or systemic postoperative chemotherapy have not been shown to be of benefit. Pseudomyxoma is a disease that progresses slowly and in which recurrences may take years to develop or become symptomatic. In a series from the Mayo Clinic, 76 percent of patients developed recurrences within the abdomen. Lymph node metastasis and distant metastasis are uncommon. Recurrences are treated by additional surgery. Surgery for recurrent disease is usually difficult and associated with an increased incidence of enterotomies, anastomotic leaks, and fistulas. With adequate primary surgery and debulking of recurrences, the median survival of pseudomyxoma is 5.9 years, with 53 percent of patients surviving 5 years.

Lymphoma

Lymphoma of the appendix is uncommon. The gastrointestinal tract is the most frequently involved extranodal site for non-Hodgkin lymphoma. Other types of lymphoma, such as Burkitt, and leukemia, have also been reported. The frequency of primary lymphoma of the appendix is 1–3 percent of gastrointestinal lymphomas. Appendiceal lymphoma usually presents as acute appendicitis and is rarely suspected preoperatively. Findings on CT scan of an appendiceal diameter greater than or equal to 2.5 cm or surrounding soft-tissue thickening should prompt suspicion of an appendiceal lymphoma. The management of appendiceal lymphoma confined to the appendix is appendectomy. Right hemicolectomy is indicated if there is extension of tumor onto the cecum or mesentery. A postoperative staging workup is indicated prior to initiating adjuvant therapy. Adjuvant therapy is not indicated for lymphoma confined to the appendix.

LIVER ANATOMY

One of the greatest advances in hepatic surgery is the understanding of the segmental anatomy of the liver. The Couinaud system for liver segmental nomenclature is widely accepted in practice. The liver is divided into longitudinal planes drawn through each hepatic vein to the vena cava, and a transverse plane at the level of the main portal bifurcation. The plane of the middle hepatic vein and the primary bifurcation of the portal vein divide the liver into a right and left lobe. This runs from the inferior vena cava to the tip of the gallbladder fossa (also known as the Cantlie line or the portal fissure). The secondary portal bifurcations on the right and left give rise to four sectors (or sections). On the right side this produces the anterior and posterior sectors, which are split by the plane of the right hepatic vein. The tertiary branches on the right supply four segments, two in each sector. The ascending branch of the left gives off recurrent branches to the medial sector of the left lobe. However, the left lateral sector is supplied by separate branches that supply the two segments (segments II and III,). Segment I, the caudate lobe, receives blood supply from both the left and right portal pedicles; bile ducts from segment I also drain into the right and left hepatic ducts.

Portal Vein

The portal vein is a valveless structure that is formed by the confluence of the superior mesenteric vein and the splenic vein. The portal vein provides approximately 75 percent of the total liver blood supply by volume. In the hepatoduodenal ligament, the portal vein is found most commonly posterior to the bile duct and hepatic artery. The normal pressure in the portal vein is between 3 and 5 mmHg. Because the portal vein and its tributaries are without valves, increases in venous pressure are distributed throughout the splanchnic circulation. In the setting of portal venous hypertension, portosystemic collaterals develop secondary to the increased pressure. The most clinically important portosystemic connections include those fed through the coronary (left gastric) and short gastric veins through the fundus of the stomach and distal esophagus to the azygos vein, resulting in gastroesophageal varices. Recanalization of the round ligament/umbilical vein leads to a caput medusae around the umbilicus. Portal hypertension through the inferior mesenteric veins and hemorrhoidal plexuses can lead to engorged external hemorrhoids.

Hepatic Veins

The majority of the venous drainage of the liver occurs through three hepatic veins. The right hepatic vein drains segments V, VI, VII, and VIII, and enters directly into the vena cava. The middle hepatic vein drains segments IVA, IVB, V, and VIII, and enters into a common orifice with the left hepatic vein that drains segments II and III. A number of small short hepatic veins enter directly into the vena cava from the undersurface of the liver in segment I. Direct venous

drainage into the vena cava is through small, short hepatic veins, although large segmental branches may also be present.

Hepatic Artery

From the level of the hepatic plate (the interface of the portal bifurcation with the liver capsule), the hepatic arterial anatomy is part of the portal triad and follows the segmental anatomy. The extrahepatic arterial anatomy can be highly variable. In roughly half of the population, the common hepatic artery arises from the celiac trunk, giving off the gastroduodenal artery followed by a right gastric artery. The proper hepatic artery gives rise to the right and left hepatic arteries. However, there is great variation in hepatic artery anatomy that is important to understand and detect in performing cholecystectomies, portal dissections, and liver resections. Replaced hepatic arteries are lobar vessels that arise from either the superior mesenteric artery (replaced right hepatic artery) or left gastric artery (replaced left hepatic artery). The replaced right hepatic artery travels posterior to the portal vein in close proximity to the posterior aspect of the pancreas and bile duct. A replaced right hepatic artery is felt behind both the bile duct and the portal vein when palpating the portal triad structures through the foramen of Winslow. The left hepatic artery, regardless of its origin, enters the liver at the base of the round ligament. A replaced or accessory left hepatic artery will run in the lesser omentum anterior to the caudate lobe and is typically very easily identified. In contrast to a replaced hepatic artery, an accessory hepatic artery is one that exists in addition to an anatomically typical originating vessel. Accessory right hepatic arteries often supply the posterior sector of the right lobe (segment VI and VII). An accessory left hepatic artery will typically supply the left lateral segment. The cystic artery most commonly arises from the right hepatic artery, but has a variety of common anomalies as well.

Biliary System

The bile duct arises at the cellular level from the hepatocyte membrane which coalesces with adjacent hepatocytes to form canaliculi. Larger collections of canaliculi form small ducts. The bile ducts follow the segmental anatomy of the intrahepatic vasculature as previously described. The confluence of the right and left hepatic ducts may be intrahepatic. The right hepatic duct is found to be largely intrahepatic, although the left hepatic duct is extrahepatic and runs perpendicular to the common hepatic duct to the level of the round ligament, in which it is formed by a confluence of ducts from segment IV and segments II/III. The confluence of the left and right hepatic ducts is cephalad and ventral to the portal vein bifurcation.

The hepatic bile duct confluence gives rise to the common hepatic duct, the duct between the confluence and the cystic duct takeoff. The common bile duct extends from the cystic duct to the ampulla of Vater. A normal common bile duct is less than 10 mm in diameter in the adult. The blood supply to the bile duct arises from the right hepatic artery superiorly and from the gastroduodenal artery inferiorly. A rich anastomosis between the right and left hepatic arteries has been demonstrated with corrosion cast analyses of the hilum, indicating that preservation of these intrahepatic anastomoses will preserve bile duct blood flow, even with extrahepatic ligation of one or the other arterial structures.

Lymphatics

The spaces of Disse and clefts of Mall produce lymph fluid at the cellular level that is collected through sub-Glissonian and periportal lymphatics that ultimately drain into larger lymphatics emptying through the porta hepatis into the cisterna chyli. The anatomy and physiology of lymphatic drainage is important in the development of ascites and in the process of tumor metastasis.

Neural Innervation

Parasympathetic fibers from the hepatic branches of the vagus nerve and both parasympathetic and sympathetic fibers derived from the celiac plexus innervate the liver and gallbladder, the latter traveling along the hepatic arteries. The functions of these nerves is not well understood, but liver transplantation shows that the nerves are not essential for normal liver function. Irritation or stretching of the Glisson capsule or gallbladder cause referred pain to the right shoulder through the third and forth cervical nerves.

INTERPRETATION OF LIVER TESTS

Liver tests are broken down into tests of liver function, parenchymal injury, and biliary obstruction (Table 30-1). The pattern of liver test abnormalities is more important than any individual test result. Deviation from this normal time course should prompt specific evaluation for potentially correctable vascular (portal vein thrombosis) or biliary (obstructive) pathology.

RADIOLOGIC EVALUATION OF THE LIVER

The liver most commonly is evaluated as part of right upper quadrant ultrasound studies for gallbladder disease. However, the indications for directed evaluation of the liver include screening or assessment of malignancy, the study of a newly diagnosed cirrhotic patient, or evaluation for living donor transplantation. A comprehensive understanding of the available tests is critical to patient management.

Ultrasound

Transcutaneous ultrasound is frequently the first radiologic evaluation performed on the liver. Ultrasound is an excellent test for identifying biliary tract stones and intrahepatic biliary ductal dilation. The echo-texture of the liver can suggest cirrhosis or fatty infiltration, and cystic and solid characteristics of tumors can be delineated. Ultrasonography is commonly used in programs that screen high-risk populations for the development of hepatocellular carcinoma (HCC). In studies from the United States and Europe, ultrasonography

TABLE 30-1 Serum Liver Tests

Parenchymal (hepatocytes)	AST, ALT
Canalicular (biliary)	ALP, 5'NT, GGT, bilirubin
Synthetic function and metabolism	INR, factors V and VII, bilirubin, albumin

ALP = alkaline phosphatase; ALT = alanine aminotransferase; AST = aspartate aminotransferase; 5'NT = 5' nucleotidase; GGT = gamma glutamyl transferase; INR = International Normalized Ratio.

has been shown to be superior to serum α -fetoprotein (AFP) measurement to detect early HCC in patients who suffer from chronic viral hepatitis.

Intraoperative ultrasonography (IOUS) has become the gold standard against which all other diagnostic imaging modalities are compared to detect the number, extent, and association of tumors with intrahepatic blood vessels in both primary and metastatic liver tumors. IOUS can be performed laparoscopically or during laparotomy. Placement of the probe directly on the surface of the liver enhances discrimination and sensitivity. Laparoscopic evaluation and laparoscopic ultrasonography have reduced the rate of unwarranted exploratory laparotomies, and thereby increased the proportion of patients who undergo successful hepatic resection at the time of laparotomy. Like IOUS, laparoscopic ultrasonography detects small metastatic or primary liver tumors not visualized on preoperative computed tomography (CT) scans or magnetic resonance imaging (MRI) studies in up to 15 percent of patients. IOUS also can be used to map the line of resection as it relates to relevant vascular structures, to avoid and anticipate possible sources of bleeding. IOUS is necessary for intraoperative image-guided procedures such as biopsy and radiofrequency ablation (RFA).

Computed Tomography Scan

Modern CT scans are helical and are highly sensitive at spatial discrimination and quantitation of lesions in the liver. Lesions can be characterized as solid or cystic and the enhancement characteristics can be evaluated during the arterial, portal, and delayed phases. The smallest detectable lesion size is approximately 1 cm. Dual- and triple-phase bolus intravenous contrast helical CT is more accurate than standard CT or portal venous phase CT in detecting colorectal liver metastases. However, the overall detection rate compared to intraoperative and pathologic findings is still approximately 85 percent with a false-positive rate of up to 5 percent. For HCC, the helical CT detection rate for small tumors is less than that for detecting hepatic metastases. The detection rate of small HCCs (< 2 cm), 40–60 percent, is based on the difficulty of detecting small tumors in cirrhotic livers, particularly in reference to the problem of distinguishing HCC from macroregenerative nodules. CT remains the preferred method for evaluating the remainder of the abdomen. Among patients with liver metastases, a CT scan is used to evaluate for the presence of peritoneal disease, portal lymphadenopathy, and other remote lesions.

Magnetic Resonance Imaging

MRI technology also is rapidly advancing. MRI is somewhat less sensitive at spatial discrimination of lesions, but provides additional tumor characterization benefits that are not available with CT scanning. MRI scans are slightly less accurate than helical CT in detecting the extent of colorectal liver metastases, but are more sensitive for detecting early HCC and in distinguishing HCC from macroregenerative nodules. Contrast enhancement provides an evaluation of vascular enhancement similar to CT, but MRI allows for better differentiation of cystic lesions and hemangiomas using T2-weighted images. This technique also is useful in magnetic resonance cholangiography (MRC). MRC is an excellent study for the evaluation of the intrahepatic biliary tree, and is critical to the operative planning for hilar bile duct malignancies requiring liver resection. Magnetic resonance venography is a very sensitive technique for the

noninvasive study of the extrahepatic portal system, and is especially useful in confirming extrahepatic portal vein thrombosis.

Positron Emission Tomography

Positron emission tomography (PET) is a whole-body, multiaxial technology that has been used to detect a variety of cancers including melanoma, breast cancer, and colorectal cancer. 18F-fluorodeoxyglucose (FDG) is injected systemically through an intravenous catheter, and axial tomography is performed of the entire body. It has been called a metabolic imaging method because FDG is taken up by active tissues (e.g., the brain) and cancer. The FDG PET is especially useful in the evaluation of patients with hepatic metastases of colorectal cancer to rule out the presence of extrahepatic disease. Similarly to other diagnostic studies, PET does have a false-negative rate of 7–10 percent, but the false-positive rate appears to be significantly lower than this value. In patients with a history of colorectal cancer, a rising serum carcinoembryonic antigen (CEA) level, and no recurrent or metastatic disease evident on CT or MRI images of the chest, abdomen, and pelvis, PET images demonstrating hypermetabolic areas may provide a clue regarding the site of recurrent disease. PET has been less useful in the evaluation of patients with HCC, as many of these tumors do not have a significantly higher uptake of the radioisotope compared to the surrounding hepatic parenchyma. Until further studies are undertaken, the use of PET scanning should be tied very closely to other forms of axial imaging studies. One method is fusion of PET scans with CT scanning. If there is a failure to correlate a hypermetabolic focus on PET scan with a tumor mass on CT scan, then directed evaluation, including biopsy of the hypermetabolic focus, should be performed prior to proceeding with liver resection.

PERCUTANEOUS BIOPSY

The role of image-guided percutaneous biopsy has become less important as the sensitivity and specificity of radiologic imaging studies had improved. In patients with a clinical picture and radiologic findings that point to a specific type of lesion, percutaneous biopsy is rarely indicated to initiate liver-directed therapy. In patients in whom the diagnosis is not evident based on clinical and radiographic grounds, a percutaneous biopsy can be done safely using either ultrasound or CT guidance. The target lesion should be accessed through a quantity of normal liver tissue sufficient to avoid free rupture of tumor into the peritoneum. This is especially important with HCCs, which are friable and vascular lesions.

LIVER FAILURE

Liver failure can be divided into two general categories: acute and chronic. Acute liver failure is relatively uncommon, with approximately 5000 new cases reported annually in the United States. The pathophysiology is related to an acute, massive loss of hepatocyte functional mass. However, there are usually no long-term sequelae in survivors. In chronic liver failure (long-term liver injury)—whether derived from viral hepatitis, metabolic diseases, ethanol abuse, or toxins—ongoing and progressive hepatocyte necrosis produces a fibrotic response and liver cell regeneration that leads to cirrhosis. Twenty-five

thousand people die each year from cirrhosis, making it the eighth leading cause of death from disease in the United States.

Cirrhosis is a histologic term that describes generalized hepatic fibrosis and nodular regeneration of the liver. Despite the wide variety of etiologies of cirrhosis, the histologic end results often are indistinguishable. As described earlier, one of the unique physiologic capabilities of the liver is regeneration. The response of the liver to hepatocyte necrosis is collapse of portal tracks with fibrous replacement and nodular regeneration.

Grossly, cirrhosis can be described as micronodular, macronodular, or mixed. The CT findings of cirrhosis can be subtle, but include right lobe atrophy, ascites, caudate lobe hypertrophy, recanalization of the umbilical vein, enlargement of the portal vein caliber and splenomegaly. Laboratory findings in the unsuspected and compensated cirrhotic patient may be absent or include mild elevations in serum transaminases, borderline thrombocytopenia, or elevations in the INR.

Risks of General Surgical Procedures in Portal Hypertension

The Child classification was originally developed to evaluate the risk of portocaval venous shunt surgery for portal hypertension, but it also has been shown to be useful in predicting the risks of other abdominal operations in cirrhotic patients and was subsequently modified by others (Table 30-2).

A dysregulation of the compensatory blood flow response (e.g., increased hepatic arterial flow in response to decreased portal vein flow) is seen in cirrhosis. A variety of studies have shown that American Society of Anesthesiologists (ASA) score, renal insufficiency, and higher Child scores are adverse prognostic factors that predict an increased probability of complications and mortality after an operation. In elective procedures, attention to preoperative control of ascites, electrolyte abnormalities, and coagulopathy are critical to the success of elective surgery. Prevention of postoperative ascites begins with restriction of sodium-containing intravenous fluids in the operating room. As ascites accumulates, continued fluid restriction, diuretic therapy, bedrest, and intermittent paracentesis may be needed. Chronic peritoneal catheter drainage should be avoided because of the risk of retrograde contamination of the peritoneal cavity. Ascites in this setting is highly morbid, especially if complicated by bacterial infection. Encephalopathy also should be anticipated. Administration of narcotic pain medicines and sedatives should be limited when possible, as the hepatic metabolism of most drugs is compromised.

TABLE 30-2 Revised Child Classification of Clinical Severity of Cirrhosis

	Class		
	A	B	C
Nutritional status	Excellent	Good	Poor
Ascites	None	Minimal, controlled	Moderate to severe
Encephalopathy	None	Minimal, controlled	Moderate to severe
Serum bilirubin (mg/dL)	< 2	2–3	> 3
Serum albumin (g/dL)	> 3.5	2.8–3.5	< 2.8
Prothrombin time (% of control)	> 70	40–70	< 40

Portal Hypertension

Portal hypertension may be classified as presinusoidal, sinusoidal, or postsinusoidal. Sinusoidal causes are the most common in the Western Hemisphere because of alcoholic cirrhosis that results from fibrous replacement in the space of Disse. Chronic liver insufficiency is common. Postsinusoidal portal hypertension often has a vascular etiology and also is associated with some degree of liver dysfunction. In contrast, patients with presinusoidal portal hypertension may have well-preserved hepatic function. Etiologies include schistosomiasis, extrahepatic portal vein thrombosis, and congenital hepatic fibrosis (most commonly seen in children).

Budd-Chiari Syndrome

Budd-Chiari syndrome, which is a rare cause of postsinusoidal liver failure and cirrhosis, can occur as a spectrum of presentations that range from asymptomatic disease to fulminant liver failure. The pathophysiology is related to thrombosis of the three major hepatic veins at the level of the inferior vena cava. The disease is more common in women and is associated with a variety of hypercoagulable states: protein C, S, or antithrombin III deficiency; polycythemia vera; lupus anticoagulant; estrogen exposure; myeloproliferative disorders; and Behçet disease. Patients often will present with jaundice, ascites and hepatomegaly. Transcutaneous Doppler-flow ultrasound will show thrombosed hepatic veins and may demonstrate large collaterals into the retrohepatic inferior vena cava. CT findings include striking caudate lobe hypertrophy and inhomogeneous contrast enhancement. Anticoagulation is the standard immediate therapy. Treatment of acute decompensated Budd-Chiari includes placement of a transjugular intrahepatic portosystemic shunt (TIPS) or a non-selective shunt.

Acute Bleeding

Patients with portal hypertension may require surgical intervention after an episode of acute upper gastrointestinal (GI) bleeding. After intravenous fluid resuscitation and correction of coagulation abnormalities, the single most important diagnostic and potentially therapeutic procedure to be performed in the cirrhotic patient with an upper GI bleed is endoscopy. The differential diagnosis must include sources other than bleeding from esophageal varices, because as many as 20 percent of patients will have bleeding from gastritis or duodenal ulcer disease.

Esophageal varices are the most common cause of massive bleeding in patients with cirrhosis, and result from shunting of blood through the coronary (left gastric) vein into the submucosal plexus of the esophagus. Prevention of the first bleeding event with prophylactic beta-adrenergic blockade is more effective than placebo, and the addition of a systemic vasodilator agent is slightly more efficacious, but at the expense of increased peripheral edema. Sclerotherapy, TIPS, or surgical shunts have not been associated with a reduction in first bleeding risk in Western, alcoholic-cirrhotic patients. Prophylaxis is important because variceal bleeding in cirrhotic patients is a grave prognostic event with 70 percent of patients dying within 1 year.

The most critical treatment for acute hemorrhage in cirrhotic patients is prompt endoscopic intervention and therapy. Acute esophageal variceal bleeding can be managed with endoscopic variceal banding in 85 percent of patients. Administration of intravenous vasopressin or octreotide can decrease

splanchnic blood flow, and are useful in reducing bleeding from esophageal varices in the acute phase of management.

Hepatic encephalopathy from absorption of the intestinal blood load, and azotemia from large-volume blood replacement, should be anticipated. It may be necessary to use oral or nasogastric lactulose elixir to promote catharsis. Emergency TIPS is successful in treating acute bleeding and in preventing rebleeding in approximately 80 percent of patients. The procedure has supplanted the surgical shunt at most institutions for the treatment of refractory bleeding.

Surgical shunts are associated with long-term survival rates of more than 70 percent in Child class A and B patients. A nonselective portocaval shunt will have the most immediate and durable effect in the acute setting. In patients who are potential liver transplant candidates, an interposition mesocaval shunt or central splenorenal shunt will avoid portal dissection and not complicate a subsequent liver transplant operation. If the patient has complete portal vein thrombosis, an end-to-side portocaval shunt will be effective and is technically straightforward.

Prevention of Rebleeding

Repeated endoscopic therapy employing sclerotherapy or banding can eradicate varices and prevent rebleeding in up to 80 percent of patients in the first year. Use of beta-adrenergic blockade or octreotide has been demonstrated to significantly reduce rebleeding rates in combination with endoscopic therapy. In the cirrhotic patient with significant hepatic dysfunction, liver transplantation must be considered. The long-term outlook in patients with preserved hepatic function may be significantly different, and these patients are candidates for surgical shunts.

Portosystemic Shunts

Transjugular intrahepatic portosystemic shunt. The TIPS procedure is minimally invasive and creates the equivalent of a nonselective surgical shunt. The indications for TIPS include bleeding refractory to endoscopic and medical management, refractory ascites, Budd-Chiari syndrome, and hepatopulmonary syndromes. The procedure involves the placement of an expandable wire mesh stent between the middle hepatic vein and region of the portal bifurcation using ultrasound and radiographic direction. The stent is expanded to a diameter that reduces the portosystemic gradient to less than 12 mmHg. TIPS is associated with postprocedure encephalopathy rates of approximately 25 percent, and patients with renal insufficiency are at risk for worsened renal function. The long-term problem with TIPS is stenosis of the shunt, which occurs in as many as two thirds of patients.

Surgical shunts. Surgical shunts are best used in patients with relatively well-preserved liver function (Child class A and B) who are not candidates for liver transplantation or who have limited access to the medical surveillance necessary for TIPS monitoring. Patients who may require liver transplant in the future (> 1 year) are also candidates for surgical shunts because surgical shunt patency is superior to that of TIPS.

Surgical shunts can be divided into two general categories: selective and nonselective. Nonselective shunts are associated with a high risk of encephalopathy, especially in patients with marginal liver function. Selective shunts are associated with a lower incidence of encephalopathy, as they maintain

hepatopetal flow although lowering portal pressure. Currently, the most useful surgical shunts are the small-diameter portacaval H graft shunt and distal splenorenal shunt (DSRS).

In general, nonselective shunts are appropriate for the management of medically refractory bleeding in the patient with preserved liver function who is not a liver transplant candidate and who has intractable ascites. In patients with complete intrahepatic portal vein thrombosis, an end-to-side portocaval shunt is the easiest to perform and the most effective shunt.

LIVER INFECTIONS

Pyogenic Liver Abscesses

Pyogenic liver abscesses have been well known for over 100 years and were a common cause of morbidity and mortality in patients with untreated appendicitis and pyelphlebitis. Currently, the most common etiologies of pyogenic liver abscesses include biliary tract manipulation, diverticular disease, inflammatory bowel disease, and systemic infections such as bacterial endocarditis.

The clinical presentation of patients with pyogenic liver abscesses is rarely subtle. Patients present with right upper quadrant abdominal pain, fever, and occasionally jaundice. In patients with chronic symptomatology, fever and weight loss with progressive fatigue may be seen. Interestingly, as many as one third of patients with pyogenic liver abscesses will not have an identifiable primary source of infection.

Ultrasound examination will demonstrate a cystic mass in the liver, often with multiple complex septations or in homogeneous fluid characteristics. CT findings will include a complex hypodense mass with peripheral enhancement. In patients with a solitary dominant abscess, percutaneous aspiration with evaluation by gram stain and culture is essential to direct further antimicrobial and drainage therapy. The placement of a percutaneous drainage catheter at the time of aspiration is beneficial for patients with a complex abscess or an abscess containing particularly thick fluid. In an immunosuppressed patient who has multiple abscesses, hepatosplenic candidiasis should be considered, and more conventional pyogenic etiologies.

In patients with intraabdominal sources leading to hepatic abscesses, Gram-negative aerobes, Gram-positive aerobes, and anaerobes are the predominant organisms found in liver abscesses. Commonly encountered organisms include *Escherichia coli*, *Klebsiella pneumoniae*, *Enterococcus faecalis* and *faecium*, and anaerobic or facultative anaerobic species such as *Bacteroides fragilis*. In patients with systemic infections from subacute bacterial endocarditis and indwelling catheter infections, Staphylococcus and Streptococcus species are more common. Monomicrobial abscesses are found in approximately 40 percent of patients, an additional 40 percent are polymicrobial, although the remaining cases are culture negative.

Parasitic Liver Abscesses

Hydatid Disease

Cystic hydatid disease is caused by the larval/cyst stage of *Echinococcus granulosus*, in which humans are an intermediate host. Hydatid cysts can be uncomplicated and asymptomatic. However, these lesions may rupture, can become secondarily infected, or may infect other organs. The diagnosis is based on an enzyme-linked immunosorbent assay (ELISA) test for echinococcal antigens,

which is positive in over 85 percent of infected patients. Ultrasound and CT scanning will typically demonstrate either simple or complex cysts with a cyst wall of varying thickness. The treatment of hydatid disease involves the use of oral anthelmintics such as albendazole. In patients with anatomically appropriate lesions percutaneous aspiration, instillation of absolute alcohol, and reaspiration (PAIR) is the preferred initial treatment. The efficacy of PAIR in managing hydatid cysts is greater than 75 percent. For patients whose disease is refractory to PAIR, laparoscopic or open complete cyst removal with instillation of a scolical agent generally is curative. If surgical cystectomy with removal of the germinal laminated layers is not technically feasible, then formal liver resection can be employed. During aspiration or surgical treatment of hydatid cysts, extreme caution must be taken to avoid rupture of the cyst with release of protoscolices into the peritoneal cavity.

Amebiasis

Entamoeba histolytica enters into humans in a cyst form but transforms into a trophozoite in the colon. It enters into the colonic mucosa and invades the portal venous system, infecting the liver. Although resulting from a colonic infection, a recent history of severe diarrhea is uncommon. Patients typically present with sweating and chills, usually of at least 1 week duration. Fevers can be high and patients typically have right upper quadrant abdominal pain and tenderness. The majority of patients have a positive fluorescent antibody test for *E. histolytica* and mild abnormalities in liver enzymes; hyperbilirubinemia is relatively uncommon.

In patients who live in or who have recently visited an endemic area and who present with right upper quadrant tenderness and hepatomegaly, an ultrasound showing an abscess should be considered diagnostic for the presence of amebiasis. Patients diagnosed with amebic liver abscesses should be treated with metronidazole for at least 1 week. Most patients will respond rapidly with complete defervescence within 3 days. Aspiration of the abscess is rarely necessary and should be avoided, except in patients in whom secondary infection from pyogenic organisms is suspected.

CYSTIC DISEASES OF THE LIVER

Noninfectious cystic lesions in the liver are common throughout all decades of life. The vast majority of hepatic cysts are asymptomatic and are found incidentally. Cysts can be categorized as congenital or neoplastic.

Congenital Cysts

Congenital cysts include simple hepatic cysts, which are the most common benign lesions found in the liver. Simple cysts result from excluded hyperplastic bile duct rests and they are commonly identified on imaging studies as unilocular, homogeneous fluid-filled structures with a thin wall without projections. The epithelium of the cyst secretes clear fluid that does not contain bile, and they rarely are symptomatic unless they are large, in which case patients may complain of pain, epigastric fullness or a mass, or early satiety related to gastric compression. Simple aspiration is not recommended as an initial therapy; however, useful information about symptom resolution often is obtained. PAIR has a success rate as high as 80 percent. In patients with easily accessible lesions and appropriate interventional radiology support, PAIR is an

excellent first line of therapy in the management of simple, congenital, hepatic cysts.

The surgical management of simple cysts centers on wide cyst fenestration. These procedures are performed laparoscopically, if technically feasible. The recurrence rate after wide cyst fenestration is usually less than 5 percent. The excised cyst wall is sent for pathologic analysis, and the remaining cyst wall within the liver should be carefully examined for the presence of gross neoplastic changes. Cystic fluid analysis by cytology and tumor markers is not indicated unless there is concern for neoplasia. A symptomatic simple cyst rarely requires complete resection, either as an enucleation or as a formal liver resection.

Polycystic Liver Disease

Polycystic disease occurs as an autosomal dominant disease presenting in adulthood. An autosomal recessive process that is associated with hepatic fibrosis also occurs in rare instances in infancy. A wide spectrum of clinical and anatomic presentations is seen in polycystic liver disease (PCLD). Symptoms of fullness, early satiety, dysphagia, and pain are often chronic and unrelenting, and as with any consideration for liver surgery of benign processes, other contributing factors should be ruled out.

In patients with dominant cysts and associated symptoms, PAIR should be used for the initial approach to manage symptoms. Obliteration of a treated cyst is normally seen in 80 percent of cases; however, careful patient selection is necessary to avoid recurrence. In patients who are not candidates for PAIR or who have failed PAIR, fenestration or resection of the cyst(s) should be undertaken. Formal lobectomy along the border of the majority of the cystic disease may be required and is expected to be associated with a durable correction of symptoms in up to 90 percent of carefully selected patients. In patients with massive hepatomegaly but no dominant anatomic presentation, a transverse hepatectomy (resection of segments III, IVB, V, and VI at the level of the rib cage) has been reported to be associated with excellent improvement of symptoms.

Neoplastic Cysts

Neoplastic cysts are more common in women and in those individuals older than 40 years of age. Neoplastic cysts tend to have papillary excrescences and may have multiple loculations within the cyst. Percutaneous aspiration is rarely indicated, but if performed will typically yield mucinous fluid.

The surgical management of neoplastic cysts further relies on the initial differentiation between biliary cystadenoma and biliary cystadenocarcinoma. Biliary cystadenocarcinoma is uncommon and is associated with marked thickening of the cyst wall and vascular enhancement on axial imaging studies. Biliary cystadenomas can be either enucleated or resected as dictated by the anatomy.

BENIGN SOLID LIVER TUMORS

Benign solid liver tumors are increasingly identified with the more common use of axial imaging studies. Differentiation of benign tumors from malignancies including metastatic lesions is achieved based on the clinical scenario and interpretation of radiologic images.

Hepatic Adenoma

Hepatic adenomas (e.g., liver cell adenoma and hepatocellular adenoma) are the most significant benign liver tumors that surgeons encounter. These lesions occur in reproductive-aged women, and are an order of magnitude more common in women who use oral contraceptive pills (OCPs). Histologically, these lesions are composed of sheets of hepatocytes with no nonparenchymal cells (Kupffer cells) or bile ducts present. Up to 75 percent of adenomas may be symptomatic at the time of presentation, with abdominal pain being the most common presenting symptom. Hepatocellular adenomas are significant in that they can rupture and as many as 25 percent of these lesions are identified after an acute episode of hemorrhage.

Radiographically, it is difficult to distinguish hepatic adenomas from focal nodular hyperplasia (FNH). Both lesions demonstrate rapid contrast enhancement followed by rapid washout of contrast within the tumor on CT scan and MRI. Adenomas may demonstrate increased fat signal on MRI when compared to FNH, and do not have a central scar, which is frequently seen in FNH.

The management of patients with hepatic adenomas is evolving. Cessation of OCPs in patients with lesions less than 4 cm in diameter is prudent. Regression of the lesion is commonly seen and such a regression may obviate or facilitate liver-directed intervention. Surgical intervention is recommended in patients with lesions larger than 4 cm in diameter, in patients whose lesions do not shrink after cessation of OCP use, those who medically cannot stop OCP use, or in patients who plan to become pregnant.

Focal Nodular Hyperplasia

In contrast to hepatic adenomas, focal nodular hyperplasia typically is not associated with symptoms and does not pose any risks of rupture or malignant degeneration. Characteristically, up to two thirds of lesions will demonstrate a central scar. The lesions are often peripherally located and histologically composed of regenerative nodules with hyperplastic bile ducts and connective tissue septae.

FNH is rarely symptomatic. Therefore other etiologies for symptoms should be explored. In patients with symptoms related to FNH, resection is indicated. Because the lesions often are peripheral, minimally invasive (laparoscopic) approaches to resection should be advocated for the experienced surgeon.

Hemangiomas

Hemangiomas, also known as cavernous hemangiomas, are common benign liver lesions generally discovered incidentally on axial imaging studies. Patients with hemangiomas may present with chronic low-intensity right upper quadrant abdominal pain, especially when the lesions are quite large. Ultrasound can be helpful in identifying hemangiomas, but a CT scan or contrast-enhanced MRI are diagnostic. CT and MRI will demonstrate peripheral nodular contrast enhancement followed by gradual centripetal enhancement, and finally washout of contrast in the lesion on further delayed films. On MRI, these lesions will be bright on T2-weighted evaluation. In rare instances, hemangiomas are difficult to differentiate on MRI and are termed atypical hemangiomas. An atypical hemangioma can be further evaluated using ^{99}Tc -labeled red cell study. Angiography is rarely necessary.

As with other benign lesions, when symptoms are present other causes of abdominal pain should always be ruled out. Resection can be recommended if symptoms can be clearly ascribed to a large hemangioma. Hemangiomas can be resected by enucleation or more standard formal liver resection. Enucleation of hemangiomas follows the line of compressed liver tissue, and great care must be taken to ensure control of any biliary radicals that are opened in the process.

Bile Duct Hamartomas

Bile duct hamartomas are the most common liver lesions seen at laparotomy. Hamartomas are peripheral in location, and are firm, smooth, and white in appearance. They are less than 1 cm in size and usually only 1–3 mm in diameter. The lesions can be difficult to differentiate from miliary metastatic lesions, especially those derived from colorectal cancer and bile duct cancers. Biopsy is indicated for grossly equivocal lesions.

MALIGNANT LIVER TUMORS

Hepatocellular cancer (HCC) is one of the most common solid human cancers, with an annual incidence estimated to be approximately 1 million new patients. In addition to being a common site for the development of primary malignancy, the liver is second only to lymph nodes as a common site of metastasis from other solid cancers. It is not uncommon, particularly in patients with colorectal adenocarcinoma, for the liver to be the only site of metastatic disease. Surgical resection of HCC, colorectal cancer hepatic metastases, and carefully selected patients with liver-only metastases from other types of primary tumors can result in significant long-term survival benefit in 20–45 percent of patients.

Indications for Resection

The important role of liver resection as a treatment for colorectal cancer metastases was solidified by the report in 1988 from the Registry of Hepatic Metastases. This retrospective chart review from 24 institutions identified 859 patients who underwent resection of colorectal liver metastases between 1948 and 1985. The 5-year actuarial survival rate in these patients was 33 percent, with a 5-year actuarial disease-free survival rate of 21 percent.

The Registry of Hepatic Metastases report is a retrospective review of patients who underwent operation largely before the availability of adequate pre-operative and intraoperative imaging modalities. Furthermore, careful pathologic analysis and an accurate count of the number of lesions were not available in all of the patients. Most of the patients were identified by the development of symptoms, abnormalities in serum liver tests, or an elevated serum tumor marker in the later period of the study. The study included 509 (59 percent) patients with a solitary liver metastasis, indicating that this was a highly selected group of patients. Of the 149 patients who had three or more metastases, a breakdown of survival by number of metastases was not provided, and the actuarial 5-year survival rate for this group was 18 percent.

Recent re-evaluations of the number of metastases that should be considered for resection have demonstrated that there is a potential survival benefit in patients with four or more metastases. A study of 235 patients from Japan who underwent hepatic resection for metastatic colorectal cancer included 53 patients (22.6 percent) who had more than four metastases, including some

patients with as many as 10–15 lesions. The actuarial 10-year life expectancy of patients with four or more lesions was 29 percent, which was almost equivalent to the long-term survival of patients who underwent resection of a solitary metastasis. Patients with two or three metastases actually had a slightly worse long-term survival than patients with more than four tumors. A study from the United States of 155 patients who underwent resection of more than four colorectal liver metastases revealed an overall 5-year survival rate of 23 percent. As the number of resected metastases increased above nine, there was a significant reduction in long-term survival probability. On multivariate analysis, only positive resection margins and a large number of metastases were significant prognostic indicators for poor outcome.

The indications for resection of HCC also have been re-evaluated. Studies from the 1980s and early 1990s suggested that the presence of cirrhosis or multiple tumors were harbingers of poor outcome after resection of HCC. However, these studies were performed during a time when operative mortality rates in cirrhotic HCC patients ranged from 6–15 percent, and the need for intraoperative and postoperative blood transfusion was common. Improved outcomes have been demonstrated in more recent studies in which modern hepatic resection techniques were employed. Specifically, perioperative blood transfusion rates fell from 69–87 percent in the earlier time period to 23–39 percent in more recent series. The operative and hospital death rate was reduced from 13.2 percent to under 2 percent, and 5-year survival rates improved from 19–32 percent to 25–49 percent, despite all patients harboring pathologically proven cirrhosis.

Laparoscopic Hepatic Resection

Laparoscopy has a definite role in the diagnosis and staging of patients with gastrointestinal malignancies. A therapeutic role for laparoscopic liver resection has yet to be established. The development of endoscopic vascular staplers and the harmonic scalpel have increased interest in laparoscopic approaches to benign and malignant liver tumors, although minimally invasive liver resection has not advanced as far as laparoscopic colon, adrenal, and spleen resection. The large majority of liver resection cases completed laparoscopically have been left lateral segmentectomies, segmental or partial segmental resections, or wedge resections. Laparoscopic ultrasonography is performed to localize tumors and to mark the surface of the liver with electrocautery to ensure an adequate margin-negative resection. The parenchyma can be transected using endovascular staplers, the harmonic scalpel, or with finger fracture through a hand port using a pneumosleeve.

Repeat Hepatectomy for Recurrent Malignant Tumors

The long-term, disease-free survival rates for patients undergoing surgical resection of primary or metastatic liver tumors is usually below 40 percent in the most optimistic reports, and may be below 20 percent in others. Clearly, the majority of patients develop recurrent malignant disease after hepatic resection. In a subset of these patients, the only site of recurrence will be new tumor deposits in the liver. Yet a further subset of these patients may have undergone significant hepatic regeneration and have tumors in locations amenable to repeat liver resection.

The group of patients most frequently considered for repeat hepatectomy are those with recurrent colorectal metastases. Only 10–15 percent of patients

who develop recurrent disease after liver resection for colorectal metastases will be considered as candidates for a second or third resection. The incidence of extrahepatic disease in patients being considered for repeat hepatectomy may be as high as 30 percent; thus they should undergo thorough preoperative evaluation with state-of-the-art helical CT imaging and PET scans. Although technically challenging because of adhesions and altered vascular anatomy related to the previous hepatic resection, repeat hepatectomy can be performed with low morbidity and mortality rates.

Repeat hepatic resection also may be applied in selected patients with HCC. Intrahepatic recurrence as the only site of disease is more common in HCC patients than those with metastatic liver tumors, but the number of patients who are candidates for repeated surgical treatment is less than 10 percent of those who develop recurrent disease. Patients who develop hepatic recurrence of HCC after hepatic resection of their primary tumor may not be candidates for repeat resection because of multifocality, vascular invasion by tumor, or the severity of underlying cirrhosis. In properly selected patients, repeat hepatic resection for HCC can be performed and result in long-term survival rates of up to 30 percent.

Portal Vein Embolization

Direct tumor invasion of a lobar portal vein branch may lead to ipsilateral hepatic lobe atrophy and contralateral lobe hypertrophy. The development of compensatory hypertrophy of a lobe or segments of the liver following tumor occlusion of contralateral portal venous branches led to the concept of planned portal vein embolization (PVE) to initiate hypertrophy in segments of the liver that would remain following a major liver resection.

Indications for Portal Vein Embolization

In patients with normal hepatic parenchyma, preservation of a perfused section of liver comprising 25 percent of the total hepatic volume is usually sufficient to prevent major postoperative complications and hepatic insufficiency. This 25 percent value has been determined somewhat empirically, and there is a paucity of data regarding the exact volume of liver that can be resected safely without postoperative liver failure when the remaining liver parenchyma is completely normal. The functional capacity of liver compromised by cholestasis, acute or chronic inflammation, steatosis, or cirrhosis is variable. A larger future liver remnant is required to avoid posthepatectomy hepatic insufficiency or failure in patients with diseased hepatic parenchyma. Two recent studies suggest that at least 40 percent of the total hepatic volume should remain to minimize postoperative complications in patients who have underlying chronic liver disease or who have received high-dose chemotherapy.

Preoperative Volumetric Determination of the Future Liver Remnant

Rapid-sequence, thin-section, helical CT is used to make direct measurements of total liver volume, volume of the liver to be resected, and volume of the future liver remnant. The total liver volume also can be estimated based on the described association between body surface area (BSA) and the total liver volume, in which $\text{total liver volume} = 706.2 \times \text{BSA (in m}^2\text{)} + 2.4$. The future liver remnant volume, for example the volume of segments I, II, and III in a patient undergoing an extended right hepatectomy, can be directly measured on a helical CT, and then divided by the total estimated liver volume to calculate the

percentage of the future liver remnant. If the future liver remnant is estimated to be too small when also considering the presence or absence of chronic liver disease, PVE may be considered to increase the size of the future liver remnant.

Approach for Portal Vein Embolization

A percutaneous transhepatic approach has become the standard technique for PVE. The principal advantage of this technique is that it allows direct access to the portal venous branches of the lobe and segments to be embolized via an ipsilateral approach. This technique minimizes the risk of thrombosis of the main trunk of the portal vein and vascular injury to the portal venous branches supplying the future liver remnant. The side effects are minor and transient and include pain from the transhepatic access site and low-grade fever.

It is important to embolize not only the main right portal vein, but also the portal venous branches to segment IV if an extended right hepatic lobectomy is planned. Systematic embolization of segment IV branches is imperative for two reasons. First, all segments of the liver-bearing tumor are embolized to minimize the risk of accelerated tumor growth. Accelerated tumor growth has been reported when incomplete right trisectoral embolization has been performed. Second, embolization of segment IV portal vein branches in addition to the main right portal vein may contribute to better hypertrophy of segments I, II, and III prior to the extended right hepatic lobectomy.

Results After Portal Vein Embolization

Preoperative PVE has been used to treat primary liver malignancies, including HCC and cholangiocarcinoma, and metastatic liver tumors, particularly colorectal cancer metastases. Studies that report outcome after PVE indicate that the predicted future liver remnant volume increased from 19–36 percent of total liver volume preembolization to 31–59 percent postembolization. Complications are rare (0–10 percent) and there were no reported deaths after PVE. Not all patients who undergo PVE undergo surgery, because some patients fail to develop adequate hypertrophy, or more commonly will develop intrahepatic or extrahepatic progression of their disease in the interval between PVE and the planned resection.

Almost 250 reported extended liver resections have been performed following PVE. Perioperative mortality rates range from 0–7 percent, with no significantly higher mortality rate in cirrhotic compared to noncirrhotic patients. The reported complication rate of more than 15 percent following extended hepatic resection in patients who first underwent PVE is equivalent or better than most reports describing complication rates following this type of procedure without preoperative PVE. Unfortunately, few of the studies report long-term outcome and survival data.

RADIOFREQUENCY ABLATION

A radiofrequency (RF) needle electrode is advanced into the liver tumor to be treated via either a percutaneous, laparoscopic, or open (laparotomy) route. Using transcutaneous or intraoperative ultrasonography to guide placement, the needle electrode is advanced to the targeted area of the tumor, and then the individual wires or tines of the electrode are deployed into the tissues. Once the tines have been deployed, the needle electrode is attached to a RF generator and dispersive electrodes (return or grounding pads) are placed on the patient,

one or two on each thigh. The RF energy is then applied following an established treatment algorithm to create a zone of cellular necrosis. Tumors less than 2.5 cm in their greatest dimension can be ablated with the placement of a needle electrode with an array diameter of 3.5–4.0 cm when the electrode is positioned in the center of the tumor. Tumors larger than 2.5 cm require more than one deployment of the needle electrode. For larger tumors, multiple placements and deployments of the electrode array may be necessary to completely destroy the tumor. To mimic a surgical margin in these unresectable tumors, the needle electrode is used to produce a thermal lesion that incorporates not only the tumor, but also nonmalignant liver parenchyma in a zone 1-cm wide surrounding the tumor. Tumors in proximity to major blood vessels also may require additional probe deployment and duration of RFA, as these structures can act as heat sinks.

Indications for Radiofrequency Ablation of Liver Tumors

RF energy has been used to produce coagulative necrosis in hepatic malignancies in patients who did not meet the criteria for resectability of HCC and metastatic liver tumors, and yet were candidates for a liver-directed procedure based on the presence of disease confined to the liver. The selection of patients to be treated with RFA is based on rational principles and goals. Any local therapy for malignant hepatic tumors, be it surgical resection, RFA, or some other tumor ablative technique, is generally performed with curative intent; however, a significant proportion of patients will subsequently develop hepatic or extrahepatic recurrence from their coexistent micrometastatic disease. Occasionally, patients with tumor types usually associated with disseminated, systemic metastatic disease, such as breast or renal cancer, may be considered for RFA if they have been treated with at least 6 months of effective systemic chemotherapy, and have only liver metastasis. Thus RFA should be performed only in patients with no preoperative or intraoperative evidence of extrahepatic disease, and only for tumor histologies with a reasonable probability of disease metastatic only to the liver. The notable exception to considering RFA in patients with low-volume extrahepatic disease and multiple liver metastases is the subgroup of patients with functional endocrine syndromes from neuroendocrine tumor liver metastases, as some patients can survive years with their disease. The goal of RFA in this group is to perform a safe, palliative, rather than curative, treatment.

RFA can be used to treat patients with a solitary hepatic tumor in a location that precludes a margin-negative hepatic resection, such as a tumor nestled between the inferior vena cava and the entry of the three hepatic veins into the liver. The only area of the liver to avoid when treating a tumor with RFA is the hilar plate in which the portal vein and hepatic arterial branches enter the liver. Although these blood vessels can tolerate the heat associated with the RFA treatment, the large bile ducts coursing with them do not, and biliary fistulae or strictures are likely to occur. Lastly, RFA is ideally suited to treat small HCCs in cirrhotic patients who may not be candidates for resection based on the severity of their liver dysfunction.

When considering patients for a combined approach of liver resection of large tumors and RFA of smaller lesions in the opposite lobe, standard surgical considerations apply. Thus an adequate volume of perfused, functional hepatic parenchyma must remain to avoid postoperative liver failure. The volume of

liver that must remain varies from patient to patient, depending on the presence of normal liver versus diseased liver related to chronic hepatitis viral infection, ethanol abuse, or some other cause of chronic hepatic inflammation leading to cirrhosis. RFA does not replace standard hepatic resection in patients with resectable disease. RFA expands the population of patients who may be treated with aggressive liver-directed therapy in attempts to improve survival, quality of life, or palliation. Some patients heretofore not candidates for surgical therapy because of the presence of bilobar liver tumors now can be treated with a combination of liver resection and RFA.

Radiofrequency Ablation of Primary Liver Tumors

One hundred and ten HCC patients were followed for a minimum of 12 months after RFA; the median follow-up period was 19 months. Percutaneous or intraoperative RFA was performed in 76 (69 percent) and 34 patients (31 percent), respectively, and a total of 149 discrete HCC tumor nodules were treated with RFA. Local tumor recurrence at the RFA site developed in four patients (3.6 percent), all with tumors greater than 4.0 cm in diameter; all four subsequently developed recurrent HCC in other areas of the liver. New liver tumors or extrahepatic metastases developed in 50 patients (45.5 percent), but 56 patients (50.9 percent) had no evidence of recurrence. Clearly, a longer follow-up period is required to establish long-term, disease-free, and overall survival rates.

Procedure-related complications were minimal in patients with HCC. There were no treatment-related deaths, but complications developed in 12.7 percent of the HCC patients. The overall complication rate following RFA of HCC was low, which is particularly notable because there were 50 child class A, 31 class B, and 29 class C cirrhotic patients treated.

Radiofrequency Ablation of Metastatic Liver Tumors

Procedure-related complications were infrequent in patients with metastatic liver tumors. A few of the sites (10 percent) of intraoperative RFA expressed bleeding when the needle was withdrawn from the needle electrode track, but in all cases this was minimal (< 5 mL) and controlled easily with electrocauterization of the puncture site at the surface of the liver. Complications following RFA arose in less than 10 percent of the patients.

Local recurrence or persistence of metastatic tumors at the site of the RFA occurred in approximately 7 percent of the patients, and over 80 percent of the local recurrences developed in tumors more than 5 cm in diameter. All regions of recurrence or persistence were at the periphery of the necrotic tissue of the ablated tumors. No recurrence or persistence was noted within the center of the thermal lesions produced by RFA. New occurrences of additional hepatic or extrahepatic metastases were found in 46 percent of patients within 18 months post-RFA. The use of a combination of regional and systemic chemotherapy after RFA of colorectal cancer liver metastases to reduce recurrence and improve survival is currently under study by the authors.

The results of 109 patients with 172 metastatic hepatic lesions who underwent percutaneous RFA were described. The median follow-up period was 3 years (range 5–52 months), and local control was achieved in 121 (70 percent) of the lesions, but local recurrence developed in 51 (30 percent). Of these

51 lesions, 24 had repeat RFA and 11 (45 percent) achieved local control. A significant difference in local recurrence rates was observed when comparing lesions less than 3 cm (16 percent) to those greater than 3 cm (56 percent) in diameter. Median time to local recurrence was 16 months. There were no deaths and only one major complication (colonic perforation) after 162 RFA sessions (0.6 percent), with seven minor complications (4 percent). New metastases developed in 50 percent of the patients at a median time to recurrence of 12 months after RFA. Overall 2- and 3-year survival rates were 67 and 33 percent, respectively, with a median survival of 30 months. Thus percutaneous RFA was associated with a high incomplete treatment (local recurrence) rate because of less accurate resolution with transabdominal ultrasonography, making precise needle electrode placement to ablate the entire tumor and a surrounding rim of hepatic parenchyma more difficult.

Neuroendocrine tumors metastatic to the liver often produce symptoms secondary to excessive hormone production and release. Although only a minority of patients with neuroendocrine liver metastases may be curable by surgical techniques, significant symptomatic relief can be obtained by debulking, which may include resection combined with RFA, or RFA alone. One group reported 18 patients with 115 neuroendocrine tumors (carcinoid, islet cell, or medullary thyroid cancers) treated with RFA. The mean lesion size was 3.2 cm (range 1.3–10.0 cm), and the average number of lesions ablated per patient was six (range 1–14). Fifteen patients (83 percent) with 100 lesions were followed for a mean of 12.1 months (range 3–35 months). Local recurrence in tumors treated with RFA was detected in six lesions (6 percent) in three of these 15 patients (20 percent); three patients died of progressive metastatic disease during follow up. Although the exact number was not indicated, the authors reported that most patients had significant improvement in hormone-related symptoms following RFA.

MICROWAVE COAGULATION THERAPY FOR HEPATIC TUMORS

Background and Principles of Microwave Coagulation Therapy

The generators developed for microwave coagulation therapy (MCT) produce microwaves with a frequency of 2450 MHz and a wavelength of 12 cm. Biologically, microwaves applied to living tissues produce dielectric heat by stimulation of water molecules within the tissue and cells. The rapid agitation of water molecules within cells and tissues with direct application of microwaves produces rapid frictional heating and coagulative necrosis. The microwave generators available for clinical use have an output of 70–90 watts. The microwave-emitting needle (14–22-gauge) is placed directly into the hepatic tumor to be treated, usually using ultrasonographic guidance, then is attached to the microwave generator, the generator is activated, and each area of the tumor is treated for 30 to 60 s at 70–90 watts of power. The rapid generation of heat using MCT produces 10–25-mm zones of coagulative necrosis after only 30–60 s. The lesions can range from spherical to elliptical in shape. The rapid development of coagulative necrosis within the tissue around the MCT needle produces a tissue coagulum that inhibits further dissipation of heat into the tissue. MCT can be performed percutaneously using ultrasound or CT guidance for needle placement, or can be performed laparoscopically or

during an open surgical procedure using intraoperative ultrasound guidance to place the MCT needle.

Results of Microwave Coagulation Therapy for Treatment of Malignant Hepatic Tumors

A study of 19 patients with unresectable HCC reported that MCT was performed during laparotomy in 12 patients, laparoscopically in 5 patients, and using a thoracotomy approach in two patients with tumors at the dome of the liver. A solitary HCC tumor was treated in 13 patients, although the remaining six patients had between two and five HCC tumors treated with MCT. MCT was performed to palliate symptoms from a large tumor in 6 of the 19 patients who had additional intrahepatic or extrahepatic metastases. The mean size of the tumors treated with MCT was 21 mm (range 5–90 mm), and the mean duration of operation was 4.7 h (range 1.8–7.0 h). The reproducible and reliable zone of complete coagulative necrosis around the MCT needle electrode is only 10 mm; thus the mean number of electrode insertions to treat the HCC tumors was 46 (range 10–135). The authors report that the follow-up period in these patients ranged from 4–64 months; there were two patients treated with curative intent who were alive 47 and 64 months, respectively, after MCT, with no evidence of recurrent or new metastatic HCC. In the entire group of 19 patients, six patients had died of recurrent HCC or progressive liver failure, 10 were alive without radiographic evidence of recurrent HCC, and three were alive with evidence of new HCC metastases. The authors reported that there was no evidence of local recurrence in 28 of the 31 nodules (90 percent) treated with MCT. However, it is difficult to assess the true local recurrence rate, because most of the patients were treated with hepatic arterial chemoembolization after MCT.

There is a striking paucity of data on local recurrence rates and complications following MCT to treat HCC or other malignant liver tumors. Some authors mention that MCT should not be performed near the hepatic hilum, where major bile ducts and blood vessels are located, or near any major hepatic blood vessels, suggesting that there is experience with vascular and biliary complications related to treatment of tumors in these locations. It is unlikely that MCT will be widely applied to treat patients with unresectable malignant hepatic tumors unless modifications in equipment and treatment algorithms occur to produce larger zones of coagulative necrosis around the MCT needle.

ANATOMY

The Gallbladder

The gallbladder is a pear-shaped sac, about 7–10 cm long with an average capacity of 30–50 mL. When obstructed, the gallbladder can distend markedly and contain up to 300 mL. The same peritoneal lining that covers the liver covers the fundus and the inferior surface of the gallbladder. The gallbladder is lined by a single, highly folded, tall columnar epithelium that contains cholesterol and fat globules. The epithelial lining of the gallbladder is supported by a lamina propria. The muscle layer has circular longitudinal and oblique fibers, but without well-developed layers. The perimuscular subserosa contains connective tissue, nerves, vessels, lymphatics, and adipocytes. It is covered by the serosa except where the gallbladder is embedded in the liver. The gallbladder differs histologically from the rest of the gastrointestinal tract in that it lacks a muscularis mucosa and submucosa.

The cystic artery that supplies the gallbladder usually is a branch of the right hepatic artery (>90 percent of the time). The course of the cystic artery may vary, but it nearly always is found within the hepatocystic triangle, the area bound by the cystic duct, common hepatic duct, and the liver margin (triangle of Calot). Venous return is carried either through small veins that enter directly into the liver, or rarely to a large cystic vein that carries blood back to the portal vein. Gallbladder lymphatics drain into nodes at the neck of the gallbladder. Frequently, a visible lymph node overlies the insertion of the cystic artery into the gallbladder wall. The nerves of the gallbladder arise from the vagus and from sympathetic branches that pass through the celiac plexus.

The Bile Ducts

The extrahepatic bile ducts consist of the right and left hepatic ducts, the common hepatic duct, the cystic duct, and the common bile duct or choledochus. The common bile duct enters the second portion of the duodenum through a muscular structure, the sphincter of Oddi.

The left hepatic duct is longer than the right and has a greater propensity for dilatation as a consequence of distal obstruction. The two ducts join to form a common hepatic duct, close to their emergence from the liver. The common hepatic duct is 1–4 cm in length and has a diameter of approximately 4 mm. It lies in front of the portal vein and to the right of the hepatic artery. The common hepatic duct is joined at an acute angle by the cystic duct to form the common bile duct.

Variations of the cystic duct and its point of union with the common hepatic duct are surgically important. The segment of the cystic duct adjacent to the gallbladder neck bears a variable number of mucosal folds called the spiral valves of Heister. The common bile duct is about 7–11 cm in length and 5–10 mm in diameter. The common bile duct runs obliquely downward within

the wall of the duodenum for 1–2 cm before opening on a papilla of mucous membrane (ampulla of Vater), about 10 cm distal to the pylorus. The pancreatic duct frequently joins the common bile duct outside the duodenal wall and traverses the duodenal wall as a single duct. The sphincter of Oddi controls the flow of bile, and in some cases pancreatic juice, into the duodenum.

The extrahepatic bile ducts are lined by a columnar mucosa with numerous mucous glands in the common bile duct. A fibroareolar tissue containing scant smooth muscle cells surrounds the mucosa. The arterial supply to the bile ducts is derived from the gastroduodenal and the right hepatic arteries, with major trunks running along the medial and lateral walls of the common duct.

Anomalies

The classic description of the extrahepatic biliary tree and its arteries applies only in about one third of patients. The gallbladder may have abnormal positions, be intrahepatic, be rudimentary, have anomalous forms, or be duplicated. Isolated congenital absence of the gallbladder is rare. Duplication of the gallbladder with two separate cavities and two separate cystic ducts has an incidence of about one in every 4000 persons. A partial or totally intrahepatic gallbladder is associated with an increased incidence of cholelithiasis.

Small ducts (of Luschka) may drain directly from the liver into the body of the gallbladder. If present, but not recognized at the time of a cholecystectomy, a bile leak with the accumulation of bile (biloma) may occur in the abdomen. An accessory right hepatic duct occurs in about 5 percent of patients. Anomalies of the hepatic artery and the cystic artery are quite common, occurring in as many as 50 percent of patients.

PHYSIOLOGY

Bile Formation and Composition

The liver produces bile continuously and excretes it into the bile canaliculi. The normal adult consuming an average diet produces within the liver 500–1000 mL of bile a day. The secretion of bile is responsive to neurogenic, humoral, and chemical stimuli. With an intact sphincter of Oddi, bile flow is directed into the gallbladder.

Bile is mainly composed of water, electrolytes, bile salts, proteins, lipids, and bile pigments. Sodium, potassium, calcium, and chlorine have the same concentration in bile as in plasma or extracellular fluid. The primary bile salts, cholate and chenodeoxycholate, are synthesized in the liver from cholesterol. They are conjugated there with taurine and glycine, and act within the bile as anions (bile acids) that are balanced by sodium. Bile salts are excreted into the bile by the hepatocyte and aid in the digestion and absorption of fats in the intestines. About 95 percent of the bile acid pool is reabsorbed and returned via the portal venous system to the liver, the so-called enterohepatic circulation. Five percent is excreted in the stool, leaving the relatively small amount of bile acids to have maximum effect.

Cholesterol and phospholipids synthesized in the liver are the principal lipids found in bile. The synthesis of phospholipids and cholesterol by the liver is in part regulated by bile acids. The color of the bile is because of the presence of the pigment bilirubin diglucuronide, which is the metabolic product from the breakdown of hemoglobin, and is present in bile in concentrations 100 times

greater than in plasma. Once in the intestine, bacteria convert it into urobilinogen, a small fraction of which is absorbed and secreted into the bile.

Gallbladder Function

The gallbladder, the bile ducts, and the sphincter of Oddi act together to store and regulate the flow of bile. The main function of the gallbladder is to concentrate and store hepatic bile and to deliver bile into the duodenum in response to a meal.

Absorption and Secretion

In the fasting state, approximately 80 percent of the bile secreted by the liver is stored in the gallbladder. It rapidly absorbs sodium, chloride, and water against significant concentration gradients, concentrating the bile as much as tenfold and leading to a marked change in bile composition. The epithelial cells of the gallbladder secrete at least two important products into the gallbladder lumen: glycoproteins and hydrogen ions. The mucosal glands in the infundibulum and the neck of the gallbladder secrete mucus glycoproteins. This mucus makes up the colorless “white bile” seen in hydrops of the gallbladder resulting from cystic duct obstruction. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in the gallbladder bile pH. The acidification promotes calcium solubility, thereby preventing its precipitation as calcium salts.

Motor Activity

Gallbladder filling is facilitated by tonic contraction of the sphincter of Oddi, which creates a pressure gradient between the bile ducts and the gallbladder. In response to a meal, the gallbladder empties by a coordinated motor response of gallbladder contraction and sphincter of Oddi relaxation. One of the main stimuli to gallbladder emptying is the hormone cholecystokinin (CCK). CCK is released endogenously from the duodenal mucosa in response to a meal. When stimulated by eating, the gallbladder empties 50–70 percent of its contents within 30–40 min. Over the following 60–90 min the gallbladder gradually refills. This is correlated with a reduced CCK level.

Neurohormonal Regulation

The vagus nerve stimulates contraction of the gallbladder, and splanchnic sympathetic stimulation is inhibitory to its motor activity. Antral distention of the stomach causes both gallbladder contraction and relaxation of the sphincter of Oddi.

Hormonal receptors are located on the smooth muscles, vessels, nerves, and epithelium of the gallbladder. CCK is a peptide that comes from epithelial cells of the upper gastrointestinal tract and is found in the highest concentrations in the duodenum. CCK acts directly on smooth muscle receptors of the gallbladder and stimulates gallbladder contraction. It also relaxes the terminal bile duct, the sphincter of Oddi, and the duodenum. VIP inhibits contraction and causes gallbladder relaxation. Somatostatin and its analogues are potent inhibitors of gallbladder contraction.

Sphincter of Oddi

The sphincter of Oddi regulates flow of bile (and pancreatic juice) into the duodenum, prevents the regurgitation of duodenal contents into the biliary

tree, and diverts bile into the gallbladder. The sphincter of Oddi is about 4–6 mm in length and has a basal resting pressure of about 13 mmHg above the duodenal pressure. Relaxation occurs with a rise in CCK, allowing increased flow of bile into the duodenum.

DIAGNOSTIC STUDIES

Blood Tests

An elevated white blood cell (WBC) count may indicate or raise suspicion of cholecystitis. If associated with an elevation of conjugated bilirubin, alkaline phosphatase, and aminotransferase, cholangitis should be suspected. Cholestasis, an obstruction to bile flow, is characterized by an elevation of bilirubin and a rise in alkaline phosphatase. Serum aminotransferases may be normal or mildly elevated. In patients with biliary colic, blood tests typically will be normal.

Ultrasonography

An ultrasound is the initial investigation of any patient suspected of disease of the biliary tree. It is dependent on the skills and the experience of the operator and it is dynamic. Adjacent organs can frequently be examined at the same time. Obese patients, patients with ascites, and patients with distended bowel may be difficult to examine satisfactorily with an ultrasound.

An ultrasound will show stones in the gallbladder with sensitivity and specificity of over 90 percent. Stones are acoustically dense and reflect the ultrasound waves back to the ultrasonic transducer. Because stones block the passage of sound waves to the region behind them, they also produce an acoustic shadow. Stones also move with changes in position. Some stones form a layer in the gallbladder; others a sediment or sludge. A thickened gallbladder wall and local tenderness indicate cholecystitis. The patient has acute cholecystitis if a layer of edema is seen within the wall of the gallbladder or between the gallbladder and the liver. When a stone obstructs the neck of the gallbladder, the gallbladder may become very large, but thin walled. A contracted, thick-walled gallbladder indicates chronic cholecystitis.

The extrahepatic bile ducts also are well visualized by ultrasound, except for the retroduodenal portion. Dilation of the ducts in a patient with jaundice establishes an extrahepatic obstruction as a cause for the jaundice. Frequently the site, and sometimes the cause of obstruction, can be determined by ultrasound. Small stones in the common bile duct frequently get lodged at the distal end of it, behind the duodenum, and are therefore difficult to detect. Perampullary tumors can be difficult to diagnose on ultrasound, but beyond the retroduodenal portion, the level of obstruction and the cause may be visualized quite well. Ultrasound can be helpful in evaluating tumor invasion and flow in the portal vein, an important guideline for resectability of perampullary tumors.

Oral Cholecystography

Oral Cholecystography involves oral administration of a radiopaque compound that is absorbed, excreted by the liver, and passed into the gallbladder. Stones are noted on a film as filling defects in a visualized, opacified gallbladder. Oral cholecystography is of no value in patients with intestinal malabsorption, vomiting, obstructive jaundice, and hepatic failure.

Biliary Radionuclide Scanning (HIDA Scan)

Biliary scintigraphy provides a noninvasive evaluation of the liver, gallbladder, bile ducts, and duodenum with both anatomic and functional information. 99m-Techetium-labeled derivatives of dimethyl iminodiacetic acid (HIDA) are injected intravenously, cleared by the Kupffer cells in the liver, and excreted in the bile. Uptake by the liver is detected within 10 min, and the gallbladder, the bile ducts, and the duodenum are visualized within 60 min in fasting subjects. The primary use of biliary scintigraphy is in the diagnosis of acute cholecystitis, which appears as a nonvisualized gallbladder, with prompt filling of the common bile duct and duodenum. Filling of the gallbladder and common bile duct with delayed or absent filling of the duodenum indicates an obstruction at the ampulla. Biliary leaks as a complication of surgery of the gallbladder or the biliary tree can be confirmed and frequently localized by biliary scintigraphy.

Computed Tomography

Abdominal computed tomography (CT) scans are inferior to ultrasonography in diagnosing gallstones. CT scan is the test of choice in evaluating the patient with suspected malignancy of the gallbladder, the extrahepatic biliary system, or nearby organs, in particular the head of the pancreas. Use of CT scan is an integral part of the differential diagnosis of obstructive jaundice. Spiral CT scanning provides additional staging information, including vascular involvement in patients with periampullary tumors.

Percutaneous Transhepatic Cholangiography

An intrahepatic bile duct is accessed percutaneously with a small needle under fluoroscopic guidance. Once the position in a bile duct has been confirmed, a guidewire is passed and subsequently a catheter passed over the wire. Through the catheter, a cholangiogram can be performed and therapeutic interventions done, such as biliary drain insertions and stent placements. Percutaneous transhepatic cholangiography is particularly useful in patients with bile duct strictures and tumors, as it defines the anatomy of the biliary tree proximal to the affected segment.

Magnetic Resonance Imaging

Using magnetic resonance imaging (MRI) with newer techniques and contrast materials, accurate anatomic images can be obtained of the bile ducts and the pancreatic duct. It has a sensitivity and specificity of 95 and 89 percent, respectively, at detecting choledocholithiasis. If available, MRI with magnetic resonance cholangiopancreatography (MRCP) offers a single noninvasive test for the diagnosis of biliary tract and pancreatic disease.

Endoscopic Retrograde Cholangiography and Endoscopic Ultrasound

Using a side-viewing endoscope, the common bile duct can be cannulated and a cholangiogram performed using fluoroscopy. Endoscopic retrograde cholangiography (ERC) provides direct visualization of the ampullary region and direct access to the distal common bile duct, with the possibility of therapeutic intervention. The test rarely is needed for uncomplicated gallstone disease. Once the endoscopic cholangiogram has shown ductal stones, sphincterotomy

and stone extraction can be performed, and the common bile duct cleared of stones. In the hands of experts, the success rate of common bile duct cannulation and cholangiography is more than 90 percent. Complications of diagnostic ERC include pancreatitis and cholangitis, and occur in up to 5 percent of patients.

An endoscopic ultrasound requires a special endoscope with an ultrasound transducer at its tip. It offers noninvasive imaging of the bile ducts and adjacent structures. It is of particular value in the evaluation of tumors and their resectability. The ultrasound endoscope has a biopsy channel, allowing needle biopsies of a tumor under ultrasonic guidance.

GALLSTONE DISEASE

Prevalence and Incidence

Gallstone disease is one of the most common problems affecting the digestive tract. Autopsy reports have shown a prevalence of gallstones from 11–36 percent. Obesity, pregnancy, dietary factors, Crohn disease, terminal ileal resection, gastric surgery, hereditary spherocytosis, sickle cell disease, and thalassemia all are associated with an increased risk of developing gallstones. Women are three times more likely to develop gallstones than men, and first-degree relatives of patients with gallstones have a 2-fold greater prevalence.

Natural History

Most patients will remain asymptomatic from their gallstones throughout life. For unknown reasons some patients progress to a symptomatic stage, with biliary colic caused by a stone obstructing the cystic duct. Symptomatic gallstone disease may progress to complications related to the gallstones. Rarely, complication of gallstones is the presenting picture.

Gallstones in patients without biliary symptoms are commonly diagnosed incidentally. Approximately 3 percent of asymptomatic individuals develop biliary colic each year. Once symptomatic, patients tend to have recurring bouts of biliary colic. Complicated gallstone disease develops in 3–5 percent of symptomatic patients per year. Over a 20-year period, about two-thirds of asymptomatic patients with gallstones remain symptom free.

Since few patients develop complications without previous biliary symptoms, prophylactic cholecystectomy in asymptomatic persons with gallstones rarely is indicated. For older adult patients with diabetes, for individuals who will be isolated from medical care for extended periods of time, and in populations with increased risk of gallbladder cancer, a prophylactic cholecystectomy may be advisable. Porcelain gallbladder, a rare premalignant condition in which the wall of the gallbladder becomes calcified, is an absolute indication for cholecystectomy.

Gallstone Formation

Gallstones form as a result of solids settling out of solution. Gallstones are classified by their cholesterol content as either cholesterol stones or pigment stones. Pigment stones can be further classified as either black or brown. In Western countries, about 80 percent of gallstones are cholesterol stones and about 15–20 percent are black pigment stones. Brown pigment stones account

for only a small percentage. Both types of pigment stones are more common in Asia.

Cholesterol Stones

Pure cholesterol stones are uncommon and account for less than 10 percent of all stones. They usually occur as single large stones with smooth surfaces. Most other cholesterol stones contain variable amounts of bile pigments and calcium, but are always more than 70 percent cholesterol by weight. These stones are usually multiple, of variable size, and may be hard and faceted or irregular, mulberry-shaped and soft. Colors range from whitish yellow and green to black. Most cholesterol stones are radiolucent. Whether pure or of mixed nature, the common primary event in the formation of cholesterol stones is supersaturation of bile with cholesterol.

Pigment Stones

Pigment stones contain less than 20 percent cholesterol and are dark because of the presence of calcium bilirubinate. Otherwise, black and brown pigment stones have little in common and should be considered as separate entities.

Black pigment stones are usually small, brittle, black, and sometimes spiculated. They are formed by supersaturation of calcium bilirubinate, carbonate, and phosphate, most often secondary to hemolytic disorders such as hereditary spherocytosis and sickle cell disease, and in those with cirrhosis. Like cholesterol stones, they almost always form in the gallbladder. When altered conditions lead to increased levels of deconjugated bilirubin in bile, precipitation with calcium occurs. In Asian countries such as Japan, black stones account for a much higher percentage of gallstones than in the Western hemisphere.

Brown stones are usually less than 1 cm in diameter, brownish-yellow, soft, and often mushy. They may form either in the gallbladder or in the bile ducts, usually secondary to bacterial infection caused by bile stasis. Precipitated calcium bilirubinate and bacterial cell bodies compose the major part of the stone. Brown stones are typically found in the biliary tree of Asian populations and are associated with stasis secondary to parasite infection. In Western populations, brown stones occur as primary bile duct stones in patients with biliary strictures or other common bile duct stones that cause stasis and bacterial contamination.

Symptomatic Gallstones

Chronic Cholecystitis

About two thirds of patients with gallstone disease present with chronic cholecystitis characterized by recurrent attacks of pain, often inaccurately labeled biliary colic. The pain develops when a stone obstructs the cystic duct, resulting in a progressive increase of tension in the gallbladder wall. The pathologic changes, vary from an apparently normal gallbladder with minor chronic inflammation in the mucosa, to a shrunken, nonfunctioning gallbladder with gross transmural fibrosis and adhesions to nearby structures.

Clinical presentation. The chief symptom associated with symptomatic gallstones is pain. The pain is constant and increases in severity over the first half hour or so and typically lasts 1–5 h. It is located in the epigastrium or right upper quadrant and frequently radiates to the right upper back or between

the scapulae. The pain is severe and comes on abruptly, typically during the night or after a fatty meal. It often is associated with nausea and sometimes vomiting. The pain is episodic. The patient suffers discrete attacks of pain, between which they feel well. Physical examination may reveal mild right upper quadrant tenderness during an episode of pain. If the patient is pain free, the physical exam usually is unremarkable. Laboratory values, such as white blood cell count and liver function tests, usually are normal in patients with uncomplicated gallstones.

Atypical presentation of gallstone disease is common. In patients with atypical presentation, other conditions with upper abdominal pain should be sought out, even in the presence of gallstones. When the pain lasts more than 24 h, an impacted stone in the cystic duct or acute cholecystitis (see below) should be suspected. An impacted stone will result in what is called hydrops of the gallbladder. The bile gets absorbed, but the gallbladder epithelium continues to secrete mucus and the gallbladder becomes distended with mucinous material. Early cholecystectomy generally is indicated to avoid complications.

Diagnosis. An abdominal ultrasound is the standard diagnostic test for gallstones. Sometimes only sludge in the gallbladder is demonstrated on ultrasonography. If the patient has recurrent attacks of typical biliary pain and sludge is detected on two or more occasions, cholecystectomy is warranted. In addition to sludge and stones, cholesterosis and adenomyomatosis of the gallbladder may cause typical biliary symptoms and may be detected on ultrasonography. In symptomatic patients, cholecystectomy is the treatment of choice for patients with these conditions.

Management. Patients with symptomatic gallstones should be advised to have elective laparoscopic cholecystectomy. While waiting for surgery, or if surgery has to be postponed, the patient should be advised to avoid dietary fats and large meals. Diabetic patients with symptomatic gallstones should have a cholecystectomy promptly, as they are more prone to develop acute cholecystitis that often is severe. Pregnant women with symptomatic gallstones who cannot be managed expectantly with diet modifications can safely undergo laparoscopic cholecystectomy during the second trimester. Laparoscopic cholecystectomy is safe and effective in children and in older adults. Cholecystectomy, open or laparoscopic, for patients with symptomatic gallstones offers excellent long-term results. About 90 percent of patients with typical biliary symptoms and stones are rendered symptom free after cholecystectomy. For patients with atypical symptoms or dyspepsia (flatulence, belching, bloating, and dietary fat intolerance) the results are not as favorable.

Acute Cholecystitis

Pathogenesis. Acute cholecystitis is secondary to gallstones in 90–95 percent of cases. Acute acalculous cholecystitis is a condition that typically occurs in patients with other acute systemic diseases (see acalculous cholecystitis section, below). In less than 1 percent of acute cholecystitis, the cause is a tumor obstructing the cystic duct. Obstruction of the cystic duct by a gallstone is the initiating event that leads to gallbladder distention, inflammation, and edema of the gallbladder wall. Initially, acute cholecystitis is an inflammatory process. Secondary bacterial contamination is documented in over one half of patients undergoing early cholecystectomy for acute uncomplicated cholecystitis. In acute cholecystitis the gallbladder wall becomes grossly thickened and reddish with subserosal hemorrhages. Pericholecystic fluid often is present.

The mucosa may show hyperemia and patchy necrosis. In severe cases, about 5–10 percent, the inflammatory process progresses and leads to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged and the inflammation resolves.

When the gallbladder remains obstructed and secondary bacterial infection supervenes, an acute gangrenous cholecystitis develops and an abscess or empyema forms within the gallbladder. Rarely, perforation of ischemic areas occurs. The perforation usually is contained in the subhepatic space by the omentum and adjacent organs.

Clinical manifestations. About 80 percent of patients with acute cholecystitis give a history compatible with chronic cholecystitis. Acute cholecystitis begins as an attack of biliary colic, but in contrast to biliary colic, the pain does not subside; it is unremitting and may persist for several days. The patient often is febrile, complains of anorexia, nausea, and vomiting, and is reluctant to move, as the inflammatory process affects the parietal peritoneum. On physical exam, focal tenderness and guarding are usually present in the right upper quadrant. A mass, the gallbladder and adherent omentum, is occasionally palpable; however, guarding may prevent this. A Murphy's sign, an inspiratory arrest with deep palpation in the right subcostal area, is characteristic of acute cholecystitis.

A mild to moderate leukocytosis ($12,000\text{--}15,000$ cells/mm³) usually is present. However, some patients may have a normal WBC. Serum liver chemistries usually are normal, but a mild elevation of serum bilirubin, less than 4 mg/mL, may be present along with mild elevation of alkaline phosphatase, transaminases, and amylase. Severe jaundice is suggestive of common bile duct stones or obstruction of the bile ducts by severe pericholecystic inflammation secondary to impaction of a stone in the infundibulum of the gallbladder that mechanically obstructs the bile duct (Mirizzi syndrome). In older adult patients and in those with diabetes mellitus, acute cholecystitis may have a subtle presentation resulting in a delay in diagnosis. The incidence of complications is higher in these patients, who also have approximately tenfold the mortality rate compared to that of younger and healthier patients.

Diagnosis. Ultrasonography is the most useful radiologic test for diagnosing acute cholecystitis. It has a sensitivity and specificity of 95 percent. It will show the thickening of the gallbladder wall and the pericholecystic fluid. Focal tenderness over the gallbladder when compressed by the sonographic probe (sonographic Murphy sign) also is suggestive of acute cholecystitis. Biliary radionuclide scanning (HIDA scan) may be of help in the atypical case. A normal HIDA scan excludes acute cholecystitis. CT scan is frequently performed on patients with acute abdominal pain. It demonstrates thickening of the gallbladder wall, pericholecystic fluid, and the presence of gallstones and air in the gallbladder wall, but is less sensitive than ultrasonography.

Treatment. Patients who present with acute cholecystitis will need intravenous fluids, antibiotics, and analgesia. The antibiotics should cover Gram-negative aerobes and anaerobes. Although the inflammation in acute cholecystitis may be sterile in some patients, more than one half will have positive cultures from the gallbladder bile.

Cholecystectomy is the definitive treatment for acute cholecystitis. Early cholecystectomy performed within 2–3 days of the illness is preferred over interval or delayed cholecystectomy that is performed 6–10 weeks after initial

medical treatment and recuperation. Early cholecystectomy offers the patient a definitive solution in one hospital admission, quicker recovery times, and an earlier return to work.

Laparoscopic cholecystectomy is the procedure of choice for acute cholecystitis. The conversion rate to an open cholecystectomy is higher (10–15 percent) in the setting of acute cholecystitis than with chronic cholecystitis. The procedure is more tedious and takes longer than in the elective setting.

When patients present late, after 3–4 days of illness, or are for some reason unfit for surgery, they are treated with antibiotics with laparoscopic cholecystectomy scheduled for approximately 2 months later. Approximately 20 percent of patients will fail to respond to initial medical therapy and require an intervention. For those unfit for surgery, a percutaneous cholecystostomy or an open cholecystostomy under local analgesia can be performed. Failure to improve after cholecystostomy usually is because of gangrene of the gallbladder or perforation. For these patients, surgery is unavoidable. For those who respond after cholecystostomy, the tube can be removed once cholangiography through it shows a patent ductus cysticus. Laparoscopic cholecystectomy may then be scheduled in the near future.

Cholelithiasis

Common bile duct stones may be small or large, single or multiple, and are found in 6–12 percent of patients with stones in the gallbladder. The incidence increases with age. About 20–25 percent of patients older than the age of 60 with symptomatic gallstones have stones in the common bile duct and in the gallbladder. The vast majority of ductal stones in Western countries are formed within the gallbladder and migrate down the cystic duct to the common bile duct. These are classified as secondary common bile duct stones, in contrast to the primary stones that form in the bile ducts.

Clinical manifestations. Choledochal stones may be silent and often are discovered incidentally. They may cause obstruction, complete or incomplete, or they may manifest with cholangitis or gallstone pancreatitis. The pain caused by a stone in the bile duct is similar to that of biliary colic. Nausea and vomiting are common. Physical exam may be normal, but mild epigastric or right upper quadrant tenderness and mild icterus are common. The symptoms may also be intermittent, such as pain and transient jaundice caused by a stone that temporarily impacts the ampulla but subsequently moves away, acting as a ball valve. A small stone may pass through the ampulla spontaneously with resolution of symptoms. Finally the stones may become completely impacted, causing severe progressive jaundice. Elevation of serum bilirubin, alkaline phosphatase, and transaminases are commonly seen in patients with bile duct stones. However, in about one third of patients with common bile duct stones, the liver chemistries are normal.

Commonly the first test, ultrasonography is useful for documenting stones in the gallbladder, and determining the size of the common bile duct. As stones in the bile ducts tend to move down to the distal part of the common duct, bowel gas can preclude their demonstration on ultrasonography. A dilated common bile duct (> 8 mm in diameter) on ultrasonography in a patient with gallstones, jaundice, and biliary pain is highly suggestive of common bile duct stones. Magnetic resonance cholangiography (MRC) provides excellent anatomic detail and has a sensitivity and specificity of 95 and 89 percent, respectively, at detecting choledocholithiasis. Endoscopic cholangiography is the gold standard

for diagnosing common bile duct stones. It has the distinct advantage of providing a therapeutic option at the time of diagnosis. In experienced hands, cannulation of the ampulla of Vater and diagnostic cholangiography are achieved in over 90 percent of cases, with associated morbidity of less than 5 percent (mainly cholangitis and pancreatitis). Percutaneous transhepatic cholangiography (PTC) rarely is needed in patients with secondary common bile duct stones, but frequently is performed for both diagnostic and therapeutic reasons in patients with primary bile duct stones.

Treatment. For patients with symptomatic gallstones and suspected common bile duct stones, either preoperative endoscopic cholangiography or an intraoperative cholangiogram will document the bile duct stones. If an endoscopic cholangiogram reveals stones, sphincterotomy and ductal clearance of the stones is appropriate, followed by a laparoscopic cholecystectomy. An intraoperative cholangiogram at the time of cholecystectomy also will document the presence or absence of bile duct stones. Laparoscopic common bile duct exploration via the cystic duct or with formal choledochotomy allows the stones to be retrieved in the same setting (see following section). If the expertise and/or the instruments for laparoscopic common bile duct exploration are not available, a drain should be left adjacent to the cystic duct and the patient scheduled for endoscopic sphincterotomy the following day. An open common bile duct exploration is an option if the endoscopic method has already been tried or is for some reason not feasible. If a choledochotomy is performed, a τ tube is left in place. Stones impacted in the ampulla may be difficult for both endoscopic ductal clearance and common bile duct exploration (open or laparoscopic). In these cases the common bile duct usually is quite dilated (about 2 cm in diameter). A choledochoduodenostomy or a Roux-en-Y choledochojejunostomy may be the best option for these circumstances.

Retained or recurrent stones following cholecystectomy are best treated endoscopically. If a common bile duct exploration was performed and a τ tube left in place, a τ -tube cholangiogram is obtained prior to its removal. Retained stones can be retrieved either endoscopically or via the τ -tube tract once it has matured (2–4 weeks). Under fluoroscopic guidance the stones are retrieved with baskets or balloons. Recurrent stones may be multiple and large. A generous endoscopic sphincterotomy will allow stone retrieval and spontaneous passage of retained and recurrent stones.

Cholangitis

Cholangitis is one of the two main complications of choledochal stones, the other being gallstone pancreatitis. Acute cholangitis is an ascending bacterial infection in association with partial or complete obstruction of the bile ducts. Hepatic bile is sterile, and bile in the bile ducts is kept sterile by continuous bile flow and by the presence of antibacterial substances in bile such as immunoglobulin. The combination of both significant bacterial contamination and biliary obstruction is required for its development. Gallstones are the most common cause of obstruction in cholangitis. The most common organisms cultured from bile in patients with cholangitis include *Escherichia coli*, *Klebsiella pneumoniae*, *Streptococcus faecalis*, and *Bacteroides fragilis*.

Clinical presentation. Cholangitis may present as anything from a mild, intermittent, and self-limited disease to a fulminant, potentially life-threatening septicemia. The most common presentation is fever, epigastric or right upper quadrant pain, and jaundice. These classic symptoms, well known as Charcot

triad, are present in about two thirds of patients. The illness may progress rapidly with septicemia and disorientation, known as Reynolds pentad (e.g., fever, jaundice, right upper quadrant pain, septic shock, and mental status changes). However, the presentation may be atypical, with little if any fever, jaundice, or pain. This occurs most commonly in older adults, who may have unremarkable symptoms until they collapse with septicemia. On abdominal examination, the findings are indistinguishable from those of acute cholecystitis.

Diagnosis and management. Leukocytosis, hyperbilirubinemia, and elevation of alkaline phosphatase and transaminases are common, and when present, support the clinical diagnosis of cholangitis. Ultrasonography is helpful if the patient has not been diagnosed previously with gallstones, as it will document the presence of gallbladder stones and demonstrate dilated ducts. The definitive diagnostic test is ERC. In cases in which ERC is not available, PTC is indicated. Both ERC and PTC will show the level and the reason for the obstruction, allow culture of the bile, possibly allow the removal of stones if present, and drainage of the bile ducts with drainage catheters or stents. CT scanning and MRI will show pancreatic and periampullary masses, if present, in addition to the ductal dilatation.

The initial treatment of patients with cholangitis includes intravenous antibiotics and fluid resuscitation. Most patients will respond to these measures. However, the obstructed bile duct must be drained as soon as the patient has been stabilized. About 15 percent of patients will not respond to antibiotics and fluid resuscitation, and an emergency biliary decompression may be required. Biliary decompression may be accomplished endoscopically, via the percutaneous transhepatic route, or surgically. Patients with choledocholithiasis or periampullary malignancies are best approached endoscopically, with sphincterotomy and stone removal, or by placement of an endoscopic biliary stent. In patients in whom the obstruction is more proximal or perihilar, percutaneous transhepatic drainage is used. Where neither ERC nor PTC is possible, an emergent operation and decompression of the common bile duct with a τ tube may be necessary and life-saving. Definitive operative therapy should be deferred until the cholangitis has been treated and the proper diagnosis established. Patients with indwelling stents and cholangitis usually require repeated imaging and exchange of the stent over a guidewire.

Acute cholangitis is associated with an overall mortality rate of approximately 5 percent.

Biliary Pancreatitis

Gallstones in the common bile duct are associated with acute pancreatitis. Obstruction of the pancreatic duct by an impacted stone or temporary obstruction by a stone passing through the ampulla may lead to pancreatitis. An ultrasonogram of the biliary tree in patients with pancreatitis is essential. If gallstones are present and the pancreatitis is severe, an ERC with sphincterotomy and stone extraction may abort the episode of pancreatitis. Once the pancreatitis has subsided, the gallbladder should be removed during the same admission. When gallstones are present and the pancreatitis is mild and self-limited, the stone has probably passed. For these patients a cholecystectomy and an intraoperative cholangiogram or a preoperative ERC is indicated.

Cholangiohepatitis

Cholangiohepatitis, also known as recurrent pyogenic cholangitis, is endemic to the Orient. It also has been encountered in the Chinese population in the United States and in Europe and Australia. Cholangiohepatitis is caused by bacterial contamination (commonly *E. coli*, *Klebsiella* species, *Bacteroides* species, or *Enterococcus faecalis*) of the biliary tree, and often is associated with biliary parasites such as *Clonorchis sinensis*, *Opisthorchis viverrini*, and *Ascaris lumbricoides*. Bacterial enzymes cause deconjugation of bilirubin, which precipitates as bile sludge. The sludge and dead bacterial cell bodies form brown pigment stones. These stones are formed throughout the biliary tree and cause partial obstruction that contributes to the repeated bouts of cholangitis.

The patient usually presents with pain in the right upper quadrant and epigastrium, fever, and jaundice. Recurrence of symptoms is one of the most characteristic features of the disease. An ultrasound will detect stones in the biliary tree, pneumobilia from infection because of gas-forming organisms, liver abscesses, and occasionally strictures. MRCP and PTC are the mainstays of biliary imaging for cholangiohepatitis. The long-term goal of therapy is to extract stones and debris and relieve strictures. It may take several procedures and require a Roux-en-Y hepaticojejunostomy to establish biliary-enteric continuity.

OPERATIVE INTERVENTIONS FOR GALLSTONE DISEASE

Cholecystostomy

A cholecystostomy decompresses and drains the distended, inflamed, hydropic, or purulent gallbladder. Ultrasound guided percutaneous drainage with a pig-tail catheter is the procedure of choice. By passing the catheter through the liver, the risk of bile leak around the catheter is minimized. The catheter can be removed when the inflammation has resolved and the patient's condition improved.

Cholecystectomy

Cholecystectomy is the most common major abdominal procedure performed in Western countries. Open cholecystectomy is a safe and effective treatment for both acute and chronic cholecystitis. In 1987, laparoscopic cholecystectomy was introduced. Today laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones.

Symptomatic gallstones are the main indication for cholecystectomy. Absolute contraindications for the procedure are uncontrolled coagulopathy and end-stage liver disease. When important anatomic structures cannot be clearly identified or when no progress is made over a set period of time, a conversion to an open procedure usually is indicated. In the elective setting, conversion to an open procedure is needed in about 5 percent of patients. Emergent procedures may require more skill on the part of the surgeon, and be needed in patients with complicated gallstone disease; the incidence of conversion is 10–30 percent. Serious complications are rare. The mortality rate for laparoscopic cholecystectomy is about 0.1 percent. Wound infection and cardiopulmonary complication rates are considerably lower following laparoscopic cholecystectomy than are those for an open procedure, in which injury to the bile ducts is slightly more frequent.

Patients undergoing cholecystectomy should have a complete blood count (CBC) and liver function tests preoperatively. Prophylaxis against deep venous thrombosis with either low-molecular-weight heparin or compression stockings is indicated.

Laparoscopic Cholecystectomy

The patient is placed supine on the operating table with the surgeon standing at the patient's left side. The pneumoperitoneum is created with carbon dioxide gas, either with an open technique or by closed needle technique. Once an adequate pneumoperitoneum is established, a 10-mm trocar is inserted through the supraumbilical incision. The laparoscope with the attached video camera is passed through the umbilical port and the abdomen inspected. Three additional ports are placed under direct vision.

Through the lateral-most port a grasper is used to grasp the gallbladder fundus. The dissection starts at the junction of the gallbladder and the cystic duct. A helpful anatomic landmark is the cystic artery lymph node. The peritoneum, fat, and loose areolar tissue around the gallbladder and the cystic duct-gallbladder junction is dissected off toward the bile duct. The next step is the identification of the cystic artery, which usually runs parallel to and somewhat behind the cystic duct. A wide cystic duct may be too big for clips, requiring the placement of a pretied loop ligature to close. The cystic artery is then clipped and divided. Finally, the gallbladder is dissected out of the gallbladder fossa, using either a hook or scissors with electrocautery. The gallbladder is removed through the umbilical incision. If the gallbladder is acutely inflamed or gangrenous, or if the gallbladder is perforated, it is placed in a retrieval bag before it is removed from the abdomen. A closed suction drain can be placed through one of the 5-mm ports and left underneath the right liver lobe close to the gallbladder fossa.

Open Cholecystectomy

Open cholecystectomy has become an uncommon procedure, usually performed either as a conversion from laparoscopic cholecystectomy or as a second procedure in patients who require laparotomy for another reason. After the cystic artery and cystic duct have been identified, the gallbladder is dissected free from the liver bed, starting at the fundus. The dissection is carried proximally toward the cystic artery and the cystic duct, which are then ligated and divided.

Intraoperative Cholangiogram or Ultrasound

The bile ducts are visualized under fluoroscopy by injecting contrast through a catheter placed in the cystic duct. Routine intraoperative cholangiography will detect stones in approximately 7 percent of patients, and outlining the anatomy and detecting injury. A selective intraoperative cholangiogram can be performed when the patient has a history of abnormal liver function tests, pancreatitis, jaundice, a large duct and small stones, a dilated duct on preoperative ultrasonography, and if preoperative endoscopic cholangiography for the above reasons was unsuccessful. Laparoscopic ultrasonography is as accurate as intraoperative cholangiography in detecting common bile duct stones and it is less invasive; however, it requires more skill to perform and interpret.

Choledochal Exploration

Common bile duct stones that are detected intraoperatively on intraoperative cholangiography or ultrasonography may be managed with laparoscopic choledochal exploration as a part of the laparoscopic cholecystectomy procedure. Patients with common bile duct stones detected preoperatively, but endoscopic clearance was either not available or unsuccessful, should also have their ductal stones managed during the cholecystectomy.

If the stones in the duct are small, they may sometimes be flushed into the duodenum with saline irrigation via the cholangiography catheter after the sphincter of Oddi has been relaxed with glucagon. By managing common bile duct stones at the time of the cholecystectomy, the patients can have all of their gallstone disease treated with one invasive procedure. It does, however, depend on the available surgical expertise.

Choledochal Drainage Procedures

Rarely, when the stones cannot be cleared and/or when the duct is very dilated (larger than 1.5 cm in diameter), a choledochal drainage procedure is performed.

Transduodenal Sphincterotomy

In the majority of cases, endoscopic sphincterotomy has replaced open transduodenal sphincterotomy. If an open procedure for common bile duct stones is being done in which the stones are impacted, recurrent, or multiple, the transduodenal approach may be feasible. The duodenum is incised transversely. The sphincter then is incised at the 11 o'clock position to avoid injury to the pancreatic duct. The impacted stones are removed as are large stones from the duct.

OTHER BENIGN DISEASES AND LESIONS

Acalculous Cholecystitis

Acute inflammation of the gallbladder can occur without gallstones. Acalculous cholecystitis typically develops in critically ill patients in the intensive care unit. The cause is unknown, but gallbladder distention with bile stasis and ischemia have been implicated as causative factors.

The symptoms and signs depend on the condition of the patient, but in the alert patient they are similar to acute calculous cholecystitis. In the sedated or unconscious patient the clinical features often are masked, but fever and elevated white blood cell count, and elevation of alkaline phosphatase and bilirubin are indications for further investigation.

Ultrasonography is usually the diagnostic test of choice. Abdominal CT scan is as sensitive as ultrasonography and additionally allows imaging of the abdominal cavity and chest. A HIDA scan will not visualize the gallbladder. Acalculous cholecystitis requires urgent intervention. Percutaneous ultrasound- or CT-guided cholecystostomy is the treatment of choice for these patients, as they usually are unfit for surgery. About 90 percent of patients will improve with the percutaneous cholecystostomy. However, if they do not improve, other steps, such as open cholecystostomy or cholecystectomy, may be required.

Biliary Cysts

Choledochal cysts are congenital cystic dilatations of the extrahepatic and/or intrahepatic biliary tree. They are rare—the incidence is between 1:100,000 and 1:150,000. Choledochal cysts affect females three to eight times more often than males. Although frequently diagnosed in infancy or childhood, as many as one half of the patients have reached adulthood when diagnosed. The cause is unknown. Choledochal cysts are classified into five types. The cysts are lined with cuboidal epithelium and can vary in size from 2 cm in diameter to giant cysts.

Adults commonly present with jaundice or cholangitis. Less than one half of patients present with the classic clinical triad of abdominal pain, jaundice, and a mass. Ultrasonography or CT scanning will confirm the diagnosis, but endoscopic, transhepatic, or MRC is required to assess the biliary anatomy and to plan the appropriate surgical treatment. For types I, II, and IV, excision of the extrahepatic biliary tree, including cholecystectomy, with a Roux-en-Y hepaticojejunostomy are ideal. In type IV, additional segmental resection of the liver may be appropriate, particularly if intrahepatic stones, strictures, or abscesses are present, or if the dilatations are confined to one lobe. The risk of cholangiocarcinoma developing in choledochal cysts is as high as 15 percent in adults, and supports complete excision when they are diagnosed. For type III, sphincterotomy is recommended.

Sclerosing Cholangitis

Sclerosing cholangitis is an uncommon disease characterized by inflammatory strictures involving the intrahepatic and extrahepatic biliary tree. It is a progressive disease that eventually results in secondary biliary cirrhosis. Sometimes, biliary strictures are clearly secondary to bile duct stones, acute cholangitis, previous biliary surgery, or toxic agents, and are termed secondary sclerosing cholangitis. However, primary sclerosing cholangitis is a disease entity of its own, with no known attributing cause. It is associated with ulcerative colitis in about two thirds of patients. Other diseases associated with sclerosing cholangitis include Riedel thyroiditis and retroperitoneal fibrosis. Patients with sclerosing cholangitis are at risk for developing cholangiocarcinoma. Eventually 10–20 percent of the patients will develop cancer.

The mean age of presentation is 30–45 years and men are affected twice as commonly as women. The usual presentation is intermittent jaundice, fatigue, weight loss, pruritus, and abdominal pain. In several patients with ulcerative colitis, abnormal liver function tests found on routine testing lead to the diagnosis. The clinical course in sclerosing cholangitis is highly variable, but cyclic remissions and exacerbations are typical. However, some patients remain asymptomatic for years, although others progress rapidly with the obliterative inflammatory changes leading to secondary biliary cirrhosis and liver failure. The median survival for patients with primary sclerosing cholangitis from the time of diagnosis ranges from 10 to 12 years, and most die from hepatic failure.

The clinical presentation and elevation of alkaline phosphatase and bilirubin may suggest the diagnosis, but ERC, revealing multiple dilatations and strictures (beading) of both the intra- and extrahepatic biliary tree confirms it. The hepatic duct bifurcation is often the most severely affected segment. Sclerosing cholangitis is followed by ERC and liver biopsies to provide appropriate management.

There is no known effective medical therapy for primary sclerosing cholangitis and no known curative treatment. Corticosteroids, immunosuppressants, ursodeoxycholic acid, and antibiotics have been disappointing. Biliary strictures can be dilated and stented either endoscopically or percutaneously. Surgical management with resection of the extrahepatic biliary tree and hepaticojejunostomy has produced reasonable results in patients with extrahepatic and bifurcation strictures. In patients with sclerosing cholangitis and advanced liver disease, liver transplantation is the only option. It offers excellent results with overall 5-year survival as high as 85 percent. Primary sclerosing cholangitis recurs in 10–20 percent of patients and may require retransplantation.

Stenosis of the Sphincter of Oddi

A benign stenosis of the outlet of the common bile duct usually is associated with inflammation, fibrosis, or muscular hypertrophy. Episodic pain of the biliary type with abnormal liver function tests is a common presentation. However, recurrent jaundice or pancreatitis also may play a role. A dilated common bile duct that is difficult to cannulate with delayed emptying of the contrast are useful diagnostic features. If the diagnosis is well established, endoscopic or operative sphincterotomy will yield good results.

Bile Duct Strictures

Benign bile duct strictures can have numerous causes. However, the vast majority are caused by operative injury, most commonly by laparoscopic cholecystectomy (see below). Other causes include fibrosis because of chronic pancreatitis, common bile duct stones, acute cholangitis, biliary obstruction because of cholecystolithiasis (Mirizzi syndrome), sclerosing cholangitis, cholangiohepatitis, and strictures of a biliary-enteric anastomosis. Bile duct strictures that go unrecognized or are improperly managed may lead to recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension.

Patients with bile duct strictures most commonly present with episodes of cholangitis. An ultrasound or a CT scan will show dilated bile ducts proximal to the stricture, and provide some information about the level of the stenosis. MRC will also provide good anatomic information about the location and the degree of dilatation. In patients with intrahepatic ductal dilatation, a percutaneous transhepatic cholangiogram will outline the proximal biliary tree, define the stricture and its location, and allow decompression of the biliary tree with transhepatic catheters or stents. An endoscopic cholangiogram will outline the distal bile duct. Percutaneous or endoscopic dilatation and/or stent placement give good results in more than one half of patients. Surgery with Roux-en-Y choledochojejunostomy or hepaticojejunostomy is the standard of care with good or excellent results in 80–90 percent of patients. Choledochoduodenostomy may be a choice for strictures in the distal-most part of the common bile duct.

INJURY TO THE BILIARY TRACT

The Gallbladder

Injuries to the gallbladder are uncommon. Penetrating injuries usually are caused by gunshot wounds or stab wounds, and rarely by a needle biopsy procedure of the liver. The treatment of choice is cholecystectomy and the prognosis is directly related to the type and incidence of associated injury.

The Extrahepatic Bile Ducts

Penetrating trauma to the extrahepatic bile ducts is rare and usually is associated with trauma to other viscera. The great majority of injuries of the extrahepatic biliary duct system are iatrogenic, occurring in the course of laparoscopic or open cholecystectomies. The exact incidence of bile duct injury during cholecystectomy is unknown, but data suggest that during open cholecystectomy the incidence is relatively low (about 0.1–0.2 percent). However, the incidence during laparoscopic cholecystectomy, as derived from state and national databases, estimates the rate of major injury to be about 0.55 percent, and the incidence of minor injuries and bile leaks to be about 0.3 percent, a total of 0.85 percent.

Factors associated with bile duct injury include acute or chronic inflammation, obesity, anatomic variations, and bleeding. Surgical technique with inadequate exposure and failure to identify structures before ligating or dividing them are the most common cause of significant biliary injury. The bile ducts may be narrow and can be mistaken for the cystic duct. The cystic duct may run along side the common bile duct before joining it, leading the surgeon to the wrong place. Additionally, the cystic duct may enter the right hepatic duct, and the right hepatic duct may run aberrantly, coursing through the triangle of Calot and entering the common hepatic duct. Intraoperative technical factors implicated in biliary injuries include excessive cephalad retraction of the gallbladder, the use of an end-viewing laparoscope instead of an angled one, careless use of electrocautery, dissection deep into the liver parenchyma and poor clip placement.

The routine use of intraoperative cholangiography to prevent bile duct injury is controversial. If a bile duct injury is suspected during cholecystectomy, a cholangiogram must be obtained to identify the anatomic features.

Diagnosis

Only about 25 percent of major bile duct injuries (common bile duct or hepatic duct) are recognized at the time of operation. Most commonly, intraoperative bile leakage, recognition of the correct anatomy, and an abnormal cholangiogram lead to the diagnosis of a bile duct injury. Within the first postoperative month more than half of patients with injury have presented. The remainder present months or years later. Bile leak, most commonly from the cystic duct stump, a transected aberrant right hepatic duct, or a lateral injury to the main bile duct usually presents with pain, fever, and a mild elevation of liver function tests. A CT scan or an ultrasound will show either a collection (biloma) in the gallbladder area or free fluid (bile) in the peritoneum. Biliious drainage through operatively placed drains or through the wounds is abnormal. An active leak and the site of the bile leak can be confirmed noninvasively with a HIDA scan. CT scan and ultrasound also are important in the initial evaluation of the jaundiced patient, as they can demonstrate the dilated part of the biliary tree proximal to the stenosis or obstruction, and may identify the level of the extrahepatic bile duct obstruction. In the jaundiced patient with dilated intrahepatic ducts, a percutaneous cholangiogram will outline the anatomy and the proximal extent of the injury and allow decompression of the biliary tree with catheter or stent placements. An endoscopic cholangiogram demonstrates the anatomy distal to the injury and may allow the placement of stents across a stricture to relieve an obstruction. MRI cholangiography, if available, provides an excellent,

noninvasive delineation of the biliary anatomy both proximal and distal to the injury.

Management

Initial proper treatment of bile duct injury diagnosed during the cholecystectomy can avoid the development of a bile duct stricture. If a major injury is discovered and an experienced biliary surgeon is not available, an external drain and, if necessary, transhepatic biliary catheters, are placed and the patient is transferred to a referral center.

Transected bile ducts smaller than 3 mm or those draining a single hepatic segment can safely be ligated. If the injured duct is 4 mm or larger, it is likely to drain multiple segments or an entire lobe, and thus needs to be reimplanted. Lateral injury to the common bile duct or the common hepatic duct, recognized at the time of surgery, is best managed with a τ -tube placement. If the injury is a small incision in the duct, the τ tube may be placed through it as if it were a formal choledochotomy. In more extensive lateral injuries the τ tube should be placed through a separate choledochotomy and the injury closed over the τ tube end to minimize the risk of subsequent stricture formation.

Major bile duct injuries such as transection of the common hepatic or common bile duct are best managed at the time of injury. In many of these major injuries the bile duct has not only been transected, but a variable length of the duct removed. This injury usually requires a biliary enteric anastomosis with a jejunal loop. Transhepatic biliary catheters are placed through the anastomosis to stent it and to provide access to the biliary tract for drainage and imaging. Although rare, when the injury is to the distal common bile duct, a choledochoduodenostomy can be performed. If there is no or minimal loss of ductal length, a duct-to-duct repair may be done over a τ tube that is placed through a separate incision. Cystic duct leaks usually can be managed with percutaneous drainage of intraabdominal fluid collections followed by an endoscopic biliary stenting.

Major injuries diagnosed postoperatively require transhepatic biliary catheter placement for biliary decompression and percutaneous drainage of intraabdominal bile collections, if any. When the acute inflammation has resolved 6–8 weeks later, operative repair is performed.

Patients with bile duct stricture from an injury or as a sequela of previous repair usually present with either progressive elevation of liver function tests or cholangitis. The initial management usually includes transhepatic biliary drainage catheter placement for decompression and for defining the anatomy and the location and the extent of the damage. An anastomosis is performed between the duct proximal to the injury and a Roux loop of jejunum. Self-expanding metal or plastic stents, placed either percutaneously or endoscopically across the stricture, can provide temporary drainage, and in the high-risk patient, permanent drainage of the biliary tree.

Outcome

Good results can be expected in 70 to 90 percent of patients with bile duct injuries. The best results are obtained when the injury is recognized during the cholecystectomy and repaired by an experienced biliary tract surgeon. The operative mortality rate is about 5–8 percent. Restenosis of a biliary enteric anastomosis occurs in about 10 percent of patients, and may manifest up to 20 years after the initial procedure. Approximately two thirds of recurrent strictures become symptomatic within 2 years after repair. The more proximal

strictures are associated with a lower success rate than are distal ones. Patients with deteriorating liver function are candidates for liver transplants.

TUMORS

Carcinoma of the Gallbladder

Cancer of the gallbladder is a rare malignancy that occurs predominantly in older adults. It is an aggressive tumor, with poor prognosis except when incidentally diagnosed at an early stage after cholecystectomy for cholelithiasis. The overall reported 5-year survival rate is about 5 percent.

Incidence

Gallbladder cancer is the fifth most common gastrointestinal malignancy in Western countries. However, it accounts for only 2–4 percent of all malignant gastrointestinal tumors. It is two to three times more common in females than males, and the peak incidence is in the seventh decade of life. Approximately 1 percent of patients undergoing cholecystectomy for gallstone disease are found incidentally to have gallbladder cancer. The incidence of gallbladder cancer is particularly high in native populations of the United States, Mexico, and Chile. The annual incidence in Native American females with gallstones approaches 75 per 100,000, compared with the overall incidence of gallbladder cancer of 2.5 cases per 100,000 residents in the United States.

Etiology

Approximately 90 percent of patients with carcinoma of the gallbladder have gallstones. However, the 20-year risk of developing cancer for patients with gallstones is less than 0.5 percent for the overall population and 1.5 percent for high-risk groups. Polypoid lesions of the gallbladder are associated with increased risk of cancer, particularly in polyps larger than 10 mm. The calcified “porcelain” gallbladder is associated with more than a 20 percent incidence of gallbladder carcinoma. These gallbladders should be removed, even if the patients are asymptomatic.

Pathology

Between 80 and 90 percent of the tumors are adenocarcinomas. The histologic subtypes of gallbladder adenocarcinomas include papillary, nodular, and tubular. Cancer of the gallbladder spreads through the lymphatics, with venous drainage, and with direct invasion into the liver parenchyma. Lymphatic flow from the gallbladder drains first to the cystic duct node (Calot), then the pericholedochal and hilar nodes. The gallbladder veins drain directly into the adjacent liver, usually segments IV and V, although tumor invasion is common. When diagnosed, about 25 percent of gallbladder cancers are localized to the gallbladder wall, 35 percent have regional nodal involvement and/or extension into adjacent liver, and approximately 40 percent have distant metastasis.

Clinical Manifestations and Diagnosis

Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis. These include abdominal discomfort, right upper quadrant pain, nausea, and vomiting. Jaundice, weight loss, anorexia, ascites, and abdominal mass are less common presenting symptoms. More than one-half of gallbladder cancers are

not diagnosed before surgery. Ultrasonography often reveals a thickened, irregular gallbladder wall or a mass replacing the gallbladder. Ultrasonography may visualize tumor invasion of the liver, lymphadenopathy, and a dilated biliary tree. The sensitivity of ultrasonography in detecting gallbladder cancer ranges from 70–100 percent. CT scan may demonstrate a gallbladder mass or an invasion into adjacent organs. Additionally, a spiral CT scan demonstrates the vascular anatomy. MRCP has evolved into a single noninvasive imaging method that allows complete assessment of biliary, vascular, nodal, hepatic, and adjacent organ involvement. If diagnostic studies suggest that the tumor is unresectable, a CT scan or ultrasound-guided biopsy of the tumor can be obtained.

Treatment

Surgery remains the only curative option for gallbladder cancer and for cholangiocarcinoma. However, palliative procedures for patients with unresectable cancer and jaundice or duodenal obstruction remain the most frequently performed surgery for gallbladder cancers. Today, patients with obstructive jaundice can frequently be managed with either endoscopic or percutaneously placed biliary stents. There are no proven effective options for adjuvant radiation or chemotherapy for patients with gallbladder cancer.

Patients without evidence of distant metastasis warrant exploration for tissue diagnosis, pathologic staging, and possible curative resection.

Tumors limited to the muscular layer of the gallbladder (T1), usually are identified incidentally, after cholecystectomy for gallstone disease. There is near-universal agreement that simple cholecystectomy is an adequate treatment for T1 lesions and results in a near 100 percent overall 5-year survival rate. When the tumor invades the perimuscular connective tissue without extension beyond the serosa or into the liver (T2 tumors), an extended cholecystectomy should be performed. That includes resection of liver segments IVB and V, and lymphadenectomy of the cystic duct, and pericholedochal, portal, right celiac, and posterior pancreatoduodenal lymph nodes. One half of patients with T2 tumors are found to have nodal disease on pathologic examination. For tumors that grow beyond the serosa or invade the liver or other organs (T3 and T4 tumors), there is a high likelihood of intraperitoneal and distant spread. If no peritoneal or nodal involvement is found, complete tumor excision with an extended right hepatectomy (segments IV, V, VI, VII, and VIII) must be performed for adequate tumor clearance. An aggressive approach in patients who will tolerate surgery has resulted in an increased survival for T3 and T4 lesions.

Prognosis

Most patients with gallbladder cancer have unresectable disease at the time of diagnosis. The 5-year survival rate of all patients with gallbladder cancer is less than 5 percent, with a median survival of 6 months. Patients with T1 disease treated with cholecystectomy have an excellent prognosis (85–100 percent 5-year survival rate). The 5-year survival rate for T2 lesions treated with an extended cholecystectomy and lymphadenectomy compared with simple cholecystectomy is over 70 percent versus 25–40 percent, respectively. The median survival for patients with distant metastasis at the time of presentation is only 1–3 months.

Recurrence after resection of gallbladder cancer occurs most commonly in the liver or the celiac or retropancreatic nodes. The prognosis for recurrent

disease is very poor. Death occurs most commonly secondary to biliary sepsis or liver failure.

Bile Duct Carcinoma

Cholangiocarcinoma is a rare tumor arising from the biliary epithelium and may occur anywhere along the biliary tree. About two-thirds are located at the hepatic duct bifurcation. Surgical resection offers the only chance for cure, however, many patients have advanced disease at the time of diagnosis. Therefore palliative procedures aimed to provide biliary drainage to prevent liver failure and cholangitis are often the only therapeutic possibilities. Most patients with unresectable disease die within a year of diagnosis.

Incidence

The autopsy incidence of bile duct carcinoma is about 0.3 percent. The overall incidence of cholangiocarcinoma in the United States is about 1.0 per 100,000 people per year.

Etiology

Risk factors associated with cholangiocarcinoma include primary sclerosing cholangitis, choledochal cysts, ulcerative colitis, hepatolithiasis, biliary-enteric anastomosis, and biliary tract infections with *Clonorchis* or in chronic typhoid carriers.

Pathology

Over 95 percent of bile duct cancers are adenocarcinomas. Morphologically they are divided into nodular (the most common type), scirrhous, diffusely infiltrating, or papillary. Anatomically they are divided into distal, proximal, or perihilar tumors. Intrahepatic cholangiocarcinomas occur, but they are treated like hepatocellular carcinoma, with hepatectomy when possible. About two thirds of cholangiocarcinomas are located in the perihilar location. Perihilar cholangiocarcinomas, also referred to as Klatskin tumors, are further classified based on anatomic location by the Bismuth-Corlette classification.

Clinical Manifestations and Diagnosis

Painless jaundice is the most common presentation. Pruritus, mild right upper quadrant pain, anorexia, fatigue, and weight loss also may be present.

The initial tests are usually ultrasound or CT scan. A perihilar tumor causes dilatation of the intrahepatic biliary tree, but normal or collapsed gallbladder and extrahepatic bile ducts distal to the tumor. Distal bile duct cancer leads to dilatation of the extra- and the intrahepatic bile ducts and the gallbladder. Ultrasound can establish the level of obstruction and rule out the presence of bile duct stones as the cause of the obstructive jaundice. The biliary anatomy is defined by cholangiography. PTC defines the proximal extent of the tumor, which is the most important factor in determining resectability. ERC is used, particularly in the evaluation of distal bile duct tumors. MRI, a single noninvasive test, has the potential of evaluating the biliary anatomy, lymph nodes, and vascular involvement, and the tumor growth itself.

Tissue diagnosis may be difficult to obtain nonoperatively except in advanced cases. Patients with potentially resectable disease should therefore be offered surgical exploration based on radiographic findings and clinical suspicion.

Treatment

Surgical excision is the only potentially curative treatment for cholangiocarcinoma. Patients should undergo surgical exploration if they have no signs of metastasis or locally unresectable disease. However, more than one half of the patients who are explored are found to have peritoneal implants, nodal or hepatic metastasis, or locally advanced disease that precludes resection. For these patients surgical bypass for biliary decompression and cholecystectomy to prevent the occurrence of acute cholecystitis should be performed.

For unresectable perihilar cholangiocarcinoma, Roux-en-Y choledochojejunostomy to either segment II or III bile ducts or to the right hepatic duct can be performed.

For curative resection, the location and local extension of the tumor dictates the extent of the resection. Perihilar tumors involving the bifurcation or proximal common hepatic duct (Bismuth-Corlette type I or II) with no signs of vascular involvement are candidates for local tumor excision with portal lymphadenectomy, cholecystectomy, common bile duct excision, and bilateral Roux-en-Y hepaticojejunostomies. If the tumor involves the right or left hepatic duct (Bismuth-Corlette type IIIa or IIIb), right or left hepatic lobectomy, respectively, should also be performed. Distal bile duct tumors more often are resectable. They are treated with pylorus-preserving pancreatoduodenectomy (Whipple procedure). For patients with distal bile duct cancer found to be unresectable on surgical exploration, Roux-en-Y hepaticojejunostomy, cholecystectomy, and gastrojejunostomy to prevent gastric outlet obstruction should be performed.

Nonoperative biliary decompression is performed for patients with unresectable disease on diagnostic evaluation. Percutaneous placement of expandable metal stents or drainage catheters is usually the appropriate approach for proximal tumors. However, for distal bile duct tumors, endoscopic placement is often the preferred approach. There is no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. Adjuvant radiation therapy also has not been shown to increase either quality of life or survival in resected patients.

Prognosis

Most patients with perihilar cholangiocarcinoma present with advanced, unresectable disease. Patients with unresectable disease have a median survival between 5 and 8 months. The most common causes of death are hepatic failure and cholangitis. The overall 5-year survival rate for patients with resectable perihilar cholangiocarcinoma is between 10 and 30 percent, but for patients with negative margins it may be as high as 40 percent. The operative mortality for perihilar cholangiocarcinoma is 6–8 percent. The overall 5-year survival rate for patients with distal cholangiocarcinoma is 30–50 percent, and the median survival is 32–38 months.

ANATOMY AND PHYSIOLOGY

Situated deep in the center of the abdomen, the pancreas is surrounded by numerous important structures and major blood vessels. Surgeons typically describe the location of pathology within the pancreas in relation to four regions: the head, neck, body, and tail. The neck of the pancreas lies directly over the portal vein. At the inferior border of the neck of the pancreas, the superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The common bile duct runs in a deep groove on the posterior aspect of the pancreatic head until it passes through the pancreatic parenchyma to join the main pancreatic duct at the ampulla of Vater. The body and tail of the pancreas lie just anterior to the splenic artery and vein.

Pancreatic Duct Anatomy

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion of a ventral and dorsal bud. The duct from the smaller ventral bud, which arises from the hepatic diverticulum, connects directly to the common bile duct. The duct from the larger dorsal bud, which arises from the duodenum, drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, although the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct, into the common channel formed from the bile duct and pancreatic duct. The length of the common channel is variable. In about one third of patients the two ducts remain distinct to the end of the papilla, the two ducts merge at the end of the papilla in another one third, and in the remaining one-third a true common channel is present for a distance of several millimeters. Commonly, the duct from the dorsal anlage, the duct of Santorini, persists as the lesser pancreatic duct, and sometimes drains directly into the duodenum through the lesser papilla just proximal to the major papilla. In approximately 30 percent of patients, the duct of Santorini ends as a blind accessory duct and does not empty into the duodenum. In 10 percent of patients, the ducts of Wirsung and Santorini fail to fuse. This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, although the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as pancreas divisum. In a minority of these patients, the minor papilla can be inadequate to handle the flow of pancreatic juices from the majority of the gland. This relative outflow obstruction can

result in pancreatitis and is sometimes treated by sphincteroplasty of the minor papilla.

Vascular and Lymphatic Anatomy

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries. The common hepatic artery gives rise to the gastroduodenal artery before continuing toward the porta hepatis as the proper hepatic artery. The gastroduodenal artery becomes the superior pancreaticoduodenal artery as it passes behind the first portion of the duodenum and branches into the anterior and posterior superior pancreaticoduodenal arteries. As the superior mesenteric artery passes behind the neck of the pancreas, it gives off the inferior pancreaticoduodenal artery at the inferior margin of the neck of the pancreas. This vessel quickly divides into the anterior and posterior inferior pancreaticoduodenal arteries. The superior and inferior pancreaticoduodenal arteries join together within the parenchyma of the anterior and posterior sides of the head of the pancreas along the medial aspect of the C-loop of the duodenum to form arcades that give off numerous branches to the duodenum and head of the pancreas. Therefore it is impossible to resect the head of the pancreas without devascularizing the duodenum, unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, common hepatic artery, or gastroduodenal arteries can arise from the superior mesenteric artery. In 15–20 percent of patients, the right hepatic artery will arise from the superior mesenteric artery and travel upwards toward the liver along the posterior aspect of the head of the pancreas (referred to as a “replaced right hepatic artery”). During the Whipple procedure, it is important to look for this variation so the hepatic artery is recognized and injury is avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery arises from the superior mesenteric artery and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery. Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas, and account for the rich blood supply of the organ. The venous drainage of the pancreas follows a pattern similar to that of the arterial supply. The lymphatic drainage from the pancreas is diffuse and widespread and this contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection.

Neuroanatomy

The pancreas is innervated by the sympathetic and parasympathetic nervous systems. The parasympathetic system stimulates endocrine and exocrine secretion and the sympathetic system inhibits secretion. The pancreas also has a rich supply of afferent sensory fibers, which are responsible for the intense pain associated with advanced pancreatic cancer, and acute and chronic pancreatitis. These somatic fibers travel superiorly to the celiac ganglia. Interruption of these somatic fibers can stop transmission of pain sensation.

HISTOLOGY AND PHYSIOLOGY

The exocrine pancreas accounts for about 85 percent of the pancreatic mass; 10 percent of the gland is accounted for by extracellular matrix, and 4 percent by blood vessels and the major ducts, whereas only 2 percent of the gland is comprised of endocrine tissue. The endocrine and exocrine pancreas are sometimes thought of as functionally separate, but these different components of the organ are coordinated to allow an elegant regulatory feedback system for digestive enzyme and hormone secretion.

Exocrine Pancreas

The pancreas secretes approximately 500–800 mL per day of colorless, odorless, alkaline, isosmotic pancreatic juice. Pancreatic juice is a combination of acinar cell and duct cell secretions. The acinar cells secrete amylase, proteases and lipases, enzymes responsible for the digestion of all three food types: carbohydrate, protein, and fat. The acinar cells are pyramid-shaped, with their apices facing the lumen of the acinus. Near the apex of each cell are numerous enzyme-containing zymogen granules which fuse with the apical cell membrane.

Amylase is the only pancreatic enzyme secreted in its active form, and it hydrolyzes starch and glycogen to glucose, maltose, maltotriose, and dextrins. These simple sugars are transported across the brush border of the intestinal epithelial cells by active transport mechanisms. The proteolytic enzymes are secreted as proenzymes that require activation. Trypsinogen is converted to its active form, trypsin, by another enzyme, enterokinase, which is produced by the duodenal mucosal cells. Trypsin in turn activates the other proteolytic enzymes. Chymotrypsinogen is activated to form chymotrypsin. Elastase, carboxypeptidase A and B, and phospholipase also are activated by trypsin. Trypsin, chymotrypsin, and elastase cleave bonds between amino acids within a target peptide chain, and carboxypeptidase A and B cleave amino acids at the end of peptide chains. Individual amino acids and small dipeptides are then actively transported into the intestinal epithelial cells. Pancreatic lipase hydrolyzes triglycerides to 2-monoglyceride and fatty acid. Pancreatic lipase is secreted in an active form. Colipase also is secreted by the pancreas and binds to lipase, changing its molecular configuration and increasing its activity. Phospholipase A2 is secreted by the pancreas as a proenzyme which becomes activated by trypsin. Phospholipase A2 hydrolyzes phospholipids, and as with all lipases, requires bile salts for its action. Carboxylic ester hydrolase and cholesterol esterase hydrolyze neutral lipid substrates like esters of cholesterol, fat-soluble vitamins, and triglycerides. The hydrolyzed fat is then packaged into micelles for transport into the intestinal epithelial cells, in which the fatty acids are reassembled and packaged inside chylomicrons for transport through the lymphatic system into the bloodstream. The centroacinar and intercalated duct cells secrete the water and electrolytes present in the pancreatic juice.

Endocrine Pancreas

There are nearly one million islets of Langerhans in the normal adult pancreas. They vary greatly in size from 40–900 μm . Most islets contain 3000–4000 cells of four major types: alpha cells which secrete glucagon, beta cells which secrete insulin, delta cells which secrete somatostatin, and pancreatic polypeptide (PP) cells, which secrete pancreatic polypeptide.

There are two phases of insulin secretion. In the first phase, stored insulin is released. This phase lasts about 5 min after a glucose challenge. The second phase of insulin secretion is a longer, sustained release because of ongoing production of new insulin. Insulin's function is to inhibit endogenous (hepatic) glucose production and to facilitate glucose transport into cells, thus lowering plasma glucose levels. Insulin also inhibits glycogenolysis, fatty acid breakdown and ketone formation, and stimulates protein synthesis. If the remaining portion of the pancreas is healthy, about 80 percent of the pancreas can be resected without the patient becoming diabetic. In patients with chronic pancreatitis, or other conditions in which much of the gland is diseased, resection of a smaller fraction of the pancreas can result in diabetes.

Glucagon promotes hepatic glycogenolysis and gluconeogenesis and counteracts the effects of insulin through its hyperglycemic action. Somatostatin inhibits endocrine and exocrine secretion and affects neurotransmission, gastrointestinal and biliary motility, intestinal absorption, vascular tone and cell proliferation. Pancreatic polypeptide is known to inhibit bile secretion, gallbladder contraction, and secretion by the exocrine pancreas. A number of studies suggest that PPs most important role is in glucose regulation through its regulation of hepatic insulin receptor gene expression. Deficiencies in PP secretion because of proximal pancreatectomy or severe chronic pancreatitis, are associated with diminished hepatic insulin sensitivity because of reduced hepatic insulin receptors.

In addition to the four main peptides secreted by the pancreas, there are a number of other peptide products of the islet cells, including amylin and pancreastatin, and neuropeptides such as VIP, galanin, and serotonin. Amylin or islet amyloid polypeptide (IAPP) is stored along with insulin in secretory granules. The function of IAPP seems to be the modulation or counterregulation of insulin secretion and function. Pancreastatin is a recently discovered pancreatic islet peptide product that inhibits insulin, and possibly somatostatin release, and augments glucagon release. In addition to this effect on the endocrine pancreas, pancreastatin inhibits pancreatic exocrine secretion.

ACUTE PANCREATITIS

Definition and Incidence

Acute pancreatitis is an inflammatory disease of the pancreas that is associated with little or no fibrosis of the gland. It can be initiated by several factors including gallstones, alcohol, trauma, and infections, and in some cases it is hereditary. Very often patients with acute pancreatitis develop additional complications such as sepsis, shock, and respiratory and renal failure, resulting in considerable morbidity and mortality.

The etiology of acute pancreatitis is a complex subject because many different factors have been implicated in the causation of this disease, and sometimes there are no identifiable causes. Two factors, biliary tract stone disease and alcoholism, account for 80–90 percent of the cases. The remaining 10–20 percent is accounted for either by idiopathic disease or by a variety of miscellaneous causes including trauma, surgery, drugs, heredity, infection and toxins. A tumor should be considered in a nonalcoholic patient with acute pancreatitis who has no demonstrable biliary tract disease. Approximately 1–2 percent of patients with acute pancreatitis have pancreatic carcinoma, and an episode of acute pancreatitis can be the first clinical manifestation of a periampullary tumor. Acute pancreatitis can be associated with a number of surgical procedures,

most commonly those performed on or close to the pancreas, such as pancreatic biopsy, biliary duct exploration, distal gastrectomy, and splenectomy. Endoscopic retrograde cholangiopancreatography results in pancreatitis in 2–10 percent of patients, because of direct injury and/or intraductal hypertension.

Certain drugs are known to be capable of causing acute pancreatitis. These include the thiazide diuretics, furosemide, estrogens, azathioprine, L-asparaginase, 6-mercaptopurine, methyldopa, the sulfonamides, tetracycline, pentamidine, procainamide, nitrofurantoin, dideoxyinosine, valproic acid, and acetylcholines-terase inhibitors. Patients with types I and V hyperlipoproteinemia often experience attacks of abdominal pain that are thought to indicate episodes of acute pancreatitis. These episodes are frequently associated with marked hypertriglyceridemia and lactescent serum, and can be prevented by dietary modifications that restrict serum triglycerides. Hypercalcemic states arising from hyperparathyroidism can result in both acute and chronic pancreatitis; the mechanism most likely involves hypersecretion and the formation of calcified stones intraductally. Finally, no apparent cause can be ascribed to some episodes of acute pancreatitis, and these constitute the group referred to as “idiopathic pancreatitis.” Some of these patients are eventually found to have gallstone-related pancreatitis, which calls for caution in labeling any episode “idiopathic.”

Pathophysiology

Pancreatitis begins with the activation of digestive zymogens inside acinar cells which cause acinar cell injury. Recent studies suggest that the ultimate severity of the resulting pancreatitis may be determined by the events that occur subsequent to acinar cell injury. These include inflammatory cell recruitment and activation, and generation and release of cytokines and other chemical mediators of inflammation.

Diagnosis

The clinical diagnosis of pancreatitis is one of exclusion. The other upper abdominal conditions that can be confused with acute pancreatitis include perforated peptic ulcer, a gangrenous small bowel obstruction, and acute cholecystitis. Because these conditions often have a fatal outcome without surgery, urgent intervention is indicated in the small number of cases in which doubt persists.

All episodes of acute pancreatitis begin with severe pain, generally following a substantial meal. The pain is usually epigastric, but can occur anywhere in the abdomen or lower chest. It has been described as “knifing” or “boring through” to the back, and may be relieved by the patient leaning forward. It precedes the onset of nausea and vomiting, with retching often continuing after the stomach has emptied. Vomiting does not relieve the pain, which is more intense in necrotizing than in edematous pancreatitis. An episode of acute pancreatic inflammation in a patient with known chronic pancreatitis has the same findings.

On examination the patient may show tachycardia, tachypnea, hypotension, and hyperthermia. The temperature is usually only mildly elevated in uncomplicated pancreatitis. Voluntary and involuntary guarding can be seen over the epigastric region. The bowel sounds are decreased or absent. There are usually no palpable masses. The abdomen may be distended with intraperitoneal fluid. There may be pleural effusion, particularly on the left side.

With increasing severity of disease, the intravascular fluid loss may become life-threatening as a result of sequestration of edematous fluid in the retroperitoneum. Hemoconcentration then results in an elevated hematocrit. However, there also may be bleeding into the retroperitoneum or the peritoneal cavity. In some patients (approximately 1 percent), the blood from necrotizing pancreatitis may dissect through the soft tissues and manifest as a blueish discoloration around the umbilicus (Cullen sign) or in the flanks (Grey Turner sign). The severe fluid loss may lead to prerenal azotemia with elevated blood urea nitrogen and creatinine levels. There also may be hyperglycemia, hypoalbuminemia, and hypocalcemia sufficient in some cases to produce tetany.

Serum Markers

Because pancreatic acinar cells synthesize, store, and secrete a large number of digestive enzymes (e.g., amylase, lipase, trypsinogen, and elastase), the levels of these enzymes are elevated in the serum of most pancreatitis patients. Because of the ease of measurement, serum amylase levels are measured most often. Serum amylase concentration increases almost immediately with the onset of disease and peaks within several h. It remains elevated for 3–5 days before returning to normal. There is no significant correlation between the magnitude of serum amylase elevation and severity of pancreatitis; in fact, a milder form of acute pancreatitis is often associated with higher levels of serum amylase as compared with that in a more severe form of the disease.

It is important to note that hyperamylasemia also can occur as a result of conditions not involving pancreatitis. For example, hyperamylasemia can occur in a patient with small bowel obstruction, perforated duodenal ulcer, or other intraabdominal inflammatory conditions. In contrast, a patient with acute pancreatitis may have a normal serum amylase level.

Other pancreatic enzymes also have been evaluated to improve the diagnostic accuracy of serum measurements. Specificity of these markers ranges from 77–96 percent, the highest being for lipase. Measurements of many digestive enzymes also have methodologic limitations and cannot be easily adapted for quantitation in emergency labs. Because serum levels of lipase remain elevated for a longer time than total or pancreatic amylase, it is the serum indicator of highest probability of the disease.

Abdominal ultrasound examination is the best way to confirm the presence of gallstones in suspected biliary pancreatitis. It also can detect extra-pancreatic ductal dilations and reveal pancreatic edema, swelling, and peripancreatic fluid collections. However, in about 20 percent of patients, the ultrasound examination does not provide satisfactory results because of the presence of bowel gas, which may obscure sonographic imaging of the pancreas. A computed tomographic (CT) scan of the pancreas more commonly is used to diagnose pancreatitis. CT scanning is used to distinguish milder (non-necrotic) forms of the disease from more severe necrotizing or infected pancreatitis, in patients whose clinical presentation raises the suspicion of advanced disease.

Assessment of Severity

An early discrimination between mild edematous and severe necrotizing forms of the disease is of the utmost importance to provide optimal care to the patient. In 1974, Ranson identified a series of prognostic signs for early identification of patients with severe pancreatitis. Out of these 11 objective parameters, 5

TABLE 32-1 Ranson's Prognostic Signs of Pancreatitis

Criteria for acute pancreatitis not due to gallstones

<i>At admission</i>	<i>During the initial 48 h</i>
Age > 55 y	Hematocrit fall > 10 points
WBC > 16,000/mm ³	BUN elevation > 5 mg/dL
Blood glucose > 200 mg/dL	Serum calcium < 8 mg/dL
Serum LDH > 350 IU/L	Arterial Po ₂ < 60 mm Hg
Serum AST > 250 U/dL	Base deficit > 4 mEq/L
	Estimated fluid sequestration > 6 L

Criteria for acute gallstone pancreatitis

<i>At admission</i>	<i>During the initial 48 h</i>
Age > 70 y	Hematocrit fall > 10 points
WBC > 18,000/mm ³	BUN elevation > 2 mg/dL
Blood glucose > 220 mg/dL	Serum calcium < 8 mg/dL
Serum LDH > 400 IU/L	Base deficit > 5 mEq/L
Serum AST > 250 U/dL	Estimated fluid sequestration > 4 L

AST = aspartate transaminase; BUN = blood urea nitrogen; LDH = lactate dehydrogenase; Po₂ = partial pressure of oxygen; WBC = white blood cell count.

are measured at the time of admission, whereas the remaining 6 are measured within 48 h of admission (Table 32-1). Morbidity and mortality of the disease are directly related to the number of signs present. If the number of positive Ranson signs is less than 2, the mortality is generally zero; with 3–5 positive signs, mortality is increased to 10–20 percent. The mortality rate increases to more than 50 percent when there are more than seven positive Ranson signs. It is important to realize that Ranson prognostic signs are best used within the initial 48 h of hospitalization and have not been validated for later time intervals.

Several recent research studies have suggested additional markers that may have prognostic value, including acute phase proteins such as C-reactive protein (CRP), α 2-macroglobulin, PMN-elastase, α 1-antitrypsin, and phospholipase A2. While CRP measurement is commonly available many of the others are not. Therefore, at this time CRP seems to be the marker of choice in clinical settings.

Computed Tomography Scan

CT scanning with bolus intravenous contrast has become the standard criterion for detecting and assessing the severity of pancreatitis. While clinically mild pancreatitis usually is associated with interstitial edema, severe pancreatitis is associated with necrosis. In interstitial pancreatitis, the microcirculation of the pancreas remains intact, and the gland shows uniform enhancement on intravenous, contrast-enhanced CT scan. In necrotizing pancreatitis, however, the microcirculation is disrupted; therefore the enhancement of the gland on contrast-enhanced CT scan is considerably decreased. The presence of air bubbles on a CT scan is an indication of infected necrosis or pancreatic abscess.

Currently, intravenous (bolus), contrast-enhanced CT scanning is routinely performed on patients who are suspected of harboring severe pancreatitis, regardless of their Ranson or APACHE scores.

Treatment

The severity of acute pancreatitis covers a broad spectrum of illness, ranging from the mild and self-limiting to the life-threatening necrotizing variety. Regardless of severity, hospitalization of the patient with suspected acute pancreatitis for observation and diagnostic study is usually mandatory. On confirmation of the diagnosis, patients with moderate to severe disease should be transferred to the intensive care unit for observation and maximal support. The most important initial treatment is conservative intensive care with the goals of oral food and fluid restriction, replacement of fluids and electrolytes parenterally as assessed by central venous pressure and urinary excretion, and control of pain. In severe acute pancreatitis, or when signs of infection are present, most experts recommend broad-spectrum antibiotics (e.g., imipenem) and careful surveillance for complications of the disease.

Mild Pancreatitis

The current principles of treatment are physiologic monitoring, metabolic support, and maintenance of fluid balance, which can become dangerously disturbed even in mild acute pancreatitis because of fluid sequestration, vomiting, and sudoresis. Because hypovolemia can result in pancreatic and other visceral ischemia, fluid balance should be assessed at least every 8 h initially.

Cautious resumption of oral feeding consisting of small and slowly increasing meals is permissible after the abdominal pain and tenderness have subsided, serum amylase has returned to normal, and the patient experiences hunger. This usually occurs within a week of the onset of an attack of mild acute pancreatitis. A low-fat, low-protein diet is advocated as the initial form of nutrition following an attack of acute pancreatitis.

Severe Pancreatitis

Pancreatitis can be classified as severe based on predictors such as APACHE-II scores and Ranson signs, and any evidence that the condition is severe mandates care of the patient in the intensive care unit. Such evidence may take various forms, such as the onset of encephalopathy, a hematocrit over 50, urine output less than 50 mL/h, hypotension, fever, or peritonitis. Older adult patients with three or more Ranson criteria also should be monitored carefully despite the absence of severe pain.

Patients may develop adult respiratory distress syndrome (ARDS), and many patients who die during the early stages of severe acute pancreatitis have this complication. The presence of ARDS usually requires assisted ventilation with positive end-expiratory pressure. The value of peritoneal lavage in removing enzyme-rich ascites remains unclear. It has been advocated in patients with deteriorating respiratory function and/or shock that is refractory to maximal management, but its effectiveness in reducing the mortality risk of severe acute pancreatitis remains unproven.

Acute pancreatitis may be accompanied by cardiovascular events such as cardiac arrhythmia, myocardial infarction, cardiogenic shock, and congestive

heart failure. The conventional modalities of treatment apply in these cases in addition to the support described above.

Infections

Infection is a serious complication of acute pancreatitis and is the most common cause of death. It is caused most often by translocated enteric bacteria, and is seen commonly in necrotizing rather than interstitial pancreatitis. If there is an indication of infection (e.g., retroperitoneal air on CT scan), then a CT- or ultrasound-guided fine-needle aspiration should be performed for Gram stain and culture of the fluid or tissue, and the indicated antibiotic therapy initiated. However, antibiotics alone may not be effective in infected necrosis, which has a mortality of nearly 50 percent unless débrided surgically. The long-held opinion that antibiotic prophylaxis in necrotizing pancreatitis is of little use has been altered by recent studies showing a beneficial prophylactic effect with antibiotics such as metronidazole, imipenem, and third-generation cephalosporins. Because *Candida* species are common inhabitants of the upper gastrointestinal tract, *Candida* sepsis and secondary fungal infection of pancreatic necrosis is a risk in severe disease. The role of empiric therapy with fluconazole in cases of severe acute pancreatitis is currently being investigated in large-scale clinical trials.

Sterile Necrosis

Patients with sterile necrosis have a far better prognosis than those with infected necrosis, with a reported mortality of near zero in the absence of systemic complications. However, others report mortality rates as high as 38 percent in patients with a single systemic complication.

Treatment of sterile necrotic pancreatitis falls into three degrees of aggressiveness. At one end of the scale is the patient with no systemic complications and no concerns about secondary infections, who can be managed with the supportive care described previously and be cautiously brought back to refeeding. The area of sterile necrosis may evolve into a chronic pseudocyst, or may resolve. An intermediate course is demonstrated by the patient who develops systemic complications, and in whom a secondary infection is suspected. A CT-guided, fine-needle aspiration then confirms or disproves infection, and in the latter instance the patient can be managed medically. The last and most serious condition is that of the patient who appears to be very ill, has high APACHE-II and Ranson scores, and shows evidence of systemic toxicity including shock. Patients in this category have a poor chance of survival without aggressive débridement, and a decision may be made to proceed with exploration simply because of a relentless course of deterioration despite maximal medical therapy. It must be emphasized that current opinion is against débridement in sterile necrosis unless it is accompanied by life-threatening systemic complications.

Pancreatic Abscess

A pancreatic abscess occurs 2–6 weeks after the initial attack, in contrast to infected necrosis, which occurs in the first few h or days. The mechanism of delayed infection is not clear, but the treatment consists of external drainage, whether established by surgical or by percutaneous catheter-based methods.

Nutritional Support

The guiding principle of resting the pancreas dictates that patients with acute pancreatitis not be fed orally until their clinical condition improves. This generally occurs in 3–7 days in patients with mild pancreatitis, but the situation in patients with severe pancreatitis is more complicated, requiring nutritional support for several weeks. This can be provided by total parenteral nutrition (TPN) or by enteral nutrition through a jejunal tube. There is some debate regarding the preferred route, because TPN is known to result in early atrophy of the gut mucosa, a condition that favors transmigration of luminal bacteria, and intrajejunal feeding still stimulates pancreatic exocrine secretion through the release of enteric hormones. Recent animal studies and preliminary clinical trials on humans suggest that on balance, jejunal feeding may be superior to TPN.

Treatment of Biliary Pancreatitis

Gallstones are the most common cause of acute pancreatitis worldwide. Most patients pass the offending gallstone(s) during the early h of acute pancreatitis, but have additional stones capable of inducing future episodes. This raises the question of the timing of surgical or endoscopic clearance of gallstones. The issue of when to intervene is controversial. When choledocholithiasis is suspected, clearance of stones by endoscopic retrograde cholangiography is indicated. Most surgeons favor cholecystectomy during the same hospitalization as the acute episode of pancreatitis but surgery is delayed until the pancreatitis is resolved. Routine endoscopic retrograde cholangiopancreatography (ERCP) for examination of the bile duct is discouraged in cases of biliary pancreatitis, as the probability of finding residual stones is low, and the risk of ERCP-induced pancreatitis is significant.

CHRONIC PANCREATITIS

Etiology

Worldwide, alcohol consumption and abuse is associated with chronic pancreatitis in up to 70 percent of cases. Other major causes worldwide include tropical (nutritional) and idiopathic disease, and hereditary causes.

Alcohol

There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis. The risk of disease is present in patients with even a low or occasional exposure to alcohol (1–20 g/day), so there is no threshold level of alcohol exposure below which there is no risk of developing chronic pancreatitis. Furthermore, although the risk of disease is dose related, and highest in heavy (150 g/day) drinkers, fewer than 15 percent of confirmed alcohol abusers suffer from chronic pancreatitis. However, the duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35–40, after 16–20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years. It remains to be determined whether alcohol sensitizes the pancreas of susceptible individuals to another cause of acute inflammation, or whether genetic or other factors predispose to direct alcohol-related injury.

Hereditary pancreatitis. Typically, patients first present in childhood or adolescence with abdominal pain, and are found to have chronic calcific pancreatitis on imaging studies. Progressive pancreatic dysfunction is common, and many patients present with symptoms because of pancreatic duct obstruction. The risk of subsequent carcinoma formation is increased, reaching a prevalence in some series of 40 percent, but the age of onset for carcinoma is typically over 50 years. The disorder is characterized by an autosomal dominant pattern of inheritance, with 80 percent penetrance and variable expression. The incidence is equal in both sexes. Whitcomb and colleagues, and separately LeBodic and associates, performed gene linkage analysis and identified a linkage for hereditary pancreatitis to chromosome 7q35. Subsequently, the region was sequenced, and revealed eight trypsinogen genes. Mutational analysis revealed a missense mutation resulting in an Arg to His substitution at position 117 of the cationic trypsinogen gene, or PRSS1, one of the primary sites for proteolysis of trypsin. This mutation prevents trypsin from being inactivated by itself or other proteases, and results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas. The position 117 mutation of PRSS1 and an additional mutation, now known collectively as the R122H and N291 mutations of PRSS1, account for about two-thirds of cases of hereditary pancreatitis. Recently, Schneider and Whitcomb described a probable mutation in the anionic trypsinogen gene which may also be present in some cases. Thus, hereditary pancreatitis results from one or more mutational defects, which incapacitate an autoprotective process that normally prevents proteolysis within the pancreas.

Similarly, PSTI, also known as SPINK1, has been found to have a role in hereditary pancreatitis. SPINK1 specifically inhibits trypsin action by competitively blocking the active site of the enzyme. Witt and colleagues investigated 96 unrelated children with chronic pancreatitis in Germany and found a variety of SPINK1 mutations in 23 percent of the patients. Several studies have now confirmed an association of SPINK1 mutations with familial and idiopathic forms of chronic pancreatitis, and tropical pancreatitis. SPINK1 mutations are common in the general population as well, and the frequency of these mutations varies in different cohorts of idiopathic chronic pancreatitis, from 6.4 percent in France to 25.8 percent in the United States. It is likely that many of the "idiopathic" forms of chronic pancreatitis, and some patients with the more common forms of the disease, will be found to have a genetic linkage or predisposition.

Autoimmune pancreatitis. A variant of chronic pancreatitis is a nonobstructive, diffusely infiltrative disease associated with fibrosis, a mononuclear cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies. Compressive stenosis of the intrapancreatic portion of the common bile duct is frequently seen, along with symptoms of obstructive jaundice. Increased levels of serum β -globulin or immunoglobulin G also are present. Steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression. The differential diagnosis includes lymphoma, plasmacytoma ("pseudotumor" of the pancreas), and diffuse infiltrative carcinoma. Although the diagnosis is confirmed on pancreatic biopsy, presumptive treatment with steroids usually is undertaken, especially when clinical and laboratory findings support the diagnosis. Failure to obtain a cytologic specimen may lead to an unnecessary resectional procedure, and

an untreated inflammatory component may cause sclerosis of the extrahepatic or intrahepatic bile ducts, with eventual liver failure.

Pancreas divisum represents a special case of obstructive pancreatitis. It is the most common congenital anomaly involving the pancreas and occurs in up to 10 percent of children. It is thought to predispose the pancreas to recurrent acute pancreatitis and chronic pancreatitis, because of functional obstruction of a diminutive duct of Santorini which fails to communicate with the Wirsung duct. However, the classic picture of obstructive pancreatopathy with a dilated dorsal duct is unusual in pancreas divisum, so a decompressive operation or a lesser papilla sphincteroplasty is frequently not feasible or unsuccessful. Endoscopic stenting through the lesser papilla may result in temporary relief of symptoms, and this response would increase the possibility that a permanent surgical or endoscopic intervention will be successful. Although some authors emphasize the pathologic implications of pancreas divisum, others express skepticism that it represents a true risk to pancreatic secretory capacity or contributes to the development of chronic pancreatitis.

Idiopathic pancreatitis. When a definable cause for chronic pancreatitis is lacking, the term “idiopathic” is used to categorize the illness. Not surprisingly, as diagnostic methods and clinical awareness of disease improve, fewer patients fall into the idiopathic category. Classically, the idiopathic group includes young adults and adolescents who lack a family history of pancreatitis, but who may represent individuals with spontaneous gene mutations encoding for regulatory proteins in the pancreas. Additionally, the idiopathic group has included a large number of older patients for whom no obvious cause of recurrent or chronic pancreatitis can be found. However, because the prevalence of biliary calculi increases steadily with age, it is not surprising that as methods to detect biliary stone disease and microlithiasis have improved, a larger proportion of older adult “idiopathic” pancreatitis patients are found to have biliary tract disease.

Radiology

Radiologic imaging of chronic pancreatitis assists in four areas: (1) diagnosis, (2) the evaluation of severity of disease, (3) detection of complications, and (4) assistance in determining treatment options. With the advent of cross-sectional imaging techniques such as CT and magnetic resonance imaging (MRI), the contour, content, ductal pattern, calcifications, calculi, and cystic disease of the pancreas are all readily discernible. Endoscopic ultrasound (EUS) is now frequently employed as a preliminary step in the evaluation of patients with pancreatic disease, and magnetic resonance cholangiopancreatography (MRCP) is increasingly being used to select patients who are candidates for the most invasive imaging method, ERCP. The staging of disease is important in the care of patients, and a combination of imaging methods is usually employed.

Presentation, Natural History, and Complications

Presenting Signs and Symptoms

Pain is the most common symptom of chronic pancreatitis. It is usually midepigastria in location, but may localize or involve either the left or right upper quadrant of the abdomen. Occasionally it is perceived in the lower mid-abdomen, but is frequently described as penetrating through to the back. The pain is typically steady and boring, but not colicky. It persists for hours or days,

and may be chronic with exacerbations caused by eating or drinking alcohol. Chronic alcoholics also describe a steady, constant pain that is temporarily relieved by alcohol, followed by a more severe recurrence later.

Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting may accompany the pain, but anorexia is the most common associated symptom.

Malabsorption and Weight Loss

When pancreatic exocrine capacity falls below 10 percent of normal, diarrhea and steatorrhea develop. Patients describe a bulky, foul-smelling, loose (but not watery) stool that may be pale in color and float on the surface of toilet water. Frequently, patients will describe a greasy or oily appearance to the stool, or may describe an “oil slick” on the water’s surface. In severe steatorrhea, an orange, oily stool often is reported. As exocrine deficiency increases, symptoms of steatorrhea often are accompanied by weight loss. Patients may describe a good appetite despite weight loss, or diminished food intake because of abdominal pain.

In severe symptomatic chronic pancreatitis, anorexia or nausea may occur with or separate from abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight.

Pancreatogenic Diabetes

The islets comprise only 2 percent of the mass of the pancreas, but they are preferentially conserved when pancreatic inflammation occurs. In chronic pancreatitis, acinar tissue loss and replacement by fibrosis is greater than the degree of loss of islet tissue, although islets are typically smaller than normal, and may be isolated from their surrounding vascular network by the fibrosis. With progressive destruction of the gland, endocrine insufficiency commonly occurs. Frank diabetes is seen initially in about 20 percent of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70 percent of patients.

Pancreatogenic diabetes is more common after surgical resection for chronic pancreatitis. Distal pancreatectomy and Whipple procedures have a higher incidence of diabetes than do drainage procedures, and the severity of diabetes is frequently worse after partial pancreatectomy.

The etiology and pathophysiology of pancreatogenic or type III diabetes is distinct from that of either insulin-dependent (type I) or non-insulin-independent (type II) diabetes. In pancreatogenic diabetes, because of the loss of functioning pancreatic tissue by disease or surgical removal, there is a global deficiency of all three glucoregulatory islet cell hormones: insulin, glucagon, and PP. Additionally, there is a paradoxical combination of enhanced peripheral sensitivity to insulin, and decreased hepatic sensitivity to insulin. As a result, insulin therapy is frequently difficult; patients are hyperglycemic when insulin replacement is insufficient (because of unsuppressed hepatic glucose production) or hypoglycemic when insulin replacement is barely excessive (because of enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion to counteract the hypoglycemia).

This form of diabetes is referred to as “brittle” diabetes, and requires special attention.

Laboratory Studies

Indirect tests of pancreatic exocrine function are based on the measurement of metabolites of compounds which are altered (“digested”) by pancreatic exocrine products, and which can be quantified by serum or urine measurements. A commonly used indirect test is the bentiromide test, in which nitroblue tetrazolium-paraaminobenzoic acid (NBT-PABA) is ingested by the subject, and the urinary excretion of the proteolytic metabolite paraaminobenzoic acid (PABA) is measured. Free PABA is absorbed from the small intestine and excreted by the kidney in a linear correlation with the degree of chymotrypsin degradation of NBT-PABA. Although the sensitivity of the test is as high as 100 percent in patients with severe chronic pancreatitis, it identifies only 40–50 percent of patients with mild disease. Furthermore, reduced PABA excretion is found in patients with a variety of other gastrointestinal, hepatic, and renal diseases. Therefore the test is of value not for the diagnosis of chronic pancreatitis, but for determining the extent of exocrine pancreatic insufficiency in patients with known disease.

The quantification of stool fat also has been used as a measure of pancreatic lipase secretion, either through the direct measurement of total fecal fat levels while the subject consumes a diet of known fat content, or by the measurement of exhaled 4CO_2 after ingestion of $[4\text{C}]$ -triolein or $[4\text{C}]$ -olein. This so-called triolein breath test avoids the necessity of stool collections and analysis, but has a high false-negative rate.

Prognosis and Natural History

The prognosis for patients with chronic pancreatitis is dependent on the etiology of disease, the development of complications, and on the age and socioeconomic status of the patient. Several studies have demonstrated that although symptoms of pain decrease over time in about half of the patients, this decline also is accompanied by a progression of exocrine and endocrine insufficiency. In general, the likelihood of eventual pain relief is dependent on the stage of disease at diagnosis, and the persistence of alcohol use in patients with alcoholic chronic pancreatitis. Miyake and colleagues found that pain relief was achieved in 60 percent of alcoholic patients who successfully discontinued drinking, but in only 26 percent who did not.

In addition to progressive endocrine and exocrine dysfunction, and the risk of the specific complications outlined below, the other significant long-term risk for the patient with chronic pancreatitis is the development of pancreatic carcinoma. There is a progressive, cumulative increased risk of carcinoma development in patients with chronic pancreatitis, which continues throughout the subsequent lifetime of the patient. The incidence of carcinoma in patients with chronic pancreatitis ranges from 1.5–2.7 percent, which is at least tenfold greater than that of patients of similar age seen in a hospital setting. In patients with advanced chronic pancreatitis referred for surgical therapy, the risk of indolent carcinoma can be over 10 percent. The development of carcinoma in the setting of chronic pancreatitis is no doubt related to the dysregulation of cellular proliferation and tissue repair processes in the setting of chronic inflammation, as is seen throughout the alimentary tract and elsewhere. In the setting of chronic pancreatitis, carcinoma development can be especially

cryptic, and the diagnosis of early stage tumors is particularly difficult. Awareness of this risk justifies close surveillance for cancer in patients with chronic pancreatitis. Periodic measurement of tumor markers such as CA19-9, and periodic imaging of the pancreas with CT scan and EUS are necessary to detect the development of carcinoma in the patient with chronic pancreatitis.

Complications

Pseudocyst. A chronic collection of pancreatic fluid surrounded by a nonepithelialized wall of granulation tissue and fibrosis is referred to as a pseudocyst. Pseudocysts occur in up to 10 percent of patients with acute pancreatitis, and in 20–38 percent of patients with chronic pancreatitis, and thus they comprise the most common complication of chronic pancreatitis.

Acute pseudocysts may resolve spontaneously in up to 50 percent of cases, over a course of 6 weeks or longer. Pseudocysts larger than 6 cm resolve less frequently than smaller ones, but may regress over a period of weeks to months. Pseudocysts are multiple in 17 percent of patients, or may be multilobulated. Pseudocysts may become secondarily infected, in which case they become abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric-portal vein thrombosis or splenic vein thrombosis. They can erode into visceral arteries and cause intracystic hemorrhage or pseudoaneurysms. They also can perforate and cause peritonitis or intraperitoneal bleeding.

Pseudocysts usually cause symptoms of pain, fullness, or early satiety. Asymptomatic pseudocysts can be managed expectantly, and may resolve spontaneously or persist without complication. Symptomatic or enlarging pseudocysts require treatment, and any presumed pseudocyst without a documented antecedent episode of acute pancreatitis requires investigation to determine the etiology of the lesion. Although pseudocysts comprise roughly two-thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinoma radiographically. An incidentally discovered cystic lesion should be examined by EUS and aspirated to determine whether it is a true neoplasm or a pseudocyst.

The timing and method of treatment requires careful consideration. Pitfalls in the management of pseudocysts result from the incorrect (presumptive) diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of a pseudocyst which appears to be fluid filled on CT scan, and a failure to document true adherence with an adjacent portion of the stomach before attempting transgastric internal drainage. If infection is suspected, the pseudocyst should be aspirated (not drained) by CT- or US-guided fine-needle aspiration, and the contents examined for organisms by Gram stain and culture. If infection is present, and the contents resemble pus, external drainage is employed using either surgical or percutaneous techniques.

If the pseudocyst has failed to resolve with conservative therapy and symptoms persist, internal drainage usually is preferred to external drainage, to avoid the complication of a pancreaticocutaneous fistula. Pseudocysts communicate with the pancreatic ductal system in up to 80 percent of cases, so external drainage creates a pathway for pancreatic duct leakage to and through the catheter exit site. Internal drainage may be performed with either percutaneous catheter-based methods (transgastric puncture and stent placement to create a cystogastrostomy), endoscopic methods (transgastric or transduodenal

puncture and multiple stent placements, with or without a nasocystic irrigation catheter), or surgical methods (a true cystoenterostomy, biopsy of cyst wall, and evacuation of all debris and contents). Surgical options include a cystogastrostomy, a Roux-en-Y cystojejunostomy, or a cystoduodenostomy. Cystojejunostomy is the most versatile method, and it can be applied to pseudocysts that penetrate into the transverse mesocolon, the paracolic gutters, or the lesser sac. Cystogastrostomy can be performed endoscopically, laparoscopically, or by a combined laparoscopic-endoscopic method.

Because pseudocysts often communicate with the pancreatic ductal system, two newer approaches to pseudocyst management are based on main duct drainage, rather than pseudocyst drainage per se. Transpapillary stents inserted at the time of ERCP may be directed into a pseudocyst through the ductal communication itself, or can be left across the area of suspected duct leakage to facilitate decompression and cyst drainage, analogous to the use of common bile duct stents in the setting of a cystic duct leak. In a surgical series of patients with chronic pancreatitis, ductal dilatation, and a coexisting pseudocyst, Nealon and Walser showed that duct drainage alone, without a separate cystoenteric anastomosis, was as successful as a combined drainage procedure. Furthermore, the "duct drainage only" group enjoyed a shorter hospital stay and fewer complications than the group who underwent a separate cystoenterostomy. These observations suggest that transductal drainage may be a safe and effective approach to the management of pseudocystic disease. The endoscopic approach seems logical in the treatment of postoperative or post-traumatic pseudocysts when duct disruption is documented, or in those patients with pseudocysts that communicate with the duct. Whether the technique will be as effective for chronic pseudocysts without demonstrable communication with the pancreatic duct remains open to investigation.

The complications of endoscopic or radiologic drainage of pseudocysts often require surgical intervention. Bleeding from the cystoenterostomy, and inoculation of a pseudocyst with failure of resolution and persistence of infection, may require surgical treatment. Bleeding risks may be lessened by the routine use of EUS in the selection of the site for transluminal stent placement. Percutaneous and endoscopic treatment of pseudocysts requires large-bore catheters, multiple stents, and an aggressive approach to management for success to be achieved. Failure of nonsurgical therapy, with subsequent salvage procedures to remove infected debris and establish complete drainage, is associated with increased risks for complications and death. The most experienced therapeutic endoscopists report a complication rate of 17–19 percent for the treatment of sterile pseudocysts, and deaths as a result of endoscopic therapy have occurred. The use of endoscopic methods to treat sterile or infected pancreatic necrosis has a higher complication rate, and is indeed still controversial.

Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail, or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis.

Pancreatic ascites and pleural effusion. When a disrupted pancreatic duct leads to pancreatic fluid extravasation that does not become sequestered as a pseudocyst, but drains freely into the peritoneal cavity, pancreatic ascites occurs. Occasionally, the pancreatic fluid tracks superiorly into the thorax, and a pancreatic pleural effusion occurs. Referred to as internal pancreatic fistulae,

both complications are seen more often in patients with chronic pancreatitis, rather than after acute pancreatitis. Pancreatic ascites and pleural effusion occur together in 14 percent of patients, and 18 percent have a pancreatic pleural effusion alone. Paracentesis or thoracentesis reveals noninfected fluid with a protein level greater than 25 g/L and a markedly elevated amylase level. Serum amylase may also be elevated, presumably from reabsorption across the parietal membrane. Serum albumin may be low, and patients may have coexisting liver disease. Paracentesis is therefore critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak, and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP, but if nonsurgical therapy is undertaken and then abandoned, repeat imaging of the pancreatic duct is appropriate to guide surgical treatment.

Antisecretory therapy with the somatostatin analog octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients. Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage may facilitate closure of the internal fistula. Surgical therapy is reserved for those who fail to respond to medical treatment. If the leak originates from the central region of the pancreas, a Roux-en-Y pancreaticojejunostomy is performed to the site of duct leakage. If the leak is in the tail, a distal pancreatectomy may be considered, or an internal drainage procedure can be performed. The results of surgical treatment are usually favorable if the ductal anatomy has been carefully delineated preoperatively.

Head-of-pancreas mass. In up to 30 percent of patients with advanced chronic pancreatitis, an inflammatory mass develops in the head of the pancreas. The clinical presentation includes severe pain, and frequently includes stenosis of the distal common bile duct, duodenal stenosis, compression of the portal vein, and stenosis of the proximal main pancreatic duct. Treatment in the majority of cases is a duodenum-preserving pancreatic head resection.

Splenic and portal vein thrombosis. Vascular complications of chronic pancreatitis are fortunately infrequent, because they are difficult to treat successfully. Portal vein compression and occlusion can occur as a consequence of an inflammatory mass in the head of the pancreas, and splenic vein thrombosis occurs in association with chronic pancreatitis in 4 to 8 percent of cases. Variceal formation can occur as a consequence of either portal or splenic venous occlusion, and splenic vein thrombosis with gastric variceal formation is referred to as left-sided or sinistral portal hypertension. Although bleeding complications are infrequent, the mortality risk of bleeding exceeds 20 percent. When gastroesophageal varices are caused by splenic vein thrombosis, the addition of splenectomy to prevent variceal hemorrhage is prudent when surgery is otherwise indicated to correct other problems.

Treatment

Medical Therapy

The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, and oral enzyme

therapy. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment.

Endoscopic Management

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and for drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct. Pancreatic duct stents can induce an inflammatory response within the duct, so prolonged stenting is usually avoided.

Surgical Therapy

Indications and history. The traditional approach to surgical treatment of chronic pancreatitis and its complications has maintained that surgery should be considered only when the medical therapy of symptoms has failed. The role of surgery in the treatment of chronic pancreatitis, and its timing, is now based on the elucidation of pancreatic ductal disease. Nealon and Thompson published a landmark study in 1993 that showed that the progression of chronic obstructive pancreatitis could be delayed or prevented by pancreatic duct decompression. No other therapy has been shown to prevent the progression of chronic pancreatitis, and this study demonstrated the role of surgery in the early management of the disease. However, small-duct disease or the absence of a clear obstructive component are causes for caution. Major resections have a high complication rate, both early and late, in chronic alcoholic pancreatitis, and lesser procedures often result in symptomatic recurrence. So the choice of operation and the timing of surgery are based on each patient's pancreatic anatomy, the likelihood (or lack thereof) that further medical and endoscopic therapy will halt the symptoms of the disease, and the chance that a good result will be obtained with the lowest risk of morbidity and mortality. Finally, preparation for surgery should include restoration of protein-caloric homeostasis, abstinence from alcohol and tobacco, and a detailed review of the risks and likely outcomes, to establish a bond of trust and commitment between the patient and the surgeon.

ERCP and CT scans are used to differentiate obstructive and sclerotic disease, and this information is used to guide the rational selection of operative procedures. Resection of the pancreatic head (Whipple) is more common in the United States than the Beger procedure. The most common drainage procedure is a longitudinal pancreaticojejunostomy. The Frey procedure combines resection of a portion of the pancreatic head with a longitudinal pancreaticojejunostomy.

Sphincteroplasty. Although endoscopic techniques are now used routinely to perform sphincterotomy of either the common bile duct or pancreatic duct, a true (permanent) sphincteroplasty can only be performed surgically. Transduodenal sphincteroplasty with incision of the septum between the pancreatic duct and common bile duct appears to offer significant relief for patients with obstruction and inflammation isolated to this region.

Drainage procedures. In 1958, Puestow and Gillesby described segmental narrowings and dilatations of the ductal system as a "chain of lakes," and proposed a longitudinal decompression of the body and tail of the pancreas into a Roux limb of jejunum. Four of Puestow and Gillesby's 21 initial cases

were side-to-side anastomoses, and 2 years after their report, Partington and Rochelle described a much simpler version of the longitudinal, or side-to-side Roux-en-Y pancreaticojejunostomy that became universally known as the Puestow procedure.

The effectiveness of decompression of the pancreatic duct is dependent on the extent to which ductal hypertension is the etiologic agent for the disease. Thus the diameter of the pancreatic duct is a surrogate for the degree of ductal hypertension, and the Puestow procedure has been shown to be effective for pain relief when the maximum duct diameter exceeds 6 or 7 mm. Results are less impressive in glands with smaller caliber ducts.

Successful pain relief after the Puestow-type decompression procedure has been reported in 75 to 85 percent of patients for the first few years after surgery, but pain recurs in over 20 percent of patients after 5 years, even in patients who are abstinent from alcohol. In 1987, Frey and Smith described the extended lateral pancreaticojejunostomy with excavation of the pancreatic head down to the ductal structures. The Frey procedure provides thorough decompression of the pancreatic head and the body and tail of the gland, and a long-term follow up suggested that improved outcomes are associated with this more extensive decompressive procedure.

The degree and technique of pancreatic head decompression may be critical for good long-term pain relief. The Frey procedure opens the head of the gland down to the proximal ductal system, but was not described as a duct-removing procedure *per se*. However, an actual excavation of the head of the pancreas, including the ductal system, may provide the best protection against recurrent stenosis.

Resectional Procedure

In 1965, Fry and Child proposed the more radical 95 percent distal pancreatectomy, which was intended for patients with sclerotic (small duct) disease, and which attempted to avoid the morbidity of total pancreatectomy by preserving the rim of pancreas in the pancreaticoduodenal groove, along with its associated blood vessels and distal common bile duct. The operation was found to be associated with pain relief in 60–77 percent of patients long-term, but is accompanied by a high risk of brittle diabetes, hypoglycemic coma, and malnutrition.

Although the operation is seldom used today, there is great interest in combining this procedure with autologous islet transplantation. Avoiding the metabolic consequences of subtotal or total pancreatectomy, although preserving the duodenum and distal bile duct, is an attractive surgical goal for the relief of nonobstructive pancreatic sclerosis.

Pancreaticoduodenectomy, with or without pylorus preservation, has been widely employed for the treatment of chronic pancreatitis. In the three largest modern (circa 2000) series of the treatment of chronic pancreatitis by the Whipple procedure, pain relief 4–6 years after operation was found in 71–89 percent of patients.

Beger and associates described the duodenum-preserving pancreatic head resection (DPPHR) in 1980, and published long-term results with DPPHR for the treatment of chronic pancreatitis in 1985, and more recently in 1999. In 388 patients who were followed for an average of 6 years after DPPHR, pain relief was maintained in 91 percent, mortality was less than 1 percent, and diabetes developed in 21 percent with 11 percent demonstrating a reversal of

their preoperative diabetic status. These authors also compared the DPPHR procedure with the pylorus-sparing Whipple procedure in a randomized trial in 40 patients with chronic pancreatitis. The mortality was zero in both groups, and the morbidity was also comparable. Pain relief (over 6 months) was seen in 94 percent of DPPHR patients, but in only 67 percent of Whipple patients. Furthermore, the insulin secretory capacity and glucose tolerance were noted to deteriorate in the Whipple group, but actually improved in the DPPHR patients.

The DPPHR requires the careful dissection of the gastroduodenal artery and the creation of two anastomoses, and carries a similar complication risk as the Whipple procedure because of the risk of pancreatic leakage and intraabdominal fluid collections. Izbicki and associates conducted a randomized trial comparing the Frey procedure with the DPPHR in patients with chronic pancreatitis, and confirmed a reduced morbidity of 9 percent after the Frey procedure, compared to 20 percent after DPPHR. No significant differences were found in postoperative pain relief after the Frey or DPPHR (89 and 95 percent, respectively, over a mean follow up of 1.5 years), nor were there any differences in the ability to return to work, or in endocrine or exocrine function postoperatively.

In a retrospective review of both the DPPHR and Frey procedures performed at Yale, Aspelund and associates found a 25 percent incidence of major complications after the DPPHR, but only a 16 percent incidence after Frey procedures performed for chronic pancreatitis. During the same interval, major complications occurred after 40 percent of Whipple procedures, and new diabetes developed in 25 percent of Whipple patients. New diabetes occurred in only 8 percent of both DPPHR and Frey patients, during a follow-up period of 3 years, and preoperative diabetes improved in an equal number of DPPHR and Frey patients. These results corroborate the findings in the studies from Ulm and Hamburg, and suggest that duodenum-sparing pancreatic head resection, either in the form of the DPPHR (Beger) procedure or the Frey procedure, may provide better outcomes compared to the Whipple procedure for benign disease including chronic pancreatitis.

The decreased incidence of postoperative diabetes after the duodenum-sparing operations may be the result of a preserved β -cell mass in the more conservative resections, and may also be because of the conservation of the pancreatic polypeptide-secreting cells localized to the posterior head and uncinate process. Preservation of near-normal glucose metabolism and the avoidance of pancreatogenic diabetes is a significant benefit of the newer operative procedures.

Autotransplantation of islets. Islet cell transplantation for the treatment of diabetes is an attractive adjunct to pancreatic surgery in the treatment of benign pancreatic disease, but problems because of rejection of allotransplanted islets have plagued this method since its initial clinical application in the early 1970s. However, despite the difficulties in recovering islets from a chronically inflamed gland, Najarian and associates demonstrated the utility of autotransplantation of islets in patients with chronic pancreatitis in 1980. Subsequently, through refinements in the methods of harvesting and gland preservation, and through standardization of the methods by which islets are infused into the portal venous circuit for intrahepatic engraftment, the success of autotransplantation has steadily increased to achieve insulin independence in the majority of patients treated in recent series. Although 2–3 million islets are required for

successful engraftment in an allogeneic recipient, the autotransplant recipient usually can achieve long-term, insulin-independent status after engraftment of only 300,000–400,000 islets. However, the ability to recover a sufficient quantity of islets from a sclerotic gland is dependent on the degree of disease present, so the selection of patients as candidates for autologous islet transplantation is important. As success with autotransplantation increases, patients with nonobstructive, sclerotic pancreatitis may be considered for resection and islet autotransplantation earlier in their course, as end-stage fibrosis bodes poorly for transplant success. As the necessary expertise with islet transplantation becomes more widespread, this therapy may become routine in the treatment of chronic pancreatitis.

Denervation procedures. In patients who have persistent and disabling pain, but who are poor candidates for resection or drainage procedures, a denervation procedure may provide symptomatic relief. Neural ablation is a valid treatment strategy to block afferent sympathetic nociceptive pathways. In addition to direct infiltration of the celiac ganglia with long-acting analgesics or neurolytic agents, a variety of true denervation procedures have been described for symptomatic relief in chronic pancreatitis. These include operative celiac ganglionectomy or splanchnicectomy, transhiatal splanchnicectomy, transthoracic splanchnicectomy with or without vagotomy, and videoscopic transthoracic splanchnicectomy. For the patient who is a poor candidate for an abdominal procedure, the transthoracic ablation of the sympathetic chain, either on the left side alone or bilaterally, has been shown to result in pain relief in 60–66 percent of patients. The application of videoscopic techniques to thoracic splanchnicectomy has further reduced the risks and discomfort of these procedures in chronically ill patients, and provides a valuable alternative to a direct attack on the pancreas.

PANCREATIC NEOPLASMS

Neoplasms of the Endocrine Pancreas

Neoplasms of the endocrine pancreas are relatively uncommon, but do occur with enough frequency (five cases per million population) that most surgeons will encounter them in an urban practice. Most pancreatic endocrine neoplasms are functional, secreting peptide products that produce interesting clinical presentations. Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a pancreatic endocrine tumor. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases. Unfortunately, most pancreatic endocrine tumors are malignant, but the course of the disease is far more favorable than that seen with pancreatic exocrine cancer. The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward. The goals of surgery range from complete resection, often accomplished with insulinomas, to controlling symptoms with debulking procedures, as is the case with most other pancreatic endocrine neoplasms.

As with pancreatic exocrine tumors, the initial diagnostic imaging test of choice for pancreatic endocrine tumors is a dynamic abdominal CT scan with

fine cuts through the pancreas. Endoscopic ultrasound also can be valuable in localizing these tumors, which can produce dramatic symptoms despite their small (< 1 cm) size. In contrast to pancreatic exocrine tumors, many of the endocrine tumors have somatostatin receptors that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analog is injected intravenously, followed by whole-body radionuclide scanning. The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling.

Insulinoma

Insulinomas are the most common pancreatic endocrine neoplasms and present with a typical clinical syndrome known as Whipple triad. The triad consists of symptomatic fasting hypoglycemia, a documented serum glucose level less than 50 mg/dL, and relief of symptoms with the administration of glucose. Patients often will present with a profound syncopal episode and will admit to similar less severe episodes in the recent past. They also may admit to palpitations, trembling, diaphoresis, confusion or obtundation, and seizure, and family members may report that the patient has undergone a personality change. Routine laboratory studies will uncover a low blood sugar, the cause of all of these symptoms. The diagnosis is clinched with a monitored fast in which blood is sampled every 4–6 h for glucose and insulin levels until the patient becomes symptomatic. Elevated C-peptide levels rule out the unusual case of surreptitious administration of insulin or oral hypoglycemic agents, because excess endogenous insulin production leads to excess C-peptide. Insulinomas usually are localized with CT scanning and endoscopic ultrasound (EUS). Technical advances in EUS have led to preoperative identification of more than 90 percent of insulinomas. Visceral angiography with venous sampling is rarely required to accurately localize the tumor. Insulinomas are evenly distributed throughout the head, body, and tail of the pancreas. Unlike most endocrine pancreatic tumors, the majority (90 percent) of insulinomas are benign and solitary, with only 10 percent malignant. They are typically cured by simple enucleation. However, tumors located close to the main pancreatic duct and large (> 2 cm) tumors may require a distal pancreatectomy or pancreaticoduodenectomy. Intraoperative ultrasound is useful to determine the tumor's relation to the main pancreatic duct and guide intraoperative decision making. Enucleation of solitary insulinomas and distal pancreatectomy for insulinoma can be performed using a minimally invasive technique.

Ninety percent of insulinomas are sporadic and 10 percent are associated with the MEN-1 syndrome. Insulinomas associated with the MEN-1 syndrome are more likely to be multifocal and have a higher rate of recurrence.

Gastrinoma

Zollinger-Ellison syndrome (ZES) is caused by a gastrinoma, an endocrine tumor that secretes gastrin, leading to acid hypersecretion and peptic ulceration. Many patients with ZES present with abdominal pain, peptic ulcer disease, and severe esophagitis. However, in the era of effective antacid therapy, the presentation can be less dramatic. While most of the ulcers are solitary, multiple ulcers in atypical locations that fail to respond to antacids should raise suspicion for ZES and prompt a work-up. Twenty percent of patients with gastrinoma have diarrhea at the time of diagnosis.

The diagnosis of ZES is made by measuring the serum gastrin level. It is important that patients stop taking proton pump inhibitors for this test. In most patients with gastrinomas, the level is greater than 1000 pg/mL. Gastrin levels can be elevated in conditions other than ZES. Common causes of hypergastrinemia include pernicious anemia, treatment with proton pump inhibitors, renal failure, G-cell hyperplasia, atrophic gastritis, retained or excluded antrum, and gastric outlet obstruction. In equivocal cases, when the gastrin level is not markedly elevated, a secretin stimulation test is helpful.

In 70–90 percent of patients, the primary gastrinoma is found in the Passaro triangle, an area defined by a triangle with points located at the junction of the cystic duct and common bile duct, the second and third portion of the duodenum, and the neck and body of the pancreas. However, because gastrinomas can be found almost anywhere, whole-body imaging is required. The test of choice is somatostatin receptor (octreotide) scintigraphy in combination with CT. The octreotide scan is more sensitive than CT, locating about 85 percent of gastrinomas and detecting tumors smaller than 1 cm. With the octreotide scan, the need for tedious and technically demanding selective angiography and measurement of gastrin gradients has declined. Endoscopic ultrasound is another new modality that assists in the preoperative localization of gastrinomas. It is particularly helpful in localizing tumors in the pancreatic head or duodenal wall, in which gastrinomas are usually less than 1 cm in size. A combination of octreotide scan and EUS detects more than 90 percent of gastrinomas.

Multiple tumors are more common in patients with MEN-1 syndrome. Aggressive surgical treatment is justified in patients with sporadic gastrinomas. If patients have MEN-1 syndrome, the parathyroid hyperplasia is addressed with total parathyroidectomy and implantation of parathyroid tissue in the forearm.

Fifty percent of gastrinomas metastasize to lymph nodes or the liver, and are therefore considered malignant. Patients who meet criteria for operability should undergo exploration for possible removal of the tumor. Although the tumors are submucosal, a full-thickness excision of the duodenal wall is performed if a duodenal gastrinoma is found. All lymph nodes in the Passaro triangle are excised for pathologic analysis. If the gastrinoma is found in the pancreas and does not involve the main pancreatic duct, it is enucleated. Pancreatic resection is justified for solitary gastrinomas with no metastases. A highly selective vagotomy can be performed if unresectable disease is identified or if the gastrinoma cannot be localized. This may reduce the amount of expensive proton pump inhibitors required. In cases in which hepatic metastases are identified, resection is justified if the primary gastrinoma is controlled and the metastases can be safely and completely removed. Debulking or incomplete removal of multiple hepatic metastases is probably not helpful in the setting of MEN-1. Postoperatively, patients are followed with fasting serum gastrin levels, secretin stimulation tests, octreotide scans, and CT scans. Unfortunately, a biochemical cure is achieved in only about one third of the patients operated on for ZES. Despite the lack of success, long-term survival rates are good, even in patients with liver metastases. The 15-year survival rate for patients without liver metastases is about 80 percent, although the 5-year survival rate for patients with liver metastases is 20–50 percent. Pancreatic tumors are usually larger than tumors arising in the duodenum, and more often have lymph node metastases. In gastrinomas, liver metastases decrease survival rates, but lymph node metastases do not. The best results are seen after complete

excision of small sporadic tumors originating in the duodenum. Large tumors associated with liver metastases, located outside of Passaro's triangle, have the worst prognosis.

VIPoma

In 1958, Verner and Morrison first described the syndrome associated with a pancreatic neoplasm secreting vasoactive intestinal polypeptide (VIP). The classic clinical syndrome associated with this pancreatic endocrine neoplasm consists of severe intermittent watery diarrhea leading to dehydration, and weakness from fluid and electrolyte losses. Large amounts of potassium are lost in the stool. The VIPoma syndrome also is called the WDHA syndrome because of the presence of watery diarrhea, hypokalemia, and achlorhydria. The massive (5 L/d) and episodic nature of the diarrhea associated with the appropriate electrolyte abnormalities should raise suspicion of the diagnosis. Serum VIP levels must be measured on multiple occasions because the excess secretion of VIP is episodic, and single measurements might be normal and misleading. A CT scan localizes most VIPomas, although as with all islet cell tumors, EUS is the most sensitive imaging method. Electrolyte and fluid balance is sometimes difficult to correct preoperatively and must be pursued aggressively. Somatostatin analogs are helpful in controlling the diarrhea and allowing replacement of fluid and electrolytes. VIPomas are more commonly located in the distal pancreas and most have spread outside the pancreas. Palliative debulking operations can sometimes improve symptoms for a period, along with somatostatin analogs. Hepatic artery embolization also has been reported as a potentially beneficial treatment.

Glucagonoma

Diabetes in association with dermatitis should raise the suspicion of a glucagonoma. The diabetes usually is mild. The classic necrolytic migratory erythema manifests as cyclic migrations of lesions with spreading margins and healing centers typically on the lower abdomen, perineum, perioral area, and feet. The diagnosis is confirmed by measuring serum glucagon levels, which usually are over 500 pg/mL. Glucagon is a catabolic hormone and most patients present with malnutrition. The rash associated with glucagonoma is thought to be caused by low levels of amino acids. Preoperative treatment usually includes control of the diabetes, parenteral nutrition, and octreotide. Like VIPomas, glucagonomas are more often in the body and tail of the pancreas and tend to be large tumors with metastases. Again, debulking operations are recommended in good operative candidates to relieve symptoms.

Somatostatinoma

Because somatostatin inhibits pancreatic and biliary secretions, patients with a somatostatinoma present with gallstones because of bile stasis, diabetes because of inhibition of insulin secretion, and steatorrhea because of inhibition of pancreatic exocrine secretion and bile secretion. Most somatostatinomas originate in the proximal pancreas or the pancreatoduodenal groove, with the ampulla and periampullary area as the most common site (60 percent). The most common presentations are abdominal pain (25 percent), jaundice (25 percent), and cholelithiasis (19 percent). This rare type of pancreatic endocrine

tumor is diagnosed by confirming elevated serum somatostatin levels, which are usually above 10 ng/mL. Although most reported cases of somatostatinoma involve metastatic disease, an attempt at complete excision of the tumor and cholecystectomy is warranted in fit patients.

Nonfunctioning Islet-Cell Tumors

Most pancreatic endocrine neoplasms do secrete one or more hormones and are associated with characteristic clinical syndromes. After insulinoma, however, the most common islet-cell tumor is the nonfunctioning islet-cell neoplasm. Because it is clinically silent until its size and location produce symptoms, it is usually malignant when first diagnosed. Some presumably nonfunctional pancreatic endocrine neoplasms stain positive for PP and elevated PP levels are therefore a marker for the lesion. Because clinical manifestations are absent, the tumors are usually large and metastatic at the time of diagnosis, unless they are detected serendipitously on CT scan or sonogram. Nonfunctioning islet-cell tumors also are seen in association with other multiple neoplasia syndromes, such as von Hippel-Lindau syndrome. The tumors grow slowly and 5-year survival is common, as opposed to pancreatic exocrine tumors, for which 5-year survival is extraordinarily rare.

Neoplasms of the Exocrine Pancreas

Epidemiology and Risk Factors

Cancer of the pancreas is the fifth leading cause of cancer death in the United States, with approximately 30,300 new cases and 29,700 deaths reported in 2002. The etiology of pancreatic cancer likely involves a complex interaction of genetic and environmental factors.

A risk factor that is consistently linked to pancreatic cancer is cigarette smoking. Smoking increases the risk of developing pancreatic cancer by at least 2-fold because of the carcinogens in cigarette smoke. Long-standing diabetes may be a risk factor for pancreatic cancer. The new onset of diabetes or a sudden increase in insulin requirement in an older adult patient with preexisting diabetes should provoke concern for the presence of pancreatic cancer. Recent epidemiologic studies have confirmed the fact that patients with chronic pancreatitis have an increased risk of developing pancreatic cancer. Large, retrospective cohort studies of patients with pancreatitis have revealed up to a 20-fold increase in risk for pancreatic cancer. A family history of pancreatic cancer is also a well-recognized risk factor. A family history of pancreatic cancer in a first-degree relative increases the risk of pancreatic cancer by about twofold.

Diagnosis and Staging

Table 32-2 shows the tumor-node-metastasis (TNM) staging of pancreatic cancer. T1 lesions are smaller than 2 cm in diameter and are limited to the pancreas. T2 lesions also are limited to the pancreas, but are larger than 2 cm. T3 lesions extend into the duodenum or extrapancreatic bile duct. T4 lesions extend in to the portal vein, superior mesenteric vein, superior mesenteric artery, stomach, spleen, or colon. T1 and T2 tumors with no lymph node involvement are considered stage I disease, although more extensive invasion, such as that associated with T3 tumors, indicates stage II disease. Any lymph node involvement indicates stage III disease. Stage IV disease is divided into

TABLE 32-2 Staging of Pancreatic Cancer

Primary tumor (T)				
T1	Limited to pancreas, < 2 cm			
T2	Limited to pancreas, > 2 cm			
T3	Extension into duodenum or bile duct			
T4	Extension into portal vein, superior mesenteric vein, superior mesenteric artery, stomach, spleen, colon			
Regional lymph nodes (N)				
N0	No nodal metastases			
N1	Regional nodal metastases			
Distant metastases (M)				
M0	No distant metastases			
M1	Distant metastases (liver, lung)			
Stage	T	N	M	Description
I	1, 2	0	0	Tumor confined to pancreas
[2pt] II	3	0	0	Tumor invades duodenum and/or bile duct outside pancreas; no lymph node involvement
[2pt] III	1, 2, 3	1	0	Tumor has not spread beyond duodenum or bile duct, but includes regional lymph nodes
[2pt] IVA	4	Any	0	Locally advanced tumor growing into blood vessels, stomach, spleen, and colon, with or without lymph node involvement
[2pt] IVB	Any	Any	1	Distant metastases (liver, lungs) present

patients with locally advanced tumors (T4) without metastatic disease (stage IVA), and patients with metastases to distant sites such as the liver or lungs (stage IVB).

The most critical deficit in the ability to treat pancreatic cancer effectively is the lack of tools for early diagnosis. Ultimately, the majority of patients present with pain and jaundice. On physical exam, weight loss is evident and the skin is icteric; a distended gallbladder is palpable in about one fourth of patients. More fortunate patients have tumors situated such that biliary obstruction and jaundice occurs early and prompts diagnostic tests. Unfortunately, however, the vast majority of patients are not diagnosed until weight loss has occurred—a sign of advanced disease.

Although it often is taught that carcinoma of the pancreas presents with painless jaundice (to help distinguish it from choledocholithiasis), this aphorism is not accurate. Most patients do experience pain as part of the symptom complex of pancreatic cancer, and it is often the first symptom.

Unfortunately, at this time there is no sensitive and specific serum marker to assist in the timely diagnosis of pancreatic cancer. With jaundice, direct hyperbilirubinemia and elevated alkaline phosphatase are expected, but do not serve much of a diagnostic role other than to confirm the obvious. With longstanding biliary obstruction, the prothrombin time will be prolonged because of a depletion of vitamin K, a fat-soluble vitamin dependent on bile flow for absorption.

CA19-9 is a mucin-associated carbohydrate antigen that can be detected in the serum of patients with pancreatic cancer. Serum levels are elevated in about 75 percent of patients with pancreatic cancer; however, CA19-9 also is elevated in about 10 percent of patients with benign diseases of the pancreas, liver, and bile ducts. CA19-9 is thus neither sufficiently sensitive nor specific to allow an earlier diagnosis of pancreatic cancer. Despite the fact that many tumor markers, such as CA19-9, have been studied in an attempt to facilitate early diagnosis, there are still no effective screening tests for pancreatic cancer.

In patients presenting with jaundice, a reasonable first diagnostic imaging study is abdominal ultrasound. If bile duct dilation is not seen, hepatocellular disease is likely. Demonstration of cholelithiasis and bile duct dilation suggests a diagnosis of choledocholithiasis, and the next logical step would be endoscopic retrograde cholangiopancreatography (ERCP) to clear the bile duct. In the absence of gallstones, malignant obstruction of the bile duct is likely and a CT scan rather than ERCP would be the next logical step. For patients suspected of having pancreatic cancer who present without jaundice, ultrasound is not appropriate, and a CT scan should be the first test.

The current diagnostic and staging test of choice for pancreatic cancer is a dynamic contrast-enhanced CT scan, and techniques are constantly improving. The accuracy of CT scanning for predicting unresectable disease is 90–95 percent. CT findings that indicate a tumor is unresectable include invasion of the hepatic or superior mesenteric artery, enlarged lymph nodes outside the boundaries of resection, ascites, distant metastases (e.g., liver), and distant organ invasion (e.g., colon). Invasion of the superior mesenteric vein or portal vein is not in itself a contraindication to resection as long as the veins are patent. In contrast, CT scanning is less accurate in predicting resectable disease. CT scanning will miss small liver metastases and predicting vascular involvement is sometimes difficult.

Currently, CT is probably the single most versatile and cost-effective tool for the diagnosis of pancreatic cancer. Abdominal MRI is rapidly evolving but currently provides essentially the same information as CT scanning. Positron emission tomography (PET) scanning is becoming more widely available and may help distinguish chronic pancreatitis from pancreatic cancer. EUS can be used to detect small pancreatic masses that could be missed by CT scanning, and is commonly used when there is a high suspicion for pancreatic cancer but no mass is identified by the CT scan. EUS is a sensitive test for portal/superior mesenteric vein invasion, although it is somewhat less effective at detecting superior mesenteric artery invasion. When all of the current staging modalities are used, their accuracy in predicting resectability is reported to be about 80 percent, meaning that one in five patients brought to the operating room with the intent of a curative resection will be found at the time of surgery to have unresectable disease.

In an attempt to avoid such futile laparotomies, some surgeons have advocated the use of preliminary laparoscopy for patients with disease felt to be resectable by imaging. Diagnostic laparoscopy with the use of ultrasound is reported to improve the accuracy of predicting resectability to about 98 percent. The technique involves more than simple visualization with the scope, and requires the placement of three ports and manipulation of the tissues. The ultrasound probe is used to examine the liver, porta hepatis, and the portal vein and superior mesenteric artery.

Diagnostic laparoscopy is possibly best applied to patients with pancreatic cancer on a selective basis. Diagnostic laparoscopy will have a higher yield in

patients with large tumors (> 2 cm), tumors located in the body or tail, patients with equivocal findings of metastasis or ascites on CT scan, and patients with other indications of advanced disease such as marked weight loss or markedly elevated CA19-9.

Palliative Surgery and Endoscopy

In general, there are three clinical problems in advanced pancreatic cancer that require palliation: pain, jaundice, and duodenal obstruction. The mainstay of pain control is oral narcotics. Sustained-release preparations of morphine sulfate are frequently used. Invasion of retroperitoneal nerve trunks accounts for the severe pain experienced by patients with advanced pancreatic cancer. A celiac plexus nerve block can control pain effectively for a period of months, although the procedure sometimes needs to be repeated. At the time of initial exploration for pancreatic cancer, it is a good practice to think about pain control and consider performing an intraoperative celiac block regardless of whether a resection is performed. The procedure is performed by injecting 50 percent alcohol directly into the tissues along the sides of the aorta just cephalad and posterior to the origin of the celiac trunk. This can be accomplished quite easily with either open surgery or laparoscopic surgery, and does not prolong the operation by more than a few min. If necessary, the procedure can be repeated postoperatively, either percutaneously or with use of endoscopic ultrasound guidance.

Jaundice is present in the majority of patients with pancreatic cancer, and the most troublesome aspect for the patient is the accompanying pruritus. Biliary obstruction may also lead to cholangitis, coagulopathy, digestive symptoms, and hepatocellular failure. In the past, surgeons traditionally performed a biliary bypass when unresectable disease was found at laparotomy. As many patients today already have a bile duct stent in place by the time of operation, it is not clear that operative biliary bypass is required. If an operative bypass is performed, choledochojejunostomy is the preferred approach. Although an easy procedure to perform, choledochoduodenostomy is felt to be unwise because of the proximity of the duodenum to tumor. Some have discouraged the use of the gallbladder for biliary bypass; however, it is suitable as long as the cystic duct clearly enters the common duct well above the tumor.

Duodenal obstruction is usually a late event in pancreatic cancer and occurs in only about 20 percent of patients. Therefore, in the absence of signs or symptoms of obstruction, such as nausea or vomiting, or a tumor that is already encroaching on the duodenum at the time of surgery, the routine use of prophylactic gastrojejunostomy when exploration reveals unresectable tumor is controversial. Although anastomotic leaks are uncommon, gastrojejunostomy is sometimes associated with delayed gastric emptying, the very symptom the procedure is designed to treat.

Whether performing a biliary and enteric bypass or just a biliary bypass, the jejunum is brought anterior to the colon rather than retrocolic, in which the tumor potentially would invade the bowel sooner. Some surgeons use a loop of jejunum with a jejunojejunostomy to divert the enteric stream away from the biliary-enteric anastomosis. Others use a Roux-en-Y limb with the gastrojejunostomy located 50 cm downstream from the hepaticojejunostomy. Potential advantages of the defunctionalized Roux-en-Y limb include the ease with which it will reach up to the hepatic hilum, probable

decreased risk of cholangitis, and easier management of biliary anastomotic leaks. If a gastrojejunostomy is performed, it should be placed dependently and posterior along the greater curvature to improve gastric emptying, and a vagotomy should not be performed. If patients are explored laparoscopically and found to have unresectable disease, palliation of jaundice can be achieved in a minimally invasive fashion with ERCP and placement of a coated, expandable metallic endoscopic biliary stent. Endoscopic stents are definitely not as durable as a surgical bypass. Recurrent obstruction and cholangitis is more common with stents and results in inferior palliation. However, this minimally invasive approach is associated with considerably less initial morbidity and mortality than surgical bypass. Newer, expandable metallic Wallstents demonstrate improved patency and provide better palliation than plastic stents.

If an initial diagnostic laparoscopy reveals a contraindication to the Whipple procedure, such as liver metastases, it is not appropriate to perform a laparotomy simply to create a biliary bypass. In such a patient it is better to place an endoscopic stent. In contrast, if a laparotomy already has been performed as part of the assessment of resectability and the Whipple procedure is not possible, a surgical bypass usually is performed.

Palliative Chemotherapy and Radiation

In patients with unresectable pancreatic cancer, gemcitabine results in symptomatic improvement, improved pain control and performance status, and weight gain. However, survival is improved by only 1–2 months. Although these results may warrant treatment in patients who understand the benefits and risks, the lack of significant survival advantage should encourage physicians to refer motivated patients for experimental protocols because it is only through continued clinical research that more meaningful treatments for pancreatic cancer will be developed.

Surgical Resection: Pancreaticoduodenectomy

In a patient with appropriate clinical and/or imaging indications of pancreatic cancer, a tissue diagnosis prior to performing a pancreaticoduodenectomy is not essential. Although percutaneous CT-guided biopsy is usually safe, complications such as hemorrhage, pancreatitis, fistula, abscess, and even death can occur. Tumor seeding along the subcutaneous tract of the needle is uncommon. Likewise, fine-needle aspiration under endoscopic ultrasound guidance is safe and well tolerated. The problem with preoperative or even intraoperative biopsy is that many pancreatic cancers are not very cellular and contain a significant amount of fibrous tissue, so a biopsy may be misinterpreted as showing chronic pancreatitis if it does not contain malignant glandular cells. In the face of clinical and radiologic preoperative indications of pancreatic cancer, a negative biopsy should not preclude resection. In patients who are not candidates for resection because of metastatic disease, biopsy for a tissue diagnosis becomes important because these patients may be candidates for palliative chemotherapy and radiation therapy trials. It is especially important to make an aggressive attempt at tissue diagnosis prior to surgery in patients whose clinical presentation and imaging studies are more suggestive of alternative diagnoses such as pancreatic lymphoma or pancreatic islet-cell tumors. These patients might avoid surgery altogether in the case of lymphoma, or warrant an aggressive debulking approach in the case of islet-cell carcinoma.

Variations and Controversies in Whipple Procedure

The preservation of the pylorus has several theoretical advantages including prevention of reflux of pancreaticobiliary secretions into the stomach, decreased incidence of marginal ulceration, normal gastric acid secretion and hormone release, and improved gastric function. Patients with pylorus-preserving resections have appeared to regain weight better than historic controls in some studies. Return of gastric emptying in the immediate postoperative period may take longer after the pylorus-preserving operation, and it is controversial whether there is any significant improvement in long-term quality of life with pyloric preservation.

Techniques for the pancreaticojejunostomy include end-to-side or end-to-end and duct-to-mucosa sutures or invagination. Pancreaticogastrostomy also has been investigated. Some surgeons use stents, glue to seal the anastomosis, or octreotide to decrease pancreatic secretions. No matter what combination of these techniques is used, the pancreatic leakage rate is always about 10 percent. Therefore the choice of techniques depends more on the surgeon's personal experience.

Traditionally, most surgeons place drains around the pancreatic and biliary anastomoses because the most dreaded complication of pancreaticoduodenectomy, disruption of the pancreaticojejunostomy, cannot be avoided in 1 out of 10 patients. This complication can lead to the development of an upper abdominal abscess or can present as an external pancreatic fistula. Usually a pure pancreatic leak is controlled by the drains and will eventually seal spontaneously. Combined pancreatic and biliary leaks are cause for concern because bile will activate the pancreatic enzymes. In its most virulent form, disruption leads to necrotizing retroperitoneal infection, which can erode major arteries and veins of the upper abdomen, including the exposed portal vein and its branches or the stump of the gastroduodenal artery. Impending catastrophe often is preceded by a small herald bleed from the drain site. Such an event is an indication to return the patient to the operating room to widely drain the pancreaticojejunostomy and to repair the involved blood vessel. Open packing may be necessary to control diffuse necrosis and infection.

Many patients with pancreatic cancer are malnourished preoperatively and suffer from gastroparesis in the immediate postoperative period. Some surgeons routinely place a feeding jejunostomy tube and gastrostomy tube in all pancreaticoduodenectomies, although others make the decision on a case-by-case basis. Gastrostomy tubes may decrease the length of stay in patients with gastroparesis. Jejunostomy tubes are certainly not benign and can result in leaks and intestinal obstruction. However, parenteral nutrition also is associated with serious complications such as line sepsis, loss of gut mucosal integrity, and hepatic dysfunction.

Because of the high incidence of direct retroperitoneal invasion and regional lymph node metastasis at the time of surgery, it has been argued that the scope of resection for pancreatic cancer should be enlarged to include a radical regional lymphadenectomy and resection of areas of potential retroperitoneal invasion. The "radical pancreaticoduodenectomy" includes extension of the pancreatic resection to the middle body of the pancreas, segmental resection of the portal vein if necessary, resection of retroperitoneal tissue along the right perinephric area, and lymphadenectomy to the region of the celiac plexus. In the hands of experienced surgeons, these techniques are associated

with greater blood loss but no increase in mortality; however, improved survival has not been demonstrated. Total pancreatectomy also has been considered in the past. Although pancreatic leaks are eliminated, major morbidity from brittle diabetes and exocrine insufficiency outweigh any theoretical benefit.

Pancreatic cancer usually recurs locally after pancreaticoduodenectomy. Intraoperative radiotherapy (IORT) delivers a full therapeutic dose of radiation to the operative bed at the time of resection. Radiation to surrounding normal areas is minimized, but the radiation is delivered all in one setting, usually about 15 min, rather than in fractionated doses over time. IORT is best performed in a shielded, dedicated, operating room suite rather than by transporting the patient in the middle of an already long and complicated operation. IORT may improve local control and palliate symptoms after pancreaticoduodenectomy. However, IORT has not been shown to be superior to standard external beam radiation therapy, and further randomized trials are needed to determine how this modality should be used.

Complications of Pancreaticoduodenectomy

The operative mortality rate for pancreaticoduodenectomy has decreased to less than 5 percent in “high volume” centers (where more than five cases per year are performed), suggesting that patients in rural areas would benefit from referral to large urban centers. The most common causes of death are sepsis, hemorrhage, and cardiovascular events. Postoperative complications are unfortunately still very common, and include delayed gastric emptying, pancreatic fistula, and hemorrhage. Delayed gastric emptying is common after pancreaticoduodenectomy and is treated conservatively as long as complete gastric outlet obstruction is ruled out by a contrast study. Hemorrhage can occur either intraoperatively or postoperatively. Intraoperative hemorrhage typically occurs during the dissection of the portal vein. A major laceration of the portal vein can occur at a point in the operation at which the portal vein is not yet exposed. Temporary control of hemorrhage is generally possible in this situation by compressing the portal vein and superior mesenteric vein against the tumor with the surgeon’s left hand behind the head of the pancreas. An experienced assistant is needed to divide the neck of the pancreas to the left of the portal vein and achieve proximal and distal control. Sometimes the vein can be sutured closed with minimal narrowing. Other times, a patch repair or segmental resection and interposition graft may be needed.

Postoperative hemorrhage can occur from inadequate ligature of any one of numerous blood vessels during the procedure. Hemorrhage also can occur because of digestion of retroperitoneal blood vessels because of a combined biliary-pancreatic leak. Uncommonly, a stress ulcer, or later a marginal ulcer, can result in gastrointestinal hemorrhage. Typically, a vagotomy is not performed when pancreaticoduodenectomy is performed for pancreatic cancer, but patients are placed on proton pump inhibitors.

Outcome and Value of Pancreaticoduodenectomy for Cancer

Survival figures indicate that few, if any, patients are cured indefinitely of pancreatic cancer with pancreaticoduodenectomy. The tumor tends to recur locally with retroperitoneal and regional lymphatic disease. Additionally, most

patients also develop hematogenous metastases, usually in the liver. Malignant ascites, peritoneal implants, and malignant pleural effusions are all common. Median survival after pancreaticoduodenectomy is about 12–15 months. Even long-term (5-year) survivors often eventually die because of pancreatic cancer recurrence. Although pancreaticoduodenectomy may be performed with the hope of the rare cure in mind, the operation more importantly provides better palliation than any other treatment, and is the only modality that offers any meaningful improvement in survival. If the procedure is performed without major complications, many months of palliation are usually achieved. It is the surgeon's duty to make sure patients and their families have a realistic understanding of the true goals of pancreaticoduodenectomy.

Adjuvant Chemotherapy and Radiation

Small studies in the 1980s suggested that adjuvant chemotherapy with 5-fluorouracil combined with radiation improves survival by about 9 months after pancreatic resection for pancreatic adenocarcinoma. Subsequent non-controlled studies have reinforced that concept. However, a recent European multicenter trial concluded that there was no value to chemoradiotherapy, although the study suggested the possibility that chemotherapy alone might have survival benefit. Remarkable results in adjuvant therapy have been reported by the Virginia Mason Clinic with combination 5-FU, cisplatin, interferon- α and external beam radiation. Although the toxicity is high, the promising results have prompted larger confirmatory studies. Nevertheless, pending further study, it is typical in the United States for patients with acceptable functional status to receive adjuvant chemoradiotherapy after surgery.

Neoadjuvant Treatment

There are several potential advantages to the use of chemoradiation prior to an attempt at surgical resection. For example, it avoids the risk that adjuvant treatment is delayed by complications of surgery. Neoadjuvant treatment also may decrease the tumor burden at operation, increasing the rate of resectability and killing some tumor cells before they can be spread intraoperatively. Preoperative chemoradiation has been shown not to increase the perioperative morbidity or mortality of pancreaticoduodenectomy. It may even decrease the incidence of pancreatic fistula. Studies so far indicate that local or regional recurrence is decreased with this technique, but there is no proven survival advantage compared to traditional postoperative therapy.

Management of Periampullary Adenomas

Benign villous adenomas of the ampullary region can be excised locally. This technique is applicable only for small tumors (approximately 2 cm or less) with no evidence of malignancy on biopsy. A longitudinal duodenotomy is made and the tumor is excised with a 2–3-mm margin of normal duodenal mucosa. The edges of the bile duct and pancreatic duct are sewn to the duodenal wall as the excision progresses. A preoperative diagnosis of cancer is a contraindication to transduodenal excision and pancreaticoduodenectomy should be performed. Likewise, if final pathologic examination of a locally excised tumor reveals invasive cancer, the patient should be returned to the operating room for a pancreaticoduodenectomy.

An important subset of patients is one with familial adenomatous polyposis (FAP), who develop periampullary or duodenal adenomas. These lesions have a high incidence of harboring carcinoma, and frequently recur unless the mucosa at risk is resected. A standard (not pylorus-sparing) Whipple is the procedure of choice in FAP patients with periampullary lesions.

Cystic Neoplasms of the Pancreas

Cystic epithelial tumors need to be excluded when patients present with a fluid-containing pancreatic lesion. A variety of cystic neoplasms exist, and include benign serous cystic neoplasms, benign and malignant mucinous cystic neoplasms, and benign and malignant forms of intraductal papillary-mucinous neoplasms (IPMNs). IPMNs can present with a dilated pancreatic duct because of the production of mucin by the lesion. At ERCP or upper endoscopy, mucus may be seen extruding from a gaping ampullary orifice. This confirms the presence of an IPMN, and further investigation is warranted to localize the lesion. It is important to not assume that all fluid-filled pancreatic abnormalities represent pseudocysts, or that a dilated pancreatic duct represents only chronic pancreatitis. The presence of a solid component in a cystic lesion, septations within the cyst, and the absence of a clinical history of pancreatitis are factors that should alert the surgeon to the possible presence of a neoplasm. Even in the absence of these factors, presumed pseudocysts should be biopsied at the time of internal drainage to confirm the absence of malignancy, and dilated pancreatic ducts should be biopsied at the time of a decompression procedure to rule out a ductular neoplasm.

Cystic neoplasms with septations and/or irregular nodularity of the cyst wall are more suspicious for malignancy. In an effort to establish a preoperative diagnosis of malignancy, the cyst fluid can be aspirated using EUS and analyzed. Cysts containing viscous fluid with a low amylase content and an elevated carcinoembryonic antigen level are more likely to be malignant. Cytologic examination of the aspirate also can be performed to aid in the diagnosis.

Cystic pancreatic lesions are usually resected if there is any concern regarding malignant potential. Enucleation of small cystic pancreatic neoplasms that are presumed to be benign may be a valid approach; the use of intraoperative ultrasound in such cases is helpful in avoiding injury to the main pancreatic duct and postoperative fistulas. Laparoscopic distal pancreatectomy with or without splenic preservation may be employed for cystic lesions located in the tail of the pancreas. With limited experience worldwide with laparoscopic pancreatic resection, caution is warranted before application of this technique to potentially malignant lesions.

Small cystic lesions in the head of the pancreas present a difficult challenge. Because of the morbidity and mortality risk of pancreaticoduodenectomy, a more conservative operative approach is attractive in a patient with a premalignant lesion such as a mucinous cystadenoma. The duodenum-preserving pancreatic head resections described earlier may offer a safer option when the lesion does not encroach on the duodenum and appears well delineated.

Pseudopapillary and Papillary-Cystic Neoplasms

An unusual form of exocrine neoplasm occurs predominantly in young women, and is characterized by a large, cystic or partially cystic appearing lesion which contains frond-like papillary elements on histologic examination.

Pseudopapillary and papillary-cystic neoplasms are usually benign, but may assume malignant (metastatic) behavior when they are discovered late in their course. Typically occurring in women from adolescence through the age of menopause, these lesions have been found to express estrogen and progesterone receptors in large numbers. Resection for cure is usually possible despite their typically large size.

Pancreatic Lymphoma

Lymphoma can affect the pancreas. Primary involvement of the pancreas with no disease outside the pancreas also occurs. The clinical presentation often is similar to pancreatic adenocarcinoma, with vague abdominal pain and weight loss. Identification of a large mass often involving the head and body of the pancreas should raise suspicion. Percutaneous or EUS-guided biopsy will confirm the diagnosis in most cases. If the diagnosis cannot be confirmed preoperatively, laparoscopic exploration and biopsy is indicated. There is no role for resection in the management of pancreatic lymphoma. Endoscopic stenting to relieve jaundice followed by chemotherapy is the standard treatment, and long-term remission often is achieved.

Until modern times removal of the spleen usually resulted in death of the patient. Pre-nineteenth century splenectomy carried a mortality rate in excess of 90 percent. By 1920 the Mayo Clinic experience with splenectomy reported an 11 percent mortality rate. Currently, the largest series of laparoscopic splenectomies report an overall mortality of 1 percent or less.

EMBRYOLOGY AND ANATOMY

The spleen is the largest reticuloendothelial organ in the body. Arising from the primitive mesoderm as an outgrowth of the left side of the dorsal mesogastrium, by the fifth week of gestation the spleen is evident. The organ continues its differentiation and migration to the left upper quadrant, in which it comes to rest with its smooth, diaphragmatic surface facing posterosuperiorly.

The accessory spleen, the most common anomaly of splenic embryology, is present in up to 20 percent of the population and up to 30 percent of patients with hematologic disease. Over 80 percent of the time, the accessory spleen is found in the splenic hilum and vascular pedicle region.

The abdominal surface of the diaphragm separates the spleen from the lower left lung and pleura and the ninth to eleventh ribs. The spleen's visceral surface faces the abdominal cavity and contains gastric, colic, renal, and pancreatic impressions. A capsule 1–2-mm thick, rich in collagen, and containing elastin fibers contains the spleen. An average adult spleen is 7–11 cm in length and weighs 150 g (range 70–250 g). The term splenomegaly is generally applied to organs weighing 500 mg or more and/or 15 cm or more in length.

Of particular clinical relevance, the spleen is suspended in position by several ligaments and peritoneal folds to the colon (splenocolic ligament); the stomach (gastrosplenic ligament); the diaphragm (phrenosplenic ligament); and the kidney, adrenal gland, and tail of the pancreas (splenorenal ligament). The gastrosplenic ligament contains the short gastric vessels. The remaining ligaments are usually avascular. In cadaveric anatomic series, the tail of the pancreas lies within 1 cm of the splenic hilum 75 percent of the time and actually abuts the spleen in 30 percent of patients.

The spleen derives most of its blood from the splenic artery. Splenic arteries are of two types: the most common (70 percent) distributed type is distinguished by a short trunk with many long branches entering over three fourths of the medial surface of the spleen whereas the less common (30 percent) magistral type has a long main trunk dividing near the hilum into short terminal branches entering over 25–30 percent of the medial surface. The spleen also receives some of its blood supply from the short gastric vessels, which are branches of the left gastroepiploic artery. The splenic vein accommodates the major venous drainage of the spleen.

The splenic parenchyma is composed of two main elements: the red pulp, approximately 75 percent of total splenic volume, and the white pulp. The red pulp is comprised of large numbers of venous sinuses, which ultimately drain into tributaries of the splenic vein and are surrounded and separated by a fibrocellular network, called the reticulum, consisting of collagen fibers and fibroblasts. Within this network or mesh lie splenic macrophages. These

intersinusoidal regions appear as splenic cords. The venous sinuses are lined by long, narrow endothelial cells that are variably in close apposition to one another or separated by intercellular gaps in a configuration unique to the spleen. The red pulp serves as a dynamic filtration system, enabling macrophages to remove microorganisms, cellular debris, antigen/antibody complexes, and senescent erythrocytes from circulation.

Around the terminal millimeters of splenic arterioles, a periarticular lymphatic sheath replaces the native adventitia of the vessel. The sheath is comprised of T lymphocytes and intermittent aggregations of B lymphocytes or lymphoid follicles. When antigenically stimulated, the follicles, which are centers of lymphocyte proliferation, develop germinal centers that regress as the stimulus or infection subsides. This white pulp, normally consisting of nodules 1 mm or less in size, can increase to several centimeters in size when nodules coalesce. At the interface between the white and red pulp is the marginal zone, in which lymphocytes are more loosely aggregated. Blood is delivered from this zone to the red pulp, in which lymphocytes and locally produced immunoglobulins ultimately enter the systemic circulation.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Splenic function has historically been summarized as: (1) filtration, (2) host defense, (3) storage, and (4) cytopoiesis. Total splenic inflow of blood is approximately 250–300 mL/min. As blood enters the red pulp, its rate of flow through the spleen can vary greatly. The filtration function of the spleen occurs primarily via the slower circulation. In open circulation, blood percolates through reticular space and splenic cords, gaining access through gaps or slits in the endothelial cell lining to venous sinuses. Blood is thus exposed to extensive contact with splenic macrophages. Plasma is not similarly slowed during its passage through these spaces. Thus, temporary and unique adhesive contact between blood cells and components of the splenic cord may occur. Further evidence of the selective slowing of blood cell flow versus plasma flow is indicated by a concentration of erythrocytes (hematocrit) twice that of the general circulation within the spleen. It is likely during this contact with splenic macrophages that removal of cellular debris and senescent blood cells occurs.

The spleen is the major organ clearing damaged or aged red blood cells and it also plays a role in removing abnormal white blood cells and platelets. During an erythrocyte's 120-day life cycle, a 2-day minimum is spent sequestered in the spleen, in which approximately 20 mL of aged red blood cells are removed daily.

The spleen plays a significant, although not indispensable role in host defense, contributing to both humoral and cell-mediated immunity. Antigens are filtered in the white pulp and presented to immunocompetent centers within the lymphoid follicles, giving rise to the elaboration of immunoglobulins (predominantly IgM). Such an acute IgM response results in the release of opsonic antibodies from the spleen's white pulp. Clearance of the antigen by the splenic and hepatic reticuloendothelial (RE) systems then occurs.

The spleen also produces the opsonins, tuftsin and properdin. Tuftsin, a likely stimulant to general phagocytic function in the host, appears to specifically facilitate clearance of bacteria. Circulating monocytes converted into fixed macrophages with the red pulp account for the spleen's remarkable phagocytic activity.

The spleen also appears to be a major source of properdin, the protein important in the initiation of the alternate pathway of complement activation. The splenic RE system is better able to clear bacteria poorly or inadequately opsonized from the circulation than is the hepatic RE system. There appears to be sufficient physiologic capacity within the complement cascade to withstand the loss of tuftsin and properdin production without increasing patient vulnerability postsplenectomy.

In patients suffering chronic hemolytic disorders, splenic tissue may become permanently hypertrophied. The reticular spaces of the red pulp sometimes become distended with macrophages engorged with the products of erythrocyte breakdown, and as a result the spleen may greatly enlarge (splenomegaly). Splenomegaly alone is an uncommon indication for splenectomy. Hypersplenism or the presence of cytopenia (of one or more blood cell lines) in the context of normally responding bone marrow is one of the most common indications.

Disorders causing hypersplenism in an intrinsically normal spleen can be categorized as either those in which occurs (1) increased destruction of abnormal blood cells or (2) increased sequestration and destruction of normal blood cells.

Hypersplenism may result in neutropenia by sequestration of normal white blood cells or the removal of abnormal ones. Platelets, on the other hand, generally survive in the circulation for 10 days. Under normal circumstances one third of the total platelet pool is sequestered in the spleen. Thrombocytopenia may result from excessive sequestration of platelets and accelerated platelet destruction in the spleen. Splenomegaly may result in sequestration of up to 80 percent of the platelet pool. The spleen may also contribute to the immunologic alteration of platelets, leading to thrombocytopenia in the absence of splenomegaly.

As a site of blood-borne antigen presentation and the initiation of T and B lymphocyte activities involved in humoral and cellular immune responses, the spleen is consistent in immunologic function with other lymphoid organs. Alteration of splenic immune function often gives rise to antibody production, resulting in blood cell destruction.

EVALUATION OF SIZE AND FUNCTION

Before elective splenectomy, imaging of the spleen is frequently indicated to assess size and to determine degree, if any, of splenomegaly.

The sensitivity of ultrasound for detecting textural lesions of the spleen is as high as 98 percent in experienced hands. Computed tomography (CT) scanning affords a high degree of resolution and detail of the spleen and is useful for assessment of splenomegaly, identification of splenic lesions, and guidance for percutaneous procedures. Iodinated contrast material adds diagnostic clarity to CT imaging.

Besides US and CT scan, plain radiography, magnetic resonance imaging (MRI), and radioscinigraphy can be used to image the spleen. Plain radiography, rarely used alone for splenic imaging, can provide an outline of the spleen in the left upper quadrant, suggest splenomegaly, or demonstrate calcifications. MRI offers no advantages in depicting anatomic spleen abnormalities. Radioscinigraphy with ^{99m}Tc sulfur colloid demonstrates splenic location and size; there is little benefit to its use as a preoperative scan.

The splenic index (SI) expresses spleen size as a volume in milliliters (mL) and is obtained by multiplying the spleen's length, width, and height as determined by a reliable imaging modality. Normal values for SI range from 120–480 mL. The normal *ex vivo* weight of the spleen is 150 g.

INDICATIONS FOR SPLENECTOMY

The conditions for which splenectomy is therapeutic include disorders of red blood cells, early cell lines (myeloproliferative disorders), white blood cells, platelets, and miscellaneous disorders and lesions (Table 33-1).

The most common indication for splenectomy is trauma to the spleen, whether iatrogenic or otherwise. Splenectomy for traumatic rupture is addressed in Chapter 6. The most frequent indication for elective splenectomy had been staging for Hodgkin disease, but more recent data suggest it is now idiopathic thrombocytopenic purpura (ITP). In descending order of frequency, other indications include hereditary spherocytosis, autoimmune hemolytic anemia, and thrombotic thrombocytopenic purpura.

TABLE 33-1 Indications for Splenectomy

-
1. Red cell disorders
 - a. Congenital
 - i. Hereditary spherocytosis
 - ii. Hemoglobinopathies
 1. Sickle cell disease
 2. Thalassemia
 3. Enzyme deficiencies
 - b. Acquired
 - i. Autoimmune hemolytic anemia
 - ii. Parasitic diseases
 2. Platelet disorders
 - a. Idiopathic thrombocytopenic purpura (ITP)
 - b. Thrombotic thrombocytopenic purpura (TTP)
 3. White cell disorders
 - a. Leukemias
 - b. Lymphomas
 - c. Hodgkin disease
 4. Bone marrow disorders (myeloproliferative disorders)
 - a. Myelofibrosis (myeloid metaplasia)
 - b. Chronic myeloid leukemia (CML)
 - c. Acute myeloid leukemia (AML)
 - d. Chronic myelomonocytic leukemia (CMML)
 - e. Essential thrombocythemia
 - f. Polycythemia vera
 5. Miscellaneous disorders and lesions
 - a. Infections/abscess
 - b. Storage diseases/infiltrative disorders
 - i. Gaucher disease
 - ii. Niemann-Pick disease
 - iii. Amyloidosis
 - c. Felty syndrome
 - d. Sarcoidosis

Red Blood Cell Disorders

Acquired

Autoimmune hemolytic anemia. The autoimmune hemolytic anemias are a set of disorders characterized by autoantibodies against antigens on red blood cells, which decrease the erythrocyte life span. Autoimmune hemolytic anemia (AIHA) is classified into “warm” or “cold” categories, based on the temperature at which the autoantibodies exert their effect. Warm autoantibodies (IgG) bind erythrocytes at 37° C (98.6° F); cold agglutinins (typically IgM) cause erythrocytes to clump at cold temperatures. Warm-antibody is the type of AIHA best treated by splenectomy.

Warm-antibody AIHA. The incidence of warm-antibody AIHA is approximately 1:100,000. More common among women, AIHA occurs at all ages, but is principally seen in mid-life. About one-half of cases are idiopathic. Clinical findings include mild jaundice and symptoms and signs of anemia. Splenomegaly occurs in one third to one half of patients, sometimes enough to result in a palpable spleen on physical examination. Other physical findings may include pallor or slight jaundice. AIHA may develop acutely, with severe symptoms and signs, or gradually, with a relatively asymptomatic presentation. In acute disease, signs of congestive heart failure may be observed.

The diagnosis of AIHA is made by demonstrating hemolysis, followed by performing a direct Coombs test, in which a sample of the patient’s blood is mixed with IgG antibody (Coombs reagent). Agglutination represents a positive reaction, indicating the presence of IgG or complement bound to the red blood cell membrane. A positive direct Coombs test confirms the diagnosis of AIHA and distinguishes autoimmune from other forms of hemolytic anemia.

Red blood cells are opsonized by autoantibodies and are destroyed, either directly within the circulation (intravascular hemolysis), or removed from the circulation by tissue macrophages located primarily in the spleen and to a lesser extent in the liver (extravascular hemolysis).

Treatment of AIHA depends on how severe it is and whether it is primary or secondary. Severe anemia (<4 g/dL), causing pulmonary edema, tachycardia, postural hypotension, dyspnea, and angina, demands red blood cell transfusion. Corticosteroids act as the mainstay of treatment for both primary and secondary forms of symptomatic, unstable AIHA. Splenectomy is indicated for failure to respond to steroids, intolerance of steroid side effects, requirement for excessive steroid doses to maintain remission, or inability to receive steroids for other reasons. A favorable response to splenectomy can be expected in up to 80 percent of patients with warm-antibody AIHA.

Congenital

Hereditary spherocytosis. Hereditary spherocytosis (HS) is a disorder of the red blood cell membrane resulting in hemolytic anemia. With an estimated prevalence in Western populations of 1 in 5000, HS is the most common hemolytic anemia for which splenectomy is indicated. The underlying abnormality in HS is an inherited dysfunction or deficiency in one of the erythrocyte membrane proteins (spectrin, ankyrin, band 3 protein, or protein 4.2), resulting in lack of deformability, leading to sequestration and destruction of the spherocytic erythrocytes in the spleen.

Most patients with HS are relatively asymptomatic, although rare fatal crises occur, usually in the setting of infection (e.g., parvovirus). Patients with typical

forms of HS may have mild jaundice. Splenomegaly is usually present on physical examination. Spherocytes are readily apparent on peripheral blood film.

Splenectomy is curative for typical forms of HS and serves as the sole mode of therapy. Patients with severe disease usually show a dramatic clinical improvement, even although hemolysis may persist. Because HS may affect children, the timing of splenectomy is important to reduce the very small possibility of overwhelming postsplenectomy sepsis. Most authors recommend delaying the operation until the patient is at least age 4 but before age 7, unless the anemia and hemolysis accelerate. Intractable leg ulcers represent an indication for early splenectomy, because they heal only after removal of the spleen.

Hemoglobinopathies. Sickle cell disease is an inherited chronic hemolytic anemia resulting from the mutant sickle cell hemoglobin (Hb S) within the red blood cell. The prevalence of sickle cell carriers is about 8–10 percent among African Americans in the United States, resulting in 4000–5000 newborns per year at risk for sickle cell disease. In western Africa, by contrast, approximately 120,000 newborns are at risk annually.

The underlying genetic abnormality in sickle cell disease results in the substitution of valine for glutamic acid as the sixth amino acid of the beta-globin chain. Affected B chains lack deformability. This characteristic, in addition to other processes, results in microvascular congestion, which may lead to thrombosis, ischemia, and tissue necrosis. Intermittent painful episodes characterize the disorder.

The most frequent indications for splenectomy among patients with sickle cell disease are hypersplenism and acute sequestration crises, followed by splenic abscess. The occurrence of one major acute sequestration crisis, characterized by rapid painful enlargement of the spleen and circulatory collapse, is generally considered sufficient grounds for splenectomy, as subsequent attacks occur in 40–50 percent of patients, with a mortality rate of 20 percent. The incidence of acute sequestration crises is approximately 5 percent in children with sickle cell disease. Approximately 3 percent of children with sickle cell disease ultimately require splenectomy. Preoperative preparation includes special attention to adequate hydration and avoidance of hypothermia.

Splenectomy does not affect the sickling process, and therapy for sickle cell anemia largely remains palliative. Transfusions are indicated for anemia especially before splenectomy, and for moderately severe episodes of the acute chest syndrome characterized by a new infiltrate on chest radiograph associated with new symptoms, such as fever, cough, sputum production, or hypoxia.

Thalassemia. The thalassemias are a group of inherited disorders of hemoglobin synthesis prevalent among people of Mediterranean extraction, classified according to the hemoglobin chain affected (i.e., α , β , or γ). As a group they are the most common genetic diseases known arising from a single gene defect.

The primary defect in all forms of thalassemia is reduced or absent production of hemoglobin chains. Two significant consequences arise from this abnormality: (1) underproduction of hemoglobin, and (2) excess production of unpaired hemoglobin subunits. Both factors contribute to the morbidity and mortality associated with thalassemia.

The clinical spectrum of the thalassemias is wide. Heterozygous carriers of the disease are usually asymptomatic, but homozygous individuals typically

present before 2 years of age with pallor, growth retardation, jaundice, and abdominal swelling because of liver and spleen enlargement. Other characteristics of thalassemia major include intractable leg ulcers, head enlargement, frequent infections, and a requirement for chronic blood transfusions. Untreated individuals usually die in late infancy or early childhood from severe anemia.

Treatment for thalassemia consists of red blood cell transfusions to keep the hemoglobin count greater than 9 mg/dL, along with intensive parenteral chelation therapy with deferoxamine. Splenectomy is indicated for patients with excessive transfusion requirements (> 200 mL/kg per year), discomfort because of splenomegaly, or painful splenic infarction. A careful assessment of the risk-to-benefit ratio for splenectomy is essential, because infectious morbidity following splenectomy in patients with thalassemia is greater than in other patients undergoing splenectomy for hematologic indications.

Bone Marrow Disorders (Myeloproliferative Disorders)

The myeloproliferative disorders are characterized by an abnormal growth of cell lines in the bone marrow. They include chronic myeloid leukemia (CML), acute myeloid leukemia (AML), chronic myelomonocytic leukemia (CMML), essential thrombocythemia (ET), polycythemia vera (PV), and myelofibrosis, also known as agnogenic myeloid metaplasia (see the myelofibrosis section in this chapter). The common underlying problem leading to splenectomy in these disorders is symptomatic splenomegaly. Symptoms because of splenomegaly consist of early satiety, poor gastric emptying, heaviness or pain in the left upper quadrant, and even diarrhea. Hypersplenism, although usually associated with splenomegaly, is a distinct condition. Hypersplenism refers to the presence of one or more peripheral cytopenias in the presence of a normally compensating bone marrow, and can be corrected or improved by splenectomy.

Chronic Myeloid Leukemia

CML is a disorder of the primitive pluripotent stem cell in the bone marrow, resulting in a significant increase in erythroid, megakaryotic, and pluripotent progenitors in the peripheral blood smear. The genetic hallmark is a transposition between the *bcr* gene on chromosome 9 and the *abl* gene on chromosome 22. CML is frequently asymptomatic in the chronic phase, but symptomatic patients often present with the gradual onset of fatigue, anorexia, sweating, and left upper quadrant pain and early satiety secondary to splenomegaly. Enlargement of the spleen is found in roughly one half of patients with CML. Splenectomy is indicated to ease pain and early satiety.

Acute Myeloid Leukemia

AML is characterized by a more rapid and dramatic clinical presentation than CML. Death usually results within weeks to months if AML remains untreated. Patients with other myeloproliferative disorders, such as polycythemia vera, primary thrombocytosis, or myeloid metaplasia, are at increased risk for leukemic transformation to AML. Presenting signs and symptoms of AML include a viral-like illness with fever, malaise, and frequently bone pain because of the expansion of the medullary space. Splenomegaly is modest but palpable on physical exam in up to 50 percent of patients. Splenectomy is indicated in AML in the uncommon circumstance that left upper quadrant pain and early

satiety become unbearable. Splenectomy in AML adds further risk of infection to patients immunocompromised by neutropenia and chemotherapy.

Chronic Myelomonocytic Leukemia

Chronic myelomonocytic leukemia (CMML) differs from CML in that it is associated with monocytosis in the peripheral smear ($> 1 \times 10^3/\text{mm}^3$) and in the bone marrow. Splenomegaly occurs in one-half of these patients, and splenectomy can result in symptomatic relief.

Essential Thrombocythemia

Essential thrombocythemia (ET) represents abnormal growth of the megakaryocyte cell line, resulting in increased levels of platelets in the bloodstream. Clinical manifestations of ET include vasomotor symptoms, thrombohemorrhagic events, recurrent fetal loss, and the transformation to myelofibrosis with myeloid metaplasia or acute myeloid leukemia. Splenomegaly occurs in one-third to one-half of patients with ET, and its presence may help to distinguish essential from secondary thrombocytosis. Splenectomy is not felt to be helpful in the early stages of ET, and is best reserved for the later stages of disease, in which myeloid metaplasia has developed. Candidates should be chosen selectively, because significant bleeding has been reported to complicate splenectomy.

Polycythemia Vera

Polycythemia vera (PV) is a rare, chronic, progressive myeloproliferative disorder characterized by an increase in red blood cell mass, frequently accompanied by leukocytosis, thrombocytosis, and splenomegaly. Patients affected by PV typically enjoy prolonged survival compared to others affected by hematologic malignancies. Affected patients may present with any number of nonspecific complaints, including headache, dizziness, weakness, pruritus, visual disturbances, excessive sweating, joint symptoms, and weight loss. Physical findings include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension. Treatment ranges from phlebotomy and aspirin to chemotherapeutic agents. As in ET, splenectomy is not helpful in the early stages of disease and is best reserved for late-stage patients in whom myeloid metaplasia has developed and splenomegaly related symptoms are severe.

Myelofibrosis (Agnogenic Myeloid Metaplasia)

The term myelofibrosis may be used to describe either the generic condition of fibrosis of the bone marrow (which may be associated with a number of benign and malignant disorders) or a specific, chronic, malignant hematologic disease associated with splenomegaly, red blood cell and white blood cell progenitors in the bloodstream, marrow fibrosis, and extramedullary hematopoiesis, otherwise known as agnogenic myeloid metaplasia (AMM). Use of the term myelofibrosis in this chapter will be synonymous with AMM.

In AMM fibrosis of the bone marrow is believed to be a response to a clonal proliferation of hematopoietic stem cells. Marrow failure often ensues, but whether this failure is secondary to the fibrosis itself or to the malignant proliferation of cells is unknown. Clinical manifestations of AMM most frequently relate to anemia, including fatigue, weakness, dyspnea on exertion, and palpitations. About 20 percent of patients, however, are asymptomatic and

seek medical attention because of an enlarged spleen on physical exam or an abnormal blood smear. Other clinical manifestations of AMM include bleeding, fever, weight loss, gout/renal stones, night sweats, and symptoms because of an enlarged spleen. Nearly all patients with AMM have splenomegaly, 35 percent of patients have massive splenomegaly, and two thirds have hepatomegaly.

Nucleated red blood cells and immature myeloid elements in the blood are present in 96 percent of cases and strongly suggest the diagnosis. Care must be taken, however, to exclude a history of a primary neoplasm or tuberculosis, because patients with these conditions may develop secondary myelofibrosis.

Asymptomatic patients are closely followed, whereas symptomatic patients undergo therapeutic intervention targeted toward their symptoms. Splenomegaly related symptoms are best treated with splenectomy.

A thorough preoperative workup must precede splenectomy in patients with AMM. The candidate must possess acceptable cardiac, pulmonary, hepatic, and renal reserve for the operation. The coagulation system should be examined, including tests of coagulation factors V and VIII, fibrin split products, platelet count, and bleeding time. Low platelet counts may require adrenal steroids and/or platelet transfusion at the time of surgery. Splenectomy imparts durable, effective palliation for nearly all patients with AMM, although postoperative complications are more common in patients with AMM than in those with other hematologic indications.

White Blood Cell Disorders

Leukemias

Chronic lymphocytic leukemia. Chronic lymphocytic leukemia and hairy cell leukemia (HCL) are the two leukemias most amenable to treatment by splenectomy. Symptoms of CLL are nonspecific and include weakness, fatigue, fever without illness, night sweats, and frequent bacterial and viral infections. Splenomegaly may be massive or barely palpable below the costal margin. Splenectomy is indicated to improve cytopenias. Splenectomy may thus facilitate chemotherapy in patients whose cell counts were prohibitively low prior to spleen removal. Palliative splenectomy also is indicated for symptomatic splenomegaly.

Hairy cell leukemia. Hairy cell leukemia is characterized by splenomegaly, pancytopenia, and large numbers of abnormal lymphocytes in the bone marrow. These lymphocytes contain irregular hair-like cytoplasmic projections identifiable on the peripheral smear. Most patients seek medical attention because of symptoms related to anemia, neutropenia, thrombocytopenia, or splenomegaly.

The most common physical finding is splenomegaly, which occurs in 80 percent of patients with HCL and often is palpable 5 cm below the costal margin. Treatment is indicated for those with moderate to severe symptoms related to cytopenias, such as repeated infections or bleeding episodes, or to splenomegaly. Newer chemotherapeutic agents (the purine analogues 2'-deoxycoformycin [2'-DCF] and 2-chlorodeoxyadenosine [2-CdA]) are able to induce durable complete remission in most patients.

Lymphomas

Non-Hodgkin lymphoma. Non-Hodgkin lymphoma (NHL) encompasses all malignancies derived from the lymphoid system except classic Hodgkin disease. Surgical staging is no longer indicated for NHL, as the combination of history and physical examination, chest radiograph and abdominal/pelvic CT scan, biopsy of involved lymph nodes (including laparoscopically directed nodal and liver biopsies), and bone marrow biopsy is sufficient. Splenomegaly exists in various, but not all, forms of NHL, and splenectomy is indicated for symptoms related to an enlarged spleen and to improve cytopenias.

Hodgkin disease. Hodgkin disease (HD) is a disorder of the lymphoid system characterized by the presence of Reed-Sternberg cells, which actually form the minority of the Hodgkin's tumor. The spleen is often an occult site of spread, but massive splenomegaly is not common. Additionally, large spleens do not necessarily signify involvement.

The staging procedure for HD begins with a wedge biopsy of the liver, splenectomy, and the removal of representative nodes in the retroperitoneum, mesentery, and hepatoduodenal ligament. Staging for HD may be performed laparoscopically. A laparoscopic core biopsy of the liver is performed under direct visualization, either using a Tru-cut needle percutaneously or by wedge resection with shears and cautery. Finally, an iliac marrow biopsy is generally included. Refinements of CT scanning and the more liberal use of chemotherapy for patients with HD have significantly reduced the indications for surgical staging of the disease. Current indications for surgical staging include clinical stage I or stage II with nodular sclerosing histology and no symptoms referable to HD. Staging information affects treatment, as early stage patients who have no splenic involvement may be candidates for radiotherapy alone. Those with splenic involvement generally require chemotherapy or multimodality therapy.

Platelet Disorders

Idiopathic Thrombocytopenic Purpura (ITP)

ITP, also called immune thrombocytopenic purpura, is an autoimmune disorder characterized by a low platelet count and mucocutaneous and petechial bleeding. The low platelet count stems from premature removal of platelets opsonized by antiplatelet IgG autoantibodies produced in the spleen. The estimated incidence of ITP is 100 persons per million annually, about one-half of whom are children. Adult-onset and childhood-onset ITP are strikingly different in their clinical course and management.

Patients with ITP typically present with petechiae or ecchymosis, although some will experience major bleeding from the outset. Bleeding may occur from mucosal surfaces in the form of gingival bleeding, epistaxis, menorrhagia, hematuria, or even melena. Patients with platelet counts below $10,000/\text{mm}^3$ are at risk for internal bleeding. The incidence of major intracranial hemorrhage is about 1 percent, usually occurring early in the disease course. Children often present at a young age (peak age approximately 5 years) with sudden onset of petechiae or purpura several days to weeks after an infectious illness. In contrast, adults experience a more chronic form of disease with an insidious onset. Splenomegaly with ITP is uncommon in both adults and children, and its occurrence should prompt a search for a separate cause of thrombocytopenia.

Diagnosing ITP is based on exclusion of other possibilities (e.g., systemic lupus erythematosus, certain antimicrobials or other drugs) in the presence of

a low platelet count and mucocutaneous bleeding. In addition to low platelets, laboratory findings characteristic of ITP consist of large, immature platelets (megathrombocytes) on peripheral blood smear.

Adults generally require treatment at the time of presentation, because up to one half will present with counts below $10,000/\text{mm}^3$. The usual first line of therapy is oral prednisone at a dose of 1.0–1.5 mg/kg per day. Most responses occur within the first 3 weeks. Response rates range from 50–75 percent, but relapses are common. Intravenous immunoglobulin, given at 1.0 g/kg per day for 2–3 days, is indicated for internal bleeding when counts remain below $5000/\text{mm}^3$ or when extensive purpura exists. An immediate response is common, but a sustained remission is not. Splenectomy is indicated for failure of medical therapy, for prolonged use of steroids with undesirable effects, or for most cases of first relapse. Splenectomy provides a permanent response without subsequent need for steroids in 75–85 percent of the total number of patients undergoing splenectomy (see the “Splenectomy Outcomes” section of this chapter). Responses usually occur within the first postoperative week. Patients with extremely low platelet counts ($< 10,000/\text{mm}^3$) should have platelets available for surgery, but should not receive them preoperatively. Once the splenic pedicle is ligated, platelets are given to those who continue to bleed.

In children with ITP, the course is self-limited, with durable and complete remission in over 70 percent of patients regardless of therapy. Because of the good prognosis without treatment, children with typical ITP—and certainly those without hemorrhage—are managed principally by observation, with short-term therapy in select cases. Where therapy is indicated, intravenous immune globulin has been shown to shorten the duration of severe thrombocytopenia, and a short course of oral prednisone (4 mg/kg for 4 consecutive days) generally produces excellent results. Splenectomy is reserved for failure of medical therapy in children who have had immune thrombocytopenic purpura for at least 1 year with symptomatic, severe thrombocytopenia. Urgent splenectomy may play a role in the rare circumstance of severe, life-threatening bleeding, in conjunction with aggressive medical therapy, for both children and adults.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a serious disorder characterized by thrombocytopenia, microangiopathic hemolytic anemia, and neurologic complications. Abnormal platelet clumping occurs in arterioles and capillaries, reducing the lumen of these vessels and predisposing the patient to microvascular thrombotic episodes. TTP is a rare disorder, but its dramatic clinical sequelae and favorable response to early therapy demand an understanding of its clinical presentation to bring about an early diagnosis. Clinical features of the disorder include petechiae, fever, neurologic symptoms, renal failure, and infrequently cardiac symptoms, such as heart failure or arrhythmias. Petechial hemorrhages in the lower extremities are the most common presenting sign. Neurologic changes range from generalized headaches to altered mental status, seizures, and even coma. Generally, however, the mere presence of petechiae and thrombocytopenia are sufficient to lead to the diagnosis of TTP and consideration of treatment.

TTP may be distinguished from autoimmune causes of thrombocytopenia, such as Evans syndrome (ITP and autoimmune hemolytic anemia) or systemic lupus erythematosus, by a negative Coombs test.

The first line of therapy for TTP is plasma exchange. This treatment has dramatically improved survival from less than 10 percent to about 90 percent

since its implementation. Splenectomy plays a key role for patients who relapse or require multiple plasma exchanges to control symptoms, and is generally well-tolerated without significant morbidity. Once the spleen is removed, patients typically do not relapse. Platelet transfusions are not recommended in TTP, as severe clinical deterioration has been reported following their administration.

Miscellaneous Disorders and Lesions

Infections and Abscesses

Abscesses of the spleen are uncommon, with an incidence of 0.14–0.7 percent, based on autopsy findings. Five distinct mechanisms of splenic abscess formation have been described: (1) hematogenous infection; (2) contiguous infection; (3) hemoglobinopathy; (4) immunosuppression, including HIV and chemotherapy; and (5) trauma. The most common origins for hematogenous spread are infective endocarditis, typhoid fever, malaria, urinary tract infections, and osteomyelitis. Presentation is frequently delayed. Clinical manifestations include fever, left upper quadrant pain, leukocytosis, and splenomegaly in about one-third of patients. The diagnosis is confirmed by ultrasound or CT scan, which has a 95 percent sensitivity and specificity. On discovery of a splenic abscess, broad-spectrum antibiotics should be started and continued for 14 days. Splenectomy is the operation of choice, but percutaneous or open drainage are options for patients who cannot tolerate splenectomy. Percutaneous drainage is successful for patients with unilocular disease.

Storage Diseases and Infiltrative Disorders

Gaucher's disease. This is an inherited lipid storage disease characterized by the deposition of glucocerebroside in cells of the macrophage-monocyte system. Patients with Gaucher's disease frequently experience symptoms related to splenomegaly—including early satiety and abdominal discomfort—and hypersplenism, including thrombocytopenia, normocytic anemia, and mild leukopenia. Splenectomy alleviates hematologic abnormalities in patients with hypersplenism but does not correct the underlying disease process.

Niemann-Pick disease. This is an inherited disease of abnormal lysosomal storage of sphingomyelin and cholesterol in cells of the macrophage-monocyte system. Types A and B result from a deficiency in lysosomal hydrolase and are the forms most likely to demonstrate splenomegaly with its concomitant symptoms. Splenectomy has been reported to successfully treat symptoms of splenomegaly in these cases.

Amyloidosis. Amyloidosis is a disorder of abnormal extracellular protein deposition. If splenomegaly develops, related symptoms are relieved by splenectomy. Removal of the spleen also has been reported to cure patients of factor X deficiency associated with primary amyloidosis.

Felty Syndrome

The triad of rheumatoid arthritis (RA), splenomegaly, and neutropenia is called Felty syndrome. The spleen in Felty syndrome is four times heavier than normal. Neutropenia causing frequent infections is often the driving force behind the decision for splenectomy. Responses to splenectomy have been excellent, with over 80 percent of patients showing a durable increase in white blood cell count. Besides symptomatic neutropenia, other indications for splenectomy

include transfusion-dependent anemia and profound thrombocytopenia. Corticosteroids, hematopoietic growth factors, methotrexate, and splenectomy all have been used to treat the neutropenia of Felty syndrome.

Sarcoidosis

Sarcoidosis is an inflammatory disease of young adults, characterized by non-caseating granulomas in affected tissues. Any organ system may be involved. The most commonly involved organ is the lung, followed by the spleen. Splenomegaly occurs in about 25 percent of patients. Massive splenomegaly (>1 kg) is rare. When splenomegaly occurs and causes symptoms related to size or hypersplenism, splenectomy effectively relieves symptoms and corrects hematologic abnormalities such as anemia and thrombocytopenia.

Cysts and Tumors

Splenic cysts are rare lesions. The most common etiology for splenic cysts worldwide is parasitic infestation, particularly echinococcal. Symptomatic parasitic cysts are best treated with splenectomy, although selected cases may be amenable to percutaneous aspiration, instillation of protoscolicidal agent, and reaspiration. Nonparasitic cysts most commonly result from trauma and are called pseudocysts. The treatment of nonparasitic cysts depends on whether or not they produce symptoms. Asymptomatic nonparasitic cysts may be observed with close ultrasound follow up to exclude significant expansion. Patients should be advised of the risk of cyst rupture with even minor abdominal trauma if they elect nonoperative management for large cysts. Small symptomatic nonparasitic cysts may be excised with splenic preservation, and large symptomatic nonparasitic cysts may be unroofed. Both of these operations may be performed laparoscopically.

The most common primary tumor of the spleen is sarcomatous. Non-Hodgkin lymphoma of the spleen is rare, but splenectomy imparts an excellent prognosis. Lung cancer is the most common tumor to spread to the spleen.

Portal Hypertension

Portal hypertension can result from numerous causes, but usually is because of cirrhosis. Splenomegaly and splenic congestion often accompany portal hypertension. Splenectomy, however, is not indicated for hypersplenism *per se* in patients with portal hypertension, because no correlation exists between the degree of pancytopenia and long-term survival in these patients.

Portal hypertension secondary to splenic vein thrombosis is potentially curable with splenectomy. Patients with bleeding from isolated gastric varices in the presence of normal liver function tests, especially with a history of pancreatic disease, should be examined for splenic vein thrombosis and treated with splenectomy if positive.

Splenic Artery Aneurysm

Although rare, splenic artery aneurysm (SAA) is the most common visceral artery aneurysm. The aneurysm usually arises in the middle to distal portion of the splenic artery. The risk of rupture is between 3 and 9 percent; however, once rupture occurs, mortality is substantial (35–50 percent). SAA is particularly worrisome when discovered during pregnancy, as rupture imparts a high risk of mortality to both mother (70 percent) and fetus (95 percent). Indications for treatment include presence of symptoms, pregnancy, intention to become pregnant, and pseudoaneurysms associated with inflammatory processes. For

asymptomatic patients, size greater than 2 cm constitutes an indication for surgery. Aneurysm resection or ligation alone is acceptable for amenable lesions in the mid-splenic artery, but distal lesions in close proximity to the splenic hilum should be treated with concomitant splenectomy.

PREOPERATIVE CONSIDERATIONS

Splenic Artery Embolization

The use of splenic artery embolization (SAE) as a preoperative technique became available with advances in angiographic technology. Theoretical advantages of SAE include reduced operative blood loss from a devascularized spleen and reduced spleen size for easier dissection and removal. Potential disadvantages of the procedure, however, include acute left-sided pain (although usually of limited duration), pancreatitis, or other embolization-related complications. Not all investigators use or recommend SAE, citing equivalent splenectomy-related blood loss and morbidity. There is currently no consensus on the role of preoperative SAE for elective splenectomy.

Vaccination

Splenectomy imparts a small (<1–5 percent) but definite life-time risk of fulminant, potentially life-threatening infection. Therefore, when elective splenectomy is planned, vaccinations against encapsulated bacteria (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and meningococcus) should be given at least 2 weeks before surgery to protect against such infection. If the spleen is removed emergently (e.g., for trauma), vaccinations should be given as soon as possible following surgery, allowing at least 1–2 days for recovery. Booster injections of pneumococcal vaccine should be considered every 5–6 years regardless of the reason for splenectomy. Additionally, annual influenza immunization is advisable.

Deep Venous Thrombosis Prophylaxis

Deep venous thrombosis (DVT) is not uncommon following splenectomy, especially in cases involving splenomegaly and myeloproliferative disorders (MPD). The risk of portal vein thrombosis (PVT) may be as high as 40 percent for patients with both splenomegaly and MPD. Postsplenectomy PVT typically presents with anorexia, abdominal pain, leukocytosis, and thrombocytosis. A high index of suspicion, early diagnosis with contrast-enhanced CT, and immediate anticoagulation are keys to successful treatment for PVT. Patients undergoing splenectomy should be treated with DVT prophylaxis, including sequential compression devices with subcutaneous heparin (5000 U). Each patient's risk factors for DVT should be evaluated, and where elevated risk exists (obesity, history of prior VTE, known hypercoagulable state, age > 60), a more aggressive antithrombotic regimen, including low-molecular-weight heparin (LMWH), may be pursued.

SPLENECTOMY TECHNIQUES

Patient Preparation

All patients undergoing elective splenectomy should be vaccinated at least 1 week preoperatively with polyvalent pneumococcal, meningococcal, and *Haemophilus*. Patients' potential need for blood product transfusion must be

assessed, and their coagulation status optimized. Anemic patients should be transfused to a hemoglobin of 10 g/dL. For more complex patients, including those with splenomegaly, a type and cross is recommended for at least 2–4 units of blood. Platelet transfusions may transiently correct thrombocytopenia although preferably not preoperatively and ideally not before intraoperative ligation of the splenic artery.

Patients who have been maintained on corticosteroid therapy preoperatively should receive perioperatively parenteral corticosteroid therapy. All splenectomy patients receive deep vein thrombosis (DVT) prophylaxis and intravenous administration of a first-generation cephalosporin. A nasogastric (NG) tube is inserted after endotracheal intubation to decompress the stomach.

Open Splenectomy

Whereas laparoscopic surgery (LS) is increasingly accepted as the standard approach for normosplenic patients, open splenectomy (OS) is still widely practiced. Traumatic rupture of the spleen remains the most common indication for OS, which also may be favored for patients requiring splenectomy who have massive splenomegaly, ascites, portal hypertension, multiple prior operations, extensive splenic radiation, or possible splenic abscess.

Open Splenectomy Technique

In preparation for OS, the patient is placed in the supine position with the surgeon situated on the patient's right. A midline incision is preferable for exposure of a ruptured or massively enlarged spleen or when abdominal access is needed for a staging laparotomy. A left subcostal incision is preferred for most elective splenectomies.

Dividing ligamentous attachments, usually beginning with the splenocolic ligament, mobilizes the spleen. For patients with significant splenomegaly, early ligation of the splenic artery in continuity along the superior border of the pancreas provides for safer manipulation of the spleen and dissection of the splenic hilum, some spleen shrinkage, and an autotransfusion of erythrocytes and platelets. Incising the spleen's lateral peritoneal attachments, most notably the splenophrenic ligament, provides further medial mobilization. The short gastric vessels are then sequentially ligated and divided. Splenic hilar dissection follows with the splenic artery and vein (in that order) dissected and individually ligated prior to division. Care is taken to avoid injuring the tail of the pancreas.

With the spleen excised, the dissection bed is irrigated, suctioned, and inspected meticulously to ensure hemostasis. The splenic bed is not routinely drained. The NG tube is removed at the completion of surgery.

Laparoscopic Splenectomy

LS has supplanted OS as the elective splenectomy approach of choice. Most LS procedures are performed with the patient in the right lateral decubitus position. An angled (30 degrees or 45 degrees) laparoscope (2-mm, 5-mm, or 10-mm) facilitates the lateral approach, in which three or four trocars positioned are routinely used and vital anatomy is exposed in a manner allowing for an intuitive dissection sequence.

The splenocolic ligament and lateral peritoneal attachments are divided, resulting in medial spleen mobilization. The short gastric vessels are divided by individual clip applications, endovascular staples, or hemostatic

energy sources. With the lower spleen pole elevated, the splenic hilum is accessible for further clip applications or endovascular stapling. Usually, the splenic artery and vein are separated. With the spleen thus retracted, the surgeon easily visualizes the tail of the pancreas and can avoid its injury.

Once excised, the spleen is placed in a durable nylon sac, then drawn through a 10-mm trocar site. Blunt instruments should be used to morcellate the spleen within the sac for piecemeal extraction.

In patients with splenomegaly, hand-assisted LS can facilitate a safe, expeditious procedure. The surgeon's hand is introduced completely into the peritoneal cavity for palpation of appropriate tissues that allows for identification, retraction, and dissection. Clip, staple, and energy source use achieve hemostasis. The excised specimen is delivered through the hand-access port.

Partial Splenectomy

Certain lipid storage disorders leading to splenomegaly and some forms of traumatic splenic injury are amenable to partial splenectomy. Partial splenectomy is indicated in children to minimize postsplenectomy sepsis risk.

SPLENECTOMY OUTCOMES

Splenectomy results in characteristic changes to blood composition, including the appearance of Howell-Jolly bodies and siderocytes. Leukocytosis and increased platelet counts commonly occur following splenectomy as well.

Complications

Complications of splenectomy may be classified as pulmonary, hemorrhagic, infectious, pancreatic, and thromboembolic. The most common complication is left lower lobe atelectasis, occurring in up to 16 percent of patients following OS. Other pulmonary problems include pleural effusion and pneumonia. Hemorrhage may be intra- or postoperative. Across all elective indications, the need for transfusion arises in 3–5 percent of cases. Infectious complications include subphrenic abscess and wound infection. Pancreatic complications, including pancreatitis, pseudocyst, and pancreatic fistula, may result from intraoperative trauma to the pancreas, especially to the tail, during the dissection of the splenic hilum. Thromboembolic phenomena occur in 5–10 percent of patients undergoing splenectomy.

Hematologic Outcomes

For thrombocytopenia, a long-term response is defined as a platelet count greater than 150,000/mL more than 2 months after surgery without medications. Laparoscopic splenectomy is effective in providing a long-term platelet response in approximately 85 percent of individuals with ITP (Table 33-2). These results are consistent with the success of open splenectomy, which is associated with a long-term success rate of 65–90 percent.

For chronic hemolytic anemias, a rise in hemoglobin levels to above 10 g/dL without the need for transfusion signifies a successful response to splenectomy. By this criterion, splenectomy has been reported to be successful in 60–80 percent of patients with chronic hemolytic anemia. For the subset of patients with spherocytosis, the success rate is usually higher, ranging from 90–100 percent.

Surgical and postsurgical outcomes also include the operative time, recovery time, and morbidity and mortality rates of the procedure, which tend to vary according to the hematologic indication.

To date, no prospective, randomized comparisons between laparoscopic and open splenectomy have been published. Numerous retrospective or case-controlled comparisons between LS and OS reveal that the laparoscopic approach typically results in longer operative times, shorter hospital stays, lower morbidity rates, similar blood loss, and similar mortality rates. The laparoscopic approach has emerged as the standard for nontraumatic, elective splenectomy.

Overwhelming Postsplenectomy Infection

Regardless of technique or indication, splenectomy imparts a lifetime risk of severe infection to the patient. The true incidence of postsplenectomy sepsis remains unknown, with estimates varying between less than 1 and 5 percent during a patient's lifetime. Overwhelming postsplenectomy infection (OPSI) is more likely to occur among children compared to adults, and among those with hematologic disorders as compared to splenic trauma.

The loss of the spleen's ability to filter and phagocytose bacteria and parasitized blood cells predisposes the patient to infection by encapsulated bacteria or parasites. Splenectomy also results in the loss of a significant source of antibody production. The most common source of infection reported in the literature is *Streptococcus pneumoniae*, accounting for 50–90 percent of cases. *H. influenzae* type B, meningococcus, and group A streptococci have reportedly accounted for an additional 25 percent of infections.

OPSI is associated with pneumonia or meningitis in roughly one-half of cases, but a substantial number of patients have no clear site of bacterial colonization. OPSI may begin with a relatively mild-appearing prodrome, including fever, malaise, myalgias, headache, vomiting, diarrhea, and abdominal pain. These symptoms may then progress rapidly to fulminant bacteremic septic

shock, with accompanying hypotension, anuria, and disseminated intravascular coagulation.

Some risk factors for the development of OPSI have been identified. Patients undergoing splenectomy for hematologic indications carry a higher risk than those who undergo splenectomy for trauma. Individuals with compromised immune systems such as those with Hodgkin disease or those taking chemotherapy or radiation therapy have a higher risk of OPSI than those who do not. OPSI usually develops within the first 2 years after splenectomy, especially in children.

Prudent immunoprophylaxis consists of pneumococcal, meningococcal, and *H. influenzae* type B vaccination at least 7–14 days before splenectomy or as soon as possible after surgery. Pneumococcal vaccine booster injections every 5–6 years should be considered. Annual influenza immunization is advisable. Antibiotic prophylaxis—usually a single daily dose of penicillin or amoxicillin—is recommended for asplenic children for the first 2 years after splenectomy.

Abdominal Wall, Omentum, Mesentery, and Retroperitoneum

Robert L. Bell, M.D., and Neal E. Seymour, M.D.

ABDOMINAL WALL

Surgical Anatomy

The abdominal wall is an anatomically complex, layered structure with segmentally derived blood supply and innervation. The muscle fibers of the rectus abdominis are encased within an aponeurotic sheath, the anterior and posterior layers of which are fused in the midline at the linea alba. The lateral border of the rectus muscles assumes a convex shape that gives rise to the linea semilunaris.

Lateral to the rectus sheath, there are three muscular layers with oblique fiber orientations relative to one another. The external oblique muscle runs inferiorly and medially, arising from the margins of the lowest eight ribs and costal cartilages and the latissimus dorsi, serratus anterior and the iliac crest. Medially it forms a tendinous aponeurosis, which is contiguous with anterior rectus sheath. The inguinal ligament is the inferior-most edge of the external oblique aponeurosis reflected posteriorly in the area between the anterior superior iliac spine and pubic tubercle. The internal oblique muscle lies immediately deep to the external oblique muscle and arises from the lateral aspect of the inguinal ligament, the iliac crest and the thoracolumbar fascia. Its fibers course superiorly and medially and form a tendinous aponeurosis that contributes to both the anterior and posterior rectus sheath. The lower medial and inferior-most fibers of the internal oblique course may fuse with the lower fibers of the transversus abdominis muscle (the conjoined area). The transversus abdominis muscle is the deepest of the three lateral muscles and, as its name implies, runs transversely.

The complexities of the anterior and posterior aspects of the rectus sheath are best understood in their relationship to the arcuate line (semicircular line of Douglas), which lies roughly at the level of the anterior superior iliac spines. Above the arcuate line, the anterior rectus sheath is formed by the external oblique aponeurosis and the external lamina of the internal oblique aponeurosis whereas the posterior rectus sheath is formed by the internal lamina of the internal oblique aponeurosis, the transversus abdominis aponeurosis, and the transversalis fascia. Below the arcuate line, the anterior rectus sheath is formed by the external oblique aponeurosis, the internal oblique aponeurosis, and the transversus abdominis aponeurosis. There is no aponeurotic posterior covering of this lower portion of the rectus muscles, although the transversalis fascia remains a contiguous structure on the posterior aspect of the anterior abdominal wall.

The majority of the blood supply to the muscles of the anterior abdominal wall is derived from the superior and inferior epigastric arteries. A collateral network of branches of the subcostal and lumbar arteries also contribute the abdominal wall blood supply. Innervation of the rectus muscles, the internal

oblique muscles, and the transversus abdominis muscles arises from the anterior rami of spinal nerves at the T6–T12 levels. The overlying skin is innervated by afferent branches of the T4–L1 nerve roots, with the nerve roots of T10 subserving sensation of the skin around the umbilicus.

PHYSIOLOGY

The rectus muscles, the external oblique muscles, and the internal oblique muscles work as a unit to flex the trunk anteriorly or laterally. Rotation of the trunk is achieved by the contraction of the external oblique muscle and the contralateral internal oblique muscle. Additionally, all four muscles (rectus muscles, the external oblique muscles, the internal oblique muscle, and the transversus abdominis muscle) are involved in raising intraabdominal pressure. If the diaphragm is relaxed when the abdominal musculature is contracted, then the pressure exerted by the abdominal muscles results in expiration of air from the lungs. Thus, these abdominal muscles are the primary muscles of expiration. If the diaphragm is contracted when the abdominal musculature is contracted (Valsalva maneuver) the increased abdominal pressure aids in processes such as micturition, defecation, and childbirth.

Congenital Abnormalities

Prominent in the early embryonic abdominal wall is a large central defect through which pass the vitelline (omphalomesenteric) duct connecting the embryonic and fetal midgut to the yolk sac. During the sixth week of development, embryonic midgut herniates into the umbilical cord, and while outside the confines of the developing abdomen, undergoes a 270-degree counterclockwise rotation. At the end of the twelfth week it returns to the abdominal cavity, and attains its final position. Congenital defects in abdominal wall closure may lead to omphalocele or gastroschisis. In omphalocele, viscera protrude through an open umbilical ring and are covered by a sac derived from the amnion. In gastroschisis, the viscera protrude through a defect lateral to the umbilicus and no sac is present.

Persistence of a vitelline duct remnant on the ileal border results in a Meckel diverticulum. Complete failure of the vitelline duct to regress results in a vitelline duct fistula, which is associated with drainage of small intestinal contents from the umbilicus. If both the intestinal and umbilical ends of the vitelline duct regress into fibrous cords, a central vitelline duct (omphalomesenteric) cyst may occur. When diagnosed, vitelline duct fistulas and cysts should be excised along with any accompanying fibrous cord.

Acquired Abnormalities

Rectus Abdominis Diastasis

Rectus abdominis diastasis (or diastasis recti) describes a clinically evident separation of the rectus abdominis muscle pillars, generally as a result of decreased tone of the abdominal musculature. The characteristic bulging of the abdominal wall in the epigastrium is sometimes mistaken for a ventral hernia, despite that fact that the midline aponeurosis is intact and no hernia defect is present. Diastasis is usually easily identified on physical examination. Computed tomography (CT) scanning will differentiate rectus diastasis from a true ventral hernia if clarification is required. Surgical correction of a severe rectus diastasis by plication of the anterior rectus sheath may be undertaken

for cosmetic indications, or if it is associated with disability of abdominal wall muscular function.

Rectus Sheath Hematoma

The terminal branches of the superior and inferior epigastric arteries course deep to the posterior aspect of the left and right rectus pillars and penetrate the posterior rectus sheath. An injury to these vessels or any of the collateralizing vessels within the rectus sheath can result in a rectus sheath hematoma. Although there may be a history of significant blunt trauma, less obvious events also have been reported to cause this condition such as sudden contraction of the rectus muscles with coughing, sneezing, or any vigorous physical activity. Spontaneous rectus sheath hematomas have been described in older adults and in those on anticoagulation therapy. Patients frequently describe the sudden onset of unilateral abdominal pain that may be confused with lateralized peritoneal disorders such as appendicitis. Below the arcuate line, a hematoma may cross the midline and cause bilateral lower quadrant pain.

The diagnosis may be suggested by history and physical examination alone. Pain typically increases with contraction of the rectus muscles and a tender mass may be palpated. The ability to appreciate an intraabdominal mass is ordinarily degraded with contraction of the rectus muscles. The Fothergill sign, a palpable abdominal mass that remains unchanged with contraction of the rectus muscles, is classic for rectus hematoma. A hemoglobin/hematocrit level and coagulation studies should be obtained. Abdominal ultrasonography may show a solid or cystic mass within the abdominal wall depending on the chronicity of the bleeding event. Computed tomography is the most definitive study for establishing the correct diagnosis and excluding other intraabdominal disorders.

Specific treatment depends on the severity of the hemorrhage. Small, unilateral, and contained hematomas may be observed without hospitalization. Bilateral or large hematomas will likely require hospitalization and potential resuscitation. The need for red blood cell or coagulation factor transfusion is determined by the clinical circumstances. Reversal of Coumadin anticoagulation may be necessary. Emergent operative intervention or angiographic embolization may be necessary if hematoma enlargement, free bleeding, or clinical deterioration occurs. Surgical therapy consists of evacuation of the hematoma and ligation of any bleeding vessel identified. Mortality in this condition is rare, but has been reported in patients requiring surgical treatment and in the extremely older adult.

Abdominal Wall Hernias

Hernias of the anterior abdominal wall, or ventral hernias represent defects in the abdominal wall fascia and muscle through which intraabdominal or preperitoneal contents can protrude. Ventral hernias may be congenital or acquired. Acquired hernias may develop via slow architectural deterioration of the muscular aponeuroses or they may develop from failed healing of an anterior abdominal wall incision (incisional hernia). The most common finding is a mass or bulge on the anterior abdominal wall, which may increase in size with Valsalva. Ventral hernias may be asymptomatic or cause discomfort, and generally enlarge over time. Physical examination reveals a bulge on the anterior abdomen that may reduce spontaneously, with recumbency, or with manual pressure. A hernia that cannot be reduced is described as incarcerated and may

be accompanied by nausea, vomiting, and significant pain. Should the blood supply to the incarcerated bowel be compromised, the hernia is described as strangulated, and the localized ischemia may lead to infarction and perforation.

Primary ventral hernias (nonincisional) also are termed “true” ventral hernias. These are more properly named according to their anatomic location. Epigastric hernias are located in the midline between the xiphoid process and the umbilicus. They are generally small and usually contain omentum or a portion of the falciform ligament.

Umbilical hernias develop at the umbilical ring, and may be present at birth or develop gradually during the life of the individual. Adults with small, asymptomatic umbilical hernias may be followed clinically. Surgical treatment is offered if a hernia is observed to enlarge, is associated with symptoms, or if incarceration occurs.

Spigelian hernias can occur anywhere along the length of the Spigelian line, an aponeurotic band at the lateral border of the rectus abdominus. However, the most frequent location of these rare hernias is at or slightly above the level of the arcuate line. These are not always clinically evident as a bulge, and may come to medical attention because of pain or incarceration.

Incisional hernias result from a healing failure of a prior abdominal wall surgical closure. Although estimates of incidence vary, careful investigation shows that they occur in at least 10–15 percent of all laparotomy incisions. Incisional hernias may be asymptomatic or present with pain, incarceration or strangulation. Risk factors for the development of a ventral incisional hernia include postoperative wound infection, malnutrition, obesity, and immunosuppression.

Several techniques for the repair of ventral hernias have been described, including primary repair, open repair with mesh, and laparoscopic repair with mesh. Primary repair, even for small hernias (abdominal wall defects less than 3 cm) is associated with a high subsequent recurrence rate. Risk factors for recurrence include primary suture repair, postoperative wound infection, prostatism, and surgery for abdominal aortic aneurysm.

Open mesh repair of incisional hernias generally requires overlapping the prosthesis onto the anterior or posterior surfaces of intact abdominal wall fascia for a distance of at least 3–4 cm from defect edge. When properly performed, the peritoneum and hernia sac are dissected away from all fascial defects. A large sheet of polypropylene or polyester (Mersilene) mesh, which is isolated from peritoneal contents, is then secured to the fascia using interrupted non-absorbable sutures. Polypropylene is an inert substance that induces eventual tissue ingrowth within the interstices of the mesh. This effect is desired in a preperitoneal location, but when exposed to underlying bowel the dense adhesions to mesh can lead to chronic abdominal pain, bowel obstruction, or fistulization. Polytetrafluoroethylene (PTFE) does not become incorporated into surrounding tissues in this way, and does not induce dense adhesions to peritoneal structures such as intestine. It is therefore commonly used in intraperitoneal applications. Other available prosthetic mesh materials include polypropylene/PTFE composites, polyesters with and without adhesion barriers, and most recently engineered tissue replacements from decellularized collagen or cadaveric dermis.

Minimally invasive repair of incisional hernias now are performed at least as often as open repairs. Using this method, the entire undersurface of the abdominal wall can be examined, often revealing multiple defects. In this technique laparoscopic ports are placed laterally for midline defects and contralaterally

for lateral defects. Adhesions to the anterior abdominal wall are divided taking great care not to injure the intestines. An appropriate-sized piece of prosthetic mesh (generally PTFE) shaped to allow sufficient overlap (3–4 cm) onto healthy abdominal wall is fixed in place circumferentially with transfascial sutures and spiral tacks according to surgeon preference. With this technique, the 2-year recurrence rate is only 3.4 percent.

Omentum

Anatomy

The greater omentum and lesser omentum are fibrofatty aprons that provide support, coverage and protection of peritoneal contents. In the adult, the greater omentum lies in between the anterior abdominal wall and the hollow viscera and usually extends into the pelvis. The blood supply to the greater omentum is derived from the right and left gastroepiploic arteries.

The lesser omentum also is known as the hepatoduodenal and hepatogastric ligaments. The common bile duct, portal vein, and hepatic artery are located in the inferolateral margin of the lesser omentum, which also forms the anterior margin of the foramen of Winslow.

Physiology

The omentum has been called the “abdominal policeman” because of its tendency to wall off areas of infection and limit the spread of intraperitoneal contamination. Omentum contains a high concentration of tissue factor, which facilitates activation of coagulation at sites of inflammation, ischemia, infection or trauma within the peritoneal cavity. The consequent local production of fibrin contributes to the ability of the omentum to adhere to areas of injury or inflammation.

Omental Infarction

Interruption of the blood supply to the omentum is a rare cause of an acute abdomen that may be secondary to torsion of the omentum, thrombosis or vasculitis of the omental vessels, or omental venous outflow obstruction. Depending on the location of the infarcted omental tissue, this disease process may mimic appendicitis, cholecystitis, diverticulitis, perforated peptic ulcers, or ruptured ovarian cysts. The diagnosis is rarely made before abdominal imaging studies are obtained. Either abdominal CT or ultrasonography will show a localized, inflammatory mass of fat density. Treatment of omental infarction depends on the certainty with which the diagnosis is made. In patients who are not toxic and abdominal imaging is convincing, supportive care is sufficient. However, many cases will be indistinguishable from suppurative appendicitis, cholecystitis or diverticulitis. In these instances, laparoscopy has provided a great advance, providing access to an accurate diagnosis and treatment. Resection of the infarcted tissue results in rapid resolution of symptoms.

Omental Cysts

Cystic lesions of the omentum likely result from lymphatic degeneration. Omental cysts may present as an asymptomatic abdominal mass or may cause abdominal pain or distension. Physical examination reveals a freely mobile intraabdominal mass. Abdominal CT or ultrasonography reveals a

well-circumscribed cystic mass lesion arising from the greater omentum. Treatment involves resection of all symptomatic omental cysts.

Malignant Omental Lesions

Primary tumors of the omentum are uncommon. Benign tumors of the omentum include lipomas, myxomas, and desmoid tumors. Primary malignant tumors of the omentum include liposarcomas, leiomyosarcomas, rhabdomyosarcomas, fibrosarcomas, and mesotheliomas. Metastatic tumors involving the omentum are quite common. Metastatic ovarian tumors have a high preponderance of omental involvement. Malignant tumors of the stomach, small intestine, colon, pancreas, biliary tract, uterus, and kidney also may metastasize to the omentum.

Mesentery

The small and large intestinal mesenteries serve as the major pathway for arterial, venous, lymphatic, and neural structures coursing to and from the bowel. Their positions in the abdomen and on the retroperitoneum are determined by the previously described process of intestinal herniation, rotation, and return to the abdominal cavity during fetal development.

Sclerosing Mesenteritis

Sclerosing mesenteritis, also referred to as mesenteric panniculitis or mesenteric lipodystrophy, is a rare chronic inflammatory and fibrotic process that involves a portion of the intestinal mesentery. Sclerosing mesenteritis is most commonly diagnosed in individuals over 50 years of age with no gender or race predominance. The etiology of this process is unknown. Patients typically present with abdominal pain, a nonpainful mass or intestinal obstruction.

Abdominal CT will verify the presence of a mass lesion emanating from the mesentery. CT cannot distinguish sclerosing mesenteritis from a primary or secondary mesenteric tumor. Surgical intervention is usually necessary, if only to establish a diagnosis and rule out malignancy. The extent of the disease process will dictate the aggressiveness of the intervention, which may range from simple biopsy to mesenteric and bowel resection.

Mesenteric Cysts

Cysts of the mesentery are rare, benign lesions that may be asymptomatic or cause symptoms of a mass lesion. When symptomatic, mesenteric cysts usually cause acute or chronic, intermittent abdominal pain. Mesenteric cysts may also be the cause of nonspecific symptoms such as anorexia, nausea, vomiting, fatigue, and weight loss.

Physical examination may reveal a mass lesion which is mobile only to the right and left (Tillaux sign), in contrast to omental cysts which should be freely mobile in all directions. Abdominal CT, ultrasonography, and magnetic resonance imaging all have been used to evaluate patients with mesenteric cysts.

If feasible, simple mesenteric cysts should be surgically excised. Cyst unroofing or marsupialization is not recommended as there is a high propensity to recur after drainage alone. Rarely, adherent mesentery must be sacrificed to achieve complete excision, in which case segmental bowel resection is performed.

Mesenteric Tumors

Primary tumors of the mesentery are rare. Benign tumors of the mesentery include lipoma, cystic lymphangioma, and desmoid tumors. Malignant tumors of the mesentery include liposarcomas, leiomyosarcomas, malignant fibrous histiocytomas, lipoblastomas and lymphangiosarcomas. Treatment of mesenteric malignancies involves wide resection of the mass. Because of the proximity to blood supply to the intestine, such resections may be technically impractical or involve loss of substantial lengths of bowel.

RETROPERITONEUM

Surgical Anatomy

The retroperitoneum is defined as the space between the posterior envelopment of the peritoneum and the posterior body wall. Although technically bounded anteriorly by the posterior reflection of the peritoneum, the anterior border of the retroperitoneum is quite convoluted, extending into the spaces in between the mesenteries of the small and large intestine. Because of the rigidity of the superior, posterior, and inferior boundaries, and the compliance of the anterior margin, retroperitoneal tumors tend to expand anteriorly toward the peritoneal cavity.

Retroperitoneal Infections

The source of retroperitoneal infections is usually an organ contained within or abutting the retroperitoneum. Retrocecal appendicitis, perforated duodenal ulcers, pancreatitis, or diverticulitis may all lead to retroperitoneal infection with or without abscess formation. The substantial space and rather indiscreet boundaries of the retroperitoneum allow some retroperitoneal abscesses to become quite large prior to diagnosis.

Patients with a retroperitoneal abscess usually present with pain, fever, and malaise. The site of the patient's pain may be variable, including the back, pelvis, or thighs. Clinical findings can include tachypnea and tachycardia. A palpable flank or abdominal mass may be present. Laboratory evaluation usually reveals a leukocytosis. The diagnostic imaging modality of choice is abdominal CT, which may demonstrate stranding of the retroperitoneal soft tissues and/or a unilocular or multilocular collection.

Management of retroperitoneal infections includes identification and treatment of underlying conditions, intravenous antibiotics and drainage of all well-defined collections. Whereas unilocular abscesses are usually drained percutaneously under CT guidance, multilocular collections may require operative intervention for adequate drainage. Because of the vastness of the retroperitoneal space, patients with retroperitoneal abscesses do not usually present until the abscess is advanced. Consequently, the mortality rate of retroperitoneal abscess, even when drained, has been reported to be as high as 25 percent.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is a class of disorders characterized by hyperproliferation of fibrous tissue in the retroperitoneum. Idiopathic retroperitoneal fibrosis (Ormond disease) is a rare disorder primarily affecting individuals in the fourth to sixth decades of life. An allergic or autoimmune mechanism has been

postulated for this condition. The fibrotic process begins in the retroperitoneum below the level of the renal arteries and gradually progressed to encase the ureters, inferior vena cava, aorta, mesenteric vessels, and sympathetic nerves. Bilateral involvement is noted in two-thirds of cases.

Retroperitoneal fibrosis may also occur secondary to inflammation or as an allergic reaction to a medication. The associated conditions include abdominal aortic aneurysms, chronic pancreatitis, histoplasmosis, tuberculosis, and actinomycosis. It also has been associated with malignancies (prostate, non-Hodgkin lymphoma, sarcoma, carcinoid tumors, and gastric cancer) and autoimmune disorders (ankylosing spondylitis, systemic lupus erythematosus, Wegener granulomatosis, and polyarteritis nodosa). Although several medications have been linked to retroperitoneal fibrosis (β blockers, hydralazine, α -methyldopa, entacapone), the strongest causal relationship appears to be with Methysergide use. Fibrosis regresses on discontinuation of these medications.

Presenting symptoms depend on the structures affected by the fibrotic process. Initially, patients complain of dull, poorly localized abdominal pain. Sudden or severe abdominal pain may signify acute mesenteric ischemia. Other symptoms and signs may include: unilateral leg swelling, intermittent claudication, oliguria, hematuria, or dysuria.

Findings on physical examination may include hypertension, a palpable abdominal or flank mass, lower extremity edema, and/or diminished lower extremity pulses. Laboratory findings include an elevated erythrocyte sedimentation rate.

Many imaging modalities have been used to aid in the diagnosis of retroperitoneal fibrosis. A lower extremity ultrasound may show deep venous thrombosis, whereas abdominal ultrasonography may identify a mass lesion or hydronephrosis. Intravenous pyelography (IVP) may demonstrate ureteral compression, ureteral deviation toward the midline, and hydronephrosis. The imaging procedure of choice is abdominopelvic CT scan, which demonstrates the size and extent of the fibrotic process. For patients with renal insufficiency, magnetic resonance imaging (MRI) is the procedure of choice.

When a fibrotic mass is identified, biopsy should be performed. Once malignant, drug-induced, and infectious etiologies have been ruled out, treatment of the fibrotic process is instituted. Corticosteroids, with or without surgery, are the mainstay of therapy. Surgical debulking, ureterolysis, or ureteral stenting is required in patients with significant hydronephrosis. Patients with ilio caval thrombosis will require at least 6 months of oral anticoagulation. Cyclosporin, tamoxifen, or azathioprine have been used to treat patients who are recalcitrant to the above regimen. The reported 5-year survival rates in idiopathic retroperitoneal fibrosis are in the range of 90–100 percent.

INCIDENCE

Sarcomas are a heterogeneous group of tumors that arise predominantly from the embryonic mesoderm. In 2004, approximately 8400 new cases of soft tissue sarcoma were diagnosed in the United States representing less than 1 percent of cancers in adults. Soft tissue sarcomas, the largest of several distinct groups of sarcomas, is the focus of this chapter. Other groups include bone sarcomas (osteosarcomas and chondrosarcomas), Ewing sarcomas, and peripheral primitive neuroectodermal tumors.

Soft tissue sarcomas can occur throughout the body, most commonly in the extremity (59 percent), trunk (19 percent), retroperitoneum (13 percent), and head and neck (9 percent). The most common histologic types of soft tissue sarcoma in adults are malignant fibrous histiocytoma (28 percent), leiomyosarcoma (12 percent), liposarcoma (15 percent), synovial sarcoma (10 percent), and malignant peripheral nerve sheath tumors (6 percent).

EPIDEMIOLOGY

Except for malignant peripheral nerve sheath tumors in patients with neurofibromatosis, sarcomas do not seem to result from the progression or dedifferentiation of benign soft tissue tumors. Despite the variety of histologic subtypes, sarcomas have many common clinical and pathologic features. Overall the clinical behavior of most soft tissue sarcomas is similar and is determined by anatomic location (depth), grade, and size. The dominant pattern of metastasis is hematogenous with metastasis to the lungs. Lymph node metastases are rare.

Radiation Exposure

External radiation therapy is a well-established risk factor for soft tissue sarcoma. An 8-fold to 50-fold increase in the incidence of sarcomas has been reported among patients treated for cancer of the breast, cervix, ovary, testes, and lymphatic system.

Occupational Chemicals

Exposure to some herbicides such as phenoxyacetic acids and wood preservatives containing chlorophenols has been linked to an increased risk of soft tissue sarcoma. Several chemical carcinogens, including thorium oxide (Thorotrast), vinyl chloride, and arsenic, have been associated with hepatic angiosarcomas.

GENETICS

New developments in the field of molecular biology have led to better understanding of the basic cellular processes governed by oncogenes and tumor suppressor genes. Several oncogenes have been identified in association with soft tissue sarcomas, including MDM2, N-myc, c-erbB2, and members of the ras family. Amplification of these genes has been shown to correlate with adverse outcome in several soft tissue sarcomas.

Cytogenetic analysis of soft tissue tumors has identified distinct chromosomal translocations that seem to encode for oncogenes associated with certain histologic subtypes. The best characterized gene rearrangements are found in Ewing sarcoma (EWS—FLI-1 fusion), clear-cell sarcoma (EWS—ATF1 fusion), myxoid liposarcoma (TLS—CHOP fusion), alveolar rhabdomyosarcoma (PAX3—FHKR fusion), desmoplastic small round-cell tumor (EWS—WT1 fusion), and synovial sarcoma (SSX—SYT fusion).

Inactivation of tumor suppressor genes (also known as antioncogenes) can occur through hereditary or sporadic mechanisms. The two genes that are most relevant to soft tissue tumors are the retinoblastoma (Rb) tumor suppressor gene and the p53 tumor suppressor gene. Mutations or deletions in Rb can lead to development of retinoblastoma or sarcomas of soft tissue and bone. Mutations in the p53 tumor suppressor gene are the most common mutations in human solid tumors and have been reported in 30–60 percent of soft tissue sarcomas. Patients with germline mutations in the tumor suppressor gene p53 (the Li-Fraumeni syndrome) have a high incidence of sarcomas.

Neurofibromatosis type 1, also known as von Recklinghausen disease, occurs in approximately one of every 3000 persons, and is because of various mutations in the NF-1 tumor suppressor gene located on chromosome 17. Patients with neurofibromatosis type 1 have an estimated 3–15 percent additional lifetime risk of malignant disease that includes neurofibrosarcoma. Fifty percent of patients with neurofibrosarcomas have a mutation in NF-1.

INITIAL ASSESSMENT

Clinical Presentation

Soft tissue sarcoma most commonly presents as an asymptomatic mass. The size at presentation is usually associated with the location of the tumor. Smaller tumors are generally located in the distal extremities, whereas tumors in the proximal extremities and retroperitoneum can grow quite large before becoming apparent. Often an extremity mass is discovered after a traumatic event that draws attention to a preexisting lesion. Retroperitoneal soft tissue sarcoma almost always presents as a large asymptomatic mass.

The differential diagnosis of a soft tissue mass includes benign lesions including lipomas, lymphangiomas, leiomyomas, and neuromas. In addition to sarcomas, other malignant lesions such as primary or metastatic carcinomas, melanomas, or lymphomas must be considered. Small lesions that have not changed for several years by clinical history may be closely observed. All other tumors should be considered for biopsy to establish a definitive diagnosis.

Diagnostic Imaging

Pretreatment radiologic imaging serves several purposes; it defines the local extent of a tumor, can be used to stage malignant disease, assists in percutaneous biopsy procedures, and aids in the diagnosis of soft tissue tumors (benign versus malignant or low grade versus high grade). Imaging studies also are crucial in monitoring tumor changes after treatment, especially preoperative chemotherapy or radiation therapy, and in detecting recurrences after surgical resection.

Chest radiography should be performed for patients with primary sarcomas to assess for lung metastases. For patients with high-grade lesions or tumors

more than 5 cm (T2), computed tomography of the chest should be considered. Both ultrasonography and computed tomography can assist in guiding fine-needle aspiration or core biopsy for initial diagnosis or at recurrence.

Computed tomography (CT) is the preferred technique for evaluating retroperitoneal sarcomas, whereas magnetic resonance imaging (MRI) is often favored for soft tissue sarcomas of the extremities. MRI accurately delineates muscle groups and distinguishes among bone, vascular structures, and tumor. Sagittal and coronal views allow evaluation of anatomic compartments in three dimensions. Soft tissue sarcomas of the extremities usually present on MRI as heterogeneous masses. MRI is also valuable for assessing tumor recurrence after surgery. A baseline image is usually obtained 3 months after surgery.

Biopsy Techniques

Fine-Needle Aspiration

Fine-needle aspiration is an acceptable method of diagnosing most soft tissue sarcomas, particularly when the results correlate closely with clinical and imaging findings. However, fine-needle aspiration biopsy is indicated for primary diagnosis of soft tissue sarcomas only at centers where cytopathologists have experience with these types of tumors. Fine-needle aspiration biopsy is also the procedure of choice to confirm or rule out the presence of a metastatic focus or local recurrence. If tumor grading is essential for treatment planning, fine-needle aspiration biopsy is not the technique of choice.

Superficial lesions are often subjected to fine-needle aspiration biopsies in the clinic setting. Deeper tumors may require an interventional radiologist to perform the technique under sonographic or CT guidance. Diagnostic accuracy rates for fine-needle aspiration biopsy of primary tumors range from 60–96 percent.

Core-Needle Biopsy

Core-needle biopsy is a safe, accurate, and economical diagnostic procedure for diagnosing sarcomas. The tissue sample obtained from a core-needle biopsy is usually sufficient for several diagnostic tests such as electron microscopy, cytogenetic analysis, and flow cytometry. CT guidance can enhance the positive yield rate of a core-needle biopsy by more accurately pinpointing the location of the tumor. Precise localization in the tumor mass is particularly important to avoid sampling nondiagnostic necrotic or cystic areas of the tumor. CT guidance also permits access to tumors in otherwise inaccessible anatomic locations or near vital structures.

Incisional Biopsy

When adequate tissue for diagnosis cannot be obtained by fine-needle aspiration biopsy or core biopsy, an incisional biopsy is indicated for deep tumors or for superficial soft tissue tumors larger than 3 cm. The biopsy incision should be oriented longitudinally along the extremity to allow a subsequent wide local excision that encompasses the biopsy site, scar, and tumor en bloc. Another mandate of surgical technique is that adequate hemostasis must be achieved at the time of biopsy to prevent dissemination of tumor cells into adjacent tissue planes by hematoma.

Pathologic Classification

Some experts have suggested that pathologic classification of soft tissue sarcomas has more prognostic significance than does tumor grade when other pretreatment variables are taken into account. Tumors with limited metastatic potential include desmoids, atypical lipomatous tumors (also called well-differentiated liposarcoma), dermatofibrosarcoma protuberans, and heman-giopericytomas. Tumors with an intermediate risk of metastatic spread usually have a large myxoid component and include myxoid liposarcoma, myxoid malignant fibrous histiocytoma, and extraskeletal chondrosarcoma. Among the highly aggressive tumors that have substantial metastatic potential are angiosarcomas, clear-cell sarcomas, pleomorphic and dedifferentiated liposarcomas, leiomyosarcomas, rhabdomyosarcomas, and synovial sarcomas.

Expert sarcoma pathologists disagree about the specific histologic diagnoses and the criteria for defining tumor grade in 25–40 percent of individual cases. The high rate of discordance emphasizes the need for more objective molecular and biochemical markers to improve conventional histologic assessment.

Staging and Prognostic Factors

The current version of the American Joint Committee on Cancer staging criteria for soft tissue sarcomas relies on histologic grade, tumor size and depth, and the presence of distant or nodal metastases (Table 35-1).

Histologic grade remains the most important prognostic factor for patients with sarcomas. The features that define grade are cellularity, differentiation, pleomorphism, necrosis, and the number of mitoses. In the 2002 American Joint Committee on Cancer staging system, four tumor grades are designated: well differentiated (G1), moderately differentiated (G2), poorly differentiated (G3), and undifferentiated (G4). In this four-tiered system, grades 1 and 2 are considered “low grade” and grades 3 and 4 are considered “high grade.”

Tumor size has long been recognized to be an important prognostic variable in soft tissue sarcomas. Sarcomas have classically been stratified into two groups on the basis of size; T1 lesions are 5 cm or smaller and T2 lesions are larger than 5 cm.

The prognostic significance of anatomic tumor location with respect to its association with the investing fascia of the extremity or trunk was incorporated into the American Joint Committee on Cancer staging system in 1998. Soft tissue sarcomas above the superficial investing fascia of the extremity or trunk are designated “a” lesions in the T score, whereas tumors invading or deep to the fascia and all retroperitoneal, mediastinal, and visceral tumors are designated “b” lesions.

Nodal Metastasis

Lymph node metastasis of soft tissue sarcomas is rare; less than 5 percent manifest nodal spread. A few histologic subtypes, including rhabdomyosarcoma, epithelioid sarcoma, and malignant fibrous histiocytoma, have a higher incidence of nodal involvement. Nodal disease is designated as stage IV disease.

Distant Metastasis

Distant metastases occur most often in the lungs. Selected patients with pulmonary metastases may survive for long periods after surgical resection and chemotherapy.

TABLE 35-1 American Joint Committee on Cancer

Primary tumor (T)					
T1	Tumor ≤ 5 cm T1a Superficial tumor T1b Deep tumor				
T2	Tumor > 5 cm T2a Superficial tumor T2b Deep tumor				
Regional lymph nodes (N)					
N0	No regional lymph node metastasis				
N1	Regional lymph node metastasis				
Distance metastasis (M)					
M0	No distant metastasis				
M1	Distant metastasis				
Histologic grade (G)					
G1	Well differentiated				
G2	Moderately differentiated				
G3	Poorly differentiated				
G4	Poorly differentiated or undifferentiated				
Stage grouping					
Stage I	T1a, 1b, 2a, 2b	N0	M0	G1–2	G1
Stage II	T1a, 1b, 2a	N0	M0	G3–4	G2–3
Stage III	T2b	N0	M0	G3–4	G2–3
Stage IV	Any T	N1	M0	Any G	Any G
	Any T	N0	M1	Any G	Any G

TREATMENT

For soft tissue sarcomas of the extremities, a multidisciplinary approach to management, including margin-negative resection plus radiotherapy to the tumor bed, has resulted in local control rates up to and exceeding 90 percent. However, patients with abdominal sarcomas continue to have high rates of recurrence and poor overall survival. The overall 5-year survival rate for all stages of soft tissue sarcomas is 50–60 percent. Most patients die of metastatic disease, which becomes evident within 2–3 years of initial diagnosis in 80 percent of cases.

Surgery

Small (< 5 cm) primary tumors with no evidence of distant metastatic disease are managed by local therapy consisting of surgery, alone or in combination with radiation therapy, when wide pathologic margins are limited because of anatomic constraints. The type of surgical resection is determined by several factors, including tumor location, tumor size, depth of invasion, involvement of nearby structures, need for skin grafting or autogenous tissue reconstruction,

and the patient's performance status. In 1985, the National Institutes of Health (NIH) developed a consensus statement recommending limb-sparing surgery for most patients with high-grade extremity sarcomas. However, for patients whose tumor cannot be grossly resected with a limb-sparing procedure and preservation of function (<5 percent), amputation remains the treatment of choice.

Wide Local Excision

Wide local excision is the primary treatment strategy for extremity sarcomas. The goal of local therapy for extremity sarcomas is to resect the tumor with a 2-cm margin of surrounding normal soft tissue. In some anatomic areas, negative margins cannot be attained because of the tumor's proximity to vital structures. The biopsy site or tract (if applicable) should also be included en bloc with the resected specimen. With modern surgical and radiotherapy techniques, rates of limb preservation and local control have improved. A currently reported local failure rate of 10 percent after appropriate treatment is typical for soft tissue sarcomas of the extremity.

Amputation is the treatment of choice for patients with the rare 5 percent of tumors that cannot be grossly resected with a limb-sparing procedure and preservation of function.

Isolated Regional Perfusion

Isolated regional perfusion is an investigational approach for treating extremity sarcomas. It has been attempted mainly as a limb-sparing alternative for patients with locally advanced soft tissue sarcomas or as a palliative treatment to achieve local control for patients with distant metastatic disease.

Radiation Therapy

The evidence for adjunctive radiation therapy for patients eligible for conservative surgical resection comes from two randomized trials. In a trial by the National Cancer Institute, 91 patients with high-grade extremity tumors were treated with limb-sparing surgery followed by chemotherapy alone or radiation therapy plus adjuvant chemotherapy. A second group of 50 patients with low-grade tumors were treated with resection alone or resection with radiation therapy. The 10-year rate of local control for all patients receiving radiation therapy was 98 percent, compared with 70 percent for those not receiving radiation therapy. Similarly, in a randomized trial from the Memorial Sloan-Kettering Cancer Center, 164 patients underwent observation or brachytherapy after conservative surgery. The 5-year local control rate for patients with high-grade tumors was 66 percent in the observation group and 89 percent in the brachytherapy group. No significant difference was observed between treatment groups for patients with low-grade tumors.

Until recently, the standard treatment guidelines were to administer radiotherapy as an adjunct to surgery for all patients with intermediate or highly aggressive tumors of any size. However, in general, small tumors (≤ 5 cm) have not been associated with local recurrence, and radiation therapy may not be necessary.

The optimal mode (external beam or brachytherapy) and timing (preoperative, intraoperative, or postoperative) have yet to be defined. External-beam radiation therapy can be delivered by photons or particle beams (electrons, protons, pions, or neutrons). The optimal margin is not well defined; a radiation

margin of 5 to 7 cm is standard, although some centers advocate wider margins for tumors larger than 15 cm. At most institutions the typical preoperative dose is 50 Gy, given in 25 fractions.

Postoperative radiation therapy planning is based on tumor grade, assessment of surgical margins, and institutional preferences. The entire surgical scar and drain sites should be included in the field so that a near-full dose is given to the superficial skin. Metallic clips placed in the tumor bed during surgery can help define the limits of the resection and aid in radiation therapy planning. Doses of 60–70 Gy are usually necessary for postoperative treatment.

No consensus exists on the optimal sequence of radiation therapy and surgery. The available data come largely from single-institution, nonrandomized studies. Proponents of preoperative radiation therapy cite several advantages including multidisciplinary planning with radiation oncologists, medical oncologists, and surgeons is facilitated early in the course of therapy. Additionally, lower doses of preoperative radiation can be delivered to an undisturbed tissue bed that may have improved tissue oxygenation and result in smaller radiation fields with improved functional outcome.

Critics of preoperative radiation therapy cite as deterrents the difficulty of pathologic assessment of margins and the increased rate of wound complications. However, plastic surgery techniques with advanced tissue transfer procedures are being used more often in these high-risk wounds, with better outcomes.

The only randomized comparison of preoperative and postoperative radiation therapy conducted to date was performed by the National Cancer Institute of Canada Clinical Trial Canadian Sarcoma Group. This trial was designed to compare complications and the functional outcome of patients treated with preoperative and postoperative external-beam radiation therapy. At a median follow-up of 3.3 years, wound complications had occurred in 35 percent of patients given preoperative radiotherapy and in 17 percent of patients given postoperative radiation therapy. Both groups had achieved similarly high levels of local control and progression-free survival at 3 years.

Brachytherapy involves the placement of multiple catheters in the tumor resection bed. The primary benefit of brachytherapy is the shorter overall treatment time of 4–6 days, compared with preoperative or postoperative radiation therapy regimens, which generally take 4–6 weeks. Brachytherapy can also be used for recurrent disease previously treated with external-beam radiation. Guidelines established at the Memorial Sloan-Kettering Cancer Center recommend spacing the afterloading catheters in 1-cm increments and leaving a 2-cm margin around the surgical bed. After adequate wound healing is established, usually after the fifth postoperative day, the catheters are loaded with seeds containing iridium-192 that deliver 42–45 Gy of radiation to the tumor bed over 4–6 days. The primary disadvantage of brachytherapy is that it requires an extended inpatient stay and bedrest.

Systemic Therapy

Systemic therapy generally is limited to patients with metastatic disease, those with small-cell sarcomas of any size, or those with large (≥ 5 cm) high-grade tumors or intermediate-grade tumors larger than 10 cm. Despite improvements in local control rates, metastasis and death remain a significant problem for patients with high-risk soft tissue sarcomas. Patients considered at high risk of death from sarcoma include those presenting with metastatic disease and

those presenting with localized sarcomas at nonextremity sites or sarcomas with intermediate- or high-grade histology larger than 5 cm (T2).

Sarcomas encompass a diverse group of cancers that vary greatly in natural history and response to treatment. As a group, sarcomas include histologic subtypes that are very responsive to cytotoxic chemotherapy and subtypes that are universally resistant to current agents. Only three drugs, doxorubicin, dacarbazine, and ifosfamide, have consistently demonstrated response rates of 20 percent or more for advanced soft tissue sarcomas. Doxorubicin and ifosfamide are the two most active agents, with consistently reported response rates of 20 percent or greater.

Integrating Multimodality Therapy

The primary objective of multimodality treatment is cure; when this endpoint is not possible, the goal is palliation of symptoms. Whenever possible, patients with a deep soft tissue mass should be referred, even before a biopsy is performed, to a tertiary treatment center that offers care by a team of specialists. Such multidisciplinary teams typically include oncologists from several disciplines (medicine, pediatrics [if applicable], surgery, and radiation therapy), and a pathologist, radiologist, and ancillary staff.

Adjuvant Chemotherapy

The use of adjuvant chemotherapy for soft tissue sarcomas remains controversial. The average 5-year disease-free survival rate for patients initially presenting with localized disease is only about 50 percent. More than a dozen individual randomized trials of adjuvant chemotherapy have failed to demonstrate improvement in disease-free patients and overall survival in patients with soft tissue sarcomas.

The Sarcoma Meta-Analysis Collaboration analyzed 1568 patients from 14 trials of doxorubicin-based adjuvant chemotherapy to evaluate the effect of adjuvant chemotherapy on localized, resectable soft tissue sarcomas. At a median follow-up of 9.4 years, doxorubicin-based chemotherapy significantly improved the time to local and distant recurrence and recurrence-free survival rates. However, the absolute benefit in overall survival for the sample was only 4 percent, which was not significant.

Subsequent to this meta-analysis, additional randomized controlled trials of more modern (drugs, dose, and schedule) anthracycline/ifosfamide combinations for relatively small numbers of patients have yielded conflicting results. Because the evidence addressing treatment of stage III disease is inconclusive, considerable variation still exists in treatment standards.

Neoadjuvant (Preoperative) Chemotherapy

The rationale for using neoadjuvant and preoperative chemotherapy for soft tissue sarcomas is the belief that only 30–50 percent of patients will respond to standard (postoperative) chemotherapy. Neoadjuvant chemotherapy enables oncologists to identify patients whose disease responds to chemotherapy by assessing that response while the primary tumor is in situ. Patients whose tumors do not respond to short courses of preoperative chemotherapy are thus spared the toxic effects of prolonged postoperative or adjuvant chemotherapy.

Treatment approaches that combine systemic chemotherapy with radiosensitizers and concurrent external-beam radiation may improve disease-free survival by treating microscopic disease and enhancing the treatment of

macroscopic disease. Concurrent chemoradiotherapy with doxorubicin-based regimens reportedly produces favorable local control rates for patients with sarcoma. Since those findings were published, several groups have attempted to evaluate the optimal route of administration, alternative chemotherapeutic agents, and the toxicity of combined therapies.

Theoretical advantages of concurrent treatment notwithstanding, use of concurrent local and systemic therapy decreases the total treatment time for patients with high-risk sarcoma. This decrease represents a substantial advantage over current sequential combined-method treatment approaches, for which the total duration of treatment for radiation, chemotherapy, surgery, and rehabilitation frequently exceeds 6–9 months.

SPECIAL SITUATIONS

Retroperitoneal Sarcomas

Fifteen percent of adult soft tissue sarcomas occur in the retroperitoneum. Most retroperitoneal tumors are malignant, and about one third are soft tissue sarcomas. The most common sarcomas occurring in the retroperitoneum are liposarcomas, malignant fibrous histiocytomas, and leiomyosarcomas. Most retroperitoneal sarcomas are liposarcomas or leiomyosarcomas. In contrast to extremity sarcomas, local recurrence and intraabdominal spread are frequent patterns of relapse for retroperitoneal tumors.

Retroperitoneal sarcomas generally present as large masses; nearly 50 percent are larger than 20 cm at the time of diagnosis. They typically do not produce symptoms until they grow large enough to compress or invade contiguous structures.

The overall prognosis for patients with retroperitoneal tumors is worse than that for patients with extremity sarcomas. Tumor stage at presentation, high histologic grade, unresectability, and grossly positive resection margins are strongly associated with increased rates of death from retroperitoneal sarcoma. Survival rates at 5 years are typically reported to be 40–50 percent. The best chance for long-term survival for patients with retroperitoneal sarcoma is achieved with a margin-negative resection.

Radiologic assessment should include CT of the abdomen and pelvis to define the extent of the tumor and its relationship to surrounding structures, particularly vascular structures. Imaging should also encompass the liver for the presence of metastases, the abdomen for discontinuous disease, and the kidneys bilaterally for function. Thoracic CT is indicated to detect lung metastases.

Complete surgical resection is the most effective treatment for primary or recurrent retroperitoneal sarcomas. However, these tumors often involve vital structures, precluding surgical resection. Even if surgical resection can be performed, the margins are often compromised because of anatomic constraints. Chemotherapy has not been shown to be effective against retroperitoneal sarcomas. Protocols are ongoing at several centers to determine whether preoperative chemotherapy and radiation therapy have roles in treating these tumors.

Gastrointestinal Sarcomas

Patients with gastrointestinal sarcomas most often present with nonspecific gastrointestinal symptoms that are determined by the site of the primary tumor. Establishing the diagnosis of a gastrointestinal sarcoma preoperatively is

often difficult. Radiologic assessment, including CT of the abdomen or pelvis, is sometimes useful to determine the anatomic location, size, and extent of disease. For tumors involving the stomach, upper endoscopy with endoscopic ultrasonography and biopsy are important diagnostic tests used to distinguish adenocarcinoma from gastrointestinal stromal tumors.

For localized disease, the general recommendation is to perform a margin-negative resection with a 2–4-cm margin of normal tissue. However, some cases may be technically challenging because of the tumor's anatomic location or size. For example, for gastric tumors located near the gastroesophageal junction, achieving adequate surgical margins may not be possible without a total or proximal subtotal gastrectomy. Similarly, large tumors arising from the stomach with invasion of adjacent organs should be resected together with the adjacent involved viscera en bloc.

Segmental bowel resection is the standard treatment for sarcomas of the small or large intestine. For sarcomas originating in the rectum, the technique used for tumor resection is based on the anatomic location and size of the tumor. For small, low rectal lesions, it may be possible to achieve clear margins with a transanal excision. Large or locally invasive lesions may require more extensive operations for complete tumor extirpation.

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) constitute the majority of mesenchymal tumors involving the gastrointestinal tract. With an estimated incidence of 2,500–6,000 cases per year in the United States, the clinical presentation of these tumors varies depending on tumor size and anatomic location; however, most tumors are found incidentally at the time of endoscopy or radiologic imaging. GISTs arise most frequently in the stomach (60–70 percent), small intestine (20–25 percent), colon and rectum (5 percent) and esophagus (<5 percent). Most GISTs are sporadic and in 95 percent of cases there is a solitary lesion. Tumor size and mitotic index are the most important prognostic features of these tumors. Surgery remains the primary treatment modality for localized tumors. Until recently, there has been no effective therapy for metastatic or unresectable tumors.

Over the past decade, it has been recognized that GISTs have distinctive immunohistochemical and genetic features. GISTs originate from the intestinal pacemaker cells, the interstitial cells of Cajal (ICC), which are known to express CD117, a transmembrane tyrosine kinase receptor which is the product of the c-KIT proto-oncogene. Expression of CD117 has emerged as an important defining feature in nearly 95 percent of GISTs and the pathogenesis of these tumors is related to c-Kit mutations. Promising preclinical results have provided the driving force for the rapid clinical development of imatinib mesylate (Gleevec [Novartis], formerly known as STI571), a selective tyrosine kinase inhibitor of c-Kit. This novel, molecularly targeted therapy has produced impressive clinical responses in a large percentage of patients with advanced GISTs.

In February 2002, the U.S. Food and Drug Administration (FDA) approved imatinib mesylate for the treatment of GISTs based on promising results seen in patients with metastatic and locally advanced disease. Initial results from clinical trials indicate that about 54 percent of patients with GISTs respond to imatinib therapy and there is no benefit to doses above 400 mg daily. However, little is known about the optimal length of treatment, the duration of benefit, or the long-term toxicity. Given these results in patients with metastatic or locally

advanced GISTs, clinical trials are currently underway to study the efficacy of imatinib in the adjuvant and neoadjuvant therapy setting to determine whether it can decrease recurrence rates and prolong disease-specific survival after complete resection.

Pediatric Sarcomas

Soft tissue sarcomas account for 7–8 percent of all pediatric cancers, totaling approximately 600 new cases per year. Associated with skeletal muscle, rhabdomyosarcomas are the most common soft tissue tumors among children younger than 15 years, and they can occur at any site that has striated muscle. These tumors generally present as a painless enlarging mass; about 30 percent arise in the head and neck region, 25 percent in the genitourinary system, and 20 percent in the extremities. About 15–20 percent of cases have metastasis at presentation, most commonly involving the lungs. Several staging systems for rhabdomyosarcoma are available; that of the Intergroup Rhabdomyosarcoma Study Group is based on surgical-pathologic groupings (Table 35-2).

Rhabdomyosarcoma is classified as a small round-cell tumor that demonstrates muscle differentiation on light microscopy and immunohistochemical analysis. Two primary histologic subtypes account for 90 percent of cases, an embryonal subtype (70 percent) and an alveolar subtype (20 percent).

Complete surgical resection is the treatment of choice for rhabdomyosarcoma, when function and cosmesis can be preserved. Patients who are able to undergo a complete tumor resection with negative (group I) or microscopic surgical margins (group II) are able to undergo less intensive systemic therapy with overall survival rates approaching 90 percent. Given the morbidity associated with resections at some anatomic sites surgery is often not undertaken. Recent findings suggest that chemotherapy can adequately control several such tumors without additional local therapy.

Unlike other soft tissue sarcomas, rhabdomyosarcomas have a high propensity for lymph node metastasis, with rates up to 20–30 percent for sites such as the extremities, paratesticular nodes, and prostate. Lymph node sampling and more recently sentinel lymph node mapping have been used to evaluate regional node status in children with rhabdomyosarcoma.

In 1972, the Intergroup Rhabdomyosarcoma Study Committee was established to develop protocols for treating children with rhabdomyosarcomas. The chemotherapy regimens found to be the most active against

TABLE 35-2 Surgical-Pathologic Grouping of Soft Tissue Sarcoma (Intergroup Rhabdomyosarcoma Study Group)

Clinical group	Definition
I	a. Localized, completely resected, confined to site of origin b. Localized, completely resected, beyond site of origin
II	a. Localized, grossly resected microscopic residual tumor b. Regional disease, involved lymph nodes, completely resected c. Regional disease, involved lymph nodes grossly resected with microscopic residual tumor
III	a. Local or regional grossly visible disease after biopsy only b. Grossly visible disease after >50% resection of primary tumor
IV	Distant metastases at diagnosis

rhabdomyosarcomas have included vincristine, actinomycin D, and cyclophosphamide. Radiation therapy is given to most patients with microscopic residual disease (group II) after resection.

The prognosis for children with rhabdomyosarcoma is related to tumor site, surgical-pathologic grouping, and tumor histology. The 5-year, disease-free survival rate for all patients has been reported as 65 percent. Disease-free survival by group (see Table 35-2) has been reported as 84 percent, 74 percent, 62 percent, and 23 percent for groups I, II, III, and IV, respectively.

Recurrent Sarcomas

Up to 20 percent of patients with extremity sarcoma develop recurrent disease. The adequacy of surgical resection of sarcomas arising from any anatomic site is clearly related to local recurrence rates. Patients with microscopically positive surgical margins are at increased risk of local recurrence. The effect of local treatment failure on survival and distant disease-free survival is controversial. Many believe that recurrence is a harbinger of distant metastatic disease.

An isolated local recurrence should be treated aggressively with margin-negative resection. For patients with extremity sarcomas, this frequently requires amputation. However, some patients with recurrent extremity sarcoma can undergo function-preserving resection combined with additional radiation therapy, with or without chemotherapy, with acceptable rates of local control.

Retroperitoneal sarcomas recur locally in up to 60 percent of patients. These tumors also can spread diffusely throughout the abdominal cavity and recur as sarcomatosis. The preferred treatment for locally recurrent retroperitoneal tumors is surgical resection, if possible.

Palliative Strategies

Metastases are present at diagnosis in 40–50 percent of patients with intermediate- or high-grade extremity sarcomas, as compared with only 5 percent in patients with low-grade sarcomas. Of those patients who present with high risk localized disease, metastases to distant sites occur within 2–3 years of initial diagnosis. The pattern of recurrence is related to the anatomic site of the primary tumor. Patients with extremity sarcomas generally have recurrence as distant pulmonary metastases, whereas patients with retroperitoneal or intraabdominal sarcomas tend to have local recurrences. Other less common sites of metastasis include bone (7 percent), liver (4 percent), and lymph nodes (<5 percent). Myxoid liposarcoma of the extremity is known to metastasize to the abdomen and pelvis, and requires staging CT of these regions before definitive local therapy.

The primary determinant of survival in patients with soft tissue sarcoma is development of distant metastases. Early recognition and treatment of recurrent, local, or distant disease can prolong survival. A few reports involving small numbers of patients have indicated that salvage after recurrent local disease is possible by performing radical reexcision with or without radiation therapy. Similarly, several groups have reported that survival can be prolonged after resection of pulmonary metastases. These limited data form the basis for the use of aggressive surveillance strategies for all patients with soft tissue sarcoma.

Because most recurrences of soft tissue sarcomas occur in the first 2 years after completion of therapy, it is recommended that patients be evaluated with

a complete history and physical examination every 3 months and chest radiography every 6 months during the 2–3-year period. Additionally, most experts recommend that the tumor site be evaluated every 6 months by performing MRI for extremity tumors or CT for intraabdominal or retroperitoneal tumors. In some circumstances, ultrasonography can be used to assess recurrence of tumor in the extremities. Follow-up intervals can be lengthened to every 6 months, with annual imaging, for years 2 through 5. After 5 years, patients should be evaluated and undergo chest radiography annually.

Chemotherapy for Metastatic Sarcoma

The only available treatment for most patients with metastatic disease is chemotherapy. Historically, response rates for patients with stage IV soft tissue sarcoma have been low. Several prognostic factors have been defined for patients undergoing chemotherapy, including performance status, previous response to chemotherapy, younger age, absence of hepatic metastases, low-grade tumors, and long disease-free interval.

CONCLUSION

Soft tissue sarcomas are a family of rare tumors, constituting approximately 1 percent of adult malignancies. The etiology in the vast majority of patients is sporadic. The management of such diverse tumors is complex. Diagnosis by light microscopy is inexact. Molecular diagnosis, although still in its infancy, holds great promise for the future.

Despite these confounding issues, the natural history of soft tissue sarcomas is well established. Approximately two-thirds of cases arise in the extremities, whereas the remaining one-third are distributed between the retroperitoneum, trunk, abdomen, and head and neck. The management algorithm for soft tissue sarcomas is complex and depends on tumor stage, site, and histology. The most common site of metastasis is the lungs, and it generally occurs within 3 years of diagnosis.

The rarity of soft tissue sarcomas creates a challenge for studying the effects of treatment. Collaborative efforts are required to accrue adequate numbers of patients for such studies. Despite these obstacles, progress is being made in understanding these tumors at the molecular level. It can be anticipated that molecular-based therapies will become increasingly incorporated into treatment strategies in the near future.

The latter part of the eighteenth century heralded dramatic changes as the anatomy of the groin became better understood. In 1881, a French surgeon, Lucas-Championnière, performed high ligation of an indirect inguinal hernia sac at the internal ring with primary closure of the wound. Edoardo Bassini (1844–1924) is considered the father of modern inguinal hernia surgery. By incorporating the developing disciplines of antisepsis and anesthesia with a new operation that included reconstruction of the inguinal floor along with high ligation of the hernia sac, he was able to substantially reduce morbidity. It is universally agreed that this concept was responsible for the advent of the modern surgical era of inguinal herniorrhaphy and is still valid today. The operation resulted in a recurrence rate one-fifth of that which generally was accepted and was considered the standard criterion for inguinal hernia repair for most of the twentieth century.

Although Bassini's principle of posterior wall reinforcement remains valid in a surgical practice today, his operation has lost its popularity and is used only in selected cases in which prosthetic material is contradicted. This is because of the widespread acceptance of the concept of avoiding tension during herniorrhaphy, championed by Lichtenstein. Lichtenstein theorized that by using a mesh prosthesis to bridge the hernia defect rather than closing it with sutures, as with the Bassini repair and its modifications, tension is avoided ostensibly resulting in a less painful operation. He also felt that the lack of tension reduced the incidence of suture pullout, which would result in a lower recurrence rate. A Lichtenstein type operation has now become the method of choice in the United States.

The preperitoneal space also can be used for repair of an inguinal hernia and has strong proponents because of the mechanical advantage gained from prosthesis placement behind the abdominal wall. Access to the preperitoneal space can be gained through a lower abdominal incision, transabdominally at the time of laparotomy or with the aid of laparoscopic guidance. Irrespective of the mode of entry to the preperitoneal space, a large prosthesis is used that extends far beyond the margins of the myopectineal orifice. This brief overview of the history of inguinal herniorrhaphy provides a background for a comprehensive look at the problem of inguinal herniation.

EPIDEMIOLOGY

Seventy-five percent of all abdominal wall hernias occur in the groin. Indirect hernias outnumber direct hernias by about 2:1, with femoral hernias making up a much smaller proportion. Right-sided groin hernias are more common than those on the left. The male:female ratio for inguinal hernias is 7:1. There are approximately 750,000 inguinal herniorrhaphies performed per year in the United States, compared to 25,000 for femoral hernias, 166,000 for umbilical hernias, 97,000 for incisional hernias, and 76,000 for miscellaneous abdominal wall hernias.

Femoral hernias account for less than 10% of all groin hernias, but 40% of these present as emergencies with incarceration or strangulation. The

mortality rate for emergency repair is higher than for elective repair. Femoral hernias are more common in older patients and in men who have previously undergone an inguinal hernia repair. Although the absolute number of femoral hernias in males and females is about the same, the incidence in females is four times that of males because of the lower overall frequency of groin hernia in women.

Estimates of the risk for developing an inguinal hernia vary greatly in the literature, probably because of the lack of an entirely reproducible way to make the diagnosis. Self-reporting by patients, audits of routine physical examinations, and insurance company databases are among the diverse sources from which such figures are derived, all of which are known to be notoriously inaccurate. Physician physical examination, even by trained surgeons, also is not dependable because of the difficulty differentiating between lipomas of the cord, a normal expansile bulge and a true groin hernia.

NATURAL HISTORY

Risk factors that are useful in predicting complications in an adult patient with a groin hernia include old age, short duration, femoral hernia and coexisting medical illness. In children, the risk factors are very young age, male sex, short duration and right-sided hernia. A better understanding of the natural history therefore becomes particularly important to identify subgroups that might be at greater risk for a complication.

HERNIA ACCIDENT (INCARCERATION, BOWEL OBSTRUCTION, STRANGULATION)

An incarcerated hernia is by definition an irreducible hernia. However, this should not imply a surgical emergency, as chronic states of incarceration are common because of the size of the neck of the hernia in relationship to its contents or because of adhesions to the hernia sac. The recommended treatment of an incarcerated hernia is surgical repair, but there is no urgency because there is no life threatening complication present.

A patient with an incarcerated inguinal hernia exhibiting signs of a bowel obstruction or one who develops an acute incarceration that remains exquisitely tender represents a completely different clinical scenario. Unlike adhesive small bowel obstructions, partial small bowel obstructions are rare. Therefore, most patients will have had vomiting and absolute constipation (obstipation). In the western world, groin hernia ranks third after adhesive obstruction and cancer as the most common cause of bowel obstruction. In other areas, it remains the most common. It is common for it to be overlooked on clinical examination and therefore must be kept in mind in patients being evaluated for bowel obstruction.

Imaging studies are important in cases in which there is the slightest question about the cause of the patient's obstructive pattern. This is because a distal intestinal obstruction secondary to another cause (e.g., adhesions) may result in distention of a coincidental nonobstructing groin hernia. Should the examiner focus attention exclusively on the hernia, the stage is set for disaster when the hernia is repaired and the real cause of the obstruction is missed. Plain roentgenograms of the abdomen will reveal the usual signs of an intestinal obstruction: dilated loops of bowel with air-fluid levels, absence of bowel gas distal to the obstruction and bowel shadows in the region of the hernia. A lateral view often is useful to demonstrate this more clearly. Computerized

tomographic (CT) scans reliably demonstrate the hernia with characteristic features of obstruction and should be considered if the clinical diagnosis is not certain.

The initial treatment, in the absence of signs of strangulation, is taxis. Taxis is performed with the patient sedated and placed in the Trendelenburg position. The hernia sac neck is grasped with one hand with the other applying pressure on the most distal part of the hernia. The goal is to elongate the neck of the hernia so that the contents of the hernia may be guided back into the abdominal cavity with a rocking movement. Taxis should not be performed with excessive pressure. If the hernia is strangulated, gangrenous bowel might be reduced into the abdomen or perforated in the process. One or two gentle attempts should be made at taxis. If this is unsuccessful, the procedure should be abandoned. Rarely, the hernia together with its peritoneal sac and constricting neck may be reduced into the abdomen (reduction en masse). Reduction en masse of a hernia is defined as the displacement of a hernia mass without relief of incarceration or strangulation. This diagnosis has to be considered in all cases of intestinal obstruction after apparent reduction of an incarcerated hernia. Laparoscopy can be both diagnostic and therapeutic and therefore is a particularly good option. Surgeon expertise may make laparotomy a better choice for some.

The most significant complication of either acute incarceration or intestinal obstruction is strangulation. It is a serious, life-threatening condition because the hernia contents have become ischemic and nonviable. The clinical features of a strangulated obstruction are dramatic. In addition to the patient having developed an irreducible hernia and an intestinal obstruction, clinical signs indicate that strangulation has taken place. The hernia is tense, very tender and the overlying skin may be discolored with a reddish or bluish tinge. There are no bowel sounds present within the hernia itself. The patient commonly has a leukocytosis with a left shift, is toxic, dehydrated and febrile. Arterial blood gases may reveal a metabolic acidosis.

Rapid resuscitation with intravenous fluids is essential with electrolyte replacement, antibiotics and nasogastric suction. Urgent surgery is indicated once resuscitation has taken place. The initial surgical approach is to make a conventional inguinal hernia incision. If the bowel is viable, it is reduced into the abdominal cavity prior to repairing the hernia. The neck of the hernia is widened if any difficulty is encountered reducing the hernia. Although rare, the surgeon must be cognizant of the possibility that a nonviable abdominal organ may have been reduced into the abdominal cavity during the course of usual surgical maneuvers before it could be visualized. If such a suspicion is present, the entire GI tract must be evaluated. If the bowel is found to be obviously gangrenous, more bowel must be pulled into the hernia so that viable bowel can be transected and the gangrenous portion removed. In the ideal situation, an end to end anastomosis is performed and the bowel is reduced into the abdominal cavity, followed by hernia repair. The slightest suspicion that the entire process cannot be addressed from the groin mandates exploratory laparoscopy or laparotomy to unequivocally prove that all nonviable tissue has been resected. In the case of a femoral hernia, it is frequently necessary to incise the inguinal ligament anteriorly or the lacunar ligament medially to facilitate reduction.

ETIOLOGY

The cause of an inguinal hernia in a human is far from completely understood but is undoubtedly multifactorial (Table 36-1). Familial predisposition plays a role. However, there is increasing evidence that connective tissue disorders predispose to hernia formation by altering collagen formation. A higher prevalence of inguinal hernias is well known among patients suffering from certain congenital connective tissue disorders. In children with congenital hip dislocation, inguinal hernia occurs five times more often in girls and three times more often in boys compared to children without this disease. The role of physical exertion in the development of inguinal hernia is probably less important than is commonly believed. The cause and effect relationship between a specific lifting episode and the development of an inguinal hernia is present in less than 10 percent except in circumstances in which worker's compensation issues are involved. Additionally, athletes, even weightlifters, do not seem to have an excessive incidence of inguinal hernias. This begs the question whether patients with un-repaired inguinal hernias should be restricted from heavy lifting.

Indirect Inguinal Hernia

The so-called "saccular theory" of indirect inguinal hernia formation proposed by Russell remains popular. Russell's hypothesis that the "presence of a developmental diverticulum associated with a patent processus vaginalis, was essential in every case" is still valid in the minds of many surgeons even today. Russell felt that increased intraabdominal pressure might serve to further stretch and weaken the internal ring allowing additional intraabdominal organs to herniate through the orifice but could not actually cause an indirect inguinal hernia. This does not explain all cases of indirect groin hernias, however. First,

a patent processus vaginalis can be found at autopsy without clinical evidence of a hernia. Second, there are patients with an obliterated processus vaginalis who have an abdominal wall defect lateral to the epigastric vessels. Third, congenital structural malformations of the transversalis fascia and transversus abdominis aponeurosis can alter the strength and size of the internal inguinal ring. Denervation of the internal oblique muscle by adjacent incisions (e.g., appendectomy) also can be associated with the eventual development of an inguinal hernia.

Excessive fatty tissue involving the cord or round ligament encountered by a surgeon during elective herniorrhaphy traditionally has been referred to as a lipoma of the cord. This term is unfortunate because it implies a neoplastic process but a lipoma of the cord consists of normal fatty tissue. The reason for the term lipoma is that the fatty tissue can easily be separated from the cord structures and reduced into the preperitoneal space “en masse” as if it were a tumor. A lipoma of the cord is important from a clinical standpoint for three reasons: (1) it can cause hernia type symptoms although with less frequency than indirect hernias with a peritoneal sac; (2) it is often difficult to distinguish at physical examination from an indirect hernia with a peritoneal sac; and (3) it can be responsible for an unsatisfactory result because of an unchanged physical examination after elective inguinal herniorrhaphy, especially when a preperitoneal repair is used. For the purposes of the large clinical trials referred to in other parts of this chapter, a lipoma of the cord was classified as an indirect hernia. There is no peritoneal sac by definition because the contents of the indirect hernia (i.e., preperitoneal fat) come from the preperitoneal space rather than the abdominal cavity.

Direct Inguinal Hernias

Two major factors are felt to be important in the development of direct inguinal hernias. The first is increased intraabdominal pressure associated with a variety of conditions listed in Table 36-1. The second factor is relative weakness of the posterior inguinal wall. An abnormally high lying arch of the main body of the transversus abdominis above the superior ramus of the pubis resulting in a large area at risk has been incriminated (see Anatomy). Similarly, a limited insertion of the transversus abdominis muscle onto the pubis, weakness of the iliopubic tract, limited insertion of the iliopubic tract aponeurosis into a Cooper ligament or a combination of these have been reported to contribute.

Femoral Hernias

The size and shape of the femoral ring and increased intraabdominal pressure are factors that contribute to the development of a femoral hernia. The iliopubic tract anteriorly and medially accounts for the variability that allows the development of the hernia. The iliopubic tract normally inserts for a distance of 1–2 cm along the pectinate line between the pubic tubercle and the midportion of the superior pubic ramus. A femoral hernia can result if the insertion is less than 1–2 cm or if it is shifted medially. The net effect of either anatomic subtlety is to widen the femoral ring, predisposing to the hernia. Femoral hernias are particularly dangerous because of the rigid structures that make up the femoral ring. The slightest amount of edema at the ring can produce gangrenous changes of the sac contents continuing distally into the femoral canal and thigh.

Sliding Inguinal Hernia

A sliding inguinal hernia is defined as any hernia in which part of the sac is the wall of a viscus. Approximately 8 percent of all groin hernias present with this finding but the incidence is age related. It rarely is found in patients less than 30 years of age but increases to 20 percent after the age of 70. If the hernia is on the right, the cecum, ascending colon or appendix most commonly are involved; and on the left, the sigmoid colon. The uterus, fallopian tubes, ovaries, ureters and bladder can be involved on either side. The sliding component usually is found on the posterior lateral side of the internal ring. The importance of this condition has lessened considerably in the last several years with the realization that it is not necessary to resect hernia sacs and that simple reduction into the preperitoneal space is sufficient. This eliminates the primary danger associated with sliding hernias, which is injury to the viscus during high ligation and sac excision.

ANATOMY

The anatomy of the groin is best understood when observing from the approach for the herniorrhaphy to be performed. For a conventional operation, this means from the skin to the deeper layers. For the laparoscopic operations or the preperitoneal operations, one should consider the anatomy from the abdominal cavity to the skin. The first layers encountered beneath the skin are the Camper and Scarpa fascia in the subcutaneous tissue. The aponeurosis of the external oblique muscle is the next structure encountered as dissection proceeds through the abdominal wall. The muscle arises from the posterior aspects of the lower eight ribs. The posterior portion of the muscle is orientated vertically and inserts on the crest of the ileum. The anterior portion of the muscle courses inferiorly in an oblique direction toward the midline and pubis. The obliquely oriented anterior-inferior fibers of the aponeurosis of the external oblique muscle fold back on themselves to form the inguinal ligament which attaches laterally to the anterior superior iliac spine. The medial insertion of the inguinal ligament in most individuals is dual. One portion inserts on the pubic tubercle and the pubic bone. The other folds back as the lacunar ligament. It blends laterally with a Cooper (pectineal) ligament. The more medial fibers of the aponeurosis of the external oblique divide into a medial and a lateral crus to form the external or superficial inguinal ring through which the spermatic cord or round ligament and branches of the ilioinguinal and genitofemoral nerves pass.

The internal abdominal oblique muscle fibers fan out following the shape of the iliac crest; the superior fibers course obliquely upward toward the distal ends of the lower three or four ribs whereas the lower fibers orient themselves inferomedially toward the pubis to run parallel to the external oblique aponeurotic fibers. These fibers arch over the round ligament or the spermatic cord forming the superficial part of the internal (deep) inguinal ring.

The first lumbar nerve divides into the ilioinguinal and iliohypogastric nerves. These may divide within the psoas major muscle retroperitoneally or between the internal oblique and transversus abdominis muscles. The ilioinguinal nerve may communicate with the iliohypogastric nerve before innervating the internal oblique. The ilioinguinal nerve then passes through the external inguinal ring to run with the spermatic cord, although the iliohypogastric nerve pierces the external oblique to innervate the skin above the pubis. The cremaster muscle fibers, which are derived from the internal oblique muscle, are innervated by the genitofemoral nerve (L1, L2).

The transversus abdominis muscle arises from the inguinal ligament, the inner side of the iliac crest, the endoabdominal fascia and the lower six costal cartilages and ribs. The medial aponeurotic fibers of the transversus abdominis contribute to the rectus sheath and insert on the pecten pubis and the crest of the pubis forming the *falx inguinalis*. These fibers are infrequently joined by a portion of the internal oblique aponeurosis; only then is a true conjoint tendon formed.

The myopectineal orifice of Fruchaud refers to an anatomic area in the groin through which all hernias occur. Hesselbach's inguinal triangle is within this orifice and is the site of direct inguinal hernias. When described from the anterior aspect, the inguinal ligament forms the base of the triangle, the edge of the rectus abdominis is the medial border, and the inferior epigastric vessels are the superolateral border. It should be noted, however, that Hesselbach actually described a Cooper ligament as the base.

The transversalis fascia also is important because it forms anatomical landmarks known as analogues or derivatives. The important transversalis fascia analogues for the hernia surgeon are the iliopectineal arch, the iliopubic tract, the crura of the deep inguinal ring and a Cooper (pectineal) ligament. The superior and inferior crura form a transversalis fascia sling, a "monk's hood" shaped structure, around the deep inguinal ring. This sling has functional significance as the crura of the ring are pulled upward and laterally by the contraction of transversus abdominis, resulting in a valvular action that helps to preclude indirect hernia formation. The iliopubic tract is the thickened band of the transversalis fascia that courses parallel to the more superficially located inguinal ligament. It is attached to the iliac crest laterally and inserts on the pubic tubercle medially. The insertion curves inferolaterally for 1–2 cm along the pectinate line to blend with a Cooper (pectineal) ligament, ending at about the midportion of the superior pubic ramus. A Cooper ligament is actually a condensation of periosteum and is not a true analogue of the transversalis fascia.

The femoral ring is bordered by the superior pubic ramus inferiorly and the femoral vein laterally. The iliopubic tract with its curved insertion onto the pubic ramus is the anterior and medial border. The canal normally contains preperitoneal fat, connective tissue and lymph nodes including a Cloquet node at its entrance, the femoral ring.

The Posterior Perspective (Laparoscopic)

An excellent view of the anterior abdominal wall can be obtained from a laparoscopic vantage point. Peritoneal folds are immediately obvious which correspond to important anatomic landmarks in the preperitoneal space. The median umbilical fold extends from the umbilicus to the urinary bladder and covers the urachus, the usually fibrous remnant of the fetal allantois. The lateral umbilical fold covers the inferior epigastric artery as it courses toward the posterior rectus sheath and enters it approximately at the level of the arcuate line.

The fossa formed between the medial and the lateral ligaments is the site of direct inguinal hernias. The lateral fossa is less delineated than the other two. The deep inguinal ring is located in the lateral fossa just lateral to the inferior epigastric vessels.

When the peritoneum is divided and the preperitoneal space entered, the key anatomic elements for a preperitoneal herniorrhaphy can be appreciated.

In the midline behind the pubis, the preperitoneal space is known as the space of Retzius, although laterally it is referred to as the space of Bogros. This space is important because many of the repairs, which are described later, are performed in this area. Perhaps the single most important landmark is the inferior epigastric artery. This branch of the external iliac artery represents the primary blood supply to the deep anterior wall. The veins in this area can be troublesome especially the iliopubic, corona mortis obturator and their tributaries.

Other landmarks that require identification are the internal inguinal ring just lateral to the take off of the inferior epigastric vessels, the internal spermatic artery and vein, and the vas deferens that join to form the spermatic cord just before entering the internal ring. The iliopubic tract, attached to the iliac crest laterally, crosses under the internal ring to make up its inferior border and at the same time contributes to the anterior border of the femoral sheath continuing to its insertion on the pubic tubercle. A Cooper ligament extends from the pubic tubercle inferolateral along the pubic ramus crossing under the femoral vessel. The femoral ring is readily visible from this viewpoint being bordered by the femoral vein laterally, a Cooper ligament inferiorly, and the iliopubic tract superiorly.

The nerves traversing the preperitoneal space are prone to intraoperative injury. They can be damaged when fastening a prosthesis if deep penetration of the fixation device occurs. The genitofemoral nerve may occur as a single trunk lying deep to the peritoneum and fascia on the anterior surface of the psoas muscle or it may divide into its component genital and femoral branches within the muscle. The genital branch travels with the spermatic cord, entering at the deep inguinal ring; it ultimately innervates the cremaster muscle and the lateral scrotum. The femoral branch of the nerve innervates the skin of the proximal mid thigh. The lateral femoral cutaneous nerve crosses the preperitoneal space lateral to the genitofemoral nerve and enters the thigh just beneath the iliopubic tract and the inguinal ligament. This nerve supplies sensory branches for the lateral side of the thigh.

SYMPTOMS

Patients with groin hernias present with a wide range of clinical scenarios ranging from no symptoms at all to the life-threatening condition caused by strangulation of incarcerated hernia contents. Asymptomatic patients may have their hernias diagnosed at the time of a routine physical examination or seek medical attention because of a painless bulge in the groin. Indirect hernias are more likely to produce symptoms than direct hernias. Many describe an annoying heavy feeling or dragging sensation, which tends to be worse as the day wears on. The pain is commonly intermittent and radiation into the testicle is not rare. Others complain of a sharper pain that is either localized or diffuse. Particularly severe patients may need to recline for a short period of time or use other posture altering techniques. Occasionally patients must manually reduce their hernia to obtain relief.

DIAGNOSIS

Physical Examination

Physical examination is the best way to determine the presence or absence of an inguinal hernia. The diagnosis may be obvious by simple inspection

TABLE 36-2 Differential Diagnosis

Hidradenitis
Cyst of the canal of Nuck (Female)
Saphenous varix
Psoas abscess
Hematoma
Ascites

when a visible bulge is present. The differential diagnosis must be considered in questionable cases (Table 36-2). Nonvisible hernias require digital examination of the inguinal canal. Classic teaching is that an indirect hernia will push against the fingertip, whereas a direct hernia will push against the pulp of the finger. Additionally, applying pressure over the mid-inguinal point with the fingertip will control an indirect hernia and prevent it from protruding when the patient strains. A direct hernia will not be effected with this maneuver.

A femoral hernia presents as a swelling below the inguinal ligament and just lateral to the pubic tubercle. Thin patients commonly have prominent bilateral bulges below the inguinal ligament medial to the femoral vessels. They are asymptomatic and disappear spontaneously when the patient assumes a supine position. Operation is not indicated.

Radiological Investigations

Hernias are visualized as abnormal ballooning of the anteroposterior diameter of the inguinal canal and/or simultaneous protrusion of fat or bowel within the inguinal canal. Magnetic resonance imaging (MRI) with the development of the fast imaging scanners that allow dynamic imaging (i.e., performed during straining), shows particular promise for further refinement with the “tweaking” of the best weights for images and the addition of intraperitoneal contrast agents. Both MRI and computerized tomography (CT) may reveal other causes of groin pain because of their ability to visualize related structures in the groin. In a comparative study, the sensitivity and specificity was 74.5 percent and 96.3 percent for physical examination, 92.7 percent and 81.5 percent for ultrasound, and 94.5 percent and 96.3 percent for MRI, respectively.

PREOPERATIVE CARE

Nonoperative Treatment

The term “watchful waiting” is used to describe this treatment recommendation. It is only applicable in asymptomatic or minimally symptomatic hernias. Patients are counseled about the signs and symptoms of complications from their hernia so they might present promptly to their physician in cases in which an adverse event takes place. Definitive data that this recommendation is safe is not available and it is for this reason that standard surgical texts continue to recommend surgical repair of all inguinal hernias at diagnosis. However, a randomized controlled trial is currently underway which should shed some light on this subject in the next few years.

ABDOMINAL WALL SUBSTITUTES

The modern era of herniorrhaphy has seen a progressive decrease in recurrence rate because of improvement in surgical technique and prosthetics. It is apparent that the abdominal wall does not always heal satisfactorily after primary closure and that an irreducible percentage of recurrences is inevitable if one were to insist on pure tissue repairs. The only reasonable solution is the use of a structure that can bridge a defect in certain cases.

Prosthetic Materials

It has now been proven that mesh herniorrhaphy can decrease the recurrence rate by approximately 50 percent when compared to nonmesh repairs. Chronic post herniorrhaphy groin pain occasionally occurs after prosthetic repair and is relieved by prosthesis removal. However, the overall incidence of chronic post herniorrhaphy groin pain is less with a prosthetic repair. The materials that have emerged as suitable for routine use in hernia surgery include polypropylene, either monofilament (Marlex, Prolene) or polyfilament (Surgipro), Dacron (Mersilene) and expanded polytetrafluoroethylene (e-PTFE) (Gore-Tex).

ANESTHESIA FOR GROIN HERNIORRHAPHY

Most inguinal herniorrhaphies can be performed under local or regional anesthesia. Laparoscopic herniorrhaphy is the exception, as general endotracheal anesthesia is primarily mandated by the pneumoperitoneum. This is one of the strongest arguments for conventional herniorrhaphy when compared to laparoscopic herniorrhaphy. Despite this, the best available evidence suggests that the majority of conventional herniorrhaphies are performed under a general anesthetic with local and regional techniques, finding their greatest popularity in specialty clinics. Nevertheless, local anesthesia, when used in adequate doses and far enough in advance of the initial incision, proves very effective when combined with the newer, short-acting amnesic and anxiolytic agents.

One hundred milliliters of 0.5 percent Xylocaine with epinephrine or 0.25 percent bupivacaine with epinephrine or a combination of the two plus or minus sodium bicarbonate is most common. Seventy milliliters of this solution is injected by the surgeon in an adult of normal size prior to prepping and draping the patient. Ten milliliters is placed medial to the anterior superior iliac spine to block the ilioinguinal nerve, and the other 60 mL is used as a field block along the orientation of the eventual incision in the subcutaneous and deeper tissues. Care is taken to inject the areas of the pubic tubercle and

a Cooper ligament, both of which can easily be identified by tactile sensation except in the very obese. The remaining 30 mL is reserved for discretionary use during the procedure. With this technique, endotracheal intubation is avoided and the patient can be aroused from sedation at intervals to perform Valsalva maneuvers and test the repair.

INGUINAL HERNIA REPAIRS

Before discussing specific conventional herniorrhaphies, several steps will be described because they are common to all of the conventional operations.

Initial Incision: Classically an oblique skin incision is made between the anterior superior iliac spine and the pubic tubercle. Many surgeons now use a more horizontally placed skin incision in the natural skin lines for cosmetic reasons. Regardless, it is deepened through the Camper and Scarpa fascia and the subcutaneous tissue to expose the external oblique aponeurosis. This structure is incised medially down to and through the external inguinal ring.

Mobilization of the cord structures. The superior flap of the external oblique aponeurosis is bluntly dissected off the internal oblique muscle laterally and superiorly. The iliohypogastric nerve is identified at this time. It can be left in-situ or freed from the surrounding tissue and isolated from the operative field by passing a hemostat under the nerve and grasping the upper flap of the external oblique aponeurosis. Routine division of this nerve along with the ilioinguinal nerve is practiced by some surgeons but not advised by most. The cord structures are then separated from the inferior flap of the external oblique aponeurosis by blunt dissection exposing the shelving edge of the inguinal ligament and the iliopubic tract. The cord structures are lifted en-masse with the fingers of one hand at the pubic tubercle so that the index finger can be passed underneath to meet the index finger of the other hand. Blunt dissection is used to complete mobilization of the cord structures and a Penrose drain is placed around them for retraction during the course of the procedure.

Division of the cremasteric muscle. Complete division of the cremasteric muscle, especially when dealing with an indirect hernia, has been common practice. The purpose is to facilitate sac identification and to lengthen the cord for better visualization of the inguinal floor. However, adequate exposure usually can be obtained by a longitudinal opening of the muscle, which lessens the likelihood of damage to cord structures and avoids the complication of testicular descent. It is probably best not to divide the cremasteric muscle unless the surgeon cannot obtain adequate visualization of the inguinal floor any other way.

High ligation of the sac. The term "high ligation of the sac" will be used frequently as its historical significance has ingrained it in the description of most of the older operations. By convention, high ligation should be considered equivalent to reduction of the sac into the preperitoneal space without excision. Both methods work equally well and are highly effective. Sac inversion, in lieu of excision, does protect intraabdominal viscera in cases of unrecognized incarcerated sac contents or a sliding hernia.

Management of inguinal scrotal hernia sacs. Complete excision of all indirect inguinal hernia sacs is felt to be important by some. The downside to this practice is an excessive rate of ischemic orchitis caused by trauma to the

testicular blood supply, especially the delicate venous plexuses. Testicular atrophy is the logical further sequelae although the relationship has not been conclusively proven. A better approach is to divide indirect inguinal hernia sacs in the mid inguinal canal, once confident the hernia is not sliding and there are no abdominal contents. The distal sac is not dissected but the anterior wall is opened as far distally as is convenient. Contrary to popular opinion in the urological literature, this does not result in an excessive rate of postoperative hydrocele formation.

Relaxing incision. A relaxing incision divides the anterior rectus sheath extending from the pubic tubercle superiorly for a variable distance determined by the tension. The relaxing incision works by allowing the various components of the abdominal wall to displace laterally and inferiorly.

Wound closure. The external oblique fascia is closed, serving to reconstruct the superficial (external) ring. The external ring must be loose enough to prevent strangulation of the cord structures yet tight enough to avoid an inexperienced examiner from confusing a dilated ring with a recurrence. The later is sometimes referred to as an “industrial” hernia because historically it has at times been a problem during a preemployment physical. The Scarpa fascia and the skin are closed to complete the operation.

Specific Herniorrhaphies

Bassini

Bassini called his new operation the “radical cure” for an inguinal hernia. The major components of “this cure” are as follows:

- (1) Division of the external oblique aponeurosis over the inguinal canal through the external ring.
- (2) Division of the cremaster muscle lengthwise followed by resection so that an indirect hernia is not missed while exposing simultaneously the floor of the inguinal canal to more accurately assess for a direct inguinal hernia.
- (3) Division of the floor or posterior wall of the inguinal canal for its full length. This insures adequate examination of the femoral ring from above and exposes the tissue layers that will be used for reconstructing the inguinal floor
- (4) High ligation of an indirect sac.
- (5) Reconstruction of the posterior wall by suturing the transversalis fascia, the transversus abdominis muscle, the internal oblique muscle (Bassini’s famous “triple layer”) medially to the inguinal ligament laterally and possibly the iliopubic tract.

Following the initial dissection and reduction or ligation of the sac, attention turns to reconstructing the inguinal floor. Bassini began this part of the operation by opening the transversalis fascia (some prefer to use the term posterior inguinal wall) from the internal inguinal ring to the pubic tubercle, exposing the preperitoneal fat which was bluntly dissected away from the under surface of the superior flap of the transversalis fascia. This allowed him to properly prepare the deepest structure in his famous triple layer (transversalis fascia, transversus abdominis muscle and internal oblique muscle). The first stitch in the repair includes the triple layer superiorly and the periosteum of the medial side of the pubic tubercle along with the rectus sheath. Most surgeons now try to avoid the periosteum of the pubic tubercle to decrease the incidence

of osteitis pubis. The repair is continued laterally with nonabsorbable suture securing the triple layer to the reflected inguinal ligament (Poupart ligament). These sutures are continued until the internal ring has been closed on its medial side. A relaxing incision was not part of the original description but is commonly added now.

Shouldice

Local anesthesia with sedation is the rule, and epinephrine is empirically avoided in the event it might contribute to ischemic orchitis. The initial approach is similar to the Bassini repair with particular importance placed on freeing the cord from its surrounding adhesions, resection of the cremaster muscle, high dissection of the hernia sac and division of the transversalis fascia. Continuous nonabsorbable suture is used to repair the floor. Traditionally, this has been monofilament steel wire. The Shouldice surgeons feel a continuous suture distributes tension evenly and prevents defects that could potentially occur between interrupted sutures resulting in a recurrence. The repair is started at the pubic tubercle by approximating the iliopubic tract laterally to the undersurface of the lateral edge of the rectus muscle. The suture is continued laterally, approximating the iliopubic tract to the medial flap that is made up of the transversalis fascia, the internal oblique and transverse abdominis muscles. Eventually four suture lines are developed from the medial flap. The running suture is continued to the internal ring where the lateral stump of the cremaster muscle is picked up, forming a new internal ring. The direction of the suture is reversed back toward the pubic tubercle, approximating the medial edge of the internal oblique and transversus abdominis muscle to Poupart ligament and the wire is tied to itself. Thus, there are two suture lines formed by the first suture. The second wire suture is started near the internal ring and approximates the internal oblique and transversus muscles to a band of external oblique aponeurosis superficial and parallel to the inguinal ligament, in effect creating a second artificial inguinal ligament. This forms the third suture line that ends at the pubic crest. The suture is then reversed and a fourth suture line is constructed in a similar manner, superficial to the third line. At the Shouldice Clinic, the cribriform fascia always is incised in the thigh, parallel to the inguinal ligament, to make the inner side of the lower flap of the external oblique aponeurosis available for these multiple layers. This step commonly is omitted in general practice.

Conventional Anterior, Prosthetic

Lichtenstein Tension-Free Hernioplasty

At the Lichtenstein Clinic, the procedure is performed under local anesthesia with sedation using 50 mL or less of a 50/50 mixture of 1 percent lidocaine (Xylocaine) and 0.5 percent bupivacaine (Marcaine), with 1/200,000 epinephrine. General or regional anesthesia also can be used. The initial steps are similar to the Bassini repair. After the external oblique aponeurosis has been opened from just lateral to the internal ring through the external ring, the upper leaf is freed from the underlying anterior rectus sheath and internal oblique muscle aponeurosis in an avascular plane from a point at least 2 cm medial to the pubic tubercle to the anterior superior iliac spine laterally. Blunt dissection is continued in this avascular plane from lateral to the internal ring, to the pubic tubercle, along the inguinal ligament and iliopubic tract. Continuing this same motion, the cord with its cremaster covering is swept off the pubic tubercle and

separated from the inguinal floor. The ilioinguinal nerve, external spermatic vessels, and the genital branch of the genitofemoral nerve all remain with the cord structures. The effect is to create a large space for the eventual placement of the prosthesis and at the same time providing excellent visualization of the important nerves.

For indirect hernias, the cremasteric muscle is incised longitudinally and the sac dissected free and reduced into the preperitoneal space. A theoretical criticism of this operation is that unless the inguinal floor is opened, an occult femoral hernia may be overlooked. However, an excessive incidence of missed femoral hernias has not been reported. Additionally, it is possible to evaluate the femoral ring by entering the preperitoneal space through a small opening in the canal floor. Direct hernias are separated from the cord and other surrounding structures and reduced back into the preperitoneal space. Dividing the superficial layers of the neck of the sac circumferentially, which in effect opens the inguinal floor, usually facilitates reduction and aids in maintaining it while the prosthesis is placed. This opening in the inguinal floor also can be used to palpate a femoral hernia. Suture can be used to invert the sac but this adds no strength as the purpose is simply to allow the repair to proceed unencumbered by the sac continually protruding into the operative field.

A mesh prosthesis with a minimum size of 15×8 cm for an adult is positioned over the inguinal floor. The medial end is rounded to correspond to the patient's anatomy and secured to the anterior rectus sheath a minimum of 2 cm medial to the pubic tubercle. Either nonabsorbable or long acting absorbable suture should be used. The wide overlap of the pubic tubercle is important to avoid the all too common pubic tubercle recurrences seen with other operations. The suture is continued in a running locking fashion laterally, securing the prosthesis to either side of the pubic tubercle (*not into it*) and the shelving edge of the inguinal ligament. The suture is tied at the internal ring.

A slit is made at the lateral end of the mesh creating two tails, a wide one (two thirds) above and a narrower (one-third) below. The tails are positioned around the cord structures and placed beneath the external oblique aponeurosis laterally to about the anterior superior iliac spine with the upper tail being placed on top of the lower. A single interrupted suture is used to secure the lower edge of the superior tail to the lower edge of the inferior tail in effect creating a shutter valve at the internal ring. This step is considered crucial for the prevention of indirect recurrences that are occasionally seen when simple re-approximation of the tails is performed. The surgeons at the Lichtenstein Clinic also include the shelving edge of the inguinal ligament in this shutter valve stitch that serves to buckle the mesh somewhat medially over the direct space, creating a dome like effect to assure there is no tension especially when the patient assumes an upright position. Recently the Lichtenstein group has developed a customized prosthesis with a built in dome-like configuration that they feel makes suturing the approximated tails to the inguinal ligament unnecessary. A few interrupted sutures are used to secure the superior and medial aspects of the prostheses to the underlying internal oblique muscle and rectus fascia. If the iliohypogastric nerve crosses up to the external oblique aponeurosis on the medial side, the prosthesis should be slit to accommodate it. The prosthesis can be trimmed *in situ* but care should be taken to maintain sufficient laxity to account for a difference between the supine and upright positions and the fact that mesh shrinkage is a reality.

If a femoral hernia is present, the posterior surface of the mesh is sutured to a Cooper ligament after the inferior edge has been attached to the inguinal ligament. This closes the femoral canal and the wound is closed in layers.

Mesh Plug and Patch

The mesh plug technique was developed by Gilbert, and then modified by Rutkow, Robbins, Millikan and others. The groin is entered through a standard anterior approach. The hernia sac is dissected away from surrounding structures and reduced back into the preperitoneal space. A flat sheet of polypropylene mesh is rolled up like a cigarette and held in place with suture. This plug is inserted in the defect and secured to either the internal ring for an indirect hernia or the neck of the defect for a direct hernia using interrupted sutures. The use of a prefabricated, commercially available prosthesis that has the configuration of a flower is recommended by Rutkow and Robbins. The prosthesis is individualized for each patient by removing some of the petals to avoid unnecessary bulk. This step is important, as rarely erosion into a surrounding structure such as the bladder has been reported. Millikan further modified the procedure by recommending that the inside petals be sewn to the ring of the defect. For indirect hernias the inside pedals are sewn to the internal oblique portion of the internal ring which forces the outside of the prosthesis underneath the inner side of the defect making it act like a preperitoneal underlay. For direct hernias, the inside petals are sewn to a Cooper ligament and the shelving edge of the inguinal ligament and the musculoaponeurotic ring of the defect superiorly, again forcing the outside to act as an underlay. The patch portion of the procedure is optional and involves placing a flat piece of polypropylene in the conventional inguinal space widely overlapping the plug in a fashion similar to the Lichtenstein procedure. The difference is that only one or two sutures, or perhaps no sutures are used to secure the flat prosthesis to the underlying inguinal floor. Some surgeons place so many sutures that they have in effect performed a Lichtenstein operation on top of the plug. The euphemism used to describe this is the "plugtenstein." To the credit of its proponents, the plug and patch in all of its varieties has been skillfully presented and has rapidly become a popular repair. Not only is it fast but also easy to teach, making it popular in both private and academic centers.

Conventional Preperitoneal, Prosthetic

The key to the preperitoneal prosthetic repairs is the placement of a large prosthesis in the preperitoneal space between the transversalis fascia and the peritoneum. The preperitoneal repair makes use of the abdominal pressure to help fix the prosthetic material against the abdominal wall, adding strength to the repair. The preperitoneal space can be entered from its anterior or posterior aspect. The major difference between the anterior and posterior approaches is that in the latter, the inguinal canal is not entered. Proponents point out that this avoids damage to the cremasteric muscle and lessens the chance of cord injury. If an anterior approach is desirable, a groin incision is used because the space is entered directly through the inguinal floor. Either a lower midline, paramedian, or Pfannenstiel incision without opening the peritoneum can be used for the purposes of entering the preperitoneal space posteriorly as originally popularized by Cheatele, and later by Henry.

The Anterior Approach

Read-Rives. This operation starts like a classical Bassini, including opening the inguinal floor. The inferior epigastric vessels are identified and the preperitoneal space completely dissected. The spermatic cord is “parietalized” by separating the ductus deferens from the spermatic vessels. A 12- × 16-cm piece of mesh is positioned in the preperitoneal space deep to the inferior epigastric vessels and secured with three sutures; one each to the pubic tubercle, a Cooper ligament and the psoas muscle laterally. The transversalis fascia is closed over the prosthesis and the cord structures replaced. The rest of the closure is as described above for the Bassini repair.

The Posterior Approach

Wantz/stoppa/rives (giant prosthetic reinforcement of the visceral sac or GPRVS). These three procedures are grouped together under the heading of GPRVS because there are only minor variations between them. A lower midline, transverse or Pfannenstiel incision can be used according to surgeon preference. If a transverse incision is chosen, it should extend from the midline 8–9 cm in each direction laterally and 2–3 cm below the level of the anterior superior iliac spine but above the internal ring. The anterior rectus sheath and the oblique muscles are incised for the length of the skin incision. The lower flaps of these structures are retracted inferiorly toward the pubis. The transversalis fascia is incised along the lateral edge of the rectus muscle and the preperitoneal space entered. If a lower midline or Pfannenstiel incision is used, the fascia overlying the space of Retzius is opened without violating the peritoneum. A combination of blunt and sharp dissection is continued laterally, posterior to the rectus muscle and the inferior epigastric vessels. The preperitoneal space is completely dissected to a point lateral to the anterior superior iliac spine. The symphysis pubis, a Cooper ligament and the iliopubic tract are identified. Inferiorly the peritoneum is generously dissected away from the vas deferens and the internal spermatic vessels to create a large pocket that will eventually accommodate a prosthesis without the possibility of roll-up. The term “parietalization” of the spermatic cord was popularized by Stoppa and refers to the thorough dissection of the cord to provide enough length to move it laterally.

Direct hernia sacs are reduced during the course of the preperitoneal dissection. When reducing the peritoneum from a direct hernia defect, it is important to stay in the plane between the peritoneum and the transversalis fascia allowing the latter structure to retract back into the hernia defect toward the skin. The transversalis fascia can be thin and if it is inadvertently opened and incorporated with the peritoneal sac during reduction a needless and bloody dissection of the abdominal wall is the result. Indirect sacs are more difficult to deal with than direct as they can be adherent to the cord structures. Care must be taken to minimize trauma to the cord to prevent damage to the vas deferens or the blood supply to the testicle. If it is a small sac it should be mobilized from the cord structures and reduced back into the peritoneal cavity. A larger sac may be difficult to mobilize from the cord without undue trauma if an attempt is made to remove the sac in its entirety. In this situation, the sac should be divided, leaving the distal sac in situ with dissection of the proximal sac away from the cord structures. Division of the sac is easily accomplished by opening the side opposite of the cord structures. A finger can be placed in the sac to facilitate its separation from the cord. Downward traction is placed on

the cord structures to reduce excessive amounts of fatty tissue (lipoma of the cord) into the preperitoneal space to preclude the possibility of a "pseudo-recurrence" when the fatty tissue is palpated during physical examination postoperatively.

Management of the abdominal wall defect varies somewhat. Stoppa and Wantz usually leave the defect alone but the transversalis fascia in the defect occasionally is plicated by suturing it to a Cooper ligament to prevent the bulge caused by a seroma in the undisturbed sac.

The next step is the placement of the prosthesis. Dacron mesh is more pliable than polypropylene and is therefore considered particularly suitable for this procedure as it conforms well to the preperitoneal space. For unilateral repairs, the size of the prosthesis is approximately the distance between the umbilicus and the anterior superior iliac spine minus 1 cm for the width, with the height being approximately 14 cm. Wantz recommends cutting the prosthesis excentrically with the lateral side longer than the medial to achieve the best fit in the preperitoneal space. Because of his thorough parietalization of the cord structures, Stoppa indicates that it is not necessary to split the prosthesis laterally to accommodate the cord structures. This avoids the keyhole defect created when the prosthesis is split, which has been incriminated in recurrences. Rignault, on the other hand, prefers a keyhole defect in the mesh to encircle the spermatic cord, feeling that this provides the prosthesis with enough security that fixation sutures or tacks can be avoided. Minimizing fixation in this area is important because of the numerous anatomical elements in the preperitoneal space that may be inadvertently damaged during their placement. For Wantz's technique, three absorbable sutures are used to attach the superior border of the prosthesis to the anterior abdominal wall well above the defect. The three sutures are placed near the linea alba, semilunar line, and the anterior superior iliac spine from medial to lateral. A Reverdin suture needle facilitates this. Three long clamps are placed on each corner and the middle of the inferior border of the prosthesis. The medial clamp is placed in the space of Retzius and held by an assistant. The middle clamp is positioned so that the mesh covers the pubic ramus, obturator fossa and the iliac vessels, and is similarly held by an assistant. The lateral clamp is placed into the iliac fossa to cover the parietalized cord structures and the iliopsoas muscle. Care must be taken to prevent the prosthesis from rolling up as the clamps are removed. Stoppa's technique is most often associated with one large prosthesis for bilateral hernias. The dimensions of this prosthesis are the distance between the two anterior superior iliac spines minus 2 cm for the width and the height is equal to the distance between the umbilicus and the pubis. The prosthesis is cut in a chevron shape and eight clamps are positioned strategically around the prosthesis to facilitate placement into the preperitoneal space. The wound is closed in layers.

Nyhus/Condon (iliopubic tract repair). The names Nyhus and Condon are firmly associated with this preperitoneal repair, especially in North America. The two authorities carried out extensive cadaver dissections and pointed out the importance of the iliopubic tract, which is the reason why their operation is referred to as the Iliopubic Tract Repair. A transverse lower abdominal incision is made two fingerbreadths above the symphysis pubis. The anterior rectus sheath is opened on its lateral side to allow the rectus muscle to be retracted medially and the two oblique and the transversus abdominis muscles are incised exposing the transversalis fascia. A combination of sharp and blunt dissection

inferiorly opens the preperitoneal space and exposes the posterior inguinal floor. Direct or indirect defects are similarly repaired after the peritoneal sac has been reduced or divided and closed proximally. The transverse aponeurotic arch is sutured to the iliopubic tract inferiorly, occasionally including a Cooper ligament in the first few medial sutures. If the internal ring is particularly large, a suture is placed lateral to the internal ring. For femoral hernias, the iliopubic tract is sutured to a Cooper ligament to close the canal. Once the defect has been formally repaired, a tailored mesh prosthesis can be sutured to a Cooper ligament and the transversalis fascia for reinforcement. Initially this was only recommended for recurrent hernias but with further patient follow up, it has now become routine for all hernias.

Kugel/Ugahary. These conventional preperitoneal prosthetic repairs were developed to compete with laparoscopy by using a small 2–3-cm skin incision, approximately 2–3 cm above the internal ring. Kugel locates this point by making an oblique incision one third lateral and two thirds medial to a point half way between the anterior superior iliac spine and the pubic tubercle. The incision is carried deep through the external oblique fascia and the internal oblique muscle is bluntly spread. The transversalis fascia is opened vertically approximately 3 cm, but the internal ring is not violated. The preperitoneal space is entered and a blunt dissection performed. The inferior epigastric vessels are identified to assure that the dissection is in the correct plane. These vessels should be left adherent to the overlying transversalis fascia and retracted medially and anteriorly. The iliac vessels, a Cooper ligament, pubic bone, and hernia defect are identified by palpation. Most hernia sacs are simply reduced. The exception is large indirect sacs that often are divided to leave the distal sac in situ with proximal sac closure. The author feels that the cord structures must be thoroughly parietalized to allow adequate posterior dissection if recurrences are to be avoided. The basis of the procedure is a specifically designed 8- × 12-cm prosthesis made of two pieces of polypropylene with a specially extruded single monofilament fiber located near its edge circumferentially. This allows the prosthesis to be formed to fit through the small incision. Once through the incision, it springs open to regain its normal shape to provide a wide overlap of the myopectineal orifice. The prosthesis also has a slit on its anterior surface through which the surgeon places his finger to facilitate positioning.

Ugahary's operation is similar but a special prosthesis is not required. Known as the gridiron technique, the preperitoneal space is prepared through a 3 cm incision in a manner similar to Kugel. The space is held open using a narrow Langenbeck and two ribbon retractors. A 10- × 15-cm piece of polypropylene mesh is rolled onto a long forceps after the edges have been rounded and sutures placed to correspond to various anatomical landmarks. The rolled-up mesh is introduced with forceps into the preperitoneal space and the mesh unrolled using clamps and strategic movements of the ribbon retractors.

Both of these operations have been very successful in some hands and have important proponents, but because they are essentially blind, considerable experience is required to assure that the patch has been placed properly.

Laparoscopic Inguinal Herniorrhaphy

The best indications for a laparoscopic inguinal herniorrhaphy are: (1) a recurrent hernia after a conventional repair because the operation is performed in normal, nonscarred tissue; (2) bilateral hernias, as both sides can easily be repaired using the same small laparoscopic incisions; and (3) the presence of

an inguinal hernia in a patient who requires a laparoscopy for another procedure, i.e., a laparoscopic cholecystectomy (assuming the Gram stain of the bile is negative). The more contentious issue is the use of laparoscopy for the uncomplicated unilateral hernia. Meta-analyses have confirmed a significant advantage of the laparoscopic operation over the conventional nonprosthetic repairs in terms of pain, return to activity and recurrence rate. However, there is no difference in recurrence rate when comparing laparoscopy with prosthetic tension free repairs and the laparoscopic operation takes longer. Laparoscopic herniorrhaphy patients return to work quicker and have less persisting pain and numbness. The laparoscopic operation costs more but the difference may be offset by the more rapid recovery. Operative complications are uncommon for both methods but serious complications such as bowel perforation, bowel obstruction, vascular injury or adhesive problems at sites where the peritoneum has been breached or prosthetic material has been placed are seen almost exclusively with laparoscopy.

Absolute contraindications include any sign of intraabdominal infection or coagulopathy. Relative contraindications include intraabdominal adhesions from previous surgery, ascites or previous "Space of Retzius" surgery because of the increased risk of bladder injury. Severe underlying medical illness is also a relative contraindication because of the added risk of general anesthesia. These patients are better suited for a conventional operation under local anesthesia. An incarcerated sliding scrotal hernia is a relative contraindication especially when involving the sigmoid colon because of the risk of perforation because of the traction needed to reduce it.

The two commonly performed laparoscopic herniorrhaphies, the transabdominal preperitoneal (TAPP) and the totally extraperitoneal (TEP) are modeled after the conventional preperitoneal operations described above. The major difference is that the preperitoneal space is entered through three trocar sites rather than a large conventional incision. The ensuing radical dissection of the preperitoneal space with the placement of a large prosthesis is similar to the conventional preperitoneal operation.

Transabdominal Preperitoneal

The operating room setup for the TAPP procedure. The surgeon stands on the opposite side of the table from the hernia. The first assistant stands opposite the surgeon. Three laparoscopic cannulae are placed in a horizontal plane with the umbilicus. After an initial diagnostic laparoscopy, pertinent anatomic landmarks including the median and medial umbilical ligaments, the bladder, the inferior epigastric vessels, the vas deferens, the spermatic vessels, the external iliac vessels and the hernia defect are identified. An incision of the peritoneum is initiated at the medial umbilical ligament at least 2 cm above the hernia defect and extended laterally toward the anterior superior iliac spine. The preperitoneal space is exposed using a combination of blunt and sharp dissection, mobilizing the peritoneal flap inferiorly. The symphysis pubis, a Cooper ligament, the iliopubic tract, and the cord structures are identified. Direct hernia sacs are reduced during this dissection. Indirect sacs are more difficult to deal with as they can be tenaciously adherent to the cord structures. The cord structures must be skeletonized but care must be taken to minimize trauma to prevent damage to the vas deferens or the blood supply to the testicle. The peritoneal flap is dissected inferiorly well proximal to the divergence of the vas deferens and the internal spermatic vessels to assure that the prosthesis

will lie flat in the preperitoneal space and will not roll up when the peritoneum is closed.

A large piece of mesh, 15 × 11 cm or greater, is introduced into the abdominal cavity through the umbilical cannula and is positioned over the myopectineal orifice so that it completely covers the direct, indirect and femoral spaces. The landmarks for achieving this goal are the contralateral pubic tubercle and the symphysis pubis for the medial edge, a Cooper ligament or the tissue just above it for the inferior border, and the posterior rectus sheath and transversalis fascia at least 2 cm above the hernia defect superiorly. Some surgeons prefer to slit the mesh to accommodate the cord structures whereas others prefer to simply place the prosthesis over them. Fixation of the mesh is controversial. When closing the peritoneum, it is important to avoid gaps because small bowel has been known to find its way through them resulting in a clinical bowel obstruction.

Totally Extraperitoneal

The preperitoneal space is entered by establishing a plane of dissection outside of the peritoneal cavity between the posterior surface of the rectus muscle and the posterior rectus sheath and peritoneum. An incision is made at the umbilicus as if one were planning to perform open laparoscopy. The rectus sheath is opened on one side and the rectus muscle is retracted laterally. The space is enlarged by blunt or balloon dissection. Once the space is sufficiently enlarged, three additional cannulas are placed in the midline; one at the umbilicus for the optics, another approximately 5 cm above the symphysis pubis and the final cannula midway between the umbilicus and the symphysis pubis. Dissection of the preperitoneal space is now possible under direct vision. The operation then proceeds in an identical fashion to the TAPP procedure described above.

TAPP versus TEP. The Achilles heel of the TAPP procedure is the peritoneal closure. The peritoneum is frequently thin and tears easily once dissected, making it difficult to obtain complete coverage of the prosthesis. This has resulted in major complications. The TEP procedure is more demanding than the TAPP initially because of the limited working space but once mastered completely eliminates the peritoneal closure step, making it faster.

COMPLICATIONS OF GROIN HERNIA REPAIRS (Table 36-3)

Groin Hernias in Females

Groin hernias are much less common in females than males. Less than 10 percent of all elective inguinal hernia repairs are performed in women. Nevertheless, given the overall frequency of the condition, the absolute number is still significant. Femoral hernias are ten times more common in women than men (10 percent in females vs. 1 percent in males), giving rise to the false notion that it is the most common groin hernia. In fact, indirect hernias are much more common. Direct hernias are rare almost to the point of being reportable. Occult inguinal hernias are a significant problem in women because the skin of the labium majus does not allow easy examination of the inguinal canal. There is insufficient skin redundancy to invert and allow the examining finger to coapt directly to the inguinal floor. The extensive differential diagnosis of groin pain makes the definitive diagnosis of an occult hernia difficult.

TABLE 36-3 Complications

Recurrence	C) Infection
Chronic Groin Pain	D) Rejection
Nociceptive	E) Fracture
A) Somatic	Laparoscopic
B) Visceral	Vascular injury
Neuropathic	A) Intra-abdominal
A) Iliohypogastric	B) Retroperitoneal
B) Ilioinguinal	C) Abdominal wall
C) Genitofemoral	D) Gas embolism
D) Lateral Cutaneous	Visceral injury
E) Femoral	A) Bowel perforation
Cord and testicular	B) Bladder perforation
A) Hematoma	Trocar Site Complications
B) Ischemic orchitis	A) Hematoma
C) Testicular atrophy	B) Hernia
D) Dysejaculation	C) Wound infection
E) Division of vas deferens	D) Keloid
F) Hydrocele	Bowel Obstruction
G) Testicular descent	A) Trocar or peritoneal closure site hernia
Bladder Injury	B) Adhesions
Wound Infection	Miscellaneous
Seroma	A) Diaphragmatic dysfunction
Hematoma	B) Hypercapnia
A) Wound	General
B) Scrotal	Urinary
C) Retroperitoneal	Paralytic ileus
Osteitis pubis	Nausea and vomiting
Prosthetic Complications	Aspiration pneumonia
A) Contraction	Cardiovascular
B) Erosion	Respiratory insufficiency

The indications for surgery are similar in males and females. There is no place for a strategy of watchful waiting for femoral hernias as the incidence of incarceration and/or strangulation is far too high to justify such a recommendation. The choice of procedure is not unique to females and is largely left to the surgeon based on experience and training. Resection of the round ligament simplifies many of the repairs because complete closure of the internal ring is then possible. Groin hernias become evident during pregnancy (1:1000–3000 pregnancies). They are best managed expectantly and repaired after gestation is complete.

PEDIATRIC HERNIAS

Most inguinal hernias in children are indirect, related to a persistent patent processes vaginalis. Approximately 1–5 percent of children are born with or develop an inguinal hernia. However, the incidence rises in preterm infants and those with low birth weights (13 percent of patients born before 32 weeks and 30 percent of patients with a birth weight less than 1,000 g). Overall, right-sided hernias are twice as common as left, and about 10 percent of hernias diagnosed at birth are bilateral. However, this varies greatly on the basis of numerous risk factors, the most important of which is age. The right-sided

TABLE 36-4 Conditions Associated with an Increased Incidence of Pediatric Hernia

Family history
Undescended testis
Hypospadias/epispadias
Ventriculoperitoneal shunt
Peritoneal dialysis
Cryptorchism
Prematurity
Other abdominal wall defect
Cystic fibrosis
Ascites
Intersex conditions
Connective tissue disorders
Hunter-Hurler syndrome
Ehlers-Danlos syndrome

predominance is felt by most authorities to be related to the later descent of the right testicle during gestation. There are several conditions which predispose a child to develop an inguinal hernia in Table 36-4.

Infants or children may present with a mass in the groin or scrotum. The diagnosis may be obvious but one must be careful to differentiate the mass from other cord and testicular abnormalities such as a hydrocele, undescended testicle, varicocele or even a testicular tumor. Commonly no hernia is able to be demonstrated when the patient presents to the surgeon. Some surgeons rely on the so called "silk glove sign" which reflects the way the hernia sac feels as it is palpated over the cord structures. The finding is controversial and there is some evidence that what is actually being felt is hypertrophied cremasteric muscle. In the end, the diagnosis commonly hinges on the observation of the referring physician or a parent. Most surgeons feel the risk/benefit ratio favors this as an acceptable indication for operation when the source seems reliable rather than taking the chance of strangulation.

Incarceration is a more serious problem in the pediatric patient than in the adult, with large series reporting rates up to 20 percent. The patient presents with a hard, tender groin mass. In 75–80 percent of these, they can be successfully reduced initially using sedation, Trendelenburg position, ice packs and gentle taxis. A reasonable attempt at conservative management of an incarcerated pediatric hernia before proceeding to emergency surgery is in the patient's best interest because the complication rate compared to elective herniorrhaphy is twenty fold, including irreversible abnormalities such as testicular infarction or atrophy. If no progress in reduction is made within 6 h, or if the patient exhibits signs of peritonitis or systemic toxicity, immediate operation is appropriate.

Most pediatric inguinal hernias are repaired using the principle of high ligation of the sac. The external oblique aponeurosis is opened for a short distance beginning at the external ring and proceeding laterally. The sac is then gently dissected away from the cord structures proximally until the internal ring is reached, twisted, suture ligated and amputated. If the sac extends into the scrotum, it can be divided leaving the distal sac in situ. Care must be taken to exclude abdominal contents such as the tube and ovary before suture ligation. Occasionally, a Marcy repair of the internal ring is added if the structure is unusually large.

Exploration of the opposite groin remains controversial. As an alternative, ultrasound examination has become popular at some centers, however, it is largely dependent on the expertise and/or interest of the ultrasonographer. The size of the internal ring and the presence of bowel or fluid in the spermatic cord are diagnostic criteria indicative of a positive exam. Another alternative is laparoscopy using either a rigid or a flexible endoscope placed through the hernia sac to inspect the opposite side. The accuracy is high for properly trained laparoscopists, such that it is considered the gold standard in studies using both ultrasonography and laparoscopy. The disadvantage of laparoscopy is cost and potential intraabdominal complications.

THYROID**Embryology**

The thyroid gland arises as an outpouching of the primitive foregut around the third week of gestation, originating at the base of the tongue in the vicinity of the foramen cecum. Endoderm cells in the floor of the pharyngeal anlage thicken to form the medial thyroid anlage that descends in the neck anterior to structures that form the hyoid bone and larynx and gives rise to the thyroid follicular cells. Paired lateral anlages (of neuroectodermal origin) originate from the fourth branchial pouch, fuse with the median anlage at approximately the fifth week of gestation and provide the calcitonin producing parafollicular or C cells.

Developmental Abnormalities*Thyroglossal Duct Cyst and Sinus*

During the fifth week of gestation, the thyroglossal duct, which connects the thyroid with the foramen cecum, starts to obliterate. Thyroglossal duct cysts may occur anywhere along the migratory path of the thyroid, although 80 percent are found in juxtaposition to the hyoid bone. They are usually asymptomatic, but occasionally become infected by oral bacteria. Sinuses result from infection of the cyst secondary to spontaneous or surgical drainage and are accompanied by minor inflammation of the surrounding skin. The diagnosis is usually established by observing smooth, well-defined midline neck mass that moves upward with tongue protrusion. Routine thyroid imaging is not necessary. Treatment involves the “Sistrunk operation,” which consists of en bloc cystectomy and excision of the central hyoid bone to minimize recurrence.

Lingual Thyroid

This represents failure of the median thyroid anlage to descend normally and may be the only thyroid tissue present. Some patients are hypothyroid and intervention becomes necessary for obstructive symptoms such as choking, dysphagia, airway obstruction, and hemorrhage. Treatment options include administration of exogenous thyroid hormone to treat hypothyroidism or to suppress thyroid-stimulating hormone (TSH), radioactive iodine, or surgical excision.

Ectopic thyroid. Normal thyroid tissue may be found anywhere in the central neck compartment and also has been observed adjacent to the aortic arch, in the aortopulmonary window, within the upper pericardium, and in the interventricular septum. Thyroid tissue situated lateral to the carotid sheath and jugular vein, previously termed “lateral aberrant thyroid,” almost always represents metastatic thyroid cancer in lymph nodes.

Pyramidal lobe. In approximately 50 percent of individuals, the distal end of the thyroglossal duct that connects to the thyroid persists as a pyramidal lobe projecting up from the isthmus, lying just to the left or right of the midline.

Thyroid Anatomy

The adult thyroid gland is brown in color, weighs about 20 g, and is located posterior to the strap muscles. The thyroid lobes are located adjacent to the thyroid cartilage and are connected in the midline by an isthmus. The thyroid is enveloped by loosely connecting fascia that is formed from the partitioning of the deep cervical fascia into anterior and posterior divisions. The thyroid capsule is condensed into the posterior suspensory or Berry ligament near the cricoid cartilage and upper tracheal rings. The gland is well vascularized by two major sets of arteries. The superior thyroid arteries arise from the ipsilateral external carotid arteries. The inferior thyroid arteries are derived from the thyrocervical trunk shortly after their origin from the subclavian arteries. The inferior thyroid arteries travel upward in the neck posterior to the carotid sheath to enter the thyroid lobes at their midpoint. A thyroidea ima artery arises directly from the aorta or innominate in 1–4 percent of individuals, to enter the isthmus or replace a missing inferior thyroid artery. Venous drainage of the thyroid gland occurs via multiple small surface veins, which coalesce to form three sets of veins—the superior, middle, and inferior thyroid veins.

The left recurrent laryngeal nerve (RLN) arises from the vagus nerve where it crosses the aortic arch, loops around the ligamentum arteriosum and ascends medially in the neck within the tracheoesophageal groove. The right RLN arises from the vagus at its crossing with the right subclavian artery, and passes posterior to the artery before ascending in the neck. The RLNs may branch, and pass anterior, posterior or interdigitate with branches of the inferior thyroid artery and terminate by entering the larynx posterior to the cricothyroid muscle. The RLNs innervate all the intrinsic muscles of the larynx, except the cricothyroid muscles.

The superior laryngeal nerves also arise from the vagus nerves and travel along the internal carotid artery. The internal branch is sensory to the supraglottic larynx, whereas the external branch of the superior laryngeal nerve lies on the inferior pharyngeal constrictor muscle and descends alongside the superior thyroid vessels before innervating the cricothyroid muscle.

The thyroid gland is endowed with an extensive network of lymphatics. Regional lymph nodes include pretracheal, paratracheal, perithyroidal, recurrent laryngeal nerve, superior mediastinal, retropharyngeal, esophageal, and upper, middle, and lower jugular chain nodes.

Thyroid Histology

Microscopically, the thyroid is divided into lobules that contain 20–40 follicles averaging 30 μm in diameter. Each follicle is lined by cuboidal epithelial cells and contains a central store of colloid secreted from the epithelial cells under the influence of the pituitary hormone, TSH. C cells or parafollicular cells, which secrete calcitonin, are found as individual cells or clumped in the interfollicular stroma.

THYROID PHYSIOLOGY

Thyroid Hormone Synthesis, Secretion, and Transport

The average daily iodine requirement is 0.1 mg. Dietary iodine is rapidly converted to iodide and absorbed into the bloodstream. Iodide is actively transported into the thyroid follicular cells by an ATP-dependent process. The synthesis of thyroid hormone consists of several steps: (1) iodide trapping which involves ATP-dependent transport of iodide across the basement membrane of the thyrocyte via the Na^+/I^- symporter (NIS); (2) oxidation of iodide to iodine and iodination of tyrosine residues on Thyroglobulin (Tg), a 660-kDa glycoprotein, which is present in thyroid follicles, to form monoiodotyrosines (MITs) and diiodotyrosines (DITs)—both processes are catalyzed by thyroid peroxidase; (3) coupling of two DIT molecules to form tetraiodothyronine or thyroxine (T4), and one DIT molecule with one MIT molecule to form 3,5,3'-triiodothyronine (T3) or reverse 3,3',5'-triiodothyronine (rT3); (4) hydrolysis of Tg to release free iodothyronines (T3 and T4) and mono- and diiodotyrosines; and (5) deiodination of mono and diiodotyrosines to yield iodide, which is reused in the thyrocyte.

In the euthyroid state, T4 is the predominant hormone produced by the thyroid. Most T3 (80 percent) is produced by extrathyroidal, peripheral deiodination (removal of 5'-iodine from the outer ring) of T4 in the liver, muscles, kidney, and anterior pituitary, a reaction that is catalyzed by 5'-monodeiodinase. Some T4 is converted to rT3, the metabolically inactive compound, by deiodination of the inner ring of T4. Thyroid hormones are transported in serum bound to carrier proteins such as thyroxine-binding globulin (TBG), thyroxine-binding prealbumin (TBPA), and albumin. Only a small fraction (0.02 percent) of thyroid hormone (T3 and T4) is free (unbound) and is the physiologically active component. The secretion of thyroid hormone is controlled by the hypothalamic–pituitary–thyroid axis.

EVALUATION OF PATIENTS WITH THYROID DISEASE

Tests of Thyroid Function

No single test is sufficient to assess thyroid function in all situations and the results must be interpreted in the context of the patient's clinical condition.

Serum TSH – (normal 0.5 to 5 $\mu\text{U/mL}$) Serum TSH levels reflect the ability of the anterior pituitary to detect free T4 levels. There is an inverse relationship between the free T4 level and the logarithm of the TSH concentration—small changes in free T4 lead to a large shift in TSH levels. Thus, the ultrasensitive TSH assay has become the most sensitive and specific test for the diagnosis of hyper- and hypothyroidism and for optimizing T4 replacement and suppressive therapy.

Total T4 and Total T3 – Total T4 (reference range: 55–150 nmol/L) and T3 (reference range: 1.5–3.5 nmol/L) levels are measured by radioimmunoassay and measure both the free and bound components of the hormones. Total T4 levels reflect the output from the thyroid gland, whereas T3 levels in the nonstimulated thyroid gland are more indicative of peripheral thyroid hormone metabolism.

Free T4 and Free T3 – These radioimmunoassay-based tests are a sensitive and accurate measurement of biologically active thyroid hormone. Free T4 (reference range: 12 to 28 pmol/L) measurement is confined to cases of early

hyperthyroidism in which total T4 levels may be normal but free T4 levels are raised. In patients with end-organ resistance to T4 (Refetoff syndrome), T4 levels are increased, but TSH levels usually are normal. Free T3 (reference range: 3 to 9 pmol/L) is most useful in confirming the diagnosis of early hyperthyroidism, in which levels of free T4 and free T3 rise before total T4 and T3.

Thyroid Antibodies – Thyroid antibodies include antithyroglobulin (anti-Tg), antimicrosomal or antithyroid peroxidase (anti-TPO) and thyroid-stimulating immunoglobulin (TSI). Anti-Tg and anti-TPO antibody levels do not determine thyroid function; instead, they indicate the underlying disorder, usually an autoimmune thyroiditis.

Serum Thyroglobulin – Thyroglobulin is not normally released into the circulation in large amounts, but increases dramatically in thyroiditis or Graves disease and toxic multinodular goiter. The most important use for serum thyroglobulin levels is in monitoring patients with differentiated thyroid cancer for recurrence. Because only thyroid tissues produce thyroglobulin, the levels of this protein should be low after total thyroidectomy.

Thyroid Imaging

Radionuclide imaging. Both iodine-123 (¹²³I) and iodine-131 (¹³¹I) are used to image the thyroid gland. The former emits low-dose radiation, has a half-life of 12–14 h, and is used to image lingual thyroids or goiters. In contrast, ¹³¹I use leads to higher-dose radiation exposure and has a half-life of 8–10 days. Therefore, this isotope is used to screen and treat patients with differentiated thyroid cancers for metastatic disease. Areas that trap less radioactivity than the surrounding gland are termed “cold” whereas areas that demonstrate increased activity are termed “hot”. The risk of malignancy is higher in “cold” lesions (15–20 percent) than in “hot” or “warm” lesions (< 5 percent). Technetium-99m (^{99m}Tc) pertechnetate is taken up by the thyroid gland, but is not organified. It also has the advantage of having a shorter half-life and minimizes radiation exposure. It is particularly sensitive for nodal metastases. More recently, ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG PET) has been used to screen for metastases in thyroglobulin-positive patients with thyroid cancer, in whom other imaging studies are negative.

Ultrasound. Ultrasound is helpful in the evaluation of thyroid nodules, distinguishing solid from cystic ones, and providing information about size and multicentricity. Ultrasound also can be used to assess for cervical lymphadenopathy and to guide fine-needle aspiration (FNA) biopsy.

CT/MRI scan. These studies are primarily used in evaluating the extent of large, fixed, or substernal goiters and their relationship to the airway and vascular structures.

BENIGN THYROID DISORDERS

Hyperthyroidism

Graves Disease

Graves disease is, by far, the most common cause of hyperthyroidism in North America, accounting for 60–80 percent of cases. It is an autoimmune disorder of unknown cause with a strong familial predisposition, female preponderance

(5:1), and peak incidence between the ages of 40 and 60 years. It is characterized by thyrotoxicosis, diffuse goiter, and extrathyroidal manifestations, including ophthalmopathy, dermatopathy (pretibial myxedema), thyroid acropathy, gynecomastia, and others.

Etiology, pathogenesis, and pathology. The exact etiology of the initiation of the autoimmune process in Graves disease is unknown. However, conditions such as the postpartum state, iodine excess, lithium therapy, and bacterial and viral infections have been suggested as possible triggers. Graves disease also is associated with certain human leukocyte antigen (HLA) haplotypes and polymorphisms of the cytotoxic T-lymphocyte antigen 4 (CTLA-4) gene. Once initiated, the process causes sensitized T-helper lymphocytes to stimulate B lymphocytes, which produce antibodies directed against the thyroid hormone receptor (TRAbs). Thyroid stimulating immunoglobulins (TSI), and TSH-binding inhibiting immunoglobulins (TSIIs) have been described. These antibodies stimulate the thyrocytes to grow and synthesize excess thyroid hormone, which is a hallmark of Graves disease.

Clinical features. Symptoms of hyperthyroidism include heat intolerance, increased sweating and thirst, and weight loss despite adequate caloric intake. Symptoms of increased adrenergic stimulation include palpitations, nervousness, fatigue, emotional lability, hyperkinesis, and tremors. Female patients often develop amenorrhea, decreased fertility, and an increased incidence of miscarriages. Children experience rapid growth with early bone maturation, whereas older patients present with cardiovascular complications. On physical examination, weight loss and facial flushing may be evident. The skin may be warm and moist. Tachycardia or atrial fibrillation, a fine tremor, muscle wasting, and proximal muscle group weakness with hyperactive tendon reflexes often are present.

Approximately 50 percent of patients with Graves disease also develop clinically evident ophthalmopathy. Eye symptoms include lid lag (von Graefe sign), spasm of the upper eyelid revealing the sclera above the corneoscleral limbus (Dalrymple sign), and a prominent stare as a consequence of catecholamine excess. True infiltrative eye disease results in periorbital edema, conjunctival swelling and congestion (chemosis), proptosis, limitation of upward and lateral gaze, keratitis, and even blindness. The etiology of Graves ophthalmopathy is not completely known. Dermopathy occurs in 1–2 percent of patients and is characterized by deposition of glycosaminoglycans leading to thickened skin in the pretibial region. The thyroid is usually diffusely and symmetrically enlarged. There may be an overlying bruit or thrill and loud venous hum in the supraclavicular space.

Diagnostic tests. The diagnosis of hyperthyroidism is made by a suppressed TSH with or without an elevated free T4 or T3 level. In the absence of eye findings, an I231 uptake and scan should be performed. An elevated uptake, with a diffusely enlarged gland confirms the diagnosis of Graves disease and helps to differentiate it from other causes of hyperthyroidism. Anti-Tg and anti-TPO antibodies are elevated in up to 75 percent of patients, but are not specific. Elevated thyroid-stimulating hormone receptor (TSH-R) or TSAb are diagnostic of Graves disease and are increased in approximately 90 percent of patients. MRI scans of the orbits are useful in evaluating ophthalmopathy.

Treatment

Antithyroid drugs. These are generally administered in preparation for radioactive iodine ablation or surgery. The medications commonly used are propylthiouracil (PTU, 100–300 mg three times daily) and methimazole (10–30 mg three times daily). Methimazole has a longer half-life and can be dosed once daily. Both drugs reduce thyroid hormone production by inhibiting the organic binding of iodine and the coupling of iodotyrosines. Additionally, PTU also inhibits the peripheral conversion of T4 to T3. Both drugs can cross the placenta, inhibiting fetal thyroid function, and are excreted in breast milk, although PTU has a lower risk of transplacental transfer. Side effects of treatment include reversible granulocytopenia, skin rashes, fever, peripheral neuritis, polyarteritis, vasculitis, and, rarely, liver failure, agranulocytosis, and aplastic anemia.

Most patients have improved symptoms in 2 weeks and become euthyroid in about 6 weeks. Treatment with antithyroid medications is associated with a high relapse rate when these drugs are discontinued. Therefore, treatment for curative intent is reserved for patients with small, nontoxic goiters (< 40 g) and mildly elevated thyroid hormone levels. The catecholamine hyperthyroidism response can be alleviated by administering β -blocking agents. These drugs have the added effect of decreasing the peripheral conversion of T4 to T3. Propranolol is the most commonly prescribed medication in doses of about 20–40 mg four times daily.

Radioactive iodine therapy. Radioactive iodine (RAI; ^{131}I) forms the mainstay of Graves disease treatment in North America. Antithyroid drugs are discontinued to maximize drug uptake. The ^{131}I dose is calculated after a preliminary uptake and scan, and usually consists of 8–12 mCi administered orally. However, RAI is associated with the progressive development of hypothyroidism (over 70 percent at 11 years), requiring lifelong thyroxine replacement therapy and also has been shown to lead to progression of ophthalmopathy. Consequently, RAI therapy most often is used in older patients with small or moderate-size goiters, in patients who have relapsed after medical or surgical therapy, and in patients in whom antithyroid drugs or surgery are contraindicated.

Surgical treatment. In North America, surgery is recommended in patients who (1) have coexistent, confirmed cancer or suspicious thyroid nodules, (2) are young, (3) are pregnant or desire to conceive soon after treatment, (4) have allergies to antithyroid medications, (5) have large goiters causing compressive symptoms, and (6) are reluctant to undergo RAI therapy. Relative indications for thyroidectomy include patients, particularly smokers, with moderate to severe Graves ophthalmopathy, patients who desire rapid control of hyperthyroidism with a chance of being euthyroid, and patients who demonstrate poor compliance with antithyroid medications. The goal of thyroidectomy for Graves disease should be the complete and permanent control of the disease with minimal morbidity related to RLN injury or hypoparathyroidism.

Patients are rendered euthyroid before operation with antithyroid drugs that should be continued up to the day of surgery. Lugol iodide solution or supersaturated potassium iodide (SSKI) is administered preoperatively—3 drops twice daily beginning 10 days preoperatively—to reduce vascularity of the gland and decrease the risk of precipitating thyroid storm. The extent of thyroidectomy to be performed is controversial and is determined by the desired

outcome (risk of recurrence versus euthyroidism) and surgeon experience. Patients with coexistent thyroid cancer, and those patients who refuse RAI therapy, who have severe ophthalmopathy, or who have life-threatening reactions to antithyroid medications should undergo total or near-total thyroidectomy, which can be performed with minimal morbidity by an experienced thyroid surgeon. A subtotal thyroidectomy, leaving a 4–7-g remnant, is recommended for all remaining patients.

Toxic Multinodular Goiter

Toxic multinodular goiters usually occur in individuals older than 50 years of age who often have a prior history of a nontoxic multinodular goiter. Over several years, enough thyroid nodules become autonomous to cause hyperthyroidism. Symptoms and signs of hyperthyroidism are similar to Graves disease, but are less severe and extrathyroidal manifestations are absent.

Diagnostic studies and treatment. TSH is suppressed with elevated free T4 or T3 levels. RAI uptake also is increased, showing multiple nodules with increased uptake and suppression of the remaining gland. Surgical resection is the preferred treatment method, with subtotal thyroidectomy being the standard procedure. RAI therapy is reserved for older adult patients who represent very poor operative risks, provided there is no airway compression from the goiter and thyroid cancer is not a concern.

Plummer Disease (Toxic Adenoma)

Hyperthyroidism from a single hyperfunctioning nodule typically occurs in younger patients who note recent growth of a long-standing nodule along with the symptoms of hyperthyroidism. Most hyperfunctioning nodules have attained a size of at least 3 cm before hyperthyroidism occurs. RAI scanning shows a “hot” nodule with suppression of the rest of the thyroid gland. These nodules are rarely malignant. Smaller nodules may be managed with antithyroid medications and RAI, surgery (lobectomy and isthmusectomy) is recommended to treat young patients and those with larger nodules.

Thyroiditis

Thyroiditis is defined as an inflammatory disorder of the thyroid gland and usually is classified into acute, subacute, and chronic forms, each associated with a distinct clinical presentation and histology. Chronic and subacute thyroiditis are usually managed medically, but surgical treatment is occasionally needed for these conditions, and for acute suppurative thyroiditis.

Goiter

Most nontoxic goiters result from iodine deficiency and/or TSH stimulation secondary to inadequate thyroid hormone synthesis and other paracrine growth factors. Goiters may be diffuse, uninodular, or multinodular. Familial goiters result from inherited deficiencies in enzymes necessary for thyroid hormone synthesis. The term endemic goiter refers to the occurrence of a goiter in a significant proportion of individuals in a particular geographic region. In the past, dietary iodine deficiency was the most common cause of endemic goiter. This condition has largely disappeared in North America as a consequence of routine use of iodized salt and iodination of fertilizers, animal feeds, and preservatives. However, in areas of iodine deficiency, such as Central Asia,

South America, and Indonesia, up to 90 percent of the population have goiters. Other dietary goitrogens include cassava and cabbage. In many sporadic goiters, no obvious cause can be identified, but in some patients, it is familial.

Clinical Features

Most patients with nontoxic goiters are asymptomatic. As the goiters become very large compressive symptoms, such as dyspnea and dysphagia, ensue. Dysphonia from recurrent laryngeal nerve injury is rare, except when malignancy is present. Obstruction of venous return at the thoracic inlet from a substernal goiter results in a positive Pemberton sign—facial flushing and dilatation of cervical veins on raising the arms above the head. Sudden enlargement of nodules because of hemorrhage or cysts may cause acute pain. Physical examination may reveal a soft, diffusely enlarged gland (simple goiter) or nodules of various size and consistency in case of a multinodular goiter. Tracheal deviation with or without compression is common.

Diagnostic Tests and Treatment

Patients are usually euthyroid with normal TSH and low-normal or normal free T4 levels. If some nodules develop autonomy, patients have suppressed TSH levels or become hyperthyroid. FNA biopsy is recommended in euthyroid patients who have a dominant nodule or one that is painful or enlarging.

Most euthyroid patients with small, diffuse goiters do not require treatment. Some physicians give patients with large goiters exogenous thyroid hormone to reduce the TSH stimulation of gland growth; this treatment may result in a decrease and/or stabilization of goiter size. Endemic goiters are treated by iodine administration, but its use is controversial. Surgical resection is reserved for goiters that (1) continue to increase despite T4 suppression, (2) cause obstructive symptoms, (3) have substernal extension, (4) are suspected to be malignant or are proven malignant by FNA biopsy, and (5) are cosmetically unacceptable. Total lobectomy on the side of the dominant nodule and subtotal resection of the contralateral side is the treatment of choice and patients require lifelong T4 therapy to prevent recurrence.

SOLITARY THYROID NODULE

Solitary thyroid nodules are present in approximately 4 percent of the population, whereas thyroid cancer has a much lower incidence of 40 new cases per 1 million. Therefore, it is of utmost importance to determine which patients with solitary thyroid nodule would benefit from surgery.

History

Details regarding the nodule, such as time of onset, change in size, and associated symptoms, such as pain, dysphagia, dyspnea, or choking, should be elicited. Pain is an unusual symptom and when present, should raise suspicion for intrathyroidal hemorrhage in a benign nodule, thyroiditis, or malignancy. A history of hoarseness is worrisome because it may be secondary to malignant involvement of the recurrent laryngeal nerves. Most importantly, patients should be questioned regarding risk factors for malignancy, such as exposure to ionizing radiation and family history of thyroid and other malignancies associated with thyroid cancer.

Physical Examination

Thyroid masses move with swallowing, and failure to observe the patient swallowing may lead one to miss a large substernal goiter. Nodules that are hard, gritty, or fixed to surrounding structures, such as to the trachea or strap muscles, are more likely to be malignant. The ipsilateral and contralateral jugular and posterior triangle lymph nodes should be assessed.

Diagnostic Tests

A fine-needle aspiration biopsy is the most important diagnostic test. After FNA biopsy, the majority of nodules can be categorized into: benign (65 percent), suspicious (20 percent), malignant (5 percent), and nondiagnostic (10 percent). The incidence of false-positive results is approximately 1 percent and false-negative results occur in approximately 3 percent of patients. Benign lesions include cysts and colloid nodules. The risk of malignancy in this setting is less than 3 percent. The risk of malignancy in the setting of a suspicious cytology is anywhere from 10–20 percent. Most of these lesions are follicular or Hürthle cell neoplasms. In this situation, diagnosis of malignancy relies on demonstrating capsular or vascular invasion, features that cannot be determined via FNA biopsy. FNA biopsy also is less reliable in patients who have a history of head and neck irradiation or a family history of thyroid cancer, because of a higher likelihood of cancer and coexistent benign and malignant lesions. Most patients with thyroid nodules are euthyroid. Determining the blood TSH level is helpful although most patients are euthyroid. If a patient with a nodule is found to be hyperthyroid, the risk of malignancy is approximately 1 percent.

Ultrasound is helpful for detecting nonpalpable thyroid nodules, for differentiating solid from cystic nodules, for diagnosing suspicious nodules with microcalcifications and for identifying adjacent lymphadenopathy. Computed tomography (CT) and magnetic resonance imaging (MRI) are unnecessary in the routine evaluation of thyroid tumors, except for large, fixed, or substernal lesions. ^{123}I or $^{99\text{m}}\text{Tc}$ is rarely necessary, unless evaluating patients for “hot” or autonomous thyroid nodules.

Management

Malignant tumors are generally treated by total or near-total thyroidectomy. Simple thyroid cysts resolve with aspiration in approximately 75 percent of cases. If the cyst persists after three attempts at aspiration, unilateral thyroid lobectomy is recommended. Lobectomy also is recommended for cysts greater than 4 cm in diameter and for complex cysts with solid and cystic components, because the latter have a higher incidence of malignancy (15 percent). When FNA biopsy is used in complex nodules, the solid portion should be sampled. If a colloid nodule is diagnosed by FNA biopsy, patients should still be observed with serial ultrasound and Tg measurements. If the nodule enlarges, repeat FNA biopsy often is indicated. Although controversial, L-thyroxine in doses sufficient to maintain a serum TSH level between 0.1 and 1.0 $\mu\text{U/mL}$ also may be administered. Approximately 50 percent of these nodules decrease in size in response to the TSH suppression of this regimen, and others may not continue to grow, but it is most effective for nodules smaller than 3 cm. Thyroidectomy should be performed if a nodule enlarges on TSH suppression, causes compressive symptoms, or for cosmetic reasons. An exception to this general rule is the patient who has had previous irradiation of the thyroid gland

or who has a family history of thyroid cancer. In these patients total or near-total thyroidectomy is recommended because of the high incidence of thyroid cancer (≥ 40 percent) and decreased reliability of FNA biopsy in this setting.

MALIGNANT THYROID DISEASE

In the United States, thyroid cancer accounts for less than 1 percent of all malignancies (3 percent of women and 0.5 percent of men). Thyroid cancer is responsible for six deaths per 1 million persons annually. However, it is the most rapidly increasing cancer in women.

Molecular Genetics of Thyroid Tumorigenesis

Several oncogenes and tumor-suppressor genes are involved in thyroid tumorigenesis. The RET proto-oncogene, located on chromosome 10, plays a significant role. It encodes a receptor tyrosine kinase, which binds several growth factors. Germline mutations in the RET proto-oncogene are known to predispose to multiple endocrine neoplasia type 2A (MEN 2A), MEN 2B, and familial medullary thyroid cancers; and somatic mutations have been demonstrated in tumors derived from the neural crest, such as MTCs (30 percent) and pheochromocytomas. The tyrosine kinase domain of RET can fuse with other genes by rearrangement. These fusion products also function as oncogenes and have been implicated in the pathogenesis of papillary thyroid cancers. At least 15 RET/PTC rearrangements have been described and appear to be early events in tumorigenesis. Up to 70 percent of papillary cancers in children exposed to the radiation fallout from the 1986 Chernobyl disaster carry RET/PTC rearrangements. BRAF (B-type Raf kinase) mutations have recently been identified in about 40 percent of papillary thyroid cancers. Mutated ras oncogenes have been identified in up to 40 percent of thyroid follicular adenomas and carcinomas, multinodular goiters, and papillary and anaplastic carcinomas. Mutations in the TSH-R and gsp oncogenes have been noted in toxic adenomas. Mutations of p53 tumor suppressor are rare in PTCs, but are common in undifferentiated thyroid cancers and thyroid cancer cell lines. An oncogene resulting from the fusion of the DNA binding domain of the thyroid transcription factor PAX8 gene to the peroxisome proliferator-activated receptor gamma 1 (PPAR γ 1) has been noted to play an important role in the development of follicular neoplasms, including follicular cancers.

Specific Tumor Types

Papillary Carcinoma

Papillary carcinoma accounts for 80 percent of all thyroid malignancies in iodine-sufficient areas and is the predominant thyroid cancer in children and individuals exposed to external radiation. Papillary carcinoma occurs more often in women, with a 2:1 female-to-male ratio; the mean age at presentation is 30–40 years. Most patients are euthyroid and present with a slow-growing painless mass in the neck. Dysphagia, dyspnea, and dysphonia are usually associated with locally advanced invasive disease. Lymph node metastases are common, especially in children and young adults, and may be the presenting complaint. The so-called “lateral aberrant thyroid” almost always denotes a cervical lymph node metastases. Suspicion of thyroid cancer often originates through physical examination of the patient and a review of the patient’s history. Diagnosis is established by FNA biopsy of the thyroid mass or lymph node.

Distant metastases are uncommon at initial presentation, but may ultimately develop in up to 20 percent of patients. The most common sites are the lungs, followed by bone, liver, and brain.

Pathology. Calcification, necrosis, or cystic change may be apparent grossly. Histologically, papillary carcinomas may exhibit papillary projections, a mixed pattern of papillary and follicular structures, or a pure follicular pattern (follicular variant). The diagnosis is established by characteristic cellular features. Cells are cuboidal with pale, abundant cytoplasm, “grooving,” crowded nuclei, and intranuclear cytoplasmic inclusions, leading to the designation of Orphan Annie nuclei, which allows diagnosis by FNA biopsy. Psammoma bodies, which are microscopic, calcified deposits representing clumps of sloughed cells, may be present. Mixed papillary–follicular tumors and follicular variant of papillary carcinoma are classified as papillary carcinomas because they act biologically as papillary carcinomas. Multifocality is common in papillary carcinoma and may be present in up to 85 percent of cases on microscopic examination. Multifocality is associated with an increased risk of cervical nodal metastases and these tumors may rarely invade adjacent structures such as the trachea, esophagus, and recurrent laryngeal nerves. Other variants of papillary carcinoma including tall cell, columnar, diffuse sclerosing, clear cell, trabecular, Hurthle cell variant and poorly differentiated types. These variants account for approximately 1 percent of all papillary carcinomas and are generally associated with a worse prognosis.

Macroscopically, there are three recognized forms of papillary carcinoma, each based on the size and extent of the primary disease. Minimal or occult/microcarcinoma tumors are defined as tumors of 1 cm or less in size with no evidence of local invasiveness or lymph node metastases. They are nonpalpable and usually are incidental findings at operative, histologic, or autopsy examination. Occult papillary thyroid cancer is present in 2–36 percent of thyroid glands removed at autopsy. Intrathyroidal tumors are confined to the thyroid gland, with no evidence of extrathyroid invasion. Extrathyroidal tumors invade through the thyroid capsule and/or into adjacent structures. All types of primary thyroid cancers can be associated with lymph node metastases and invasion into intrathyroidal blood vessels or occasionally distant metastases. Long-term prognosis is better for patients with small, intrathyroidal lesions.

Prognostic indicators. In general, patients with papillary carcinoma have an excellent prognosis with a greater than 95 percent 10-year survival rate. Several prognostic indicators have been incorporated into various staging systems, which enable patients to be stratified into low-risk and high-risk groups.

The AGES scoring system incorporates age, histologic grade, extrathyroidal invasion and metastases, and tumor size to predict the risk of dying from papillary cancer. The MACIS scale is similar but incorporates completeness of original surgical resection with size of original lesion, invasion and metastases. The AMES system is a simpler classification that divides differentiated thyroid tumors into low- and high-risk groups using age (men < 40 years, women < 50 years), metastases, extrathyroidal spread, and size of tumors (< or > 5 cm). Another classification system is the TNM system, (tumor, nodal status, metastases; Table 37-1), used by most medical centers in North America. Unfortunately, all of these classification systems rely on data that is not available preoperatively.

TABLE 37-1 TNM Classification of Thyroid Tumors

Papillary or follicular tumors	
Stage	TNM
Younger than age 45 years	
I	Any T, Any N, M0
II	Any T, Any N, M1
Age 45 years and older	
I	T1, N0, M0
II	T2, N0, M0
III	T3, N0, M0; T1-3, N1a, M0
IVA	T4a, N0-1a, M0; T1-4a, N1b, M0
IVB	T4b, Any N, M0
IVC	Any T, Any N, M1
Medullary thyroid cancer	
Stage	TNM
I	T1, N0, M0
II	T2-3, N0, M0
III	T1-3, N1a, M0
IVA	T4a, N0-1a, M0; T1-4a, N1b, M0
IVB	T4b, any N, M0
IVC	Any T, Any N, M1
Anaplastic cancer	
Stage	TNM
IVA	T4a, Any N, M0
IVB	T4b, Any N, M0
IVC	Any T, Any M, M1
Definitions:	
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤ 2 cm in diameter, limited to thyroid
T2	Tumor > 2 cm but < 4 cm in diameter, limited to thyroid
T3	Tumor > 4 cm in diameter, limited to thyroid, or any tumor with minimal extrathyroidal invasion
T4a	Any size tumor extending beyond capsule to invade subcutaneous soft tissue, larynx, trachea, esophagus, or recurrent laryngeal nerve, or intrathyroidal anaplastic cancer
T4b	Tumor invading prevertebral fascia, or encasing carotid artery or mediastinal vessels, or extrathyroidal anaplastic cancer
Regional lymph nodes (N) include central, lateral, cervical, and upper mediastinal nodes	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastases to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
N1b	Metastases to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes
Distant metastasis (M)	
MX	Distant metastases cannot be assessed
M1	No distant metastasis

Surgical treatment. Most authors agree that patients with high-risk tumors (judged by any of the classification systems discussed above) or bilateral tumors should undergo total or near-total thyroidectomy. When patients are found to have a minimal papillary thyroid carcinoma in a thyroid specimen removed for other reasons, unilateral thyroid lobectomy and isthmusectomy is usually considered to be adequate treatment, unless the tumor has evidence of angioinvasion, multifocality, or positive margins. The optimal surgical strategy in the majority of patients with low-risk (small, unilateral) cancers remains controversial. The focus of the debate centers around outcome data and risks associated with either lobectomy or total thyroidectomy in this group of patients.

Proponents of total thyroidectomy argue that the procedure (1) enables one to use RAI to effectively detect and treat residual thyroid tissue or metastatic disease; (2) makes the serum Tg level a more sensitive marker of recurrent or persistent disease; (3) eliminates the contralateral occult cancers as sites of recurrence (because up to 85 percent of tumors are multifocal); (4) reduces the risk of recurrence and improves survival; (5) decreases the 1 percent risk of progression to undifferentiated or anaplastic thyroid cancer; and (6) reduces the need for reoperative surgery with its attendant risk of increased complication rates.

Investigators that favor lobectomy argue that (1) total thyroidectomy is associated with a higher complication rate than lobectomy; (2) recurrence in the remaining thyroid tissue is unusual (5 percent) and most are curable by surgery; (3) tumor multicentricity seems to have little prognostic significance; and (4) patients who have undergone lesser procedures, such as lobectomy, still have an excellent prognosis. However, it is known that a significant proportion (33–50 percent) of patients who develop a recurrence die from their disease, and even though the data are retrospective, long-term, follow-up studies suggest that recurrence rates are lowered, and that survival is improved in patients undergoing near-total or total thyroidectomy. Additionally, diminished survival is noted in patients with so-called low-risk disease (mortality rates of 5 percent at 10–20 years) and it is not possible to accurately risk stratify patients preoperatively. Given the above, it is recommended that even patients with low-risk tumors undergo total or near-total thyroidectomy, provided complication rates are low (< 2 percent).

Consequently, most patients with thyroid nodules should have FNA biopsy performed. When PTC is diagnosed, the definitive operation can be done without confirming the diagnosis by frozen section during the operation. Patients with a nodule that may be papillary cancer should be treated by thyroid lobectomy, isthmusectomy, and removal of any pyramidal lobe or adjacent lymph nodes. If intraoperative frozen-section examination of a lymph node or of the primary tumor confirms carcinoma, completion of total or near-total thyroidectomy should be performed. If a definitive diagnosis cannot be made, or if the surgeon is concerned about the viability of the parathyroid glands or the status of the RLN, the operation should be terminated. For patients who have minimal papillary thyroid cancer confined to the thyroid gland without angioinvasion, no further operative treatment is recommended.

During thyroidectomy, enlarged ipsilateral central neck nodes should be removed. Lymph node metastases in the lateral neck in patients with papillary carcinoma are usually managed with modified radical or functional neck dissection. Dissection of the posterior triangle and suprahyoid dissection are usually not necessary unless there is extensive metastatic disease in levels 2,

3, and 4, but should be performed when appropriate. Prophylactic neck node dissection is not necessary in patients with papillary thyroid cancer, because these cancers do not appear to metastasize systemically from lymph nodes and micrometastases appear to be ablated with RAI therapy.

Follicular Carcinoma

Follicular carcinomas account for 10 percent of thyroid cancers and occur more commonly in iodine-deficient areas. The overall incidence of this tumor is declining in the United States, probably as a result of iodine supplementation and improved histologic classification. Women have a higher incidence of follicular cancer, with a female:male ratio of 3:1, and a mean age at presentation of 50 years. Follicular cancers usually present as solitary thyroid nodules. Unlike papillary cancers, cervical lymphadenopathy is uncommon at initial presentation (approximately 5 percent), although distant metastases may be present. In less than 1 percent of cases, follicular cancers may be hyperfunctioning. FNA biopsy is unable to distinguish benign follicular lesions from follicular carcinomas. Therefore, preoperative diagnosis of cancer is difficult unless distant metastases are present. Large follicular tumors (> 4 cm) in older men are more likely to be malignant.

Pathology. Follicular carcinomas are usually solitary lesions, the majority of which are surrounded by a capsule. Histologically, follicles are present, but the lumen may be devoid of colloid. Malignancy is defined by the presence of capsular and vascular invasion. Minimally invasive tumors appear grossly encapsulated but have evidence of microscopic invasion through the tumor capsule and/or invasion into small- to medium-size vessels (venous caliber) in or immediately outside the capsule, but not within the tumor. On the other hand, widely invasive tumors demonstrate evidence of large-vessel invasion and/or broad areas of tumor invasion through the capsule. They may, in fact, be unencapsulated. However, there is a wide variation of opinion among clinicians and pathologists with respect to the above definitions.

Surgical treatment and prognosis. Patients diagnosed by FNA biopsy as having a follicular lesion should undergo thyroid lobectomy because at least 80 percent of these patients will have benign adenomas. Some surgeons recommend total thyroidectomy in older patients with follicular lesions larger than 4 cm as there is a higher risk of cancer in this setting (50 percent). Total thyroidectomy should be performed when thyroid cancer is diagnosed. There is debate among experts about whether patients with minimally invasive follicular cancers should undergo completion thyroidectomy because the prognosis is so good in these patients. A diagnosis of frankly invasive carcinoma necessitates completion of total thyroidectomy. Total thyroidectomy in patients with angioinvasion is also recommended. Prophylactic nodal dissection is not needed but in the unusual patient with nodal metastases, therapeutic neck dissection is recommended. The cumulative mortality rate from follicular thyroid cancer is approximately 15 percent at 10 years and 30 percent at 20 years.

Hürthle Cell Carcinoma

Hürthle cell carcinomas account for approximately 3 percent of all thyroid malignancies. Under the World Health Organization classification, Hürthle cell carcinomas are considered to be a subtype of follicular thyroid cancer. Like follicular cancers, Hürthle cell cancers are characterized by vascular or capsular invasion, and therefore cannot be diagnosed by FNA biopsy. Tumors contain

sheets of eosinophilic cells packed with mitochondria, which are derived from the oxyphilic cells of the thyroid gland. Hürthle cell tumors also differ from follicular carcinomas in that they are more often multifocal and bilateral (approximately 30 percent), usually do not take up RAI (approximately 5 percent), are more likely to metastasize to local nodes (25 percent) and distant sites, and are associated with a higher mortality rate (approximately 20 percent at 10 years). Hence, they are considered to be a separate class of tumors by some surgeons.

Management is similar to that of follicular neoplasms, with lobectomy and isthmusectomy being sufficient surgical treatment for unilateral Hürthle cell adenomas. When Hürthle cell neoplasms are found to be invasive on intra-operative, frozen-section, or definitive paraffin-section histology, then total thyroidectomy should be performed. These patients should also undergo routine central neck node removal, similar to patients with MTC, and modified radical neck dissection when lateral neck nodes are palpable. Although RAI scanning and ablation usually are ineffective, they probably should be considered for ablation of any residual normal thyroid tissue and, occasionally, for ablation of tumors, because there is no other good therapy.

Postoperative Management of Differentiated Thyroid Cancer

Thyroid hormone. TSH suppression reduces tumor recurrence rates, particularly in young patients with papillary and follicular thyroid cancer. Thyroxine should be administered to ensure that the patient remains euthyroid, with circulating TSH levels at about $0.1 \mu\text{U/L}$ in low-risk patients, or less than $0.1 \mu\text{U/mL}$ in high-risk patients. The risk of tumor recurrence must be balanced with the side effects associated with prolonged TSH suppression, including osteopenia and cardiac problems, particularly in older patients.

Thyroglobulin measurement. Thyroglobulin levels in patients who have undergone total thyroidectomy should be below 2 ng/mL when the patient is taking T4, and below 5 ng/mL when the patient is hypothyroid. A Tg level above 2 ng/mL after total thyroidectomy is highly suggestive of metastatic disease or persistent normal thyroid tissue.

Thyroglobulin and anti-Tg antibody levels should be measured initially at 6-month intervals and then annually if the patient is clinically disease free. High-risk patients should also have an ultrasound of the neck and CT or MRI scan of the neck and mediastinum for early detection of any persistent or recurrent disease.

Radioiodine therapy. Long-term cohort studies suggest that postoperative RAI therapy reduces recurrence and provides a small improvement in survival, even in low-risk patients. Screening and treatment are facilitated by the removal of all normal thyroid tissue, which effectively competes for iodine uptake. Metastatic differentiated thyroid carcinoma can be detected and treated by ^{131}I in approximately 75 percent of patients. Generally, T4 therapy is discontinued for approximately 6 weeks prior to scanning with ^{131}I . Patients should receive T3 during this time period to decrease the period of hypothyroidism. A low-iodine diet is also recommended during the 2-week period when all thyroid hormone has been discontinued. After a total thyroidectomy, radioactive uptake should be less than 1 percent. If there is significant uptake, then a therapeutic dose of ^{131}I should be administered to patients (low-risk patients: 30–100 mCi; high-risk patients: 100–200 mCi). The maximum dose of radioiodine that can

be administered at one time without performing dosimetry is approximately 200 mCi with a cumulative dose of 1000–1500 mCi. Up to 500 mCi can be given with proper pretreatment dosimetry. If follow-up RAI scans are negative, but Tg levels remain elevated, other imaging studies such as neck ultrasound, MRI scan, and FDG-PET scans should be considered.

External beam radiotherapy and chemotherapy. External beam radiotherapy is occasionally required to control unresectable, locally invasive or recurrent disease and to treat metastases in support bones to decrease the risk of fractures. Single and multidrug chemotherapy has been used with little success in disseminated thyroid cancer. Adriamycin and Taxol are the most frequently used agents.

Medullary Carcinoma

These tumors account for about 5 percent of thyroid malignancies and arise from the parafollicular or C cells of the thyroid, which are concentrated superolaterally in the thyroid lobes. C cells secrete calcitonin, a 32-amino-acid polypeptide. In some animals, especially those that lay eggs with shells, calcitonin is a significant regulator of calcium metabolism, but in humans, it has only minimal physiologic effects. Most medullary carcinomas occur sporadically. However, approximately 25 percent occur within the spectrum of several inherited syndromes such as familial medullary thyroid cancer, MEN2A, and MEN2B—all of which result secondary to germline mutations in the RET proto-oncogene.

Patients with medullary carcinoma often present with a neck mass that may be associated with palpable cervical lymphadenopathy (15–20 percent). Local invasion produces symptoms of dysphagia, dyspnea, or dysphonia. Distant blood-borne metastases to the liver, bone (frequently osteoblastic), and lung occur later in the disease. The female:male ratio is 1.5:1. Most patients present between 50 and 60 years of age, although patients with familial disease present at a younger age. Medullary thyroid tumors secrete not only calcitonin and carcinoembryonic antigen (CEA), but also calcitonin gene-related peptide (CGRP), histaminases, prostaglandins E₂ and F₂α, serotonin and ACTH.

Pathology. The tumors are typically unilateral, but are multicentric in familial cases. Familial cases also are associated with C-cell hyperplasia, which is considered a premalignant lesion. Microscopically, tumors are composed of sheets of infiltrating neoplastic cells separated by collagen and amyloid. The presence of amyloid is a diagnostic finding, but immunohistochemistry for calcitonin is more commonly used as a diagnostic marker.

Diagnosis. The diagnosis of medullary carcinoma is established by history, physical examination, raised serum calcitonin or CEA levels, and FNA cytology of the thyroid mass. Attention to family history is important because approximately 25 percent of patients with MTC have familial disease. All new patients with MTC should be screened for RET point mutations, pheochromocytoma, and hyperparathyroidism. It is important to rule out a coexisting pheochromocytoma to avoid precipitating a hypertensive crisis and death.

Treatment. If patients are found to have a pheochromocytoma, this must be operated on first. Total thyroidectomy is the treatment of choice for these patients because of the high incidence of multicentricity, the more aggressive course, and ¹³¹I therapy is not usually effective. The central compartment nodes are frequently involved early in the disease process, so that a bilateral

central neck node dissection should be routinely performed. In patients with palpable cervical nodes or involved central neck nodes, ipsilateral or bilateral, modified radical neck dissection is recommended. Similarly, patients with tumors larger than 1.5 cm should undergo ipsilateral prophylactic modified radical neck dissection, because greater than 60 percent of these patients have nodal metastases. Approximately 30 percent of these patients will also have contralateral nodal metastases. In the case of locally recurrent or metastatic disease, tumor debulking is advised.

In patients who have hypercalcemia at the time of thyroidectomy, only obviously enlarged parathyroid glands should be removed. The other parathyroid glands should be preserved and marked in patients with normocalcemia as only approximately 20 percent of patients with MEN 2A develop hyperparathyroidism. Total thyroidectomy is indicated in RET mutation carriers and should be performed before age 6 years in MEN 2A patients and prior to age 1 year in MEN 2B patients.

Prognosis. Prognosis is related to disease stage and type. It is best in patients with non-MEN familial medullary cancer, followed by patients with MEN 2A, and then by patients with sporadic disease. Patients with MEN 2B have the worst prognosis.

Anaplastic Carcinoma

Anaplastic carcinoma accounts for approximately 1 percent of all thyroid malignancies in the United States and is the most aggressive of thyroid tumors. The majority of tumors present in the seventh and eighth decades of life. The typical patient has a long-standing neck mass, which rapidly enlarges and may be painful. Associated symptoms, such as dysphonia, dysphagia, and dyspnea are common. Lymph nodes usually are palpable at presentation. Evidence of metastatic spread also may be present. Diagnosis is confirmed by FNA biopsy revealing characteristic giant and multinucleated cells. Foci of more differentiated thyroid tumors may be seen, suggesting that anaplastic tumors arise from more well-differentiated tumors. Incisional biopsy is occasionally needed to confirm the diagnosis and isthmusectomy is performed to alleviate tracheal compression.

Treatment and prognosis. This tumor is one of the most aggressive thyroid malignancies. If anaplastic carcinoma presents as a resectable mass, thyroidectomy may lead to a small improvement in survival. Combined radiation and chemotherapy in an adjuvant setting in patients with resectable disease has been associated with prolonged survival. Tracheostomy may be needed to alleviate airway obstruction.

Lymphoma

Lymphomas account for less than 1 percent of thyroid malignancies, are mostly of the non-Hodgkin B-cell type and tend to develop in patients with chronic lymphocytic thyroiditis. Patients usually present with symptoms similar to anaplastic carcinoma, although the rapidly enlarging neck mass often is painless. Patients may present with acute respiratory distress. The diagnosis usually is suggested by FNA biopsy, although needle-core or open biopsy may be necessary for definitive diagnosis. Staging studies should be obtained to assess the extent of extrathyroidal spread.

Treatment and prognosis. Patients respond rapidly to chemotherapy (CHOP—cyclophosphamide, doxorubicin, vincristine, and prednisone), which also is associated with improved survival. Thyroidectomy and nodal resection are reserved for patients who do not respond quickly to the above regimens, or in patients who have completed the regimen prior to diagnosis.

Metastatic Carcinoma

The thyroid gland is a rare site of metastases from other cancers, including kidney, breast, lung, and melanoma. Resection of the thyroid, usually lobectomy, may be helpful in many patients, depending on the status of their primary tumor.

THYROID SURGERY

Preoperative Preparation

Patients with any recent or remote history of altered phonation or prior neck surgery should undergo vocal cord assessment by direct or indirect laryngoscopy prior to thyroidectomy. The patient is positioned supine, with a sandbag between the scapulae. The head is placed on a donut cushion and the neck is extended and supported to provide maximal exposure without hyperextension. A Kocher transverse collar incision, typically 4–5 cm in length, is placed in or parallel to a natural skin crease 1 cm below the cricoid cartilage. Subplatysmal flaps are raised superiorly to the level of the thyroid cartilage and inferiorly to the suprasternal notch. The strap muscles are divided in the midline and the thyroid gland is exposed. The straps are then dissected off the underlying thyroid by a combination of sharp and blunt dissection, thus exposing the middle thyroid veins. The thyroid lobe is retracted medially and anteriorly and the lateral tissues are swept posterolaterally using a peanut sponge. The middle thyroid veins are ligated and divided. Attention is then turned to the midline where Delphian nodes and the pyramidal lobe are identified. Some surgeons divide the isthmus early for patients with benign or indeterminate disease. The superior thyroid pole is identified by retracting the thyroid first inferiorly and medially, and then the upper pole of the thyroid is mobilized caudally and laterally. The dissection plane is kept as close to the thyroid as possible and the superior pole vessels are individually identified, skeletonized, ligated, and divided low on the thyroid gland, to avoid injury to the external branch of the superior laryngeal nerve.

The recurrent laryngeal nerve can then be identified, most consistently at the level of the cricoid cartilage. The parathyroids can usually be identified within 1 cm of the crossing of the inferior thyroid artery and the RLN. If not present in this location, the lower glands may be found in the thyrothymic ligament or the upper thymus. The lower pole of the thyroid gland should be mobilized by gently sweeping all tissues dorsally. The inferior thyroid vessels are dissected, skeletonized, ligated, and divided as close to the surface of the thyroid gland as possible. The RLN is most vulnerable to injury in the vicinity of the ligament of Berry. Any bleeding in this area should be controlled with gentle pressure before carefully identifying the vessel and ligating it. Use of the electrocautery should be avoided in proximity to the RLN. Once the ligament is divided, the thyroid can be separated from the underlying trachea by sharp dissection. The pyramidal lobe, if present, must be dissected in a cephalad direction to above the level of the notch in the thyroid cartilage or higher in continuity with the

thyroid gland. If a lobectomy is to be performed, the isthmus is divided flush with the trachea on the contralateral side and suture ligated. The procedure is repeated on the opposite side for a total thyroidectomy.

Parathyroid glands that cannot be dissected from the thyroid with a good blood supply, or have been inadvertently removed during the thyroidectomy, should be resected, confirmed as parathyroid tissue by frozen section, divided into 1-mm fragments, and reimplanted into individual pockets in the sternocleidomastoid muscle. The sites should be marked with silk sutures and a clip. If a subtotal thyroidectomy is to be performed, once the superior pole vessels are divided and the thyroid lobe mobilized anteriorly, the thyroid lobe is cross-clamped with a Mayo clamp, leaving approximately 4 g of the posterior portion of the thyroid. The thyroid remnant is suture ligated, taking care to avoid injury to the recurrent laryngeal nerve. Routine drain placement is rarely necessary. After adequate hemostasis is obtained, the strap muscles are reapproximated in the midline using absorbable sutures. The platysma is approximated in a similar fashion. The skin can be closed with subcuticular sutures or clips.

Several approaches to minimally invasive thyroidectomy, such as video-assisted thyroidectomy and endoscopic thyroidectomy via axillary incisions, have been proposed. These methods are feasible, but clear benefits over the "traditional" open approach have not been established.

Surgical Removal of Intrathoracic Goiter

A goiter is considered mediastinal if at least 50 percent of the thyroid tissue is located intrathoracically. Mediastinal goiters can be primary or secondary. Primary mediastinal goiters (1 percent) arise from accessory (ectopic) thyroid tissue located in the chest. These goiters are supplied by intrathoracic blood vessels and do not have any connection to thyroid tissue in the neck. Secondary goiters arise from downward extension of cervical thyroid tissue along the fascial planes of the neck and derive their blood supply from thyroid arteries. Virtually all intrathoracic goiters can be removed via a cervical incision. Patients who have invasive thyroid cancers, have had previous thyroid operations (may have developed parasitic mediastinal vessels), or have primary mediastinal goiters with no thyroid tissue in the neck, may require a median sternotomy for removal.

Neck Dissection for Nodal Metastases

A modified radical (functional) neck dissection can be performed via the cervical incision used for thyroidectomy, which can be extended laterally (MacFee extension). The procedure involves removal of all fibrofatty tissue along the internal jugular vein (levels II, III, and IV) and the posterior triangle (level V). In contrast to a radical neck dissection, the internal jugular vein, the spinal accessory nerve, the cervical sensory nerves, and the sternocleidomastoid muscle are preserved unless they are adherent to or invaded by tumor. The procedure begins by opening the plane between the strap muscles medially and the sternocleidomastoid muscle laterally. The anterior belly of the omohyoid muscle is retracted laterally and the dissection is carried posteriorly until the carotid sheath is reached. The internal jugular vein is retracted medially with a vein retractor and the fibrofatty tissue and lymph nodes are dissected away from it by a combination of sharp and blunt dissection. The lateral dissection is carried along the posterior border of the sternocleidomastoid muscle, removing

the tissue from the posterior triangle. The deep dissection plane is the anterior scalenus muscle, the phrenic nerve, the brachial plexus, and the medial scalenus muscle.

Complications of Thyroid Surgery

Injury to the RLN may occur by severance, ligation, or undue traction, but should occur in less than 1 percent of patients undergoing thyroidectomy by experienced surgeons. The RLN is most vulnerable to injury during the last 2–3 cm of its course. If the injury is recognized intraoperatively, most surgeons advocate primary reapproximation of the perineurium using nonabsorbable sutures. Approximately 15 percent of patients are at risk of injury to the external branches of the superior laryngeal nerve, especially if superior pole vessels are ligated en masse. The cervical sympathetic trunk is at risk of injury in the rare scenario of retroesophageal goiter extension and might result in Horner syndrome. Transient hypocalcemia (from surgical injury or inadvertent removal of parathyroid tissue) has been reported in up to 50 percent of cases, but permanent hypoparathyroidism occurs less than 2 percent of the time. Postoperative hematomas or bleeding may also complicate thyroidectomies, and rarely necessitate emergency reoperation to evacuate the hematoma. Bilateral vocal cord dysfunction with respiratory difficulty can require immediate reintubation or tracheostomy. Seromas may need aspiration to relieve patient discomfort. Wound cellulitis and infection, and injury to surrounding structures, such as the carotid artery, jugular vein, thoracic duct and esophagus are infrequent.

PARATHYROID

Embryology

In humans, the superior parathyroid glands are derived from the fourth branchial pouch, which also gives rise to the thyroid gland. The third branchial pouches give rise to the inferior parathyroid glands and the thymus. The parathyroids remain closely associated with their respective branchial pouch derivatives. The position of normal superior parathyroid glands is more consistent, with 80 percent of these glands being found near the posterior aspect of the upper and middle thyroid lobes, at the level of the cricoid cartilage. Approximately 1 percent of normal upper glands may be found in the paraesophageal or retroesophageal space. Truly ectopic superior parathyroid glands are rare, but may be found in the middle or posterior mediastinum, commonly in the aortopulmonary window. As the embryo matures, the thymus and inferior parathyroids migrate together caudally in the neck. The most common location for inferior glands is within a distance of 1 cm from a point centered where the inferior thyroid artery and recurrent laryngeal nerve cross. Approximately 15 percent of inferior glands are found in the thymus. The position of the inferior glands, however, tends to be more variable as a consequence of their longer migratory path. Undescended inferior glands may be found near the skull base, angle of the mandible, or superior to the superior parathyroid glands, along with an undescended thymus. The frequency of intrathyroidal glands varies in the literature from 0.5–3 percent. Although some authors consider upper parathyroid glands more likely to be intrathyroidal, because of the close embryologic association of the upper glands and the lateral thyroid anlage, they may also be lower glands.

ANATOMY AND HISTOLOGY

Most patients have four parathyroid glands. Normal parathyroid glands are gray and semitransparent in newborns, but appear golden-yellow to light-brown in adults. They are located in loose tissue or fat and are ovoid and measure 5–7 mm in size (weight 40–50 mg each). The parathyroid glands derive most of their blood supply from branches of the inferior thyroid artery, although branches from the superior thyroid artery supply at least 20 percent of upper glands; venous drainage is via the ipsilateral superior, middle, and inferior thyroid veins. Akerstrom and associates, in an autopsy series of 503 cadavers, found four parathyroid glands in 84 percent of cases. Supernumerary glands were present in 13 percent of patients, most commonly in the thymus. Only 3 percent of patients had less than four glands.

Histologically, parathyroid glands are composed of chief cells (which produce PTH) and oxyphil cells arranged in trabeculae, within a stroma composed primarily of adipose cells. A third group of cells, known as water-clear cells (rich in glycogen), also are derived from chief cells. Although most, but not all, oxyphil and water-clear cells retain the ability to secrete PTH, their functional significance is unknown.

PARATHYROID PHYSIOLOGY AND CALCIUM HOMEOSTASIS

Calcium is the most abundant cation in human beings, and has several crucial functions. Calcium is absorbed from the small intestine in its inorganic form. Extracellular calcium (900 mg) accounts for only 1 percent of the body's calcium stores, the majority of which is sequestered in the skeletal system. Approximately 50 percent of the serum calcium is in the ionized form, which is the active component. The remainder is bound to albumin (40 percent) and organic anions such as phosphate and citrate (10 percent). The total serum calcium levels range from 8.5–10.5 mg/dL (2.1–2.6 mmol/L) and ionized calcium levels range from 4.4–5.2 mg/dL (1.1–1.3 mmol/L). Total serum calcium levels must always be considered in the context of serum albumin levels.

Parathyroid Hormone

Parathyroid cells rely on a G-protein-coupled membrane receptor, the calcium-sensing receptor (CASR), to regulate PTH secretion. PTH secretion is also stimulated by low levels of 1,25-dihydroxy vitamin D, catecholamines, and hypomagnesemia. The PTH gene is located on chromosome 11. PTH is synthesized as a precursor hormone, preproparathyroid hormone, which is cleaved first to parathyroid hormone and then to the final 84-amino-acid PTH. Secreted PTH has a half-life of 2–4 min.

PTH increases the resorption of bone by stimulating osteoclasts and promotes the release of calcium and phosphate into the circulation. At the kidney, PTH acts to limit calcium excretion at the distal convoluted tubule via an active transport mechanism. PTH also inhibits phosphate and bicarbonate reabsorption and enhances 1-hydroxylation of 25-hydroxyvitamin D, which is responsible for its indirect effect of increasing intestinal calcium absorption.

Calcitonin

Calcitonin inhibits osteoclast-mediated bone resorption. Its production is stimulated by calcium and pentagastrin, and also by catecholamines, cholecystokinin, and glucagon. It produces hypocalcemia, when administered

intravenously to experimental animals but plays a minimal, if any, role in the regulation of calcium levels in humans.

Vitamin D

Vitamin D₂ and vitamin D₃ are produced by photolysis of naturally occurring sterol precursors. Vitamin D is metabolized in the liver to its primary circulating form, 25-hydroxy vitamin D. Further hydroxylation in the kidney results in 1,25-dihydroxy vitamin D, which is the most metabolically active form of vitamin D. Vitamin D stimulates the absorption of calcium and phosphate from the gut.

HYPERPARATHYROIDISM

Hyperfunction of the parathyroid glands may be classified as primary, secondary, or tertiary. Primary hyperparathyroidism (PHPT) arises from increased PTH production from abnormal parathyroid glands and results from a disturbance of normal feedback control exerted by serum calcium. Elevated PTH levels may also occur as a compensatory response to hypocalcemic states resulting from chronic renal failure or gastrointestinal malabsorption of calcium. This state is referred to as secondary hyperparathyroidism (HPT) and can be reversed by correction of the underlying problem, (e.g., kidney transplantation for chronic renal failure). However, chronically stimulated glands may occasionally become autonomous, resulting in persistence or recurrence of hypercalcemia after successful renal transplantation, resulting in tertiary HPT.

Primary Hyperparathyroidism

PHPT is a common disorder, affecting 0.1–0.3 percent of the general population and is more common in women (1:500) than in men (1:2000). Increased PTH production leads to hypercalcemia via increased gastrointestinal absorption of calcium, increased production of vitamin D₃ and reduced renal calcium clearance. PHPT is characterized by increased parathyroid cell proliferation and PTH secretion which is independent of calcium levels.

Etiology

The exact cause of PHPT is unknown, although exposure to low-dose therapeutic ionizing radiation and familial predisposition account for some cases. Various diets and intermittent exposure to sunshine may also be related. Other causes include renal leak of calcium and declining renal function with age, and alteration in the sensitivity of parathyroid glands to suppression by calcium. PHPT results from the enlargement of a single gland or parathyroid adenoma in approximately 80 percent of cases, multiple adenomas or hyperplasia in 15–20 percent of patients and parathyroid carcinoma in 1 percent of patients.

Genetics

Although most cases of PHPT are sporadic, PHPT also occurs within the spectrum of a number of inherited disorders such as MEN1, MEN 2A, isolated familial HPT, and familial HPT with jaw-tumor syndrome. All of these syndromes are inherited in an autosomal dominant fashion. Primary HPT is the earliest and most common manifestation of MEN1 and develops in 80–100 percent of patients by age 40 years. These patients also are prone to pancreatic neuroendocrine tumors, pituitary adenomas, and less commonly to adrenocortical

tumors, lipomas, skin angiomas, and carcinoid tumors of the bronchus, thymus, or stomach. MEN1 has been shown to result from germline mutations in the MEN1 gene, a tumor-suppressor gene located on chromosome 11q12-13. Hyperparathyroidism develops in approximately 20 percent of patients with MEN 2A and is generally less severe. Patients with the familial HPT with jaw-tumor syndrome have an increased predisposition to parathyroid carcinoma. This syndrome maps to a tumor-suppressor locus HRPT2, on chromosome 1.

Approximately 25–40 percent of sporadic parathyroid adenomas and some hyperplastic parathyroid glands have loss of heterozygosity at 11q13, the site of the MEN1 gene. The parathyroid adenoma 1 oncogene (PRAD1), which encodes cyclin D1, a cell-cycle control protein, is overexpressed in approximately 18 percent of parathyroid adenomas. Sporadic parathyroid cancers are characterized by uniform loss of the tumor-suppressor gene RB, and mutations of HRPT2 and p53.

Clinical Manifestations

Patients with PHPT formerly presented with the “classic” pentad of symptoms (i.e., kidney stones, painful bones, abdominal groans, psychic moans, and fatigue overtones). With the advent and widespread use of automated blood analyzers in the early 1970s, there has been an alteration in the “typical” patient with PHPT, who is more likely to be minimally symptomatic or asymptomatic. Currently, most patients present with weakness, fatigue, polydipsia, polyuria, nocturia, bone and joint pain, constipation, decreased appetite, nausea, heartburn, pruritus, depression, and memory loss. Truly “asymptomatic” PHPT appears to be rare. Complications of HPT are described below.

Renal disease. Approximately 80 percent of patients with PHPT have some degree of renal dysfunction or symptoms. Kidney stones or nephrocalcinosis were previously found in up to 80 percent of patients, but now occur in approximately 20–25 percent. The calculi are typically composed of calcium phosphate or oxalate. In contrast, primary HPT is found to be the underlying disorder in only 3 percent of patients presenting with nephrolithiasis. The incidence of hypertension is variable.

Bone disease. Bone disease, including osteopenia, osteoporosis, and osteitis fibrosa cystica, is found in approximately 15 percent of patients with PHPT. Advanced PHPT and/or vitamin D deficiency leads to osteitis fibrosa cystica, a condition which now occurs in less than 5 percent of patients. It is characterized by pathognomonic radiologic findings, which are best seen on radiographs of the hands that demonstrate subperiosteal resorption (most apparent on the radial aspect of the middle phalanx of the second and third fingers), bone cysts, and tufting of the distal phalanges. The skull may also be affected and appears mottled (salt and pepper) with a loss of definition of the inner and outer cortices. Brown or osteoclastic tumors and bone cysts may also be present. Hyperparathyroidism typically results in a loss of bone mass at sites of cortical bone, such as the radius and relative preservation of cancellous bone such as that located at the vertebral bodies.

Gastrointestinal complications. PHPT has been associated with peptic ulcer disease, pancreatitis and cholelithiasis.

Neuropsychiatric manifestations. Severe hypercalcemia may lead to various neuropsychiatric manifestations such as florid psychosis, obtundation, or

coma. Other findings, such as depression, anxiety, and fatigue, are more commonly observed in patients with only mild hypercalcemia.

Other features. Primary HPT also can lead to fatigue and muscle weakness, which is prominent in the proximal muscle groups. Patients also have an increased incidence of chondrocalcinosis and pseudogout. Calcification at ectopic sites such as blood vessels, cardiac valves and skin, also has been reported, as has hypertrophy of the left ventricle independent of the presence of hypertension. Several large studies from Europe also suggest that PHPT is associated with increased death rates from cardiovascular disease and cancer, even in patients with mild HPT, although this finding was not substantiated in other studies.

Physical Findings

Parathyroid tumors are seldom palpable, except in patients with profound hypercalcemia. A palpable neck mass in a patient with PHPT is more likely to be thyroid in origin or a parathyroid cancer. Patients may also demonstrate evidence of band keratopathy, a deposition of calcium in Bowman membrane just inside the iris of the eye.

Differential Diagnosis

Hypercalcemia may be caused by a multitude of conditions (Table 37-2). PHPT and malignancy account for more than 90 percent of all cases of hypercalcemia. PHPT is more common in the outpatient setting, whereas malignancy is the leading cause of hypercalcemia in hospitalized patients. PHPT can virtually always be distinguished from other diseases causing hypercalcemia by a combination of history, physical examination, and appropriate laboratory investigations. Hypercalcemia of malignancy is known to be mediated primarily by parathyroid hormone-related peptide (PTHrP). Benign familial hypocalciuric hypercalcemia (BFHH) is a rare autosomal dominant condition with nearly 100 percent penetrance and results from inherited heterozygous mutations in the CASR gene located on chromosome 3. Patients with BFHH have lifelong hypercalcemia, which is not corrected by parathyroidectomy.

Diagnostic Investigations

Biochemical studies. The presence of an elevated serum calcium and intact PTH (iPTH) or two-site PTH levels establishes the diagnosis of PHPT with

TABLE 37-2 Differential Diagnosis of Hypercalcemia

Hyperparathyroidism
Malignancy—hematologic (multiple myeloma), solid tumors (caused by PTHrP)
Endocrine diseases—hyperthyroidism, Addisonian crisis, VIPoma
Granulomatous diseases—sarcoidosis, tuberculosis, berylliosis, histoplasmosis
Milk-alkali syndrome
Drugs—thiazide diuretics, lithium, vitamin A or D intoxication
Benign familial hypocalciuric hypercalcemia
Paget disease
Immobilization

PTHrP = parathyroid hormone-related protein; VIPoma = vasoactive intestinal peptide-secreting tumor.

virtual certainty. These sensitive PTH assays employ immunoradiometric or immunochemiluminescent techniques, and can reliably distinguish primary HPT from other causes of hypercalcemia. Furthermore, they do not cross-react with PTHrP. In patients with metastatic cancer and hypercalcemia, iPTH levels help to determine whether the patient also has concurrent PHPT. Patients with PHPT also typically have decreased serum phosphate (approximately 50 percent) and elevated 24-hour urinary calcium concentrations (approximately 60 percent). A mild hyperchloremic metabolic acidosis also is present (80 percent), thereby leading to an elevated chloride:phosphate ratio (> 33). Urinary calcium levels need not be measured routinely, except in patients who have not had previously documented normocalcemia, or who have a family history of hypercalcemia, to rule out BFHH (24-h urinary calcium excretion < 100 mg/day). Furthermore, in these patients, the serum calcium to creatinine clearance ratio is usually less than 0.01, whereas it is typically greater than 0.02 in patients with primary hyperparathyroidism. Elevated levels of alkaline phosphatase may be found in approximately 10 percent of patients with PHPT. Occasionally, patients present with normocalcemic PHPT caused by vitamin D deficiency, a low serum albumin, excessive hydration, a high phosphate diet, or a low normal blood calcium set-point.

Radiologic tests. Routine hand radiographs are only recommended for patients with an elevated alkaline phosphatase level. Bone mineral density studies using dual-energy absorptiometry are, however, being increasingly used to assess the effects of PHPT on bone. Abdominal ultrasound examination is used selectively to document renal stones.

Treatment

Rationale for parathyroidectomy and guidelines for operative treatment.

Most authorities agree that patients who have developed complications such as kidney stones, osteoporosis, or renal dysfunction, have the “classic” symptoms of PHPT, or who are younger than age 50 years, should undergo parathyroidectomy. However, the treatment of patients with asymptomatic PHPT has been the subject of controversy, partly because there is little agreement on what constitutes an “asymptomatic” patient. At the National Institutes of Health (NIH) consensus conference in 1990, “asymptomatic” PHPT was defined as “the absence of common symptoms and signs of PHPT, including no bone, renal, gastrointestinal, or neuromuscular disorders.” The panel advocated nonoperative management of these patients with mild PHPT based on observational studies, which suggested relative stability of biochemical parameters over time. However, the consensus panel considered certain asymptomatic patients to be candidates for surgery. These guidelines were reassessed at a second NIH workshop in 2002. Parathyroidectomy is now recommended for patients with (1) smaller elevations in serum calcium levels (< 1 mg/dL above the upper limit of normal), (2) a greater than 30 percent decline in creatinine clearance, (3) urinary calcium greater than 400g/day, (4) bone mineral density measured at any of three sites (radius, spine, or hip) is greater than 2.5 SD below those of gender- and race-matched, but not age-matched, controls (i.e., peak bone density or T-score [rather than Z-score] < 2.5) and (5) age less than 50 years. The panel still recommends exercising caution in using neuropsychologic abnormalities, cardiovascular disease, gastrointestinal symptoms, menopause, and elevated serum or urine indices of increased bone turnover as sole indications for parathyroidectomy.

Although bisphosphonates and calcimimetics show promise in the treatment of patients with PHPT, these therapies are experimental, long-term outcome data is lacking, and their routine use is not advocated. Parathyroidectomy also is more cost-effective than medical follow up within 5 years of initial treatment. Therefore, it is recommended that parathyroidectomy should be offered to virtually all patients, except those in whom the operative risks are prohibitive. Patients who do not undergo surgery should undergo routine follow-up consisting of biannual calcium measurements and annual measurements of bone mineral density and serum creatinine.

Preoperative localization tests. The diagnosis of PHPT is a metabolic one and localization studies should not be used to make or confirm it. Most endocrine surgeons agree that localization studies are mandatory and invaluable prior to any redo-parathyroid surgery, but their utility prior to initial neck exploration continues to be controversial. There also is little consensus on which localization studies should be used. 99m Technetium-labeled sestamibi is the most widely used and accurate modality, with a sensitivity greater than 80 percent for detection of parathyroid adenomas. Sestamibi scans are generally complemented by neck ultrasound, which can identify adenomas with greater than 75 percent sensitivity in experienced centers, and is most useful in identifying intrathyroidal parathyroids. Single-photon emission computed tomography (SPECT), when used with planar sestamibi, has particular utility in the evaluation of ectopic parathyroid adenomas, such as those located deep in the neck or in the mediastinum. Specifically, SPECT can indicate whether an adenoma is located in the anterior or posterior mediastinum (aortopulmonary window), thus enabling the surgeon to modify the operative approach accordingly. CT and MRI scans are less sensitive than sestamibi scans, but are helpful in localizing mediastinal glands. Intraoperative parathyroid hormone was initially introduced in 1993, and is used to determine the adequacy of parathyroid resection. According to one commonly used criterion, when the PTH falls by 50 percent or more in 10 min after removal of a parathyroid tumor, as compared to the highest prerule value, the test is considered positive and the operation is terminated. Although preoperative localization studies and intraoperative PTH have become widely used since their inception, long-term outcome data and cost-effectiveness studies are needed before their routine use can be recommended.

Operative Approaches

When unilateral parathyroid exploration was first carried out, the choice of side to be explored was random, but the introduction of preoperative localization studies has enabled a more directed approach. The focused approach identifies only the enlarged parathyroid gland and no attempts are made to locate other normal parathyroid glands. Unilateral neck explorations have several advantages over bilateral neck exploration, including reduced operative times and complications, such as injury to the recurrent laryngeal nerve and hypoparathyroidism. However, most existing studies comparing the two approaches are retrospective and do not analyze the results on an intention-to-treat basis. The issues relating to optimal approach will only be resolved by a large, prospective, multicenter study or by improved molecular analytic techniques. Similarly, although various videoscopic and video-assisted techniques of parathyroidectomy currently are in use, they also are associated with

increased operating times, often require more personnel, are expensive, and have, in general, not been useful for patients with multiglandular disease.

The practice of these authors involves obtaining both a sestamibi scan and neck ultrasound in patients with PHPT. Studies show that if both studies independently identify the same enlarged parathyroid gland, and no other gland, it is indeed the abnormal gland in approximately 95 percent of cases. These patients with sporadic PHPT are candidates for a focused neck exploration. A standard bilateral neck exploration is planned if parathyroid localization studies or intraoperative parathyroid hormone are not available; if the localizing studies fail to identify any abnormal parathyroid gland, or identify multiple abnormal glands, in patients with a family history of PHPT, MEN1, or MEN 2A; or if there is a concomitant thyroid disorder that requires bilateral exploration.

Conduct of Parathyroidectomy (Standard Bilateral Exploration)

The procedure is usually performed under general anesthesia. For a bilateral exploration, the neck is explored via a 3–4-cm incision just caudal to the cricoid cartilage. The initial dissection and exposure is similar to that used for thyroidectomy. After the strap muscles are separated in the midline, one side of the neck is chosen for exploration. During parathyroidectomy, the dissection is maintained lateral to the thyroid, making it easier to identify the parathyroid glands and not disturb their blood supply.

Identification of the parathyroid glands. A bloodless field is important to enable identification of parathyroid glands. The middle thyroid veins are ligated and divided, thus enabling medial and anterior retraction of the thyroid lobe. This may be facilitated by a peanut sponge or placement of 2-0 silk sutures into the thyroid substance. The space between the carotid sheath and thyroid is then opened by gentle sharp and blunt dissection, from the cricoid cartilage superiorly to the thymus inferiorly and the RLN is identified. Approximately 85 percent of the parathyroid glands are found within 1 cm of the junction of the inferior thyroid artery and recurrent laryngeal nerves. Parathyroid glands are partly surrounded by fat, therefore, any fat lobule at typical parathyroid locations should be explored, because the normal or abnormal parathyroid gland may be concealed in the fatty tissue. The thin fascia overlying a “suspicious” fat lobule should be incised using a sharp, curved hemostat and scalpel. This maneuver often causes the parathyroid gland to “pop” out. Alternatively, gentle, blunt peanut sponge dissection between the carotid sheath and the thyroid gland often reveals a “float” sign, suggesting the site of the abnormal parathyroid gland.

Several characteristics, such as size (> 7 mm), weight, and color, are used to distinguish normal from hypercellular parathyroid glands. Hypercellular glands are generally darker, more firm, and more vascular than normocellular glands. Because no single method is 100 percent reliable, the parathyroid surgeon must rely on experience, and sometimes a good pathologist, to help distinguish normal from hypercellular glands. Although several molecular studies have shown utility in distinguishing parathyroid adenomas from hyperplasia, this determination must also be made by the surgeon intraoperatively by documenting the presence of a normal parathyroid gland.

Location of parathyroid glands. The majority of lower parathyroid glands are found in proximity to the lower thyroid pole. If not found at this location, the thyrothymic ligament and thymus should be mobilized and explored. The carotid sheath should also be opened from the bifurcation to the base of the neck

if the parathyroid tumor cannot be found. If these maneuvers are unsuccessful, an intrathyroidal gland should be sought by using intraoperative ultrasound, incising the thyroid capsule on its posterolateral surface, or by performing an ipsilateral thyroid lobectomy and “bread-loafing” the thyroid lobe. Preoperative or intraoperative ultrasonography can be useful for identifying intrathyroidal parathyroid glands. Rarely, the third branchial pouch may maldescend and be found high in the neck (undescended parathymus), anterior to the carotid bulb, along with the missing parathyroid gland. Upper parathyroid glands are more consistent in position and are usually found near the junction of the upper and middle thirds of the gland, at the level of the cricoid cartilage. Ectopic upper glands may be found in the carotid sheath, tracheoesophageal groove, in the retroesophageal, or in the posterior mediastinum. Treatment depends on the number of abnormal glands.

A single adenoma is presumed to be the cause of a patient’s primary HPT if only one parathyroid tumor is identified and the other parathyroid glands are normal, a situation present in approximately 80 percent of patients with PHPT. Adenomas typically have an atrophic rim of normal parathyroid tissue, but this characteristic may be absent. If two abnormal and two normal glands are identified, the patient has double adenomas. Triple adenomas are present if three glands are abnormal and one is normal. Multiple adenomas are more common in older patients with an incidence of up to 10 percent in patients more than 60 years old. The abnormal glands should be excised, provided the remaining glands are confirmed as such, thus excluding asymmetric hyperplasia, after biopsy and frozen section.

If all parathyroid glands are enlarged or hypercellular, patients have parathyroid hyperplasia, which has been shown to occur in approximately 15 percent of patients in various series. These glands are often lobulated, usually lack the rim of normal parathyroid gland seen in adenomas, and may be variable in size. It is often difficult to distinguish multiple adenomas from hyperplasia with variable gland size. Hyperplasia may be of the chief cell (more common), mixed, or clear-cell type. Patients with hyperplasia may be treated by subtotal parathyroidectomy or by total parathyroidectomy and autotransplantation. Initial studies demonstrated equivalent cure rates and postoperative hypocalcemia for the two techniques, with the latter having the added advantage of avoiding recurrence in the neck. However, subtotal parathyroidectomy is preferred because autotransplanted tissue may fail to function in approximately 5 percent of cases.

For patients with hyperplasia, a titanium clip is placed across the most normal gland, leaving a 50-mg remnant and taking care to avoid disturbing the vascular pedicle. If the remnant appears to be viable, the remaining glands are resected. If there is any question regarding the viability of the initially subtotally resected gland, another gland is chosen for subtotal resection and the initial remnant is removed. Bilateral upper cervical thymectomy also is routinely performed because supernumerary glands occur in up to 20 percent of patients. Whenever multiple parathyroids are resected, it is preferable to cryopreserve tissue. Parathyroid tissue usually is transplanted into brachioradialis muscle of the nondominant forearm. Pockets are made in the belly of the muscle and one to two pieces of parathyroid tissue, measuring 1 mm each, are placed into each pocket. Twelve to 14 pieces are transplanted.

Indications for Sternotomy

A median sternotomy may be necessary to locate a missing gland only after a complete search has been conducted in the neck. A sternotomy is not usually

recommended at the initial operation, unless the calcium level is greater than 13 mg/dL. Rather, it is preferred to biopsy the normal glands and subsequently close the patient's neck and obtain localizing studies, if they were not obtained previously.

Special Situations

Parathyroid carcinoma. Parathyroid cancer accounts for approximately 1 percent of the cases of PHPT. It may be suspected preoperatively by the presence of severe symptoms, serum calcium levels greater than 14 mg/dL, significantly elevated PTH levels, and a palpable parathyroid gland. Local invasion is common, as are lymph node and distant metastases. Intraoperatively, parathyroid cancer is suggested by the presence of a large, gray-white to gray-brown parathyroid tumor that is adherent to or invasive into surrounding tissues such as muscle, thyroid, recurrent laryngeal nerve, trachea, or esophagus. Enlarged lymph nodes also may be present. Accurate diagnosis necessitates histologic examination, which reveals local tissue invasion, vascular or capsular invasion, trabecular or fibrous stroma, and frequent mitoses.

Treatment of parathyroid cancer consists of bilateral neck exploration, with en bloc excision of the tumor and the ipsilateral thyroid lobe. Modified radical neck dissection is recommended in the presence of lymph node metastases. Radiation and chemotherapy can be considered in patients with unresectable disease. Bisphosphonates and calcimimetic drugs may also be effective in long-term palliation.

Familial HPT. These patients generally have a higher incidence of multiglandular disease, supernumerary glands, and recurrent or persistent disease. Therefore, they warrant a more aggressive approach and are not candidates for various focused surgical approaches. Localization studies can be obtained to identify potential ectopic glands. A standard bilateral neck exploration is performed, along with a bilateral cervical thymectomy, regardless of the results of localization studies. Both subtotal parathyroidectomy and total parathyroidectomy with autotransplantation are appropriate, and parathyroid tissue should also be cryopreserved. If an adenoma is found in patients with familial HPT, the adenoma and the ipsilateral normal parathyroid glands are resected. The normal-appearing glands on the contralateral side are biopsied and marked, so that only one side of the neck will need to be explored in the event of recurrence. In patients with MEN 2A, HPT is less aggressive. Hence, only abnormal parathyroid glands need to be resected at neck exploration.

Parathyromatosis. Parathyromatosis is a rare condition characterized by the finding of multiple nodules of hyperfunctioning parathyroid tissue throughout the neck and mediastinum, usually following a previous parathyroidectomy. The true etiology of parathyromatosis is not known. Parathyromatosis represents a rare cause of persistent or recurrent HPT and can be identified intraoperatively. Aggressive local resection of these deposits can result in normocalcemia, but is rarely curative. Some studies suggest that these patients have low-grade carcinoma because of invasion into muscle and other structures distant from the resected parathyroid tumor.

Persistent and Recurrent Hyperparathyroidism

Persistence is defined as hypercalcemia that fails to resolve after parathyroidectomy and is more common than recurrence, which refers to HPT occurring after an intervening period of at least 6 months of biochemically documented

normocalcemia. The most common causes for both these states include ectopic parathyroids, unrecognized hyperplasia, supernumerary glands, subtotal resection of a parathyroid tumor, parathyroid cancer, and parathyromatosis. More rare causes include parathyroid carcinoma, missed adenoma in a normal position, incomplete resection of an abnormal gland, and an inexperienced surgeon. The most common sites of ectopic parathyroid glands in patients with persistent or recurrent HPT are paraesophageal (28 percent), mediastinal (26 percent), intrathymic (24 percent), intrathyroidal (11 percent), carotid sheath (9 percent), and high cervical or undescended (2 percent).

Once the diagnosis of persistent or recurrent HPT is suspected, it should be confirmed by the necessary biochemical tests. In particular, a 24-hour urine collection should be performed to rule out benign familial hypocalciuric hypercalcemia (BFHH). In redo parathyroid surgery, the glands are more likely to be in ectopic locations and postoperative scarring tends to make the procedure more technically demanding. Cure rates are generally lower (80–90 percent as compared with 95–99 percent for initial operation) and risk of injury to RLNs and permanent hypocalcemia are higher. Therefore, an evaluation of severity of HPT and the patient's anesthetic risk is important. High-risk patients whose tumors cannot be identified by localization studies may benefit from nonoperative management such as calcimimetic drugs or angiographic embolization.

Preoperative localization studies are routinely performed. Noninvasive studies, such as a sestamibi scan, ultrasound, and MRI, are recommended and reportedly have a combined accuracy of approximately 85 percent for these studies in cases of persistent or recurrent HPT. If these studies are negative or equivocal, highly selective venous catheterization for PTH levels is performed. Previous operative notes and pathology reports should be carefully reviewed and reconciled with the information obtained from localization studies. Generally, these patients are approached with a focused exploration with intraoperative PTH measurement to reduce the risk of complications.

Hypercalcemic Crisis

Patients with primary HPT may occasionally present acutely with nausea, vomiting, fatigue, muscle weakness, confusion and a decreased level of consciousness; a complex referred to as hypercalcemic crisis. This condition results from severe hypercalcemia from uncontrolled PTH secretion, worsened by polyuria, dehydration, and reduced kidney function, and may occur with other conditions causing hypercalcemia. Calcium levels are markedly elevated and may be as high as 16–20 mg/dL. Parathyroid glands are always large or multiple, and the tumor may be palpable. Patients with parathyroid cancer or familial HPT are more likely to present with hyperparathyroid crisis. Treatment consists of therapies to lower serum calcium levels followed by surgery to correct hyperparathyroidism.

Secondary Hyperparathyroidism

Secondary HPT commonly occurs in patients with chronic renal failure but may also occur in those with hypocalcemia secondary to inadequate calcium or vitamin D intake, or malabsorption. The pathophysiology of HPT in chronic renal failure is complex and is thought to be related to hyperphosphatemia (and resultant hypocalcemia), deficiency of 1,25-dihydroxy vitamin D as a result of loss of renal tissue, low calcium intake, decreased calcium absorption,

and abnormal parathyroid cell response to extracellular calcium or vitamin D in vitro and in vivo. Patients are generally hypocalcemic or normocalcemic. These patients are generally treated medically with a low-phosphate diet; phosphate binders; adequate intake of calcium and 1,25-dihydroxyvitamin D; and a high-calcium, low-aluminum dialysis bath. Calcimimetics control parathyroid hyperplasia and osteitis fibrosa cystica associated with secondary HPT in animal studies, and decrease plasma PTH and total and ionized calcium levels in humans.

Surgical treatment is indicated and recommended for patients with bone pain, pruritus, and (1) a calcium-phosphate product greater than or equal to 70, (2) Ca greater than 11 mg/dL with markedly elevated PTH, (3) calciphylaxis, (4) progressive renal osteodystrophy, and (5) soft-tissue calcification and tumoral calcinosis. Calciphylaxis is a rare, limb- and life-threatening complication of secondary HPT characterized by painful (sometimes throbbing), violaceous and mottled lesions, usually on the extremities, which often become necrotic and progress to nonhealing ulcers, gangrene, sepsis, and death.

Patients should undergo routine dialysis to correct electrolyte abnormalities, especially in serum potassium levels. Localizations studies are unnecessary but can identify ectopic parathyroid glands. A bilateral neck exploration is indicated. The parathyroid glands in secondary HPT are characterized by asymmetric enlargement and nodular hyperplasia. These patients may be treated by subtotal resection, leaving about 50 mg of the most normal parathyroid gland or total parathyroidectomy and autotransplantation of parathyroid tissue into the brachioradialis muscle of the nondominant forearm. Upper thymectomy usually is performed because 15–20 percent of patients have one or more parathyroid glands situated in the thymus or perithymic fat.

Tertiary Hyperparathyroidism

Tertiary hyperparathyroidism is seen most commonly in patients with long-standing renal dysfunction who undergo successful renal transplantation. Generally, renal transplantation is an excellent method of treating secondary HPT, but some patients develop autonomous parathyroid gland function and tertiary HPT. Tertiary HPT can cause problems similar to PHPT, such as pathologic fractures, bone pain, renal stones, peptic ulcer disease, pancreatitis, and mental status changes. The transplanted kidney is also at risk.

Operative intervention is indicated for symptomatic disease or if autonomous PTH secretion persists for more than 1 year after a successful transplant. All parathyroid glands should be identified. The traditional surgical management of these patients consisted of subtotal or total parathyroidectomy with autotransplantation. However, more recent studies suggest that these patients derive similar benefit from excision of only obviously enlarged glands, although avoiding the higher risks of hypocalcemia associated with the former approach. It is recommended that all parathyroid glands be identified. If one gland is distinctly abnormal and others minimally abnormal, the abnormal gland and the more-normal gland on the same side should be resected with the remaining parathyroids marked. If all the glands are abnormal, a subtotal parathyroidectomy should be performed with upper thymectomy.

COMPLICATIONS OF PARATHYROID SURGERY

Parathyroidectomy can be accomplished successfully in greater than 95 percent of patients with minimal mortality and morbidity, provided the procedure is

performed by a surgeon experienced in parathyroid surgery. General complications are similar to those for thyroidectomy. Specific complications include transient and permanent vocal cord palsy and hypoparathyroidism. The latter is more likely to occur in patients who undergo four-gland exploration with biopsies, subtotal resection with an inadequate remnant, or total parathyroidectomy with a failure of autotransplanted tissue. Furthermore, hypocalcemia is more likely to occur in patients with high turnover bone disease as evidenced by elevated preoperative alkaline phosphatase levels. Vocal cord paralysis and hypoparathyroidism are considered permanent if they persist for more than 6 months. Fortunately, these complications are rare, occurring in approximately 1 percent of patients undergoing surgery by experienced parathyroid surgeons.

Patients with symptomatic hypocalcemia or those with calcium levels less than 8 mg/dL are treated with oral calcium supplementation (up to 1–2 g every 4 h). 1,25-Dihydroxy vitamin D (Rocaltrol 0.25–0.5 μ g bid) may also be required, particularly in patients with severe hypercalcemia and elevated serum alkaline phosphatase levels preoperatively and with osteitis fibrosa cystica. Intravenous calcium supplementation is rarely needed, except in cases of severe, symptomatic hypocalcemia. Caution should be exercised in its administration because extravasation from the vein can cause extensive tissue necrosis.

HYPOPARATHYROIDISM

The parathyroid glands may be congenitally absent in the DiGeorge syndrome, which also is characterized by lack of thymic development, and, therefore, a thymus-dependent lymphoid system. Hyperparathyroidism in pregnant women can lead to hypoparathyroidism in neonates from suppression of fetal parathyroid tissue. By far, the most common cause of hypoparathyroidism is thyroid surgery, particularly total thyroidectomy with a concomitant central neck dissection. Patients often develop transient hypocalcemia as a result of bruising or damage to the vascular supply of the glands; permanent hypoparathyroidism is uncommon. Hypoparathyroidism may also occur after parathyroid surgery, which is more likely if patients have parathyroid hyperplasia and undergo a subtotal resection or total parathyroidectomy with parathyroid autotransplantation. Parathyroid tissue should be cryopreserved in any patient who could develop hypoparathyroidism, but is only needed in approximately 2 percent of patients.

Acute hypocalcemia results in decreased ionized calcium and increased neuromuscular excitability. Patients initially develop circumoral and fingertip numbness and tingling. Mental symptoms include anxiety, confusion, and depression. Physical examination reveals positive Chvostek sign (contraction of facial muscles elicited by tapping on the facial nerve anterior to the ear) and Trousseau sign (carpopedal spasm, which is elicited by occluding blood flow to the forearm with a blood pressure cuff for 2–3 min). Tetany, which is characterized by tonic–clonic seizures, carpopedal spasm, and laryngeal stridor, may prove fatal. Most patients with postoperative hypocalcemia can be treated with oral calcium and vitamin D supplements. Intravenous calcium infusion rarely is required.

ADRENAL/EMBRYOLOGY

The adrenal glands consist of an outer cortex and an inner medulla. The cortex originates around the fifth week of gestation from mesodermal tissue near the gonads on the adrenogenital ridge. Therefore, ectopic adrenocortical tissue

may be found in the ovaries, spermatic cord, and testes. In contrast, the adrenal medulla is ectodermal in origin and arises from the neural crest. At around the same time as cortical development, neural crest cells migrate to the para-aortic and paravertebral areas and toward the medial aspect of the developing cortex to form the medulla. Adrenal medullary tissue may also be found in neck, urinary bladder, and para-aortic regions.

ANATOMY

The adrenal glands are paired, retroperitoneal organs located superior and medial to the kidneys at the level of the eleventh ribs. The normal adrenal gland measures $5 \times 3 \times 1$ cm and weighs 4–5 g. Each gland is supplied by three groups of vessels: the superior adrenal arteries derived from the inferior phrenic artery, the middle adrenal arteries derived from the aorta, and the inferior adrenal arteries derived from the renal artery. Other vessels originating from the intercostal and gonadal vessels may also supply the adrenals. These arteries branch into about 50 arterioles to form a rich plexus beneath the glandular capsule. In contrast to the arterial supply, each adrenal usually is drained by a single, major adrenal vein. The right adrenal vein usually is short and drains into the inferior vena cava, whereas the left adrenal vein is longer and empties into the left renal vein after joining the inferior phrenic vein. Accessory veins occur in 5–10 percent of patients.

The adrenal cortex accounts for approximately 80–90 percent of the gland's volume and is divided into three zones: zona glomerulosa (site of aldosterone production), zona fasciculata, and zona reticularis. The latter zones are the site of production of glucocorticoids and adrenal androgens. The adrenal medulla constitutes up to 10–20 percent of the gland's volume and produces the catecholamine hormones epinephrine and norepinephrine. The cells of the adrenal medulla often are referred to as chromaffin cells because they stain specifically with chromium salts.

PHYSIOLOGY

Cholesterol, derived from the plasma or synthesized in the adrenal, is the common precursor of all steroid hormones derived from the adrenal cortex. Cholesterol is initially cleaved within mitochondria to 5- δ -pregnenolone, which, in turn, is transported to the smooth endoplasmic reticulum where it forms the substrate for various biosynthetic pathways leading to steroidogenesis.

The major adrenal mineralocorticoid hormones are aldosterone, 11-deoxycorticosterone (DOC), and cortisol. Cortisol has minimal effects on the kidney because of hormone degradation. Aldosterone secretion is regulated primarily by the renin–angiotensin system. Decreased renal blood flow, decreased plasma sodium and increased sympathetic tone, all stimulate the release of renin from juxtaglomerular cells. Renin, in turn, leads to the production of angiotensin I from its precursor angiotensinogen. Angiotensin I is cleaved by pulmonary angiotensin-converting enzyme (ACE) to angiotensin II, which is not only a potent vasoconstrictor, but also leads to increased aldosterone synthesis and release. Hyperkalemia is another potent stimulator of aldosterone synthesis, whereas ACTH, pituitary pro-opiomelanocortin (POMC), and antidiuretic hormone (ADH) are weak stimulators. Aldosterone functions mainly to increase sodium reabsorption and potassium and hydrogen ion excretion at the level of the renal distal convoluted tubule.

The secretion of cortisol, the major adrenal glucocorticoid, is regulated by ACTH secreted by the anterior pituitary, which in turn, is under the control of corticotrophin-releasing hormone (CRH) secreted by the hypothalamus. ACTH secretion may be stimulated by pain, stress, hypoxia, hypothermia, trauma, and hypoglycemia. ACTH secretion fluctuates, thus, there is a diurnal variation in the secretion of cortisol with peak cortisol excretion also occurring in the early morning and declining during the day to its lowest levels in the evening. Cortisol controls the secretion of both CRH and ACTH via a negative-feedback loop. Cortisol is transported in plasma bound primarily to cortisol-binding globulin (75 percent) and albumin (15 percent). Most of the cortisol metabolites are conjugated with glucuronic acid in the liver, thus facilitating their renal excretion. A small amount of unmetabolized cortisol is excreted unchanged in the urine. Cortisol also binds the mineralocorticoid receptor with an affinity similar to aldosterone. However, the specificity of mineralocorticoid action is maintained by the production of 11β -hydroxysteroid dehydrogenase, an enzyme that inactivates cortisol to cortisone in the kidney. Glucocorticoids have important functions in intermediary metabolism, but also affect growth and development and the connective tissue, immune, cardiovascular, renal, and central nervous systems.

Adrenal androgens are produced from 17-hydroxypregnenolone in response to ACTH stimulation. The adrenal androgens include dehydroepiandrosterone (DHEA) and its sulfated counterpart (DHEAS), androstenedione, and small amounts of testosterone and estrogen. Adrenal androgens exert their major effects by peripheral conversion to the more potent testosterone and dihydrotestosterone, but also have weak intrinsic androgen activity. During fetal development, adrenal androgens promote the formation of male genitalia, and are responsible for the development of secondary sexual characteristics at puberty.

Catecholamine hormones (epinephrine, norepinephrine, and dopamine) are produced both in the central and sympathetic nervous system and in the adrenal medulla from the substrate tyrosine. Phenylethanolamine-N-methyltransferase, which converts norepinephrine to epinephrine, is only present in the adrenal medulla and the organ of Zuckerkandl. Therefore, the primary catecholamine produced can be used to distinguish adrenal medullary tumors from those situated at extra-adrenal sites. Catecholamines are cleared by several mechanisms including reuptake by sympathetic nerve endings, peripheral inactivation by catechol-O-methyltransferase (COMT) and monoamine oxidase (MAO), and direct excretion by the kidneys. Metabolism of catecholamines leads to the formation of metabolites such as metanephrines, normetanephrines, and vanillylmandelic acid.

DISORDERS OF THE ADRENAL CORTEX

Hyperaldosteronism (Conn Syndrome)

Primary hyperaldosteronism results from autonomous aldosterone secretion, which, in turn, leads to suppression of renin secretion. Primary aldosteronism usually occurs in individuals between the ages of 30 and 50 years and accounts for 1 percent of cases of hypertension. It is usually associated with hypokalemia; however, more patients with Conn syndrome are being diagnosed with normal potassium levels. Most cases result from a solitary functioning adrenal adenoma (approximately 70 percent) and idiopathic bilateral hyperplasia (30 percent). Adrenocortical carcinoma and glucocorticoid

suppressible hyperaldosteronism are rare, each accounting for less than 1 percent of cases.

Symptoms and Signs

Patients typically present with hypertension, which is long-standing, moderate to severe, and may be difficult to control despite multiple-drug therapy. Other symptoms include muscle weakness, polydipsia, polyuria, nocturia, headaches, and fatigue.

Diagnostic Studies

Laboratory studies. Hyperaldosteronism must be suspected in any hypertensive patient who presents with coexisting spontaneous hypokalemia ($K < 3.2$ mmol/L), or hypokalemia (< 3 mmol/L) while on diuretic therapy, despite potassium replacements. However, up to 40 percent of patients may be normokalemic. Patients have an elevated plasma aldosterone concentration (PAC) level with a suppressed plasma renin activity (PRA); a PAC:PRA ratio of 25–30:1 is strongly suggestive of the diagnosis. Patients with primary hyperaldosteronism also fail to suppress aldosterone levels with sodium loading. This test can be performed by performing a 24-h urine collection for cortisol, sodium, and aldosterone after 5 days of a high-sodium diet, or, alternatively, by giving the patient a load of 2 L of saline while in the supine position, 2–3 days after being on a low-sodium diet. Plasma aldosterone levels less than 8.5 ng/mL or a 24-h urine aldosterone less than 14 μ g after saline loading essentially rules out primary hyperaldosteronism. Further evaluation should be directed at determining which patients have a unilateral aldosteronoma and will thus benefit from surgery.

Radiologic studies. CT scans with 0.5-cm cuts in the adrenal area can localize aldosteronomas with a sensitivity of 90 percent. A unilateral 0.5–2-cm adrenal tumor with a normal-appearing contralateral gland confirms an aldosteronoma in the presence of appropriate biochemical parameters. MRI scans are less sensitive, but more specific, particularly if opposed-phase chemical-shift images are obtained. Selective venous catheterization with adrenal vein sampling for aldosterone is 95 percent sensitive and 90 percent specific in localizing the aldosteronoma. A greater than 4-fold difference in the aldosterone:cortisol ratios between the adrenal veins indicates the presence of a unilateral tumor. Most groups advocate use of this modality selectively in ambiguous cases, when the tumor cannot be localized, and in patients with bilateral adrenal enlargement. Scintigraphy with ^{131}I -6 β -iodomethyl noriodocholesterol (NP-59) may also be used for the same purpose.

Treatment

Preoperatively, control of hypertension and adequate potassium supplementation (to keep $K > 3.5$ mmol/L) are important. Patients are generally treated with spironolactone (an aldosterone antagonist), amiloride (a potassium-sparing diuretic that blocks sodium channels in the distal nephron), nifedipine (a calcium channel blocker), or captopril (an ACE inhibitor). Unilateral tumors producing aldosterone are best managed by adrenalectomy, either by a laparoscopic approach (preferred) or via a posterior open approach, unless a carcinoma is suspected. For patients with bilateral hyperplasia, medical therapy with spironolactone, amiloride, or triamterene is the mainstay of management, with adrenalectomy reserved for patients with the most refractory cases. Patients

who respond to spironolactone therapy, and those with a shorter duration of hypertension with minimal end-organ (renal) damage, are more likely to achieve improvement in hypertension, whereas male patients, those older than age 50 years, and those with multiple adrenal nodules are least likely to benefit from adrenalectomy.

Cushing Syndrome

The term Cushing syndrome refers to a complex of symptoms and signs resulting from hypersecretion of cortisol. In contrast, Cushing disease refers to a pituitary tumor, usually an adenoma, which leads to bilateral adrenal hyperplasia and hypercortisolism. Cushing syndrome (endogenous) is a rare disease, affecting 10 in 1 million individuals. It is more common in adults, but may occur in children. Women are more commonly affected than men (male-to-female ratio 1:8).

Cushing syndrome may be classified as ACTH-dependent or ACTH-independent (Table 37-3). Patients with major depression, alcoholism, pregnancy, chronic renal failure, or stress may also have elevated cortisol levels and symptoms of hypercortisolism. However, these manifestations resolve with treatment of the underlying disorder (pseudo-Cushing syndrome).

Primary adrenal hyperplasia may be micronodular, macronodular, or massively macronodular. Adrenal hyperplasia resulting from ACTH stimulation is usually macronodular (3-cm nodules). Primary pigmented nodular adrenocortical disease is a rare cause of ACTH-independent Cushing's syndrome, which is characterized by the presence of small (< 5 mm), black adrenal micronodules. Primary pigmented nodular adrenocortical disease may be associated with Carney complex (atrial myxomas, schwannomas, and pigmented nevi) and is thought to be immune related.

Symptoms and Signs

Progressive truncal obesity is the most common symptom, occurring in up to 95 percent of patients. Fat deposition also occurs in unusual sites, such as the supraclavicular space and posterior neck region, leading to the so-called buffalo hump. Purple striae often are visible on the protuberant abdomen. Rounding of the face secondary to thickening of the facial fat leads to moon facies, and thinning of subcutaneous tissue leads to plethora. There is an increase in fine

TABLE 37-3 Etiology of Cushing Syndrome

hair growth on the face, upper back, and arms, although true virilization is more commonly seen with adrenocortical cancers. Endocrine abnormalities include glucose intolerance, amenorrhea, and decreased libido or impotence. Large, purple striae on the abdomen or proximal extremities are most reliable for making the diagnosis. In children, Cushing syndrome is characterized by obesity and stunted growth. Patients with Cushing disease may also present with headaches, visual field defects, and panhypopituitarism. Hyperpigmentation of the skin, if present, suggests an ectopic ACTH-producing tumor with high levels of circulating ACTH.

Diagnostic Tests

The aims of these studies are 2-fold: to confirm the presence of Cushing syndrome and to determine its etiology.

Laboratory studies. The secretion of cortisol is episodic and has a diurnal variation, therefore a single measurement of the plasma cortisol level is unreliable in diagnosing Cushing syndrome. The overnight low-dose dexamethasone suppression test is used to screen patients—1 mg of a synthetic glucocorticoid (dexamethasone) is given at 11 PM and plasma cortisol levels are measured at 8 AM the following morning. Normal adults suppress cortisol levels less than 3 $\mu\text{g/dL}$, whereas most patients with Cushing syndrome do not. False-negative results may be obtained in patients with mild disease, therefore some authors consider the test positive only if cortisol levels are suppressed to less than 1.8 $\mu\text{g/dL}$. In patients with a negative test, but a high clinical suspicion, the classic low-dose dexamethasone (0.5 mg every 6 h for 8 doses, or 2 mg over 48 h) suppression test or urinary cortisol measurement should be performed. A urinary free cortisol excretion of less than 100 $\mu\text{g/dL}$ (in most laboratories) rules out hypercortisolism. Salivary cortisol measurements using commercially available kits are being increasingly used.

Once a diagnosis is established, further testing is aimed at determining the cause by measurement of plasma ACTH levels using immunoradiometric assay (normal 10–100 pg/mL). Elevated ACTH levels indicate adrenal hyperplasia as a result of Cushing disease (15–500 pg/mL) or CRH-secreting tumors, but the highest levels are found in patients with ectopic sources of ACTH (> 1000 pg/mL). In contrast, ACTH levels are characteristically suppressed (< 5 pg/mL) in patients with primary cortisol-secreting adrenal tumors. The high-dose dexamethasone suppression test is used to distinguish between the causes of ACTH-dependent Cushing syndrome (pituitary vs. ectopic). Bilateral petrosal vein sampling also is helpful for determining whether the patient has Cushing disease or ectopic Cushing syndrome. The CRH test also is helpful in determining the etiology of Cushing syndrome. Patients with a primary adrenal cause of hypercortisolism exhibit a blunted response (ACTH peak < 10 pg/mL), whereas those with ACTH-dependent Cushing syndrome demonstrate a higher elevation of ACTH (> 30 pg/mL).

Radiologic studies. CT and MRI scans of the abdomen can identify adrenal tumors with 95 percent sensitivity. They also are helpful in distinguishing adrenal adenomas from carcinomas. Adrenal adenomas appear darker than the liver on T2-weighted imaging. Radioscintigraphic imaging of the adrenals using NP-59 also can be used to distinguish adenoma from hyperplasia. Adrenal adenomas show increased uptake of NP-59 with suppression of uptake in the contralateral gland, whereas hyperplastic glands demonstrate bilateral uptake.

NP-59 scanning is most useful in identifying patients with adrenal source of hypercortisolism and primary pigmented micronodular hyperplasia.

Contrast-enhanced MRI scans of the brain are better than CT scans for identifying pituitary tumors (sensitivity 33–67 percent), although small microadenomas may still escape detection. Inferior petrosal sinus sampling for ACTH before and after injection of CRH has been helpful in this regard, and has a sensitivity approaching 100 percent. In patients suspected of having an ectopic tumor–producing ACTH, CT or MRI scans of the chest and anterior mediastinum should be performed first, followed by imaging of the neck, abdomen, and pelvis if the initial studies are negative.

Treatment

Unilateral laparoscopic adrenalectomy is the treatment of choice for patients with adrenal adenomas. Open adrenalectomy is reserved for large tumors (≥ 6 cm) or those suspected to be adrenocortical cancers. Bilateral adrenalectomy is curative for primary adrenal hyperplasia. The treatment of choice in patients with Cushing disease is transsphenoidal excision of the pituitary adenoma, although pituitary irradiation has been used for patients with persistent or recurrent disease after surgery. Stereotactic radiosurgery, which uses CT guidance to deliver high doses of radiotherapy to the tumor (photon or gamma knife) is being increasingly used. Patients who fail to respond to either treatment are candidates for pharmacologic therapy with adrenal inhibitors such as ketoconazole, metyrapone, or aminoglutethimide, or bilateral adrenalectomy. Patients with ectopic ACTH production are best managed by treating the primary tumor, including recurrences, if possible. Medical or surgical adrenalectomy also has been shown to be safe and effective in the management of patients with Cushing disease whose ectopic ACTH-secreting tumor cannot be localized.

Adrenocortical Cancer

Adrenal carcinomas are rare neoplasms with a worldwide incidence of 2 per 1 million. These tumors have a bimodal age distribution, with an increased incidence in children and in adults in the fourth and fifth decades of life. Functioning tumors are more common in women, whereas men are more likely to develop nonfunctioning carcinomas. The majority are sporadic, but adrenocortical carcinomas also occur in association with germline mutations of p53 (Li-Fraumeni syndrome) and MENIN (multiple endocrine neoplasia 1) genes. Loci on 11p (Beckwith-Wiedemann syndrome), 2p (Carney complex), and 9q also have been implicated.

Symptoms and Signs

Approximately 50 percent of adrenocortical cancers are nonfunctioning. The remaining secrete cortisol (30 percent), androgens (20 percent), estrogens (10 percent), aldosterone (2 percent), or multiple hormones (35 percent). Patients with functioning tumors often present with the rapid onset of Cushing syndrome accompanied by virilizing features. Nonfunctioning tumors more commonly present with an enlarging abdominal mass and abdominal pain. Rarely, weight loss, anorexia, and nausea may be present.

Diagnostic Tests

Diagnostic evaluation of these patients begins with measurement of serum electrolyte levels to rule out hypokalemia, an overnight 1-mg dexamethasone

suppression test and a 24-hour urine collection for cortisol, 17-ketosteroids, and catecholamines (to rule out pheochromocytomas). CT and MRI scans are used to image these tumors. The size of the adrenal mass on imaging studies is the single most important criterion to help diagnose malignancy. In the series reported by Copeland and associates, 92 percent of adrenal cancers were greater than 6 cm in diameter. CT imaging characteristics suggesting malignancy include tumor heterogeneity, irregular margins and the presence of hemorrhage and adjacent lymphadenopathy or liver metastases. Moderately bright signal intensity on T2-weighted images (adrenal mass-to-liver ratio 1.2:2.8), significant lesion enhancement, and slow washout after injection of gadolinium contrast also indicate malignancy, as does evidence of local invasion into surrounding structures such as the liver, blood vessels (inferior vena cava), and distant metastases.

Pathology

On gross examination, areas of hemorrhage and necrosis are often evident. Microscopically, cells are hyperchromatic and typically have large nuclei and prominent nucleoli. It is very difficult to distinguish benign adrenal adenomas from carcinomas by histologic examination alone. Other criteria supporting malignancy include invasion, distant metastases, the presence of aneuploidy, increased mitotic figures and production of androgens and 11-deoxysteroids.

Treatment

The most important predictor of survival in patients with adrenal cancer is the adequacy of resection. Therefore, adrenocortical carcinomas are treated by excision of the tumor en bloc, with any contiguously involved lymph nodes or organs, such as the diaphragm, kidney, pancreas, liver, or inferior vena cava. This is best accomplished by open adrenalectomy via a generous incision. Mitotane or o, p-DDD or 1,1-dichloro-2-(o-chlorophenyl)-2-(p-chlorophenyl) ethane, which is a derivative of the insecticide DDT, has adrenolytic activity and has been used in the adjuvant setting and for the treatment of unresectable or metastatic disease. Treatment with replacement doses of steroids is essential in patients receiving mitotane. The therapeutic effectiveness of these agents is conflicting and consistent improvement in survival rates are lacking.

Adrenocortical tumors commonly metastasize to the liver, lung, and bone. Surgical debulking is recommended for isolated, recurrent disease and has been demonstrated to prolong survival. Systemic chemotherapeutic agents used in this tumor include etoposide, cisplatin, doxorubicin, and, more recently, paclitaxel, but consistent responses are rare. Adrenocortical cancers also are relatively insensitive to conventional external beam radiation therapy. Ketoconazole, metyrapone, or aminoglutethimide may also be useful in controlling steroid hypersecretion.

Sex Steroid Excess

Adrenal adenomas or carcinomas that secrete adrenal androgens lead to virilizing syndromes. Although women with virilizing tumors develop hirsutism, amenorrhea, infertility, and other signs of masculinization, men with these tumors are more difficult to diagnose and hence usually present with disease in advanced stages. Children with virilizing tumors have accelerated growth, premature development of facial and pubic hair, acne, genital enlargement, and deepening of their voice. Feminizing adrenal tumors are less common and occur in men in the third to fifth decades of life.

Virilizing tumors produce excessive amounts of the androgen precursor, DHEA, which can be measured in plasma or urine as 17-ketosteroids. Patients with feminizing tumors also have elevated urinary 17-ketosteroids, in addition to increased estrogen levels. These tumors are treated by adrenalectomy. Malignancy is difficult to diagnose histologically, but is suggested by the presence of local invasion, recurrence, or distal metastases. Adrenolytic drugs, such as mitotane, aminoglutethimide, and ketoconazole, may be useful in controlling symptoms in patients with metastatic disease.

Congenital Adrenal Hyperplasia

This refers to a group of disorders that result from deficiencies, or complete absence, of enzymes involved in adrenal steroidogenesis. 21-Hydroxylase (CYP21A2) deficiency is the most common enzymatic defect, accounting for more than 90 percent of cases of CAH. This deficiency prevents the production of 11-deoxycortisol and 11-deoxycorticosterone from progesterone precursors. Deficiency of glucocorticoids and aldosterone leads to elevated ACTH levels and overproduction of adrenal androgens and corticosteroid precursors such as 17-hydroxyprogesterone and δ 4-androstenedione. These compounds are converted to testosterone in the peripheral tissues, thereby leading to virilization. Complete deficiency of 21-hydroxylase presents at birth with virilization, diarrhea, hypovolemia, hyponatremia, hyperkalemia, and hyperpigmentation. Partial enzyme deficiency may present at birth or later with virilizing features. These patients are less prone to the salt-wasting that characterizes complete enzyme deficiency.

The particular enzyme deficiency can be diagnosed by karyotype analysis and measurement of plasma and urinary steroids. Absence of 21-hydroxylase leads to increased plasma 17-hydroxyprogesterone and progesterone levels, because these compounds cannot be converted to 11-deoxycortisol and 11-deoxycorticosterone, respectively. CT, MRI, and iodocholesterol scans are generally used to localize the tumors.

These patients have traditionally been managed medically, with cortisol and mineralocorticoid replacement to suppress the hypothalamic–pituitary–adrenal axis. However, this often leads to iatrogenic hypercortisolism. More recently, bilateral laparoscopic adrenalectomy has been proposed as an alternative treatment for this disease and has been successfully performed in a limited number of patients.

DISORDERS OF THE ADRENAL MEDULLA

Pheochromocytomas

Pheochromocytomas are rare tumors with prevalence rates ranging from 0.3–0.95 percent in autopsy series, and approximately 1.9 percent in series using biochemical screening. They can occur at any age and have no gender predilection. Extra-adrenal tumors may be found at sites of sympathetic ganglia in the organ of Zuckerkandl, neck, mediastinum, abdomen, and pelvis. Pheochromocytomas often are called the “10 percent tumor,” because 10 percent are bilateral, 10 percent are malignant, 10 percent occur in pediatric patients, 10 percent are extra-adrenal, and 10 percent are familial.

Pheochromocytomas occur in families with MEN 2A and MEN 2B, in approximately 50 percent of patients. Both syndromes are inherited in an autosomal dominant fashion and are caused by germline mutations in the RET

proto-oncogene. Another familial cancer syndrome with an increased risk of pheochromocytomas includes von Hippel-Lindau disease, which also is inherited in an autosomal dominant manner. The incidence of pheochromocytomas in the syndrome is approximately 14 percent, but varies depending on the series. The gene causing von Hippel-Lindau disease has been mapped to chromosome 3p and is a tumor-suppressor gene. Pheochromocytomas also are included within the tumor spectrum of neurofibromatosis type 1 and other neuroectodermal disorders (Sturge-Weber syndrome and tuberous sclerosis), Carney syndrome and, rarely, in the MEN1 syndrome.

Symptoms and Signs

Headache, palpitations, and diaphoresis constitute the “classic triad” of pheochromocytomas. Symptoms such as anxiety, tremulousness, paresthesias, flushing, chest pain, shortness of breath, abdominal pain, nausea, vomiting, and others are nonspecific and may be episodic in nature. Cardiovascular complications may ensue. These symptoms can be incited by a range of stimuli including exercise, micturition, and defecation. The most common clinical sign is hypertension, which may be paroxysmal with intervening normotension, sustained with paroxysms, or sustained hypertension alone.

Diagnostic Tests

Pheochromocytomas are diagnosed by testing 24-h urine samples for catecholamines and their metabolites, and by determining plasma metanephrine levels. Urinary metanephrines are 98 percent sensitive and are also highly specific for pheochromocytomas, whereas vanillylmandelic acid (VMA) measurements are slightly less sensitive and specific. Because extra-adrenal sites lack phenylethanolamine-N-methyltransferase, these tumors secrete norepinephrine, whereas epinephrine is the main hormone secreted from adrenal pheochromocytomas. Recent studies have shown that plasma metanephrines are the most reliable tests to identify pheochromocytomas.

CT scans are 85–95 percent sensitive and 70–100 percent specific for pheochromocytomas and should image the region from the diaphragm to the aortic bifurcation so as to image the organ of Zuckerkandl. MRI scans are 95 percent sensitive and almost 100 percent specific for pheochromocytomas because these tumors have a characteristic appearance on T2-weighted images or after gadolinium. ¹³¹I radiolabeled MIBG is useful for localizing pheochromocytomas, especially those in ectopic positions.

Treatment

Alpha blockers such as phenoxybenzamine are started 1–3 weeks before surgery at doses of 10 mg twice daily, which may be increased to 300–400 mg/day. Beta blockers, such as propranolol at doses of 10–40 mg every 6–8 h, often need to be added preoperatively in patients who have persistent tachycardia and arrhythmias, but only after adequate α blockade and hydration to avoid the effects of unopposed alpha stimulation, i.e., hypertensive crisis and congestive heart failure. Patients should also be volume repleted preoperatively.

Adrenalectomy is the treatment of choice. The chief goal of surgery is to resect the tumor completely with minimal tumor manipulation or rupture of the tumor capsule. Surgery should be performed with both noninvasive and invasive monitors, including an arterial line and central venous lines. The common medications used for intraoperative blood pressure control include

nitroprusside, nitroglycerin, and phentolamine. Intraoperative arrhythmias are best managed by short-acting beta blockers such as esmolol. Pheochromocytomas less than 5 cm in diameter are currently safely resected laparoscopically, others require open adrenalectomy. In case of hereditary pheochromocytomas, unilateral adrenalectomy is recommended in the absence of obvious lesions in the contralateral adrenal gland, because the high incidence of an addisonian crisis in patients undergoing bilateral adrenalectomy. For patients with tumors in both adrenal glands, cortical-sparing subtotal adrenalectomy may be offered to preserve adrenocortical function and avoid the morbidity of bilateral total adrenalectomy.

THE ADRENAL INCIDENTALOMA

Adrenal lesions discovered during imaging performed for unrelated reasons are referred to as incidentalomas. The incidence of these lesions identified by CT scans ranges from 0.4–4.4 percent. Table 37-4 lists a multitude of lesions that are included in the differential diagnosis. Nonfunctional cortical adenomas account for the majority (36–94 percent) of adrenal incidentalomas in patients without a history of cancer. By definition, patients with incidentalomas do not have clinically overt Cushing syndrome, but subclinical Cushing syndrome is estimated to occur in approximately 8 percent of patients. Examination of the natural history of subclinical Cushing syndrome indicates that although most patients of this disorder remain asymptomatic, some do progress to clinically evident Cushing syndrome. The adrenal is a common site of metastases of lung and breast tumors, melanoma, renal cell cancer, and lymphoma.

Diagnostic Investigations

The diagnostic work-up of an adrenal incidentaloma is aimed at identifying functioning tumors and those at increased risk of being malignant. It is not necessary for asymptomatic patients whose imaging studies are consistent with obvious cysts, hemorrhage, myelolipomas, or diffuse metastatic disease to undergo additional investigations. All other patients should be tested for underlying hormonally active tumors by (1) low-dose (1 mg) overnight dexamethasone suppression test or 24-h urine cortisol to rule out subclinical Cushing syndrome; (2) a 24-h urine collection for catecholamines, metanephrines, vanillylmandelic acid, or plasma metanephrine to rule out pheochromocytoma; and (3) in hypertensive patients, serum electrolytes, plasma aldosterone, and plasma renin to rule out an aldosteronoma. Confirmatory tests can be performed based on the results of the initial screening studies.

TABLE 37-4 Differential Diagnosis of Adrenal Incidentaloma

Functioning lesions	Nonfunctioning lesions
<i>Benign</i>	<i>Benign</i>
Aldosteronoma	Cortical adenoma
Cortisol-producing adenoma	Myelolipoma
Sex-steroid-producing adenoma	Cyst
Pheochromocytoma	Ganglioneuroma
	Hemorrhage
<i>Malignant</i>	<i>Malignant</i>
Adrenocortical cancer	Metastasis
Malignant pheochromocytoma	

Determination of the malignant potential of an incidentaloma is more complicated. The risk of malignancy in an adrenal lesion is related to its size. Lesions greater than 6 cm in diameter have a risk of malignancy of approximately 35 percent. However, this size cutoff is not absolute because adrenal carcinomas also have been reported in lesions smaller than 6 cm. This has led to increased use of the imaging characteristics of incidentalomas on CT scan and MRI to predict malignancy. Unfortunately, these are not 100 percent reliable either. FNA biopsy has gained widespread use for the diagnosis of many endocrine lesions, but cannot be used to distinguish adrenal adenomas from carcinomas. This being said, FNA biopsy is useful in the setting of a patient with a history of cancer and a solitary adrenal mass. The positive predictive value of FNA biopsy in this situation has been shown to be almost 100 percent, although false-negative rates of up to 33 percent have been reported. Pheochromocytomas should be excluded prior to the procedure.

Management

Patients with functional tumors, as determined by biochemical testing, or with obviously malignant lesions, should undergo adrenalectomy. Operative intervention also is advised in patients with subclinical Cushing syndrome with suppressed plasma ACTH levels and elevated urinary cortisol levels because these patients are at high risk for progression to overt Cushing syndrome. Adrenalectomy also should be considered in patients with normal ACTH and urinary free cortisol if they are younger than 50 years old or have recent weight gain, hypertension, diabetes, or osteopenia.

For nonfunctional lesions that do not meet any of the above criteria, the risk of malignancy or malignant potential needs to be balanced with operative morbidity and mortality. Lesions larger than 6 cm, or those with suspicious features on imaging studies such as heterogeneity, irregular capsule, or adjacent nodes, should be treated by adrenalectomy because of the increased prevalence of malignancy in this group. Nonoperative therapy, with close periodic follow up is advised for lesions less than 4 cm in diameter with benign imaging characteristics. However, the management of lesions 4–6 cm in size with benign imaging features remains controversial; i.e., this group of patients can be treated with observation or surgery. Recommendations from various groups of endocrine surgeons regarding this “intermediate” group of patients are variable, with some advising adrenalectomy for tumors at cutoff sizes of 3, 4, or 5 cm.

However, several important points must be considered in the management of these patients. First, size criteria for malignancy are not definitive and are derived from a selected series of patients. Second, the actual size of adrenal tumors can be underestimated by at least 1 cm by modalities such as CT scans, because tumors are larger in a cephalocaudal axis. Third, the natural history of incidentalomas is variable and depends on the underlying diagnosis, age of the study population, and the size of the mass. The current recommendation of these authors concerning size threshold for adrenalectomy is 3–4 cm in young patients with no comorbidity, and 5 cm in older patients with significant comorbidity. Lesions that grow during follow up also are treated by adrenalectomy. Resection of solitary adrenal metastases in patients with a history of nonadrenal cancer, especially non-small cell lung and renal cancers, has been demonstrated to lead to prolonged patient survival. Suspected

adrenal metastases also may be resected for diagnosis or for palliation, if large and symptomatic in good-risk patients.

ADRENAL INSUFFICIENCY

Adrenal insufficiency may be primary, resulting from adrenal disease, or secondary, as a result of a deficiency of ACTH. The most commonly encountered causes of primary adrenal insufficiency are autoimmune disease, infections, and metastatic deposits. Spontaneous adrenal hemorrhage can occur in patients with fulminant meningococcal septicemia, and in this context is referred to as the Waterhouse-Friderichsen syndrome. It also can occur secondary to trauma, severe stress, infection, and coagulopathies. Exogenous glucocorticoid therapy with suppression of the adrenal glands is the most common cause of secondary adrenal insufficiency.

Symptoms and Signs

Acute adrenal insufficiency should be suspected in stressed patients with any of the relevant risk factors. It may mimic sepsis and presents with fever, nausea, vomiting, lethargy, mild abdominal pain, or severe hypotension. Chronic adrenal insufficiency may be more subtle, with symptoms such as fatigue, salt-craving, weight loss, nausea, vomiting, abdominal pain, and diarrhea. These patients may also appear hyperpigmented.

Diagnostic Studies and Treatment

Characteristic laboratory findings include hyponatremia, hyperkalemia, eosinophilia, mild azotemia, and fasting or reactive hypoglycemia. The peripheral blood smear may demonstrate eosinophilia in approximately 20 percent of patients. Adrenal insufficiency is diagnosed by the ACTH stimulation test. ACTH (250 μ g) is infused intravenously, and cortisol levels are measured at 0, 30, and 60 min. Peak cortisol levels less than 20 μ g/dL suggest adrenal insufficiency. ACTH levels also enable one to distinguish primary from secondary causes. Treatment measures should begin based on clinical suspicion alone, and initiated even before test results are obtained or the patient is unlikely to survive. Management includes volume resuscitation with at least 2–3 L of a 0.9 percent saline solution or 5 percent dextrose in saline solution. Dexamethasone (4 mg) should be administered intravenously. Hydrocortisone (100 mg IV every 6 h) may also be used, but it interferes with testing of cortisol levels. Once the patient has been stabilized, underlying conditions, such as infection, should be sought, identified, and treated. The ACTH stimulation test should be performed to confirm the diagnosis. Glucocorticoids can then be tapered to maintenance doses. Mineralocorticoids (fludrocortisone 0.05–0.1 mg daily) may be required once the saline infusions are discontinued.

ADRENAL SURGERY

Choice of Procedure

Adrenalectomy may be performed via an open or laparoscopic technique. In either approach, the gland may be approached anteriorly, laterally, or posteriorly via the retroperitoneum. Laparoscopic adrenalectomy has rapidly become the standard procedure of choice for the excision of most benign-appearing adrenal lesions less than 6 cm in diameter. The role of laparoscopic adrenalectomy

in the management of adrenocortical cancers is controversial. Although laparoscopic adrenalectomy appears to be feasible and safe for solitary adrenal metastasis (provided there is no local invasion and the tumor can be resected intact), open adrenalectomy is the safest option for suspected or known adrenocortical cancers and malignant pheochromocytomas.

Laparoscopic Adrenalectomy

Lateral Transabdominal Approach

The patient is placed in the lateral decubitus position and the operating table is flexed at the waist to open the space between the lower rib cage and the iliac crest. The surgeon and assistant both stand on the same side, facing the front of the patient. After pneumoperitoneum is created, four 10-mm trocars are placed between the mid-clavicular line medially and the anterior axillary line laterally, 1–2 fingerbreadths below the costal margin. A 30-degree laparoscope is inserted through the second port.

For a right adrenalectomy, a fan retractor is inserted through the most medial port to retract the liver. An atraumatic grasper and an L-hook cautery are inserted via the two lateral ports for the dissection. The right triangular ligament is divided and the liver is rotated medially. Rarely, the hepatic flexure of the colon may need mobilization during a right adrenalectomy. The right kidney is identified visually and by palpation with an atraumatic grasper. The adrenal gland is identified on the superomedial aspect of the kidney. Gerota fascia is incised with the hook cautery. Dissection of the adrenal is started superomedially and then proceeds inferiorly, dissecting around the adrenal in a clockwise manner. The peri-adrenal tissues are grasped or moved with a blunt grasper to facilitate circumferential dissection. Although early identification of the adrenal vein is helpful to facilitate mobilization and prevent injury, it can be dissected whenever it is safe to do so. The right adrenal vein is identified at its junction with the inferior vena cava, ligated with clips and divided using endoscopic scissors. There may be a second adrenal vein on the right. Generally, two clips are left on the vena cava side. Early ligation of the adrenal vein makes it easier to mobilize the gland, but may make subsequent dissection more difficult because of venous congestion. The arterial branches to the adrenal gland can be electrocoagulated, if small, or clipped and divided.

For a left adrenalectomy, the fan retractor is used to retract the spleen. The splenic flexure is mobilized early and the lateral attachments to the spleen and the tail of the pancreas are divided using the electrocautery. Gravity allows the spleen and the pancreatic tail to fall medially. The remainder of the dissection proceeds similar to that described for the right adrenal. In addition to the adrenal vein, the inferior phrenic vein, which joins the left adrenal vein medially, also needs to be dissected, doubly clipped, and divided. Once the dissection is complete, the area of the adrenal bed can be irrigated and suctioned. A drain is rarely necessary. The gland is placed in a nylon specimen bag, which is brought out via one of the ports after morcellation, if necessary.

Complications of Adrenal Surgery

General complications associated with laparoscopic adrenalectomy include wound and infection, urinary tract infections, and deep vein thrombosis. Patients with Cushing syndrome are more prone to infectious (incisional and

intraabdominal abscess) and thrombotic complications. Specific complications arising from the creation of pneumoperitoneum include injury to various organs from Veress needle and trocar insertion, subcutaneous emphysema, pneumothorax, and hemodynamic compromise. Excessive retraction and dissection may lead to bleeding from injury to the inferior vena cava and renal vessels, or from injury to surrounding organs, such as the liver, pancreas, spleen, and stomach. Postoperative hemodynamic instability may be evident in patients with pheochromocytomas and patients are at risk of adrenal insufficiency after bilateral adrenalectomy and sometimes after unilateral adrenalectomy (unrecognized Cushing syndrome or, very rarely, Conn syndrome). Long-term morbidity results mainly from injury to nerve roots during trocar insertion, which can lead to chronic pain syndromes or muscle weakness, although this is more of an issue in case of open procedures.

Approximately 30 percent of patients who undergo bilateral adrenalectomy for Cushing disease are at risk of developing Nelson syndrome from progressive growth of the preexisting pituitary tumor. This leads to increased ACTH levels, hyperpigmentation, visual field defects, headaches, and extraocular muscle palsies. Transsphenoidal pituitary resection is the initial mode of therapy, and external beam radiotherapy is used in patients with residual tumor or extrasellar invasion.

In his 1953 classic textbook entitled “The Surgery of Infancy and Childhood,” Dr. Robert E. Gross summarized the essential challenge of pediatric surgery: “Those who daily operate on adults, even with the greatest of skill, are sometimes appalled—or certainly are not at their best—when called on to operate on and care for a tiny patient. Something more than diminutive instruments or scaled-down operative manipulations are necessary to do the job in a suitable manner.” To this day, surgical residents often approach the pediatric surgical patient with a mix of fear and anxiety. Nonetheless, they generally complete their pediatric surgical experience with a clear sense of the enormous ability of children to tolerate large operations, and with a true appreciation for the precision required in their care both in the operating room and during the peri-operative period. The specialty has evolved considerably in its ability to care for the smallest of patients with surgical disorders, so that in-utero surgery is now an option in certain circumstances. Similarly, our understanding of the pathophysiology of the diseases that pediatric surgeons face has increased greatly to the point in which our focus has shifted from the developmental process defining the molecular or cellular signaling pathways that regulate tissue growth and differentiation. There are few specialties in all of medicine that provide the opportunity to intervene in such a positive manner in such a wide array of diseases, and to receive the most heartfelt appreciation possible from another human being—that of a parent whose child’s life has forever been improved.

GENERAL CONSIDERATIONS

Fluid and Electrolyte Balance

In managing the pediatric surgical patient, an understanding of fluid and electrolyte balance is critical, as the margin between dehydration and fluid overload is small. Several surgical diagnoses such as gastroschisis or short-gut syndrome, for instance, are characterized by a predisposition to fluid loss. Others require judicious restoration of intravascular volume to prevent cardiac failure; as in patients with congenital diaphragmatic hernia and associated pulmonary hypertension. It is important to realize that the infant’s physiologic day is approximately eight h in duration. A careful assessment of the individual patient’s fluid balance tally—showing fluid intake and output fluid out for the previous eight h—will prevent dehydration or fluid overload. Clinical signs of dehydration include tachycardia, reduced urine output, and a depressed fontanelle, lethargy, and poor feeding. Fluid overload is often manifested by the onset of new oxygen requirement, respiratory distress, tachypnea and tachycardia.

The infant is born with a surplus of body water, which is normally excreted by the end of the first week of life. At birth, fluid requirements are 65 mL/kg (750 to mL/m²) and increase to 100 mL/kg (1000 mL/m²) by the end of the first week. Daily maintenance fluids for most children can be estimated using the formula: 100 mL/kg for the first 10 kg plus 50 mL/kg for 11 to 20 kg plus 25 mL/kg for each additional kilogram of body weight thereafter. Because intravenous (I.V.) fluid orders are written as mL per h, this can be conveniently converted to

4 mL/kg/h up to 10 kg, add 2 mL/kg/h for 11 to 20 kg, and add 1 mL/kg/h for each additional kilogram body weight thereafter. For example, a 26-kg child has an estimated maintenance fluid requirement of $(10 \times 4) + (10 \times 2) + (6 \times 1) = 66$ mL/h in the absence of massive fluid losses or shock. Fluid for maintenance is generally provided as 5 percent dextrose in one-fourth normal saline. For short-term intravenous therapy, sodium 5 mEq/kg/day and potassium 2 mEq/kg/day will satisfy the daily need. Fluid and electrolyte losses secondary to protracted vomiting or diarrhea are corrected by modifying this formula according to the measured losses. In the infant the normal serum osmolality is between 280 and 290 mO/L. Newborns have the ability to concentrate their urine well by the fifth day of life; thus urine concentration and output must be considered when ordering intravenous (IV) fluids postoperatively. If the child has a significant ongoing fluid loss (e.g., from a nasogastric tube), it is best to properly replace that loss with IV fluids at least every 4h. A typical replacement formula is D5 one-half normal saline + 20 mEq KCl/Liter. Whatever the formula used to calculate fluid replacement for the infant or small child, the optimal strategy is to analyze serum electrolytes and fluid losses, and to replace the appropriate constituents precisely.

Blood Volume and Blood Replacement

A useful guideline for estimation of blood volume for the newborn infant is 85 mL/kg of body weight. When packed red blood cells (PRBC) are used, the transfusion requirement is calculated as 10 mL/kg, which roughly is equivalent to a 500-mL transfusion for a 70-kg adult. At our institution, the following formula is used to estimate the volume of blood to be replaced in mL:

$$(\text{Target Hematocrit} - \text{Current Hematocrit}) \times \text{weight (kg)} \times 80/65$$

In the child, coagulation deficiencies may assume clinical significance rapidly after extensive blood transfusion. It is advisable to have fresh frozen plasma and platelets available if more than 30 mL/kg have been transfused. Plasma is given in a dose of 10–20 mL/kg and platelets are given in a dose of 1 unit/5 kg. Each unit of platelets consists of 40–60 mL of fluid and the platelets can be spun down to a platelet “button” for infants who require restricted fluid administration. Following transfusion of PRBC to neonates with tenuous fluid balance, a single dose of a diuretic (such as furosemide 1mg/kg) may help to facilitate excretion of the extra fluid load.

Venous Access

Obtaining reliable vascular access in an infant or child is a major responsibility of the pediatric surgeon. The goal should always be to place the catheter in the least invasive, least risky, and least painful manner, and in a location that is most accessible and facilitates use of the catheter without complications for as long as needed. In infants, our general approach is to place a central venous catheter using a cutdown approach, either in the antecubital fossa, external jugular vein, facial vein, or proximal saphenous vein. If the internal jugular vein is used, we recommend placing a purse-string suture at the venotomy site if possible, to prevent venous occlusion. In infants over 2 kg and in older children, percutaneous access of the subclavian, internal jugular or femoral veins is possible in most cases, and central access is achieved using the Seldinger technique. The catheters are tunneled to an exit site separate

from the venotomy site. Regardless of whether the catheter is placed by a cutdown or percutaneous approach, a chest radiograph to confirm central location of the catheter tip and to exclude the presence of a pneumothorax or hemothorax is mandatory. When discussing the placement of central venous catheters with parents, it is important to note that the complication rate for central venous lines in children is high. The incidence of catheter-related sepsis or infection approaches 10 percent in many series. Superior or inferior vena caval occlusion is a significant risk, particularly in the smallest premature patients.

NECK MASSES

The management of neck masses in children is determined by their location and the length of time that they have been present. Neck lesions are found either in the midline or lateral compartments. Midline masses include thyroglossal duct remnants, thyroid masses, thymic cysts, or dermoid cysts. Lateral lesions include branchial cleft remnants, cystic hygromas, vascular malformations, salivary gland tumors, torticollis and lipoblastoma (a rare benign mesenchymal tumor of embryonal fat occurring in infants and young children). Enlarged lymph nodes and rare malignancies such as rhabdomyosarcoma can occur either in the midline or laterally.

RESPIRATORY SYSTEM

Congenital Diaphragmatic Hernia (Bochdalek)

Pathology

During formation of the diaphragm, the pleural and coelomic cavities remain in continuity by means of the pleuroperitoneal canal. The posterolateral communication is the last to be closed by the developing diaphragm. Failure of diaphragmatic development leaves a posterolateral defect known as a Bochdalek hernia. This anomaly is encountered more commonly on the left (80–90 percent). Incomplete development of the posterior diaphragm allows the abdominal viscera to fill the chest cavity. The abdominal cavity is small and underdeveloped and remains scaphoid after birth. Both lungs are hypoplastic, with decreased bronchial and pulmonary artery branching. Lung weight, lung volume, and deoxyribonucleic acid (DNA) content are also decreased, but these findings are more striking on the ipsilateral side. In many instances, evidence suggests that a paucity of surfactant is present, which compounds the degree of respiratory insufficiency. Amniocentesis with karyotypes may show chromosomal defects, especially trisomy 18 and 21. Associated anomalies, once thought to be uncommon, are identified in 40 percent of these infants, and most commonly involve the heart, brain, genitourinary system, craniofacial structures, or limbs.

Prenatal ultrasonography is successful in making the diagnosis of congenital diaphragmatic hernia (CDH) as early as 15 weeks gestation. Ultrasound findings include herniated abdominal viscera, abnormal anatomy of the upper abdomen, and mediastinal shift away from the herniated viscera. Accurate prenatal prediction of outcome for fetuses with CDH is very difficult. A useful index of severity for patients with left CDH is the lung-to-head ratio (LHR), which is the product of the length and the width of the right lung at the level of the cardiac atria divided by the head circumference (all measurements in millimeters). An LHR value of less than 1.0 is associated with a very poor

prognosis, whereas an LHR greater than 1.4 predicts a more favorable outcome.

Following delivery, the diagnosis of CDH is made by chest radiograph. The differential diagnosis includes congenital cystic adenomatoid malformation, in which the intrathoracic loops of bowel may be confused with multiple lung cysts. The vast majority of infants with CDH develop immediate respiratory distress, which is because of the combined effects of three factors. First, the air-filled bowel in the chest compresses the mobile mediastinum which shifts to the opposite side of the chest, compromising air exchange in the contralateral lung. Second, pulmonary hypertension develops. This phenomenon results in persistent fetal circulation, with resultant decreased pulmonary perfusion, and impaired gas exchange. Finally, the lung on the affected side is often markedly hypoplastic, such that it is essentially nonfunctional. Varying degrees of pulmonary hypoplasia on the opposite side may compound these effects. As a result, neonates with CDH are extremely sick, and the overall mortality in most series is approximately 50 percent.

Treatment

Many infants are symptomatic at birth because of hypoxia, hypercarbia, and metabolic acidosis. Prompt cardiorespiratory stabilization is mandatory. It is interesting that the first 24–48 h after birth are often characterized by a period of relative stability with high levels of PaO_2 and relatively good perfusion. This has been termed the “honeymoon period,” and is often followed by progressive cardiorespiratory deterioration in the majority of patients. In the past, correction of the hernia was felt to be a surgical emergency; therefore, these patients underwent surgery shortly after birth. It is now accepted that the presence of persistent pulmonary hypertension that results in right-to-left shunting across the open foramen ovale or the ductus arteriosus, and the degree of pulmonary hypoplasia, are the leading causes of cardiorespiratory insufficiency. Current management therefore is directed toward preventing or reversing the pulmonary hypertension, and minimizing barotrauma while optimizing oxygen delivery. To achieve this goal, infants are placed on mechanical ventilation using relatively low or “gentle” settings that prevent overinflation of the non-involved lung. Levels of PacO_2 in the range of 50–60 mmHg or higher are accepted as long as the pH remains greater than or equal to 7.25. If these objectives cannot be achieved using conventional ventilation, high frequency oscillatory ventilation (HFOV) may be employed to avoid the injurious effects of conventional tidal volume ventilation. Echocardiography is used to assess the degree of pulmonary hypertension, and to identify the presence of a coexisting cardiac anomaly. To minimize the degree of pulmonary hypertension, inhaled nitric oxide may be used. In certain patients, this agent significantly improves pulmonary perfusion, as manifested by improved oxygenation. Nitric oxide is administered into the ventilation circuit, and is used in concentrations up to 40 parts per million. Correction of acidosis using bicarbonate solution may minimize the degree of pulmonary hypertension. As the degree of pulmonary hypertension becomes hemodynamically significant, right sided heart failure develops and systemic perfusion is impaired. Administration of excess intravenous fluid will compound the degree of cardiac failure, and lead to marked peripheral edema. Inotropic support using epinephrine is therefore useful in optimizing cardiac contractility and maintaining mean arterial pressure.

Infants with CDH who remain severely hypoxic despite maximal ventilatory support may be candidates for treatment of their respiratory failure by extracorporeal membrane oxygenation (ECMO). Venovenous or venoarterial bypass is used. Venovenous bypass is established with a single cannula through the internal jugular vein, with blood removed from, and infused into, the right atrium via separate ports. Venoarterial bypass is used preferentially by some centers because it provides the cardiac support that is often needed. The right atrium is cannulated by means of the internal jugular vein and the aortic arch through the right common carotid artery. As much of the cardiac output is shunted through the membrane oxygenator as needed to provide oxygenated blood to the infant and remove carbon dioxide. The infant is maintained on bypass until the pulmonary hypertension is reversed and lung function, as measured by compliance, is improved. This is usually seen within 7–10 days, but in some infants it may take up to 3 weeks to occur. The use of ECMO is associated with significant risk. Because patients require systemic anticoagulation, bleeding complications are the most significant. Bleeding may occur intracranially or at the site of cannula insertion, and may be life threatening. Systemic sepsis is a significant problem that may force early decannulation. Criteria for placing infants on ECMO include the presence of normal cardiac anatomy by echocardiography, the absence of fatal chromosome anomalies, and the expectation that the infant would die without ECMO. Traditionally, a threshold weight greater than 2.5 kg and gestational age older than 34 weeks have been used to select patients for ECMO, although success has been achieved at weights as low as 1.8 kg. It is important to emphasize that although ECMO may salvage a population of neonates with refractory pulmonary hypertension, the use of this technique remains controversial. A strategy that does not involve the use of ECMO but instead emphasizes the use of permissive hypercapnia and the avoidance of barotrauma may provide similar overall outcome in patients with CDH. This observation likely reflects the fact that mortality in infants with CDH is related to the degree of pulmonary hypoplasia and the presence of congenital anomalies, neither of which can be corrected by ECMO.

The timing of CDH repair is controversial. In patients that are not placed on ECMO, most surgeons perform repair the defect once the hemodynamic status has been optimized. In neonates that are on bypass, some surgeons perform early repair on bypass; others wait until the infant's lungs are fully recovered, repair the diaphragm and discontinue bypass within h of surgery. Still others repair the diaphragm only after the infant is off bypass. Operative repair of the diaphragmatic hernia is best accomplished by an abdominal approach. Through a subcostal incision, the abdominal viscera are withdrawn from the chest, exposing the defect in the diaphragm. Care must be taken when reducing the spleen and liver, as bleeding from these structures can be fatal. The anterior margin is often apparent, although the posterior muscular rim is attenuated. If the infant is heparinized on bypass, minimal dissection of the muscular margins is performed. Electrocautery is used liberally to minimize postoperative bleeding. Most infants who require ECMO support prior to hernia repair have large defects, often lacking the medial and posterior margins. Prior to the availability of ECMO therapy, most of these infants died. About three fourths of infants repaired on bypass require prosthetic material to patch the defect, suturing it to the diaphragmatic remnant or around ribs or costal cartilages for the large defects. If there is adequate muscle for closure, a single layer of nonabsorbable suture is used to close the defect. Just before the repair

is complete, a chest tube may be positioned in the thoracic cavity. We tend to reserve the use of chest tubes for patients who are repaired on ECMO, as these patients are at risk for developing a hemothorax which can significantly impair ventilation. Anatomic closure of the abdominal wall may be impossible after reduction of the viscera. Occasionally a prosthetic patch of Gore-Tex or Surgisis may be sutured to the fascia to facilitate closure. The prosthetic patch can be removed at a later time and the ventral hernia closed at that time.

If the diaphragm has been repaired on ECMO, weaning and decannulation are accomplished as soon as possible. All infants are ventilated postoperatively to maintain preductal arterial oxygenation of 80–100 torr. Very slow weaning from the ventilator may be necessary to avoid recurrent pulmonary hypertension. Oscillatory ventilation may be switched to conventional ventilation as part of the process of weaning.

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) is characterized by progressive hyperexpansion of one or more lobes of the lung. It is diagnosed during the first few months of life and can be life-threatening in the newborn period; but in the older infant, it causes less respiratory distress. Air entering during inspiration is trapped in the lobe. On expiration, the lobe cannot deflate and progressively overexpands, causing atelectasis of the adjacent lobe or lobes. This hyperexpansion eventually shifts the mediastinum to the opposite side and compromises the other lung. CLE usually occurs in the upper lobes of the lung (left greater than right), followed next in frequency by the right middle lobe, but it also can occur in the lower lobes. It is caused by intrinsic bronchial obstruction from poor bronchial cartilage development or extrinsic compression. Approximately 14 percent of children with this condition have cardiac defects, with an enlarged left atrium or a major vessel compressing the ipsilateral bronchus. Symptoms range from mild respiratory distress to full-fledged respiratory failure with tachypnea, dyspnea, cough, and late cyanosis. These symptoms may be stationary or they may progress rapidly and result in recurrent pneumonia. Occasionally, infants with CLE present with failure to thrive, which likely reflects the increased work associated with the overexpanded lung. Diagnosis is made by chest radiograph, which shows a hyperlucent affected lobe with adjacent lobar compression and atelectasis with varying degrees of shift of the mediastinum to the opposite side and compression of the contralateral lung. If definitive diagnosis is unclear by chest radiograph, CT scan may be helpful. Unless foreign body or mucous plugging is suspected as a cause of hyperinflation, bronchoscopy is not advisable because it can produce more air trapping and cause life-threatening respiratory distress in a stable infant. Treatment consists of resection of the affected lobe. Unless symptoms necessitate urgent surgery, resection can usually be performed after the infant is several months of age. The prognosis is excellent.

Congenital Cystic Adenomatoid Malformation

This malformation consists of cystic proliferation of the terminal airway, producing cysts lined by mucus-producing respiratory epithelium, and elastic tissue in the cyst walls without cartilage formation. There may be a single cyst with a wall of connective tissue containing smooth muscle. Cysts may be large and multiple (type I), smaller and more numerous (type II), or they may resemble fetal lung without macroscopic cysts (type III). Most congenital

cystic adenomatoid malformation (CCAM) frequently occur in the left lower lobe. However, this lesion can occur in any lobe and may occur in both lungs simultaneously. In the left lower lobe, type I may be confused at birth with a congenital diaphragmatic hernia. Clinical symptoms may range from none at all to severe respiratory failure at birth. The cyst(s), whether single or multiple, can produce air trapping and may be confused with congenital lobar emphysema, pneumatoceles or even pulmonary sequestrations. They can also be involved with repeated infections and produce fever and cough in older infants and children. Prenatal ultrasound may suggest the diagnosis. At birth, the diagnosis often can be confirmed by chest radiograph; in certain cases, ultrasound or CT scan may be definitive. In the newborn period, ultrasound may also be useful, especially to distinguish between CCAM and congenital diaphragmatic hernia. Resection is curative and may need to be performed urgently in the infant with severe respiratory distress. Lobectomy is usually required. Prognosis is excellent.

Pulmonary Sequestration

Pulmonary sequestration is uncommon and consists of a mass of lung tissue, usually in the left lower chest, occurring without the usual connections to the pulmonary artery or tracheobronchial tree, yet with a systemic blood supply from the aorta. There are two kinds of sequestration. Extralobar sequestration consists of a small area of nonaerated lung separated from the main lung mass, with a systemic blood supply located immediately above the left diaphragm. It is commonly found in cases of CDH. Intralobar sequestration more commonly occurs within the parenchyma of the left lower lobe but can occur on the right. There is no major connection to the tracheobronchial tree, but a secondary connection may be established, perhaps through infection or via adjacent intrapulmonary shunts. The blood supply originates from the aorta, frequently below the diaphragm. Venous drainage of both types can be systemic or pulmonary. The cause of sequestration is unknown but most probably involves an abnormal budding of the developing lung that picks up a systemic blood supply and never becomes connected with the bronchus or pulmonary vessels. Extralobar sequestration is asymptomatic and is usually discovered incidentally on chest radiograph. Diagnosis of intralobar sequestration, on the other hand, is usually made after repeated infections manifested by cough, fever, and consolidation in the posterior basal segment of the left lower lobe. Increasingly the diagnosis is being made in the early months of life by ultrasound, and color Doppler often can be helpful in delineating the systemic arterial supply. Removal of the entire left lower lobe is usually necessary because the diagnosis often is made late after multiple infections. Occasionally the sequestered part of the lung can be removed segmentally. Prognosis is excellent.

Bronchogenic Cyst

Bronchogenic cysts can occur anywhere along the respiratory tract from the neck to the lung parenchyma. They can present at any age. Histologically, they are hamartomatous and usually consist of a single cyst lined with respiratory epithelium, containing cartilage and smooth muscle. They are probably embryonic rests of foregut origin that have been pinched off from the main portion of the developing tracheobronchial tree and are closely associated in causation with other foregut duplication cysts arising from the

esophagus. Bronchogenic cysts may be seen on prenatal ultrasound but are discovered most often incidentally on postnatal chest radiograph. Although they may be completely asymptomatic, bronchogenic cysts may, however, produce symptoms, depending on their anatomic location. In the paratracheal region of the neck they can produce airway compression and respiratory distress. In the lung parenchyma, they may become infected and present with fever and cough. In addition they may cause obstruction of the bronchial lumen with distal atelectasis and infection. They may also cause mediastinal compression. Rarely, rupture of the cyst can occur. Chest radiograph usually shows a dense mass, and computed tomography (CT) scan or magnetic resonance imaging (MRI) delineates the precise anatomic location of the lesion. Treatment consists of resection of the cyst, which may need to be undertaken in emergency circumstances for airway or cardiac compression. Resection can be performed either as an open procedure, or using a thoracoscopic approach.

ESOPHAGUS

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (EA) with tracheoesophageal fistula (TEF) is one of the most gratifying pediatric surgical conditions to treat. In the distant past, nearly all infants born with EA and TEF died. In 1939, Ladd and Leven performed the first successful repair by ligating the fistula, placing a gastrostomy and reconstructing the esophagus at a later time. Subsequently, Dr. Cameron Haight in Ann Arbor, Michigan, performed the first successful primary anastomosis for esophageal atresia, which remains the current approach for treatment of this condition. Despite the fact that there are several common varieties of this anomaly and the underlying cause remains obscure, a careful approach consisting of meticulous perioperative care and attention to the technical detail of the operation can result in an excellent prognosis in most cases.

Anatomic Varieties

There are five major varieties of EA and TEF. The most commonly seen variety is esophageal atresia with distal tracheoesophageal fistula (Type C), which occurs in approximately 85 percent of the cases in most series. The next most frequent is pure esophageal atresia (Type A), occurring in 8–10 percent of patients, followed by tracheoesophageal fistula without esophageal atresia (Type E). This type occurs in 8 percent of cases, and is also referred to as an H-type fistula, based on the anatomic similarity to that letter. Esophageal atresia with fistula between both proximal and distal ends of the esophagus and trachea (Type D) is seen in approximately 2 percent of cases, and type B, esophageal atresia with tracheoesophageal fistula between distal esophagus and trachea, is seen in approximately 1 percent of all cases.

Etiology and Pathologic Presentation

The esophagus and trachea share a common embryologic origin. They typically divide into separate tubes by approximately 36 days gestation. Failure to separate can result in a spectrum of anomalies. Recent studies have shed light on some of the molecular mechanisms underlying this condition. Mice deficient in the Sonic-hedgehog signaling pathway develop a phenotype which includes EA-TEF, suggesting a role for this molecule in the pathogenesis of the anomaly in humans. In support of this theory, Sonic-hedgehog transcripts

were absent in human esophageal samples obtained from infants with TEF. Similarly, tissue obtained from the fistula tract were found to express Thyroid transcription factor one (TTF-1) and fibroblast growth factor FGF-10), suggesting that the fistula is of respiratory origin. Although a genetic basis for EA-TEF has not been definitively established, reports indicate that this anomaly may occur in several generations of the same family. Twin studies also demonstrate the presence of esophageal atresia in sets of dizygotic twins.

Other congenital anomalies frequently occur in association with EA-TEF. These defects are known by the acronym VATER or VACTERRL syndrome, which refers to vertebral (missing vertebra) and anorectal (imperforate anus) anomalies, cardiac defects (severe congenital cardiac disease), tracheoesophageal fistula, renal anomalies (renal agenesis, renal anomalies), and radial limb hyperplasia. In nearly 20 percent of the infants born with esophageal atresia, some variant of congenital heart disease occurs.

Clinical presentation of infants with esophageal atresia and tracheoesophageal fistula. The anatomic variant of infants with EA-TEF predicts the clinical presentation. When the esophagus ends either as a blind pouch or as a fistula into the trachea (as in Types A, B, C, or D), infants present with excessive drooling, followed by choking or coughing immediately after feeding is initiated as a result of aspiration through the fistula tract. As the neonate coughs and cries, air is transmitted through the fistula into the stomach, resulting in abdominal distention. As the abdomen distends, it becomes increasingly more difficult for the infant to breathe. This leads to further atelectasis, which compounds the pulmonary dysfunction. In patients with type C and D varieties, the regurgitated gastric juice passes through the fistula, where it collects in the trachea and lungs and leads to a chemical pneumonitis, which further exacerbates the pulmonary status. In many instances, the diagnosis is actually made by the nursing staff who attempt to feed the baby and notice the accumulation of oral secretions.

The diagnosis of esophageal atresia is confirmed by the inability to pass an orogastric tube into the stomach. The dilated upper pouch may be occasionally seen on a plain chest radiograph. If a soft feeding tube is used, the tube will coil in the upper pouch, which provides further diagnostic certainty. An important alternative diagnosis that must be considered when an orogastric tube does not enter the stomach is that of an esophageal perforation. This problem can occur in infants after traumatic insertion of a nasogastric or orogastric tube. In this instance, the perforation classically occurs at the level of the piriform sinus, and a false passage is created which prevents the tube from entering the stomach. Whenever there is any diagnostic uncertainty, a contrast study will confirm the diagnosis of EA and occasionally document the TEF. The presence of a tracheoesophageal fistula can be demonstrated clinically by finding air in the gastrointestinal tract. This can be proven at the bedside by percussion of the abdomen, and confirmed by obtaining a plain abdominal radiograph. Occasionally, a diagnosis of EA-TEF can be suspected prenatally on ultrasound evaluation. Typical features include failure to visualize the stomach and the presence of polyhydramnios. These findings reflect the absence of efficient swallowing by the fetus.

In a child with esophageal atresia, it is important to identify whether co-existing anomalies are present. These include cardiac defects in 38 percent, skeletal defects in 19 percent, neurological defects in 15 percent, renal defects in 15 percent, anorectal defects in 8 percent, and other abnormalities

in 13 percent. Examination of the heart and great vessels with echocardiography is important to exclude cardiac defects, as these are often the most important predictors of survival in these infants. The echocardiogram also demonstrates whether the aortic arch is left sided or right sided, which may influence the approach to surgical repair. Vertebral anomalies are assessed by plain radiography, and a spinal ultrasound is obtained if any are detected. A patent anus should be confirmed clinically. The kidneys in a newborn may be assessed clinically by palpation. An ultrasound of the abdomen will demonstrate the presence of renal anomalies, which should be suspected in the child who fails to make urine. The presence of extremity anomalies is suspected when there are missing digits, and confirmed by plain radiographs of the hands, feet, forearms and legs. Rib anomalies may also be present. These may include the presence of a thirteenth rib.

Initial management. The initial treatment of infants with EA-TEF includes attention to the respiratory status, decompression of the upper pouch, and appropriate timing of surgery. Because the major determinant of poor survival is the presence of other severe anomalies, a search for other defects including congenital cardiac disease is undertaken in a timely fashion. The initial strategy after the diagnosis is confirmed is to place the neonate in an infant warmer with the head elevated at least 30 degrees. A sump catheter is placed in the upper pouch on continuous suction. Both of these strategies are designed to minimize the degree of aspiration from the esophageal pouch. When saliva accumulates in the upper pouch and is aspirated into the lungs, coughing, bronchospasm and desaturation episodes can occur, which may be minimized by ensuring the patency of the sump catheter. Intravenous antibiotic therapy is initiated, and warmed electrolyte solution is administered. Where possible, the right upper extremity is avoided as a site to start an intravenous line, as this location may interfere with positioning of the patient during the surgical repair.

The timing of repair is influenced by the stability of the patient. Definitive repair of the EA-TEF is rarely a surgical emergency. If the child is hemodynamically stable and is oxygenating well, definitive repair may be performed within 1–2 days after birth. This allows for a careful determination of the presence of coexisting anomalies, and for selection of an experienced anesthetic team.

Management of esophageal atresia and tracheoesophageal fistula in the preterm infant. The ventilated, premature neonate with EA-TEF and associated hyaline membrane disease represents a patient who may develop severe pulmonary disease. The tracheoesophageal fistula can worsen the fragile pulmonary status as a result of recurrent aspiration through the fistula, and of increased abdominal distention which impairs lung expansion. Moreover, the elevated airway pressure that is required to ventilate these patients can worsen the clinical course by forcing air through the fistula into the stomach, thereby exacerbating the degree of abdominal distention and compromising lung expansion. In this situation, the first priority is to minimize the degree of positive pressure needed to adequately ventilate the child. This can be accomplished using high frequency oscillatory ventilation (HFOV). If the gastric distention becomes severe, a gastrostomy tube should be placed. This procedure can be performed at the bedside under local anesthesia, if necessary. The dilated, air filled stomach can easily be accessed through an incision in the left-upper quadrant of the abdomen. Once the gastrostomy tube is placed, and the abdominal pressure is relieved, the pulmonary status can paradoxically worsen. This is

because the ventilated gas may pass preferentially through the fistula, which is the path of least resistance, and bypass the lungs thereby worsening the hypoxemia. To correct this problem, the gastrostomy tube may be placed under water seal, elevated or intermittently clamped. If these maneuvers are to no avail, ligation of the fistula may be required. This procedure can be performed in the neonatal intensive care unit if the infant is too unstable to be transported to the operating room. These interventions allow for the infant's underlying hyaline membrane disease to improve, for the pulmonary secretions to clear, and for the infant to reach a period of stability so that definitive repair can be performed.

Primary Surgical Correction

In a stable infant, definitive repair is achieved through performance of a primary esophago-esophagostomy. The infant is brought to the operating room, intubated, and placed in the lateral decubitus position with the right side up in preparation for a right posterolateral thoracotomy. If a right-sided arch was determined previously by echocardiography, consideration is given to performing the repair through the left chest, although most surgeons believe that the repair can be performed safely from the right side as well. Bronchoscopy may be performed to exclude the presence of additional, upper pouch fistulae in cases of esophageal atresia. This permits differentiation of types B, C and D variants, and identification of a laryngotracheoesophageal cleft.

The operative technique for primary repair is as follows: A retropleural approach is generally used, as this technique prevents widespread contamination of the thorax if a postoperative anastomotic leak occurs. The sequence of steps includes:

1. Mobilization of the pleura to expose the structures in the posterior mediastinum.
2. Division of the fistula and closure of the tracheal opening.
3. Mobilization of the upper esophagus sufficiently to permit an anastomosis without tension, and to determine whether a fistula is present between the upper esophagus and the trachea. Forward pressure by the anesthesia staff on the sump drain in the pouch can greatly facilitate dissection at this stage of the operation. Care must be taken when dissecting posteriorly to avoid violation of the lumen of either the trachea or esophagus.
4. Mobilization of the distal esophagus. This needs to be performed judiciously to avoid devascularization, because the blood supply to the distal esophagus is segmental from the aorta. Most of the esophageal length is obtained from mobilizing the upper pouch, because the blood supply travels via the submucosa from above.
5. Performing a primary esophago-esophageal anastomosis. Most surgeons perform this procedure in a single layer using 5-0 sutures. If there is excess tension, the muscle of the upper pouch can be circumferentially incised without compromising blood supply to increase its length. Many surgeons place a transanastomotic feeding tube to institute feeds in the early postoperative period.
6. A retropleural drain is placed, and the incision is closed in layers.

Postoperative Course

The postoperative management strategy of patients with EA-TEF is influenced to a great degree by the preference of the individual surgeon and the

institutional culture. Many surgeons prefer not to leave the infants intubated postoperatively, to avoid the effects of positive pressure on the site of tracheal closure. However, extubation may not be possible in babies with underlying lung disease either from prematurity or pneumonia, or when there is vocal cord edema. When a transanastomotic tube is placed, feeds are begun slowly in the postoperative period. Some surgeons institute parenteral nutrition for several days, using a central line. The retropleural drain is assessed daily for the presence of saliva, indicating an anastomotic leak. Many surgeons obtain a contrast swallow 1 week after repair to assess the caliber of the anastomosis and to determine whether a leak is present. If there is no leak, feedings are started.

Complications of surgery. Anastomotic leak occurs in 10–15 percent of patients and may be seen either in the immediate postoperative period, or after several days. Early leakage is manifested by a new pleural effusion, pneumothorax and sepsis, and requires immediate exploration. In these circumstances, the anastomosis may be completely disrupted, possibly because of excessive tension. Revision of the anastomosis may be possible. If not, cervical esophagostomy and gastrostomy placement is required, with a staged procedure to re-establish esophageal continuity. Anastomotic leakage that is detected after several days usually heals without intervention, particularly if a retropleural approach is used. Under these circumstances, broad spectrum antibiotics, pulmonary toilet and optimization of nutrition are important. After approximately a week, a repeat contrast swallow should be performed to determine if the leakage has resolved.

Strictures are not infrequent (10–20 percent), particularly if a leak has occurred. A stricture may become apparent at any time, from the early postoperative period to months or years later. It may present as choking, gagging, or failure to thrive, but often becomes clinically apparent with transition to eating solid food. A contrast swallow or esophagoscopy is confirmatory, and simple dilatation is usually corrective. Occasionally, repeated dilatations are required. These may be performed pneumatically or in a retrograde fashion, during which a silk suture is placed into the oropharynx and delivered from the esophagus through a gastrostomy tube. Tucker dilators are then tied to the suture and passed in a retrograde fashion from the gastrostomy tube and delivered out of the oropharynx. Increasing sizes are used, and the silk is replaced at the end of the procedure in which it is taped to the side of the face at one end, and to the gastrostomy tube at the other.

“Recurrent” tracheoesophageal fistula may represent a missed upper pouch fistula or a true recurrence. This may occur after an anastomotic disruption, during which the recurrent fistula may heal spontaneously. Otherwise, re-operation may be required. Recently, the use of fibrin glue has been successful in treating recurrent fistulas, although long-term follow up is lacking. Gastroesophageal reflux commonly occurs after repair of EA-TEF, potentially because of alterations in esophageal motility and the anatomy of the gastroesophageal junction. The clinical manifestations of such reflux are similar to those seen in other infants with primary gastroesophageal reflux disease (GERD). A loose antireflux procedure, such as a Nissen fundoplication, is used to prevent further reflux, but the child may have feeding problems after antireflux surgery as a result of the innate dysmotility of the distal esophagus. The fundoplication may be safely performed laparoscopically in experienced hands, although care should be taken to ensure that the wrap is not excessively tight.

Special Circumstances

Patients with type E tracheoesophageal fistulas (also called H-type) most commonly present beyond the newborn period. Presenting symptoms include recurrent chest infections, bronchospasm and failure to thrive. The diagnosis is suspected using barium esophagography, and confirmed by endoscopic visualization of the fistula. Surgical correction is generally possible through a cervical approach, and requires mobilization and division of the fistula. Outcome is usually excellent.

Patients with duodenal atresia and EA-TEF may require urgent treatment because of the presence of a closed obstruction of the stomach and proximal duodenum. In stable patients, treatment consists of repair of the esophageal anomaly and correction of the duodenal atresia if the infant is stable during surgery. If not, a staged approach should be used consisting of ligation of the fistula and placement of a gastrostomy tube. Definitive repair can then be performed at a later point in time.

Primary esophageal atresia (type A) represents a challenging problem, particularly if the upper and lower ends are too far apart for an anastomosis to be created. Under these circumstances, treatment strategies include placement of a gastrostomy tube and performing serial bougienage to increase the length of the upper pouch. Occasionally, when the two ends cannot be brought safely together, esophageal replacement is required using either a gastric pull-up or colon interposition (see below).

Outcome

Various classification systems have been used to predict survival in patients with EA-TEF and to stratify treatment. A system devised by Waterston in 1962 was used to stratify neonates based on birth weight, the presence of pneumonia, and the identification of other congenital anomalies. In response to advances in neonatal care, the surgeons from the Montreal Children's Hospital proposed a new classification system in 1993. In the Montreal experience only two characteristics independently affected survival: preoperative ventilator dependence and associated major anomalies. Pulmonary disease as defined by ventilator dependence appeared to be more accurate than pneumonia. When the two systems were recently compared, the Montreal system more accurately identified children at highest risk. Spitz and colleagues recently analyzed risk factors in infants who died with EA-TEF. Two criteria were found to be important predictors of outcome: birth weight less than 1,500 g and the presence of major congenital cardiac disease. A new classification for predicting outcome in esophageal atresia was therefore proposed: group I: birth weight \geq 1,500 g, without major cardiac disease, survival 97 percent (283 of 293); group II: birth weight $<$ 1,500 g, or major cardiac disease, survival 59 percent (41 of 70); and group III: birth weight $<$ 1,500 g, and major cardiac disease, survival 22 percent (2 of 9).

In general, surgical correction of EA-TEF leads to a satisfactory outcome with nearly normal esophageal function in most patients. Overall survival rates of greater than 90 percent have been achieved in patients classified as stable, in all the various staging systems. Unstable infants have an increased mortality (40–60 percent survival) because of potentially fatal associated cardiac and chromosomal anomalies or prematurity. However, the

use of a staged procedure also has increased survival in even these high-risk infants.

GASTROINTESTINAL TRACT

Hypertrophic Pyloric Stenosis

Clinical Manifestations

Timely diagnosis and treatment of infants with hypertrophic pyloric stenosis (HPS) is extremely gratifying; it is one of the few instances in surgery where a relatively simple operation can have such a dramatic long-term effect. HPS occurs in approximately 1 in 300 live births and classically presents in a first-born male between 3 and 6 weeks of age. However, children outside of this age range are commonly seen, and the disease is by no means restricted to either males or first born children. The cause of HPS has not been determined. Studies have shown that HPS is found in several generations of the same family, suggesting a familial link. Administration of erythromycin in early infancy has been linked to the subsequent development of HPS, although the cause is unclear.

Infants with HPS present with nonbilious vomiting that becomes increasingly projectile over the course of several days to weeks. Eventually, the infant develops almost complete gastric outlet obstruction, and is no longer able to tolerate even clear liquids. Despite the recurrent emesis, the child normally has a voracious appetite, leading to a cycle of feeding and vomiting that invariably results in severe dehydration, if untreated. Jaundice may occur in association with HPS, although the reason for this finding is unclear. Particularly perceptible caregivers will mention that their infant is passing less flatus, which provides a further clue that gastric outlet obstruction is complete.

Infants with HPS develop a hypochloremic, hypokalemic metabolic alkalosis. The urine pH level is high initially, but eventually drops because hydrogen ions are preferentially exchanged for sodium ions in the distal tubule of the kidney as the hypochloremia becomes severe. The diagnosis of pyloric stenosis usually can be made on physical examination by palpation of the typical "olive" in the right upper quadrant and the presence of visible gastric waves on the abdomen. When the olive cannot be palpated, ultrasound can diagnose the condition accurately in 95 percent of patients. Criteria for ultrasound diagnosis include a channel length of over 16 mm and pyloric thickness over 4 mm.

Treatment

Pyloric stenosis is never a surgical emergency, although the dehydration and electrolyte abnormalities may present a medical emergency. Fluid resuscitation with correction of electrolyte abnormalities and metabolic alkalosis is essential before induction of general anesthesia for operation. For most infants, fluid containing 5 percent dextrose and 0.45 percent saline with added potassium of 2–4 mEq/kg over 24 h at a rate of approximately 150–175 mL/kg for 24 h will correct the underlying deficit. It is important to ensure that the child has an adequate urine output (>1 mL/kg/h) as further evidence that rehydration has occurred. After resuscitation, a Fredet-Ramstedt pyloromyotomy is performed. It may be performed using an open or laparoscopic approach. The open pyloromyotomy is performed through either an umbilical or a right upper quadrant transverse abdominal incision. The former route is cosmetically

more appealing, although the transverse incision provides easier access to the antrum and pylorus. In recent years, the laparoscopic approach has gained great popularity. Whether done through an open or laparoscopic approach, the operation involves splitting the pyloric muscle until the submucosa is seen bulging upwards. The incision begins at the pyloric vein of Mayo and extends onto the gastric antrum; it typically measures between 1 and 2 cm in length. Postoperatively, intravenous fluids are continued for several h after which Pedialyte followed by formula or breast milk are offered and are gradually increased to 60 mL every 3 h. Most infants can be discharged home within 24–48 h following surgery. Recently, several authors have shown that *ad lib* feeds are safely tolerated by the neonate and result in a shorter hospital stay.

The complications of pyloromyotomy include perforation of the mucosa (1–3 percent), bleeding, wound infection, and recurrent symptoms because of inadequate myotomy. When perforation occurs, the mucosa is repaired with a stitch that is placed to tack the mucosa down and re-approximate the serosa in the region of the tear. A nasogastric tube is left in place for 24 h. The outcome is generally very good.

Intestinal Obstruction in the Newborn

The cardinal symptom of intestinal obstruction in the newborn is bilious emesis. Prompt recognition and treatment of neonatal intestinal obstruction can truly be life saving.

Intestinal obstruction can be thought of as either proximal or distal to the ligament of Treitz. Proximal obstruction presents as bilious vomiting, with minimal abdominal distention. In cases of complete obstruction, either there may be a paucity of gas, or no distal air may be seen on the supine and upright films of the abdomen. In this case, the diagnosis of malrotation and midgut volvulus must be excluded. Distal obstruction presents with abdominal distention and bilious emesis. The physical examination will determine whether the anus is patent. Calcifications on the abdominal plain film may indicate meconium peritonitis; pneumatosis and/or free abdominal air indicates necrotizing enterocolitis (NEC) with or without intestinal perforation. A contrast enema will show whether there is a microcolon indicative of jejuno-ileal atresia or meconium ileus. If a microcolon is not present, then the diagnoses of Hirschsprung disease, small left colon syndrome, or meconium plug syndrome should be considered. In all cases of intestinal obstruction, it is vital to obtain abdominal films in the supine and upright (lateral decubitus) views. This is the only way to assess the presence of air-fluid levels or free air, and to characterize the obstruction as proximal or distal. Moreover, it is important to realize that in the absence of contrast, it is difficult to determine whether a loop of dilated bowel is either part of the small or large intestine, as the neonatal bowel lacks typical features, such as haustra or plicae circulares, that characterize these loops in older children or adults. For this reason, care must be taken to take a complete prenatal history, to perform a thorough physical examination, and to judiciously determine the need for further contrast studies versus immediate abdominal exploration.

Duodenal Obstruction

Whenever the diagnosis of duodenal obstruction is entertained, malrotation and midgut volvulus must be excluded. This topic is covered in further detail below. Other causes of duodenal obstruction include duodenal atresia, duodenal web,

stenosis, annular pancreas or duodenal duplication cyst. Duodenal obstruction is easily diagnosed on prenatal ultrasound, which demonstrates the fluid-filled stomach and proximal duodenum as two discrete cystic structures in the upper abdomen. Associated polyhydramnios is common and presents in the third trimester. In 85 percent of infants with duodenal obstruction, the entry of the bile duct is proximal to the level of obstruction, such that vomiting is bilious. Abdominal distention is typically not present because of the proximal level of obstruction. In those infants with obstruction proximal to the bile duct entry, the vomiting is nonbilious. The classic finding on abdominal radiography is the "double bubble" sign, which represents the dilated stomach and duodenum. In association with the appropriate clinical picture, this finding is sufficient to confirm the diagnosis of duodenal obstruction. However, if there is any uncertainty, particularly when a partial obstruction is suspected, a contrast upper gastrointestinal series is diagnostic.

Treatment

An orogastric tube is inserted to decompress the stomach and duodenum and the infant is given intravenous fluids to maintain adequate urine output. If the infant appears ill, or if abdominal tenderness is present, a diagnosis of malrotation and midgut volvulus should be considered, and surgery should not be delayed. Typically, the abdomen is soft and the infant is very stable. Under these circumstances, the infant should be evaluated thoroughly for other associated anomalies. Approximately one-third of newborns with duodenal atresia have associated Down syndrome (trisomy 21). These patients should also be evaluated for associated cardiac anomalies. Once the work-up is complete and the infant is stable, he or she is taken to the operating room and the abdomen is entered through a transverse right upper quadrant supraumbilical incision under general endotracheal anesthesia. Associated anomalies should be searched for at the time of the operation. These include malrotation, anterior portal vein, a second distal web, and biliary atresia. The surgical treatment of choice for duodenal obstruction because of duodenal stenosis or atresia or annular pancreas is a duodeno-duodenostomy. This procedure can be most easily performed using a proximal transverse-to-distal longitudinal (diamond shaped) anastomosis. In cases in which the duodenum is extremely dilated, the lumen may be tapered using a linear stapler with a large Foley catheter (24-F or greater) in the duodenal lumen. It is important to emphasize that an annular pancreas is never divided. Treatment of duodenal web includes vertical duodenotomy, excision of the web, oversewing of the mucosa and horizontal closure of the duodenotomy. Gastrostomy tubes are not placed routinely. Recently reported survival rates exceed 90 percent. Late complications from repair of duodenal atresia occur in approximately 12–15 percent of patients and include megaduodenum, intestinal motility disorders and gastroesophageal reflux.

Intestinal Atresia

Obstruction because of intestinal atresia can occur at any point along the intestinal tract. Most cases are believed to be caused by in utero mesenteric vascular accidents leading to segmental loss of the intestinal lumen. The incidence of intestinal atresia has been estimated to be between 1 in 2000 to 1 in 5000 live births, with equal representation of the sexes. Infants with jejunal or ileal atresia present with bilious vomiting and progressive abdominal

distention. The more distal the obstruction, the more distended the abdomen becomes, and the greater the number of obstructed loops on upright abdominal films.

In cases in which the diagnosis of complete intestinal obstruction is ascertained by the clinical picture and the presence of staggered air-fluid levels on plain abdominal films, the child can be brought to the operating room after appropriate resuscitation. In these circumstances, there is little extra information to be gained by performing a barium enema. By contrast, when there is diagnostic uncertainty, or when distal intestinal obstruction is apparent, a barium enema is useful to establish whether a microcolon is present, and to diagnose the presence of meconium plugs, small left colon syndrome, Hirschsprung disease or meconium ileus. Judicious use of barium enema is therefore required to safely manage neonatal intestinal obstruction, based on an understanding of the expected level of obstruction.

Surgical correction of the small intestinal atresia should be performed urgently. At laparotomy, one of several types of atresia will be encountered. In type I there is a mucosal atresia with intact muscularis. In type 2 the atretic ends are connected by a fibrous band. In type 3A the two ends of the atresia are separated by a V-shaped defect in the mesentery. Type 3B is an "apple-peel" or "Christmas tree" deformity in which the bowel distal to the atresia receives its blood supply in a retrograde fashion from the ileocolic or right colic artery. In type 4 atresia, there are multiple atresias with a "string of sausage" or "string of beads" appearance. Disparity in lumen size between the proximal distended bowel and the small diameter of collapsed bowel distal to the atresia has led to a number of innovative techniques for anastomosis. However, under most circumstances, an anastomosis can be performed using the end-to-back technique in which the distal, compressed loop is "fish-mouthed" along its antimesenteric border. The proximal distended loop can be tapered as described above. Because the distended proximal bowel rarely has normal motility, the extremely dilated portion should be resected prior to performing the anastomosis.

Occasionally the infant with intestinal atresia will develop ischemia or necrosis of the proximal segment secondary to volvulus of the dilated, bulbous, blind-ending proximal bowel. Under these conditions, an end ileostomy and mucus fistula should be created, and the anastomosis should be deferred to another time after the infant stabilizes.

Malrotation and Midgut Volvulus

Embryology

During the sixth week of fetal development, the midgut grows too rapidly to be accommodated in the abdominal cavity and therefore prolapses into the umbilical cord. Between the tenth and twelfth week, the midgut returns to the abdominal cavity, undergoing a 270-degree counterclockwise rotation around the superior mesenteric artery. Because the duodenum also rotates caudal to the artery, it acquires a C-loop, which traces this path. The cecum rotates cephalad to the artery, which determines the location of the transverse and ascending colon. Subsequently, the duodenum becomes fixed retroperitoneally in its third portion and at the ligament of Treitz, although the cecum becomes fixed to the lateral abdominal wall by peritoneal bands. The takeoff of the branches of the superior mesenteric artery elongates and becomes fixed along a line extending from its emergence from the aorta to the cecum in the right lower quadrant.

If rotation is incomplete, the cecum remains in the epigastrium, but the bands fixing the duodenum to the retroperitoneum and cecum continue to form. This results in (Ladd) bands extending from the cecum to the lateral abdominal wall and crossing the duodenum, which creates the potential for obstruction. The mesenteric takeoff remains confined to the epigastrium, resulting in a narrow pedicle suspending all the branches of the superior mesenteric artery and the entire midgut. A volvulus may therefore occur around the mesentery. This twist not only obstructs the proximal jejunum but also cuts off the blood supply to the midgut. Intestinal obstruction and complete infarction of the midgut occur unless the problem is promptly corrected surgically.

Presentation and Management

Midgut volvulus can occur at any age, although it is seen most often in the first few weeks of life. Bilious vomiting is usually the first sign of volvulus and all infants with bilious vomiting must be evaluated rapidly to insure that they do not have intestinal malrotation with volvulus. The child with irritability and bilious emesis should raise particular suspicion for this diagnosis. If left untreated, vascular compromise of the midgut initially causes bloody stools, but eventually results in circulatory collapse. Additional clues to the presence of advanced ischemia of the intestine include erythema and edema of the abdominal wall, which progresses to shock and death. It must be reemphasized that the index of suspicion for this condition must be high, because abdominal signs are minimal in the early stages. Abdominal films show a paucity of gas throughout the intestine with a few scattered air-fluid levels. When these findings are present, the patient should undergo immediate fluid resuscitation to ensure adequate perfusion and urine output followed by prompt exploratory laparotomy.

Often the patient will not appear ill, and the plain films may suggest partial duodenal obstruction. Under these conditions, the patient may have malrotation without volvulus. This is best diagnosed by an upper gastrointestinal series that shows incomplete rotation with the duodenojejunal junction displaced to the right. The duodenum may show a corkscrew effect diagnosing volvulus, or complete duodenal obstruction, with the small bowel loops entirely in the right side of the abdomen. Barium enema may show a displaced cecum, but this sign is unreliable; especially in the small infant in whom the cecum is normally in a somewhat higher position than in the older child. When volvulus is suspected, early surgical intervention is mandatory if the ischemic process is to be avoided or reversed. Volvulus occurs clockwise and it is therefore untwisted counterclockwise. This can be remembered using the memory aid "turn back the hands of time." Subsequently, a Ladd procedure is performed. This operation does not correct the malrotation, but does broaden the narrow mesenteric pedicle to prevent volvulus from recurring. This procedure is performed as follows: The bands between the cecum and the abdominal wall and between the duodenum and terminal ileum are divided sharply to splay out the superior mesenteric artery and its branches. This maneuver brings the straightened duodenum into the right lower quadrant and the cecum into the left lower quadrant. The appendix is removed to avoid diagnostic errors in later life. No attempt is made to suture the cecum or duodenum in place. With advanced ischemia, reduction of the volvulus without the Ladd procedure is accomplished, and a "second look" 24–36 h later often will show some vascular recovery. A plastic transparent silo may be placed to facilitate constant evaluation of the intestine, and to plan for the timing of re-exploration. Frankly necrotic bowel can then

be resected conservatively. With early diagnosis and correction the prognosis is excellent. However, diagnostic delay can lead to mortality, or to short-gut syndrome requiring intestinal transplantation.

A subset of patients with malrotation will demonstrate chronic obstructive symptoms. These symptoms may result from the Ladd bands across the duodenum, or occasionally, from intermittent volvulus. Symptoms include intermittent abdominal pain, and intermittent vomiting which may occasionally be bilious. Infants with malrotation may demonstrate failure to thrive, and they may be diagnosed initially as having gastroesophageal reflux disease. Surgical correction using the Ladd procedure as described above can prevent volvulus from occurring and improve symptoms in many instances.

Meconium Ileus

Pathogenesis and Clinical Presentation

Infants with cystic fibrosis have characteristic pancreatic enzyme deficiencies and abnormal chloride secretion in the intestine that result in the production of viscous, water-poor meconium. Meconium ileus occurs when this thick, highly viscous meconium becomes impacted in the ileum and leads to high grade intestinal obstruction. Meconium ileus can be either uncomplicated, in which there is no intestinal perforation, or complicated, in which prenatal perforation of the intestine has occurred or vascular compromise of the distended ileum develops. Antenatal ultrasound may reveal the presence of intraabdominal or scrotal calcifications, or distended bowel loops. These infants present shortly after birth with progressive abdominal distention and failure to pass meconium with intermittent bilious emesis. Abdominal radiographs show dilated loops of intestine. Because the enteric contents are so viscous, air-fluid levels do not form, even when obstruction is complete. Small bubbles of gas become entrapped in the inspissated meconium in the distal ileum, where they produce a characteristic "ground glass" appearance.

The diagnosis of meconium ileus is confirmed by a contrast enema which typically demonstrates a microcolon. In patients with uncomplicated meconium ileus, the terminal ileum is filled with pellets of meconium. In patients with complicated meconium ileus, intraperitoneal calcifications form, producing an eggshell pattern on plain abdominal radiograph.

Management

The treatment strategy depends on whether the patient has complicated or uncomplicated meconium ileus. Patients with uncomplicated meconium ileus can be treated nonoperatively. Dilute water soluble contrast is advanced through the colon under fluoroscopic control into the dilated portion of the ileum. Because these contrast agents act partially by absorbing fluid from the bowel wall into the intestinal lumen, maintaining adequate hydration of the infant during this maneuver is extremely important. The enema may be repeated at 12-h intervals over several days until all the meconium is evacuated. Failure to reflux the contrast into the dilated portion of the ileum signifies the presence of an associated atresia or complicated meconium ileus, and thus warrants exploratory laparotomy. If surgical intervention is required because of failure of contrast enemas to relieve obstruction, operative irrigation with dilute contrast agent, N-acetyl cysteine (Mucomyst) or saline through a purse-string suture may be successful. Alternatively, resection of the distended terminal ileum is performed and the meconium pellets are flushed from the distal small bowel.

At this point, ileostomy and mucous fistula may be created from the proximal and distal ends respectively.

Necrotizing Enterocolitis

Clinical Features

Necrotizing enterocolitis (NEC) is the most frequent and lethal gastrointestinal disorder affecting the intestine of the stressed, preterm neonate. Over 25,000 cases of NEC are reported annually. The overall mortality ranges between 10 percent and 50 percent. Advances in neonatal care such as surfactant therapy and improved methods of mechanical ventilation have resulted in increasing numbers of low birth weight infants surviving neonatal hyaline membrane disease. An increasing proportion of survivors of neonatal respiratory distress syndrome will therefore be at risk for developing NEC. Consequently, it is estimated that NEC soon will surpass respiratory distress syndrome as the principal cause of death in the preterm infant.

Multiple risk factors have been associated with the development of NEC. These include prematurity, initiation of enteral feeding, bacterial infection, intestinal ischemia resulting from birth asphyxia, umbilical artery cannulation, persistence of a patent ductus arteriosus, cyanotic heart disease and maternal cocaine abuse. Nonetheless, the mechanisms by which these complex interacting etiologies lead to the development of the disease remain undefined. The only consistent epidemiologic precursors for NEC are prematurity and enteral alimentation, representing the commonly encountered clinical situation of a stressed infant who is fed enterally. Of note, there is some debate regarding the importance of enteral alimentation in the pathogenesis of NEC. A prospective randomized study showed no increase in the incidence of NEC despite an aggressive feeding strategy, and up to 10 percent of infants with NEC have never received any form of enteral nutrition.

The indigenous intestinal microbial flora has been postulated to play a central role in the pathogenesis of NEC. Bacterial colonization may be a prerequisite for the development of this disease, as oral prophylaxis with vancomycin or gentamicin reduced the incidence of NEC. The importance of bacteria in the pathogenesis of NEC is further supported by the finding that NEC occurs in episodic waves that can be abrogated by infection control measures, and the fact that NEC usually develops at least 10 days postnatally, when the GI tract is colonized by coliforms. Common bacterial isolates from the blood, peritoneal fluid and stool of infants with advanced NEC include *Escherichia coli*, *Enterobacter*, *Klebsiella*, and occasionally, coagulase-negative *Staphylococcus* species.

NEC may involve single or multiple segments of the intestine, most commonly the terminal ileum, followed by the colon. The gross findings in NEC include bowel distention with patchy areas of thinning, pneumatosis, gangrene or frank perforation. The microscopic features include the appearance of a "bland infarct" characterized by full thickness necrosis.

Pathogenesis of NEC

The exact mechanisms that lead to the development of NEC remain incompletely understood. However, current thinking suggests that in the setting of an episode of perinatal stress, such as respiratory distress syndrome, the premature infant suffers a period of intestinal hypoperfusion. This is followed by a period of reperfusion, and the combination of ischemia and reperfusion lead to mucosal injury. The damaged intestinal mucosa can then be readily breached

by indigenous microorganisms that translocate across it. The translocated bacteria then initiate an inflammatory cascade that involves the release of various proinflammatory mediators which in turn may be responsible for further epithelial injury and the systemic manifestations of NEC. It is postulated that maintenance of the gut barrier is essential for the protection of the host against NEC, and that impairment of the mechanisms that normally repair the damaged mucosal barrier may facilitate propagation of the mucosal injury and thus, NEC.

Clinical Manifestations

Infants with NEC present with a spectrum of disease. In general, the infants are premature and may have sustained one or more episodes of stress, such as birth asphyxia, or they may have congenital cardiac disease. The clinical picture of NEC has been characterized as progressing from a period of mild illness to that of severe, life threatening sepsis by Bell and colleagues. Although not all infants progress through the various "Bell stages," this classification scheme provides a useful format to describe the clinical picture associated with the development of NEC. In the earliest stage (Bell Stage I), infants present with formula intolerance. This is manifested by vomiting or by finding a large residual volume from a previous feeding in the stomach at the time of the next feeding. Following appropriate treatment, which consists of bowel rest and intravenous antibiotics, many of these infants will not progress to more advanced stages of NEC. These infants are colloquially described as suffering from a "NEC scare," and represent a population of neonates that are at risk of developing more severe NEC if a more prolonged period of stress supervenes.

Infants with Bell Stage II have established NEC that is not immediately life threatening. Clinical findings include abdominal distention and tenderness, bilious nasogastric aspirate, and bloody stools. These findings indicate the development of intestinal ileus and mucosal ischemia respectively. Abdominal examination may reveal a palpable mass indicating the presence of an inflamed loop of bowel, diffuse abdominal tenderness, cellulitis and edema of the anterior abdominal wall. The infant may appear systemically ill, with decreased urine output, hypotension, tachycardia and noncardiac pulmonary edema. Hematologic evaluation reveals either leukocytosis or leukopenia, an increase in the number of bands, and thrombocytopenia. An increase in the blood urea nitrogen and plasma creatinine level may be found, which signify the development of renal dysfunction. The diagnosis of NEC may be confirmed by abdominal radiography. The pathognomonic radiographic finding in NEC is pneumatosis intestinalis, which represents invasion of the ischemic mucosa by gas producing microbes. Other findings include the presence of ileus or portal venous gas. The latter is a transient finding that indicates the presence of severe NEC with intestinal necrosis. A fixed loop of bowel may be seen on serial abdominal radiographs, which suggests the possibility that a diseased loop of bowel, potentially with a localized perforation, is present. Although these infants are at risk of progressing to more severe disease, with timely and appropriate treatment, they often recover.

Infants with Bell Stage III have the most advanced form of NEC. Abdominal radiographs often demonstrate the presence of pneumoperitoneum, indicating that intestinal perforation has occurred. These patients may develop a fulminant course with progressive peritonitis, acidosis, sepsis, disseminated intravascular coagulopathy, and death.

Treatment

In all infants suspected of having NEC, feedings are discontinued, a nasogastric tube is placed, and broad spectrum parenteral antibiotics are given. The infant is resuscitated, and inotropes are administered to maintain perfusion as needed. Intubation and mechanical ventilation may be required to maintain oxygenation. Total parenteral nutrition is started. Subsequent treatment may be influenced by the particular stage of NEC that is present. Patients with Bell I are closely monitored, and generally remain "nothing by mouth" (NPO) and on intravenous antibiotics for 7–10 days, prior to re-initiating enteral nutrition. After this time, provided that the infant fully recovers, feedings may be re-initiated.

Patients with Bell II disease merit close observation. Serial physical examinations are performed looking for the development of diffuse peritonitis, a fixed mass, progressive abdominal wall cellulitis or systemic sepsis. If infants fail to improve after several days of treatment, consideration should be given to exploratory laparotomy. Paracentesis may be performed, and if the gram stain demonstrates multiple organisms and leukocytes, perforation of the bowel should be suspected, and patients should be treated as Bell III patients.

In the most severe form of NEC (Bell III), patients have definite intestinal perforation, or have not responded to nonoperative therapy. Two schools of thought direct further management. One group favors exploratory laparotomy. At laparotomy, frankly gangrenous or perforated bowel is resected, and the intestinal ends are brought out as stomas. When there is massive intestinal involvement, marginally viable bowel is retained and a "second-look" procedure is carried out after the infant stabilizes (24–48 h). Patients with extensive necrosis at the second look may be managed by placing a proximal diverting stoma, resecting bowel that is definitely not viable, and leaving questionably viable bowel behind distal to the diverted segment. When the intestine is viable except for a localized perforation without diffuse peritonitis and if the infant's clinical condition permits, intestinal anastomosis may be performed either proximal or distal to the divided segment. In cases in which the diseased, perforated segment can not be safely resected, drainage catheters may be left in the region of the diseased bowel, and the infant is allowed to stabilize.

An alternative approach to the management of infants with perforated NEC involves drainage of the peritoneal cavity. This may be performed under local anesthesia at the bedside, and can be an effective means of stabilizing the desperately ill infant by relieving increased intraabdominal pressure and allowing ventilation. When successful, this method also allows for drainage of perforated bowel by establishing a controlled fistula. Approximately one-third of infants treated with drainage alone survive without requiring additional operations. Infants that do not respond to peritoneal drainage alone after 48–72 h should undergo laparotomy. This procedure allows for the resection of frankly necrotic bowel diversion of the fecal stream and facilitates more effective drainage.

Outcome

Survival in patients with NEC is dependent on the stage of disease, the extent of prematurity, and the presence of associated comorbidities. Survival by stage has recently been shown to be approximately 85 percent, 65 percent and

35 percent for stages I, II and III respectively. Strictures develop in 20 percent of medically or surgically treated patients, and a contrast enema is mandatory before re-establishing intestinal continuity. If all other factors are favorable, the ileostomy is closed when the child is between 2 and 2.5 kg. At the time of stoma closure, the entire intestine should be examined to search for areas of NEC. Patients that developed massive intestinal necrosis are at risk of developing short-gut syndrome, particularly when the total length of the viable intestinal segment is below 40 cm. These patients require TPN to provide adequate calories for growth and development, and may develop TPN-related cholestasis and hepatic fibrosis. In a significant number of these patients, transplantation of the liver and small bowel may be required.

Intussusception

Intussusception is the leading cause of intestinal obstruction in the young child. It refers to the condition whereby a segment of intestine becomes drawn into the lumen of the more proximal bowel. The process usually begins in the region of the terminal ileum, and extends distally into the ascending, transverse or descending colon. Rarely, an intussusception may prolapse through the rectum.

The cause of intussusception is not clear, although current thinking suggests that hypertrophy of the Peyer patches in the terminal ileum from an antecedent viral infection acts as a lead point. Peristaltic action of the intestine then causes the bowel distal to the lead point to invaginate into itself. Idiopathic intussusception occurs in children between the ages of approximately 6 and 24 months of age. Beyond this age group, one should consider the possibility that a pathologic lead point may be present. These include polyps, malignant tumors such as lymphoma, enteric duplication cysts or Meckel diverticulum. Such intussusceptions are rarely reduced by air or contrast enema, and thus the lead point is identified when operative reduction of the intussusception is performed.

Clinical Manifestations

Because intussusception is frequently preceded by a gastrointestinal viral illness, the onset may not be easily determined. Typically, the infant develops paroxysms of crampy abdominal pain and intermittent vomiting. Between attacks, the infant may act normally, but as symptoms progress, increasing lethargy develops. Bloody mucus ("currant-jelly" stool) may be passed per rectum. Ultimately, if reduction is not accomplished, gangrene of the intussusceptum occurs, and perforation may ensue. On physical examination, an elongated mass is detected in the right upper quadrant or epigastrium with an absence of bowel in the right lower quadrant (Dance sign). The mass may be seen on plain abdominal radiograph but is more easily demonstrated on air or contrast enema.

Treatment

Patients with intussusception should be assessed for the presence of peritonitis and for the severity of systemic illness. Following resuscitation and administration of intravenous antibiotics, the child is assessed for suitability to proceed with radiographic versus surgical reduction. In the absence of peritonitis, the child should undergo radiographic reduction. If peritonitis is present, or if the child appears systemically ill, urgent laparotomy is indicated.

In the stable patient, the air enema is both diagnostic and often curative. It constitutes the preferred method of diagnosis and nonoperative treatment of intussusception. Air is introduced with a manometer and the pressure that is administered is carefully monitored. Under most instances, this should not exceed 120 mmHg. Successful reduction is marked by free reflux of air into multiple loops of small bowel and symptomatic improvement as the infant suddenly becomes pain free. Unless both of these signs are observed, it cannot be assumed that the intussusception is reduced. If reduction is unsuccessful, and the infant remains stable, the infant should be brought back to the radiology suite for a repeat attempt at reduction after a few h. This strategy has improved the success rate of nonoperative reduction in many centers. Additionally, hydrostatic reduction with barium may be useful if pneumatic reduction is unsuccessful. The overall success rate of radiographic reduction varies based on the experience of the center, and is typically between 60 and 90 percent.

If nonoperative reduction is successful, the infant may be given oral fluids after a period of observation. Failure to reduce the intussusception mandates surgery. Two approaches are used. In an open procedure, exploration is carried out through a right lower quadrant incision, delivering the intussuscepted mass into the wound. Reduction usually can be accomplished by gentle distal pressure, where the intussusceptum is gently milked out of the intussuscipiens. Care should be taken not to pull the bowel out, as this can cause damage to the bowel wall. The blood supply to the appendix is often compromised, and appendectomy is performed. If the bowel is frankly gangrenous, resection and primary anastomosis is performed. In experienced hands, laparoscopic reduction may be performed, even in very young infants. Intravenous fluids are continued until the postoperative ileus subsides. Patients are started on clear liquids, and their diet is advanced as tolerated. Of note, recurrent intussusception occurs in 5–10 percent of patients, independent of whether the bowel is reduced radiographically or surgically. Patients present with recurrent symptoms in the immediate postoperative period. Treatment involves repeat air enema, which is successful in most cases. In patients who experience three or more episodes of intussusception, the presence of a pathologic lead point should be suspected and carefully evaluated using contrast studies. After the third episode of intussusception, many pediatric surgeons will perform an exploratory laparotomy to reduce the bowel and to resect a pathologic lead point if identified.

Appendicitis

Presentation

Correct diagnosis of appendicitis in children can be one of the most humbling and challenging tasks faced by the pediatric surgeon. The classical presentation is known to all students and practitioners of surgery: generalized abdominal pain that localizes to the right lower quadrant followed by nausea, vomiting, fever, and localized peritoneal irritation in the region of McBurney's point. When children present in this manner, there should be little diagnostic delay. The child should be made NPO, administered intravenous fluids and broad spectrum antibiotics, and brought to the operating room for an appendectomy. However, children often do not present in this manner. The co-existence of viral syndromes, and the inability of young children to describe the location and quality of their pain, often result in diagnostic delay. As a result, children with appendicitis often present with perforation, particularly those who are

younger than 5 years of age. Perforation increases the length of hospital stay, and makes the overall course of the illness significantly more complex.

Diagnosis of Appendicitis in Children

Controversy exists regarding the role of radiographic studies in the diagnosis of acute appendicitis. Because children have less peri-appendiceal fat than adults, computerized tomography is less reliable in making the diagnosis. Additionally, radiation exposure resulting from the CT scan may have potentially long-term adverse effects. Likewise, ultrasonography is neither sufficiently sensitive nor specific to accurately make the diagnosis of appendicitis, although it is very useful for excluding ovarian causes of abdominal pain. Therefore, the diagnosis of appendicitis remains largely clinical, and each clinician should develop his or her own threshold to operate or to observe the patient. A reasonable practice guideline is as follows: when the diagnosis is clinically apparent, appendectomy should obviously be performed with minimal delay. Localized right lower quadrant tenderness associated with low grade fever and leukocytosis in boys should prompt surgical exploration. In girls, ovarian or uterine pathology must also be considered. When there is diagnostic uncertainty, the child may be observed, rehydrated and reassessed. In girls of menstruating age, an ultrasound may be obtained to exclude ovarian pathology (cysts, torsion or tumor). If all studies are negative, yet the pain persists and the abdominal findings remain equivocal, diagnostic laparoscopy may be employed to determine the etiology of the abdominal pain. The appendix should be removed even if it appears to be normal, unless another pathologic cause of the abdominal pain is definitively identified and the appendectomy would substantially increase morbidity.

Management of the child with perforated appendicitis. The signs and symptoms of perforated appendicitis can closely mimic those of gastroenteritis and include abdominal pain, vomiting and diarrhea. Alternatively, the child may present with symptoms of intestinal obstruction. An abdominal mass may be present in the lower abdomen. When the symptoms have been present for more than 4 or 5 days, and an abscess is suspected, it is reasonable to obtain a computerized tomogram of the abdomen and pelvis with intravenous, oral and rectal contrast to visualize the appendix and the presence of an associated abscess, phlegmon or fecalith.

An individualized approach is necessary for the child who presents with perforated appendicitis. When there is evidence of generalized peritonitis, intestinal obstruction or systemic toxicity, the child should undergo appendectomy. This should be delayed only for as long as is required to ensure adequate fluid resuscitation and administration of broad spectrum antibiotics. The operation can be performed through an open procedure through a laparoscopic approach. One distinct advantage of the laparoscopic approach is that it provides excellent visualization of the pelvis and all four quadrants of the abdomen. At the time of surgery, adhesions are gently lysed, abscess cavities are drained and the appendix is removed. Drains are seldom used, and the skin incisions can be closed primarily. If a fecalith is identified outside the appendix on computerized tomography, every effort should be made to retrieve it and to remove it along with the appendix, if at all possible. Often, the child in whom symptoms have been present for more than 4 or 5 days will present with an abscess cavity without evidence of generalized peritonitis. Under these circumstances, it is appropriate to perform image-guided percutaneous drainage of the abscess

followed by broad spectrum antibiotic therapy. The inflammation will generally subside within several days, and the appendix can be safely removed as an outpatient 6–8 weeks later. If the child's symptoms do not improve, or if the abscess is not amenable to percutaneous drainage, then laparoscopic or open appendectomy and abscess drainage is required. Patients who present with a phlegmon in the region of a perforated appendix may be managed in a similar manner. In general, children who are younger than 4 or 5 years of age do not respond as well to initial nonoperative approach, because their bodies do not localize or isolate the inflammatory process. Thus, these patients are more likely to require early surgical intervention. Patients who have had symptoms of appendicitis for no more than four days should probably undergo "early" appendectomy, because the inflammatory response is not as excessive during that initial period and the procedure can be performed safely.

Intestinal Duplications

Duplications represent mucosa-lined structures that are in continuity with the gastrointestinal tract. Although they can occur at any level in the gastrointestinal tract, these anomalies are found most commonly in the ileum within the leaves of the mesentery. Duplications may be long and tubular, but usually are cystic masses. In all cases, they share a common wall with the intestine. Symptoms associated with enteric duplication cysts include recurrent abdominal pain, emesis from intestinal obstruction, or hematochezia. Such bleeding typically results from ulceration in the duplication or in the adjacent intestine if the duplication contains ectopic gastric mucosa. On examination, a palpable mass is often identified. Children may also develop intestinal obstruction. Torsion may produce gangrene and perforation. Computerized tomography, ultrasonography and technetium pertechnetate scanning can be very helpful in diagnosis. Occasionally, a duplication is seen on small bowel follow through or barium enema. In the case of short duplications, resection of the cyst and adjacent intestine with end-to-end anastomosis can be performed in a straightforward fashion. If resection of long duplications would compromise intestinal length, multiple enterotomies and mucosal stripping in the duplicated segment will allow the walls to collapse and become adherent. An alternative method is to divide the common wall using the GIA stapler, forming a common lumen. Patients with duplications who undergo complete excision without compromise of the length of remaining intestine have an excellent prognosis.

Meckel Diverticulum

A Meckel diverticulum is a remnant of a portion of the embryonic omphalomesenteric (vitelline) duct. It is located on the antimesenteric border of the ileum, usually within 2 ft of the ileocecal valve. It may be found incidentally at surgery or may present with inflammation masquerading as appendicitis. Perforation of a Meckel diverticulum may occur if the outpouching becomes impacted with food, leading to distention and necrosis. Occasionally, a band of scar tissue (omphalomesenteric band) may extend from the Meckel diverticulum to the anterior abdominal wall and result in an internal hernia. This is an important cause of intestinal obstruction in the older child who has a scarless abdomen. Similar to duplications, ectopic gastric mucosa may produce ileal ulcerations that bleed and lead to the passage of maroon-colored stools. Pancreatic mucosa may also be present. Diagnosis may be made by technetium pertechnetate

scans when the patient presents with bleeding. Treatment is surgical. If the base is narrow and there is no mass present in the lumen of the diverticulum, a wedge resection of the diverticulum with transverse closure of the ileum can be performed. A linear stapler is especially useful in this circumstance. When a mass of ectopic tissue is palpable, if the base is wide, or when there is inflammation, it is preferable to perform a resection of the involved bowel and end-to-end ileo-ileostomy.

Hirschsprung Disease

Pathogenesis

In his classic textbook titled “Pediatric Surgery” Dr. Orvar Swenson—who is eponymously associated with one of the classic surgical treatments for Hirschsprung disease—described this condition as follows: “congenital megacolon is caused by a malformation in the pelvic parasympathetic system which results in the absence of ganglion cells in Auerbach’s plexus of a segment of distal colon. Not only is there an absence of ganglion cells, but the nerve fibers are large and excessive in number, indicating that the anomaly may be more extensive than the absence of ganglion cells.” This narrative of Hirschsprung disease is as accurate today as it was nearly 50 years ago, and summarizes the essential pathologic features of this disease: absence of ganglion cells in Auerbach plexus and hypertrophy of associated nerve trunks. The cause of Hirschsprung disease remains incompletely understood, although current thinking suggests that the disease results from a defect in the migration of neural crest cells, which are the embryonic precursors of the intestinal ganglion cell. Under normal conditions, the neural crest cells migrate into the intestine from cephalad to caudad. The process is completed by the twelfth week of gestation, but the migration from midtransverse colon to anus takes 4 weeks. During this latter period, the fetus is most vulnerable to defects in migration of neural crest cells. This may explain why most cases of aganglionosis involve the rectum and rectosigmoid. The length of the aganglionic segment of bowel is therefore determined by the most distal region that the migrating neural crest cells reach. In rare instances, total colonic aganglionosis may occur.

Clinical presentation. The incidence of sporadic Hirschsprung disease is 1 in 5000 live births. There are reports of increased frequency of Hirschsprung disease in multiple generations of the same family. Occasionally such families have mutations in the genes described above, including the Ret gene. Because the aganglionic colon does not permit normal peristalsis to occur, the presentation of children with Hirschsprung disease is characterized by a functional distal intestinal obstruction. In the newborn period, the most common symptoms are abdominal distention, failure to pass meconium, and bilious emesis. Any infant who does not pass meconium beyond 48 h of life must be investigated for the presence of Hirschsprung disease. Occasionally, infants present with a dramatic complication of Hirschsprung disease called enterocolitis. This pattern of presentation is characterized by abdominal distention and tenderness, and is associated with manifestations of systemic toxicity that include fever, failure to thrive and lethargy. Infants are often dehydrated, and demonstrate a leukocytosis or increase in circulating band forms on hematologic evaluation. On rectal examination, forceful propulsion of foul smelling liquid feces is typically observed, and represents the accumulation of stool

under pressure in an obstructed distal colon. Treatment includes rehydration, systemic antibiotics, nasogastric decompression and rectal irrigations while the diagnosis of Hirschsprung disease is being confirmed. In children that do not respond to nonoperative management, a decompressive stoma is required. It is important to ensure that this stoma is placed in ganglion-containing bowel, which must be confirmed by frozen section at the time of stoma creation.

In approximately 20 percent of cases, the diagnosis of Hirschsprung disease is made beyond the newborn period. These children have severe constipation, which has usually been treated with laxatives and enemas. Abdominal distention and failure to thrive may also be present at diagnosis.

Diagnosis

The definitive diagnosis of Hirschsprung disease is made by rectal biopsy. Samples of mucosa and submucosa are obtained at 1 cm, 2 cm, and 3 cm from the dentate line. This can be performed at the bedside in the neonatal period without anesthesia, as samples are taken in bowel that does not have somatic innervation and is thus not painful to the child. In older children, the procedure should be performed using intravenous sedation. The histopathology of Hirschsprung disease is the absence of ganglion cells in the myenteric plexuses, increased staining of an acetyl cholinesterase staining and the presence of hypertrophied nerve bundles.

It is important to obtain a barium enema in children in whom the diagnosis of Hirschsprung disease is suspected. This test may demonstrate the location of the transition zone between the dilated ganglionic colon and the distal constricted aganglionic rectal segment. Our practice is to obtain this test before instituting rectal irrigations, so that the difference in size between the proximal and distal bowel is preserved. Although the barium enema can only suggest, but not reliably establish, the diagnosis of Hirschsprung disease, it is very useful in excluding other causes of distal intestinal obstruction. These include small left colon syndrome (as occurs in infants of diabetic mothers), colonic atresia, meconium plug syndrome or the unused colon observed in infants after the administration of magnesium or tocolytic agents. The barium enema in total colonic aganglionosis may show a markedly shortened colon. Some surgeons have found the use of rectal manometry helpful, particularly in older children, although it is relatively inaccurate.

Treatment

The diagnosis of Hirschsprung disease requires surgery in all cases. The classic surgical approach consisted of a multiple stage procedure. This included a colostomy in the newborn period, followed by a definitive pull-through operation after the child was over 10 kg. There are three viable options for the definitive pull through procedure that are currently used. Although individual surgeons may advocate one procedure over another, studies have demonstrated that the outcome after each type of operation is similar. For each of the operations that is performed, the principles of treatment include confirming the location in the bowel where the transition zone between ganglionic and aganglionic bowel exists, resecting the aganglionic segment of bowel and performing an anastomosis of ganglionated bowel to either the anus or a cuff of rectal mucosa.

Recently, it has been shown that a primary pull-through procedure can be performed safely—even in the newborn period. This approach follows the same treatment principles as a staged procedure, and saves the patient from

an additional surgical procedure. Many surgeons perform the intraabdominal dissection using the laparoscope. This approach is especially useful in the newborn period, as this provides excellent visualization of the pelvis. In children with significant colonic distention, it is important to allow for a period of decompression using a rectal tube if a single staged pull through is to be performed. In older children with very distended, hypertrophied colon, it may be prudent to perform a colostomy to allow the bowel to decompress, prior to performing a pull through procedure. However, it should be emphasized that there is no upper age limit for performing a primary pull through.

Of the three pull-through procedures performed for Hirschsprung disease, the first is the original Swenson procedure. In this operation, the aganglionic rectum is dissected in the pelvis and removed down to the anus. The ganglionic colon is then anastomosed to the anus via a perineal approach. In the Duhamel procedure, dissection outside the rectum is confined to the retrorectal space, and the ganglionic colon is anastomosed posteriorly just above the anus. The anterior wall of the ganglionic colon and the posterior wall of the aganglionic rectum are anastomosed, using a stapler. Although both of these procedures are extremely effective, they are limited by the possibility of damage to the parasympathetic nerves that are adjacent to the rectum. To circumvent this potential problem, the Soave procedure involves dissection entirely within the rectum. The rectal mucosa is stripped from the muscular sleeve, and the ganglionic colon is brought through this sleeve and anastomosed to the anus. This operation may be performed completely from below. In all cases, it is critical that the level at which ganglionated bowel exists be determined. Most surgeons believe that the anastomosis should be performed at least 5 cm from the point at which ganglion cells are determined. This avoids performing a pull-through in the transition zone, which is associated with a high incidence of complications because of inadequate emptying of the pull-through segment. Up to one-third of patients who undergo a transition zone pull through will require a re-operation.

The main complications of all procedures include postoperative enterocolitis, constipation and anastomotic stricture. As mentioned, long-term results with the three procedures are comparable and generally excellent in experienced hands. These three procedures also can be adapted for total colonic aganglionosis in which the ileum is used for the pull-through segment.

JAUNDICE

The Approach to the Jaundiced Infant

Jaundice is present during the first week of life in 60 percent of term infants and 80 percent of preterm infants. There is usually accumulation of unconjugated bilirubin, but there may also be deposition of direct bilirubin. During fetal life, the placenta is the principal route of elimination of unconjugated bilirubin. In the newborn infant, bilirubin is conjugated through the activity of glucuronyl transferase. In the conjugated form, bilirubin is water soluble, which results in its excretion into the biliary system, then into the gastrointestinal tract. Newborns have a relatively high level of circulating hemoglobin, and relative immaturity of the conjugating machinery. This results in a transient accumulation of bilirubin in the tissues, which is manifested as jaundice. Physiologic jaundice is evident by the second or third day of life, and usually resolves within approximately 5–7 days. By definition, jaundice that persists beyond 2 weeks is considered pathologic.

Pathologic jaundice may be because of biliary obstruction, increased hemoglobin load or to liver dysfunction. The work-up of the jaundiced infant therefore should include a search for the following possibilities: (1) obstructive disorders, including biliary atresia, choledochal cyst and inspissated bile syndrome; (2) hematologic disorders, including ABO incompatibility, Rh incompatibility, spherocytosis; (3) metabolic disorders, including α_1 antitrypsin deficiency, galactosemia; pyruvate kinase deficiency; and (4) congenital infection, including syphilis and rubella.

Biliary Atresia

Pathogenesis

The most important surgical cause of jaundice in the newborn period is biliary atresia. The incidence of this disease is approximately 1 in 20,000. This disease is characterized by an obliterative process of the extrahepatic bile ducts, and is associated with hepatic fibrosis. The etiology is unknown. In the classic textbook, "Abdominal Surgery of Infancy And Childhood," Ladd and Gross described the cause of biliary atresia as an "arrest of development during the solid stage of bile duct formation." More recent evidence suggests an acquired basis for this disease, and studies in both animals and humans have implicated a role for the immune system and systemic viral infections in its pathogenesis.

Clinical Presentation

Jaundice, a constant finding, is usually present at birth or shortly thereafter but may go undetected or may be regarded as "physiologic" until the child is 2 or 3 weeks old. The infant demonstrates acholic, grey appearing stools, secondary to obstructed bile flow. Infants with biliary atresia also manifest progressive failure to thrive, and if untreated, progress to develop stigmata of liver failure and portal hypertension; particularly splenomegaly and esophageal varices.

The obliterative process involves the common duct, cystic duct, one or both hepatic ducts, and the gallbladder, in a variety of combinations. Approximately 25 percent of the patients have coincidental malformations, often associated with polysplenia and may include intestinal malrotation, preduodenal portal vein, and intrahepatic vena cava.

Diagnosis

Generally, a combination of investigations is required to ascertain the diagnosis of biliary atresia, as no single test is sufficiently sensitive or specific. In many centers the nuclear medicine scan using technetium-99m IDA (DISIDA), performed after pretreatment of the patient with phenobarbital, has proven to be an accurate and reliable study. If radionuclide appears in the intestine, extrahepatic bile duct patency is ensured and the diagnosis of biliary atresia is excluded. If radiopharmaceutical is normally concentrated by the liver but not excreted despite treatment with phenobarbital, and the metabolic screen, particularly α_1 -antitrypsin determination, is normal, the presumptive diagnosis is biliary atresia. An ultrasound may be performed to assess for the presence of other causes of biliary tract obstruction including choledochal cyst. The presence of a gallbladder is also evaluated, although it is important to emphasize that the presence of a gallbladder does not exclude the diagnosis of biliary atresia. In approximately 10 percent of patients, the distal biliary tract is patent and a

gall bladder may be visualized, even though the proximal ducts are atretic. It is worth noting that the intrahepatic bile ducts are never dilated in the patient with biliary atresia. A percutaneous liver biopsy may, at times, differentiate biliary atresia from neonatal hepatitis. When these tests point to a diagnosis of biliary atresia, surgical exploration is warranted. At surgery, a cholangiogram is performed, using the gallbladder as a conduit. This demonstrates the anatomy of the biliary tree, determines whether extrahepatic bile duct atresia is present and evaluates whether there is distal bile flow into the duodenum. The cholangiogram may demonstrate hypoplasia of the extrahepatic biliary system. This condition is associated with hepatic parenchymal disorders that cause severe intrahepatic cholestasis, including α 1-antitrypsin deficiency and arteriohepatic dysplasia (Alagille syndrome).

The presentation of biliary atresia closely mimics that of inspissated bile syndrome. This term is applied to patients with normal biliary tracts who have persistent obstructive jaundice. Increased viscosity of bile and obstruction of the canaliculi are implicated as causes. The condition has been seen in infants receiving parenteral nutrition, but it is also encountered in conditions associated with hemolysis, or in cystic fibrosis. In some instances, no etiologic factors can be defined. Neonatal hepatitis may present in a similar fashion to biliary atresia. This disease is characterized by persistent jaundice because of acquired biliary inflammation without obliteration of the bile ducts. There may be a viral etiology, and the disease is usually self limited.

Treatment

If the intraoperative cholangiogram confirms the presence of biliary atresia, then surgical correction should be immediately undertaken. The most effective surgical treatment for biliary atresia is the hepatopertoenterostomy, as described by Kasai. The purpose of this procedure is to promote bile flow into the intestine. The procedure is based on Kasai's observation that the fibrous tissue at the porta hepatis invests microscopically patent biliary ductules that, in turn, communicate with the intrahepatic ductal system. Transecting this fibrous tissue, invariably encountered cephalad to the bifurcating portal vein, opens these channels and establishes bile flow into a surgically constructed intestinal conduit, usually a Roux-en-Y limb of jejunum. Some authors believe that an intussuscepted antireflux valve is useful in preventing retrograde bile reflux, although the data suggest that it does not impact outcome. A liver biopsy is performed at the time of surgery to determine the degree of hepatic fibrosis that is present. The likelihood of surgical success is increased if the procedure is accomplished before the infant attains the age of 8 weeks. Although the outlook is less favorable for patients after the twelfth week, it is reasonable to proceed with surgery even beyond this time point, as the alternative is certain liver failure. It is noteworthy that a significant number of patients do have favorable outcomes when operated on at this time point.

Bile drainage is anticipated when the operation is carried out early; however, bile flow does not necessarily imply cure. Approximately a third of patients remain symptom-free after portoenterostomy, the remainder require liver transplantation because of progressive liver failure. Independent risk factors that predict failure of the procedure include bridging liver fibrosis at the time of surgery and postoperative cholangitic episodes. A recent review of the data of the Japanese Biliary Atresia Registry (JBAR), which includes the results of

1,381 patients, showed that the 10-year survival rate was 53 percent without transplantation, and with transplantation was 66.7 percent. A common post-operative common is cholangitis. There is no effective strategy to completely eliminate this complication, and the effectiveness of long-term prophylactic antibiotics has not been fully resolved.

DEFORMITIES OF THE ABDOMINAL WALL

Embryology of the Abdominal Wall

The abdominal wall is formed by four separate embryologic folds—cephalic, caudal, and right and left lateral folds—each of which is composed of somatic and splanchnic layers. Each of the folds develops toward the anterior center portion of the coelomic cavity, joining to form a large umbilical ring that surrounds the two umbilical arteries, the vein, and the yolk sac or omphalomesenteric duct. These structures are covered by an outer layer of amnion, and the entire unit composes the umbilical cord. Between the fifth and tenth weeks of fetal development the intestinal tract undergoes a rapid growth outside the abdominal cavity within the proximal portion of the umbilical cord. As development is completed, the intestine gradually returns to the abdominal cavity. Contraction of the umbilical ring completes the process of abdominal wall formation.

Failure of the cephalic fold to close results in sternal defects such as congenital absence of the sternum. Failure of the caudal fold to close results in exstrophy of the bladder and, in more extreme cases, exstrophy of the cloaca. Interruption of central migration of the lateral folds results in omphalocele. Gastroschisis, originally thought to be a variant of omphalocele, probably results from a fetal accident in the form of intrauterine rupture of a hernia of the umbilical cord.

Umbilical Hernia

Failure of the umbilical ring to close results in a central defect in the linea alba. The resulting umbilical hernia is covered by normal umbilical skin and subcutaneous tissue, but the fascial defect allows protrusion of abdominal contents. Hernias less than a cm in size at the time of birth usually will close spontaneously by four years of life. Sometimes the hernia is large enough that the protrusion is disfiguring and disturbing to both the child and the family. In such circumstances early repair may be advisable.

Repair of uncomplicated umbilical hernia is performed under general anesthesia as an outpatient procedure. A small curving incision that fits into the skin crease of the umbilicus is made, and the sac is dissected free from the overlying skin. The fascial defect is repaired with permanent or long-lasting absorbable, interrupted sutures that are placed in a transverse plane. The skin is closed using subcuticular sutures.

Omphalocele

Presentation

Omphalocele refers to a congenital defect of the abdominal wall in which the bowel and solid viscera are covered by peritoneum and amniotic membrane. The umbilical cord inserts into the sac. The abdominal wall defect measures 4 cm or more in diameter. The incidence is approximately 1 in 5000 live

births, and occurs in association with special syndromes such as exstrophy of the cloaca (vesicointestinal fissure), the Beckwith-Wiedemann constellation of anomalies (macroglossia, macrosomia, hypoglycemia, and visceromegaly and omphalocele) and the Cantrell Pentology (lower thoracic wall malformations [cleft sternum], ectopia cordis, epigastric omphalocele, anterior midline diaphragmatic hernia and cardiac anomalies). The size of the defect may be very small or large enough that it contains most of the abdominal viscera. There is a 60–70 percent incidence of associated anomalies, especially cardiac (20–40 percent of cases) and chromosomal abnormalities. Chromosomal anomalies are more common in children with smaller defects. Omphalocele is associated with prematurity (10–50 percent of cases) and intrauterine growth restriction (20 percent of cases).

Treatment

Immediate treatment of an infant with omphalocele consists of attending to the vital signs and maintaining the body temperature. The omphalocele should be covered with saline-soaked gauze and the trunk should be wrapped circumferentially. No pressure should be placed on the omphalocele sac in an effort to reduce its contents, as this maneuver may increase the risk of rupture of the sac, or may interfere with abdominal venous return. Prophylactic antibiotics should be administered in case of rupture. Whenever possible, a primary repair of the omphalocele should be undertaken. This involves resection of the omphalocele membrane and closure of the fascia. A layer of prosthetic material may be required to achieve closure.

Occasionally, an infant will have a giant omphalocele (defect greater than 7 cm in diameter) that cannot be closed primarily because there is simply no room to reduce the viscera into the abdominal cavity. Other, infants may have associated congenital anomalies that complicate surgical repair. Under these circumstances, a nonoperative approach can be used. The omphalocele sac can be treated with desiccating substances such as Silvadene. It typically takes two to three months before re-epithelialization occurs. In the past, mercury compounds were used, but they have been discontinued because of associated systemic toxicity.

Gastroschisis

Presentation

Gastroschisis represents a congenital defect characterized by a defect in the anterior abdominal wall through which the intestinal contents freely protrude. Unlike the omphalocele, there is no overlying sac and the size of the defect is much smaller (< 4 cm). The abdominal wall defect is located at the junction of the umbilicus and normal skin, and is almost always to the right of the umbilicus. The umbilicus becomes partly detached, allowing free communication with the abdominal cavity. The appearance of the bowel provides some information with respect to the in utero timing of the defect. The intestine may be normal in appearance, suggesting that the rupture occurred relatively late during the pregnancy. More commonly however, the intestine is thick, edematous, discolored, and covered with exudate, implying a more longstanding process.

Unlike infants born with omphalocele, associated anomalies seen with gastroschisis consist mostly of intestinal atresia. This defect can readily be diagnosed on prenatal ultrasound. There is no advantage in performing a cesarian

section over a vaginal delivery. Even though the thickness of the peel on the surface of the bowel indicates that a shorter gestational time would be less injurious, there is no benefit to early versus late delivery.

Treatment

All infants born with gastroschisis require urgent surgical treatment. In many instances, the intestine can be returned to the abdominal cavity, and a primary surgical closure of the abdominal wall is performed. Techniques that facilitate primary closure include mechanical stretching of the abdominal wall, thorough orogastric suctioning with foregut decompression, rectal irrigation and evacuation of all the meconium. Care must be taken to prevent increased abdominal pressure during the reduction, which would lead to compression of the inferior vena cava, respiratory embarrassment and result in abdominal compartment syndrome. To avoid this complication, it is helpful to monitor the bladder or airway pressure during reduction. In infants whose intestine has become thickened and edematous, it may be impossible to reduce the bowel into the peritoneal cavity in the immediate post natal period. Under such circumstances, a plastic spring-loaded silo can be placed onto the bowel and secured beneath the fascia. The silo covers the bowel and allows for graduated reduction on a daily basis as the edema in the bowel wall decreases. Surgical closure can usually be accomplished within approximately one week. A prosthetic piece of material (Gore-Tex, Surgisis) may be required to bring the edges of the fascia together. If an atresia is noted at the time of closure, it is prudent to reduce the bowel at the first operation, then to return after several weeks once the edema has resolved, to correct the atresia. Intestinal function does not typically return for several weeks in patients with gastroschisis. This is especially true if the bowel is thickened and edematous. As a result, these patients will require central line placement and institution of total parenteral nutrition to grow.

Inguinal Hernia

An understanding of the management of pediatric inguinal hernias is a central component of modern pediatric surgical practice. Inguinal hernia repair represents one of the most common operations performed in children. The presence of an inguinal hernia in a child is an indication for surgical repair. The operation to perform an inguinal hernia is termed a herniorrhaphy because it involves closing the patent processus vaginalis. This is to be contrasted with the hernioplasty that is performed in adults, which requires a reconstruction of the inguinal floor.

Embryology

To understand how to diagnose and treat inguinal hernias in children, it is critical to understand the embryologic origin. It is very useful to describe these events to the parents, who often are under the misconception that the hernia was somehow caused by their inability to console their crying child, or the child's high activity level. Inguinal hernia results from a failure of closure of the processus vaginalis; a finger-like projection of the peritoneum that accompanies the testicle as it descends into the scrotum. Closure of the processus vaginalis normally occurs a few months prior to birth. This explains the high incidence of inguinal hernias in premature infants. When the processus vaginalis remains completely patent, a communication persists between

the peritoneal cavity and the groin, resulting in a hernia. Partial closure can result in entrapped fluid, which results in the presence of a hydrocele. A communicating hydrocele refers to a hydrocele that is in communication with the peritoneal cavity, and can therefore be thought of as a hernia. Using the classification system that is typically applied to adult hernias, all congenital hernias in children are by definition indirect inguinal hernias. Children also present with direct inguinal and femoral hernias, although these are much less common.

Clinical Manifestation

Inguinal hernias occur more commonly in males than females (10:1), and are more common on the right side than the left. Infants are at high risk for incarceration of an inguinal hernia because of the narrow inguinal ring. Patients most commonly present with a groin bulge that is noticed by the parents as they change the diaper. Older children may notice the bulge themselves. On examination, the cord on the affected side will be thicker, and pressure on the lower abdomen usually will display the hernia on the affected side. The presence of an incarcerated hernia is manifested by a firm bulge that does not spontaneously resolve, and may be associated with fussiness and irritability in the child. The infant that has a strangulated inguinal hernia will manifest an edematous, tender bulge in the groin, occasionally with overlying skin changes. The child will eventually develop intestinal obstruction, peritonitis and systemic toxicity.

Usually an incarcerated hernia can be reduced. Occasionally this may require light sedation. Gentle pressure is applied on the sac from below in the direction of the internal inguinal ring. Following reduction of the incarcerated hernia, the child may be admitted for observation, and herniorrhaphy is performed within the next 24 h to prevent recurrent incarceration. Alternatively, the child may be scheduled for surgery at the next available time slot. If the hernia cannot be reduced, or if evidence of strangulation is present, emergency operation is necessary. This may require a laparotomy and bowel resection.

When the diagnosis of inguinal hernia is made in an otherwise normal child, operative repair should be planned. Spontaneous resolution does not occur and therefore a nonoperative approach can not be ever justified. An inguinal hernia in a female frequently contains an ovary rather than intestine. Although the gonad usually can be reduced into the abdomen by gentle pressure, it often prolapses in and out until surgical repair is carried out. In some patients, the ovary and fallopian tube constitute one wall of the hernia sac (sliding hernia), and in these patients the ovary can be reduced effectively only at the time of operation. If the ovary is irreducible, prompt hernia repair is indicated to prevent ovarian torsion or strangulation.

When a hydrocele is diagnosed in infancy and there is no evidence of a hernia, observation is proper therapy until the child is older than 12 months. If the hydrocele has not disappeared by 12 months, invariably there is a patent processus vaginalis, and hydrocelectomy with excision of the processus vaginalis is indicated. When the first signs of a hydrocele are seen after 12 months of age, the patient should undergo elective hydrocelectomy, which in a child is always performed through a groin incision. Aspiration of hydroceles is discouraged, because almost all without a patent processus vaginalis will resorb spontaneously, and those with a communication to the peritoneum will recur and require operative repair eventually.

Surgical Repair

The repair of a pediatric inguinal hernia can be extremely challenging, particularly in the premature child with incarceration. A small incision is made in a skin crease in the groin directly over the internal inguinal ring. The Scarpa fascia is seen and divided. The external oblique muscle is dissected free from overlying tissue, and the location of the external ring is confirmed. The external oblique aponeurosis is then opened along the direction of the external ring. The undersurface of the external oblique is then cleared from surrounding tissue. The cremasteric fibers are separated from the cord structures and hernia sac, and these are then elevated into the wound. Care is taken not to grasp the vas deferens. The hernia sac is then dissected up to the internal ring and doubly suture ligated. The distal part of the hernia sac is opened widely to drain any hydrocele fluid. When the hernia is very large and the patient very small, tightening of the internal inguinal ring or even formal repair of the inguinal floor may be necessary, although the vast majority of children do not require any treatment beyond high ligation of the hernia sac.

Controversy exists regarding the role for exploration of an asymptomatic opposite side in a child with an inguinal hernia. Several reports indicate that frequency of a patent processus vaginalis on the side opposite the obvious hernia is approximately 30 percent, although this figure decreases with increasing age of the child. Management options include never exploring the opposite side, to exploring only under certain conditions such as in premature infants or in patients in whom incarceration is present. The opposite side may be explored laparoscopically. To do so, a blunt 4-mm trocar is placed into the hernia sac of the affected side. The abdominal cavity is insufflated, and the 4-mm, 70-degree camera is placed through the trocar such that the opposite side is visualized. The status of the processus vaginalis on the opposite side can be visualized. However, the presence of a patent processus vaginalis by laparoscopy does not always imply the presence of a hernia.

Several authors have now reported a completely laparoscopic approach in the management of inguinal hernias in children. This technique requires insufflation through the umbilicus, and the placement of an extraperitoneal suture to ligate the hernia sac. Proponents of this procedure emphasize the fact that no groin incision is used and there is a decreased chance of injuring cord structures. The long term results of this technique remain to be established.

Inguinal hernias in children recur in less than 1 percent of patients, and recurrences usually result from missed hernia sacs at the first procedure, a direct hernia, or a missed femoral hernia. All children should have local anesthetic administered either by caudal injection or by direct injection into the wound. Spinal anesthesia in preterm infants decreases the risk of postoperative apnea when compared with general anesthesia.

GENITALIA

Undescended Testis

Embryology

The term undescended testicle (cryptorchidism) refers to the interruption of the normal descent of the testis into the scrotum. The testicle may reside in the retroperineum, in the internal inguinal ring, in the inguinal canal, or even at the

external ring. The testicle begins as a thickening on the urogenital ridge in the fifth to sixth week of embryologic life. In the seventh and eighth months the testicle descends along the inguinal canal into the upper scrotum, and with its progress the processus vaginalis is formed and pulled along with the migrating testicle. At birth, approximately 95 percent of infants have the testicle normally positioned in the scrotum.

A distinction should be made between the undescended testicle and the ectopic testicle. An ectopic testis, by definition, is one that has passed through the external ring in the normal pathway and then has come to rest in an abnormal location overlying either the rectus abdominis or external oblique muscle, or the soft tissue of the medial thigh, or behind the scrotum in the perineum. A congenitally absent testicle results from failure of normal development or an intrauterine accident leading to loss of blood supply to the developing testicle.

Clinical Presentation

The incidence of undescended testes is approximately 30 percent in preterm infants and 1–3 percent at term. For diagnosis, the child should be examined in the supine position, where visual inspection may reveal a hypoplastic or poorly rugated scrotum. Usually a unilateral undescended testicle can be palpated in the inguinal canal or in the upper scrotum. Occasionally, the testicle will be difficult or impossible to palpate, indicating either an abdominal testicle or congenital absence of the gonad. If the testicle is not palpable in the supine position, the child should be examined with his legs crossed while seated. This maneuver diminishes the cremasteric reflex and facilitates identification of the location of the testicle.

It is now established that cryptorchid testes demonstrate an increased predisposition to malignant degeneration. Additionally, fertility is decreased when the testicle is not in the scrotum. For these reasons, surgical placement of the testicle in the scrotum (orchidopexy) is indicated. It should be emphasized that this procedure does improve the fertility potential, although it is never normal. Similarly, the testicle is still at risk of malignant change, although its location in the scrotum facilitates potentially earlier detection of a testicular malignancy. Other reasons to consider orchidopexy include the risk of trauma to the testicle located at the pubic tubercle, and increased incidence of torsion, and the psychological impact of an empty scrotum in a developing male. The reason for malignant degeneration is not established, but the evidence points to an inherent abnormality of the testicle that predisposes it to incomplete descent and malignancy rather than malignancy as a result of an abnormal environment.

Treatment

Males with bilateral undescended testicles are often infertile. When the testicle is not within the scrotum, it is subjected to a higher temperature, resulting in decreased spermatogenesis. Mengel and coworkers studied 515 undescended testicles by histology and demonstrated a decreasing presence of spermatogonia after 2 years of age. Consequently it is now recommended that the undescended testicle be surgically repositioned by 2 years of age at the latest. Despite orchidopexy, the incidence of infertility is approximately two times higher in men with unilateral orchidopexy compared to men with normal testicular descent.

The use of chorionic gonadotropin occasionally may be effective in patients with bilateral undescended testes, suggesting that these patients are more apt to have a hormone insufficiency than children with unilateral undescended

testicle. If there is no testicular descent after a month of endocrine therapy, operative correction should be undertaken. A child with unilateral cryptorchidism should have surgical correction of the problem. The operation is typically performed through a combined groin and scrotal incision. The cord vessels are fully mobilized, and the testicle is placed in a dartos pouch within the scrotum. An inguinal hernia often accompanies a cryptorchid testis. This should be repaired at the time of orchidopexy.

Patients with a nonpalpable testicle present a challenge in management. The current approach involves laparoscopy to identify the location of the testicle. If the spermatic cord is found to traverse the internal ring or the testis is found at the ring and can be delivered into the scrotum, a groin incision is made and an orchidopexy is performed. If an abdominal testis is identified which is too far to reach the scrotum, a two staged Fowler-Stephens approach is used. In the first stage, the testicular vessels are clipped laparoscopically. The orchidopexy is then performed through the groin approximately 6 months later, after which time collateral flow supplies the testicle. It is preferable to preserve the testicular vessels whenever possible. When the testicle is within one or two centimeters from the ring, its blood supply may be preserved by mobilizing the testicular vessels up to the renal hilum, then releasing the peritoneal attachments. This often provides sufficient length to allow an orchidopexy to be performed through the groin.

Some patients who have an absent testis are greatly bothered by this anatomic deficiency. Prostheses of all sizes are now available and can be simply inserted into the scrotum, achieving normal appearance and a normal structure for palpation. Any patient who has an undescended testicle corrected surgically should be examined yearly by the surgeon until his mid-teen years. At that time, the individual should undergo thorough explanation about the possibility of malignant degeneration and be instructed in self-examination, which should be carried out at least twice a year for life.

Ovarian Cysts and Tumors

Pathologic Classification

Ovarian cysts and tumors may be classified as nonneoplastic or neoplastic. Nonneoplastic lesions include cysts (simple, follicular, inclusion, paraovarian, or corpus luteum), endometriosis, and inflammatory lesions. Neoplastic lesions are classified based on the three primordia that contribute to the ovary: mesenchymal components of the urogenital ridge; germinal epithelium overlying the urogenital ridge; and germ cells migrating from the yolk sac. The most common variety is germ cell tumors. Germ cell tumors are classified based on the degree of differentiation and the cellular components involved. The least differentiated tumors are the dysgerminomas, which share features similar to the seminoma in males. Although these are malignant tumors, they are extremely sensitive to radiation and chemotherapy. The most common lesions are the teratomas, which may be mature, immature, or malignant. The degree of differentiation of the neural elements of the tumor determines the degree of immaturity. The sex cord stromal tumors arise from the mesenchymal components of the urogenital ridge. These include the granulosa-theca cell tumors and the Sertoli-Leydig cell tumors. These tumors often produce hormones that result in precocious puberty or hirsutism respectively. Although rare, epithelial tumors do occur in children. These include serous and mucinous cystadenomas.

Clinical Presentation

Children with ovarian lesions usually present with abdominal pain. Other signs and symptoms include a palpable abdominal mass, evidence of urinary obstruction, symptoms of bowel obstruction, and endocrine imbalance. The surgical approach depends on the appearance of the mass at operation, i.e., whether it is benign-appearing or is suspicious for malignancy. In the case of a simple ovarian cyst, surgery depends on the size of the cyst and the degree of symptoms it causes. In general, large cysts (over 4–5 cm) in size should be resected, as they are unlikely to resolve, may be at risk of torsion, and may mask an underlying malignancy. Resection may be performed laparoscopically, and ovarian tissue should be spared in all cases.

Surgical Management

For ovarian lesions that appear malignant, it is important to obtain tumor markers including alpha fetoprotein (teratomas), LDH (dysgerminoma), beta human chorionic gonadotropin (choriocarcinoma) and CA-125 (epithelial tumors). Although the diagnostic sensitivity of these markers is not always reliable, they provide material for postoperative follow up and indicate the response to therapy. When a malignancy is suspected, the patient should undergo a formal cancer operation. This procedure is performed through either a midline incision or a Pfannenstiel approach. Ascites and peritoneal washings should be collected for cytologic study. The liver and diaphragm are inspected carefully for metastatic disease. An omentectomy is performed if there is any evidence of tumor present. Pelvic and paraaortic lymph nodes are biopsied and the primary tumor is resected completely. Finally, the contralateral ovary is carefully inspected and if a lesion is seen it should be biopsied. Dysgerminomas and epithelial tumors may be bilateral in up to 15 percent of cases. It is occasionally possible to preserve the ipsilateral fallopian tube. More radical procedures are not indicated.

Ovarian Cysts in the Newborn

An increasing number of ovarian cysts are being detected by prenatal ultrasound. In the past, surgical excision was recommended for all cysts greater than 5 cm in diameter because of the perceived risk of ovarian torsion. More recently, it has become apparent from serial ultrasound examinations that many of these lesions will resolve spontaneously. Therefore, asymptomatic, simple cysts may be observed, and surgery can be performed only when they fail to decrease in size or become symptomatic. Typically, resolution occurs by approximately 6 months of age. A laparoscopic approach may be used. By contrast, complex cysts of any size require surgical intervention at presentation.

PEDIATRIC MALIGNANCY

Cancer is the second leading cause of death in children after trauma, and accounts for approximately 11 percent of all pediatric deaths in the United States. Several features distinguish pediatric from adult cancers, including the presence of tumors that are predominantly seen in children, such as neuroblastoma and germ cell tumors, and the favorable response to chemotherapy observed for many pediatric solid malignancies, even in the presence of metastases.

Wilms Tumor

Clinical Presentation

Wilms tumor is the most common primary malignant tumor of the kidney in children. There are approximately 500 new cases annually in the United States, and most are diagnosed between 1 and 5 years of age, with the peak incidence at age 3 years. Advances in the care of patients with Wilms tumor have resulted in an overall cure rate of roughly 90 percent, even in the presence of metastatic spread. The tumor usually develops in otherwise healthy children as an asymptomatic mass in the flank or upper abdomen. Frequently, the mass is discovered by a parent while bathing or dressing the child. Other symptoms include hypertension, hematuria, obstipation or weight loss. Occasionally the mass is discovered following blunt abdominal trauma.

Genetics of Wilms tumor. Wilms tumor can arise from both germline and somatic mutations, and can occur in the presence or absence of a family history. Nearly 97 percent of Wilms tumors are sporadic in that they occur in the absence of a heritable or congenital cause or risk factor. When a heritable risk factor is identified, the affected children often present at an earlier age, and are frequently bilateral. Most of these tumors are associated with germline mutations. It is well established that there is a genetic predisposition to Wilms tumor in the WAGR syndrome, which consists of Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation. Additionally, there is an increased incidence of Wilms tumor in certain overgrowth conditions, particularly Beckwith–Wiedemann syndrome and hemi-hypertrophy. The WAGR syndrome has been shown to result from the deletion of one copy each of the Wilms tumor gene, WT1 and the adjacent aniridia gene, PAX6 on chromosome 11p13. Beckwith–Wiedemann syndrome is an overgrowth syndrome that is characterized by visceromegaly, macroglossia and hyperinsulinemic hypoglycemia. It arises from mutations at the 11p15.5 locus. There is evidence to suggest that analysis of the methylation status of several genes in the 11p15 locus could predict the individual risk to the development of Wilms tumor. Importantly, most patients with Wilms tumor do not have mutations at these genetic loci.

Surgical treatment. Before operation, all patients suspected of Wilms tumor should undergo abdominal and chest CT. These studies characterize the mass, identify the presence of metastases, and provide information on the opposite kidney. CT scanning also indicates the presence of nephrogenic rests, which are precursor lesions to Wilms tumor. An abdominal ultrasound should be performed to demonstrate the presence of renal vein or vena caval extension.

The management of patients with Wilms tumor has been carefully evaluated within the context of large studies involving thousands of patients. These studies have been coordinated by the National Wilms' Tumor Study Group (NWTSG) in North America and the International Society of Pediatric Oncology (SIOP), mainly involving European countries. Significant differences in the approach to patients that present with Wilms tumor have been highlighted by these studies. NWTSG supports a strategy of surgery followed by chemotherapy in most instances, whereas the SIOP approach is to shrink the tumor using preoperative chemotherapy. There are instances where preoperative chemotherapy is supported by both groups, including the presence of bilateral involvement or inferior vena cava involvement that extends above the hepatic

veins and involvement of a solitary kidney by Wilms tumor. The NWTSG proponents argue that preoperative therapy in other instances results in a loss of important staging information, and therefore places patients at higher risk for recurrence, alternatively it may lead to overly aggressive treatment in some cases. However, the overall survival rates are not different between the NWTSG and SIOP approaches.

The goals of surgery include complete removal of the tumor. It is crucial to avoid tumor rupture or injury to contiguous organs. A sampling of regional lymph nodes should be included and all suspicious nodes should be sampled. Typically a transverse abdominal incision is made, and a transperitoneal approach is used. The opposite side is carefully inspected to ensure that there is no disease present. A radical nephroureterectomy is then performed with control of the renal pedicle as an initial step. If there is spread above the hepatic veins, an intrathoracic approach may be required. If bilateral disease is encountered, both lesions are biopsied, and chemotherapy is administered followed by a nephron-sparing procedure.

Neuroblastoma

Clinical presentation. Neuroblastoma is the third most common pediatric malignancy, and accounts for approximately 10 percent of all childhood cancers. The vast majority of patients have advanced disease at the time of presentation, and unlike Wilms tumor, the overall survival is less than 30 percent. Over 80 percent of cases present before the age of 4 years, and the peak incidence is 2 years of age. Neuroblastomas arise from the neural crest cells and show different levels of differentiation. The tumor originates most frequently in the adrenal glands, posterior mediastinum, neck, or pelvis but can arise in any sympathetic ganglion. The clinical presentation depends on the site of the primary and the presence of metastasis.

Two-thirds of these tumors are first noted as an asymptomatic abdominal mass. The tumor may cross the midline, and a majority of patients will already show signs of metastatic disease. Occasionally, children may present with pain from the tumor mass or to bone pain from metastases. Proptosis and periorbital ecchymosis may occur because of the presence of retrobulbar metastasis. Because they originate in paraspinal ganglia, neuroblastomas may invade through neural foramina and compress the spinal cord, causing muscle weakness or sensory changes. Rarely, children may have severe watery diarrhea because of the secretion of vasoactive intestinal peptide by the tumor, or with paraneoplastic neurologic findings including cerebellar ataxia or opsoclonus/myoclonus.

Diagnostic Evaluation

Because these tumors derive from the sympathetic nervous system, catecholamines and their metabolites will be produced at increased levels. These include elevated levels of serum catecholamines (dopamine, norepinephrine) or urine catecholamine metabolites: vanillylmandelic acid (VMA) or homovanillic acid (HVA). Measurement of VMA and HVMA in serum and urine aids in the diagnosis and in monitoring adequacy of future treatment and recurrence. The minimum criterion for a diagnosis of neuroblastoma is based on 1 of the following: (1) An unequivocal pathologic diagnosis made from tumor tissue by light microscopy (with or without immunohistology, electron microscopy, or increased levels of serum catecholamines or urinary catecholamine

metabolites); (2) The combination of bone marrow aspirate or biopsy containing unequivocal tumor cells and increased levels of serum catecholamines or urinary catecholamine metabolites as described above.

The patient should be evaluated by abdominal computerized tomography, which usually shows displacement and occasionally obstruction of the ureter of an intact kidney. Prior to the institution of therapy, a complete staging work-up should be performed. This includes radiograph of the chest, bone marrow biopsy, and radionuclide scans to search for metastases. Any abnormalities on chest radiograph should be followed up with computerized tomography of the chest.

Prognostic Indicators

A number of biologic variables have been studied in children with neuroblastoma. An open biopsy is required to obtain sufficient tissue for this analysis. Hyperdiploid tumor DNA is associated with a favorable prognosis, and N-myc amplification is associated with a poor prognosis regardless of patient age. The Shimada classification describes tumors as either favorable or unfavorable histology based on the degree of differentiation, the mitosis-karyorrhexis index, and the presence or absence of schwannian stroma. In general, children of any age with localized neuroblastoma and infants younger than 1 year of age with advanced disease and favorable disease characteristics have a high likelihood of disease free survival. By contrast, older children with advanced-stage disease, have a significantly decreased chance for cure despite intensive therapy. For example, aggressive multiagent chemotherapy has resulted in a 2-year survival rate of approximately 20 percent in older children with stage IV disease. Neuroblastoma in the adolescent has a worse long-term prognosis regardless of stage or site and, in many cases, a more prolonged course.

Surgery

The goal of surgery is complete resection. However, this is often not possible because of the extensive locoregional spread of the tumor at the time of presentation. Under these circumstances, a biopsy is performed and preoperative chemotherapy is provided based on the stage of the tumor. After neoadjuvant treatment has been administered, surgical resection is performed. The principal goal of surgery is to obtain at least a 95 percent resection, without compromising major structures. Abdominal tumors are approached through a transverse incision. Thoracic tumors may be approached through a posterolateral thoracotomy or through a thoracoscopic approach. These may have an intraspinal component.

Neuroblastoma in Infants

Spontaneous regression of neuroblastoma has been well described in infants, especially in those with Stage 4S disease. Regression generally occurs only in tumors with a near triploid number of chromosomes that also lack N-myc amplification and loss of chromosome 1p. Recent studies indicate that infants with asymptomatic, small, low-stage neuroblastoma detected by screening, may have tumors that spontaneously regress. These patients may be observed safely without surgical intervention or tissue diagnosis.

TRAUMA IN CHILDREN

Injury is the leading cause of death among children older than 1 year. In fact, trauma accounts for almost half of all pediatric deaths; more than cancer,

congenital anomalies, pneumonia, heart disease, homicide, and meningitis combined. Death from unintentional injury accounts for 65 percent of all injury deaths in children younger than 19 years. From 1972–1992, motor vehicle collisions were the leading cause of death in people aged 1–19 years, followed by homicide or suicide (predominantly with firearms) and drowning. Each year, approximately 20,000 children and teenagers die as a result of injury in the United States. For every child who dies from an injury, it is calculated that 40 others are hospitalized and 1120 are treated in emergency departments. An estimated 50,000 children acquire permanent disabilities each year, most of whom are the result of head injuries. Thus, pediatric trauma continues to be one of the major threats to the health and well-being of children.

Specific considerations apply to trauma in children that influence management and outcome. These relate to the mechanisms of injury, the anatomic variations in children compared to adults and the physiologic responses.

Mechanisms of Injury

Most pediatric trauma is blunt. Penetrating injuries are seen in the setting of gun violence, falls onto sharp objects, or penetration by glass after falling through windows. Age and gender significantly influence the patterns of injury. Male children younger than 18 years are exposed to contact sports and drive motor vehicles. As a result, they have a different pattern of injury than younger children, characterized by higher injury severity scores. In the infant and toddler age group, falls are a common cause of severe injury. Injuries in the home are extremely common. These include falls, near-drownings, caustic ingestion and nonaccidental injuries.

Initial Management

The goals of managing the pediatric trauma patient are similar to that of adults, and follow Advanced Trauma Life Support guidelines as established by the American College of Surgeons. Airway control is the first priority. In a child, respiratory arrest can proceed quickly to a cardiac arrest. It is important to be aware of the anatomic differences between the airway of the child and the adult. The child has a shorter neck, smaller and anterior larynx, floppy epiglottis, short trachea, and large tongue. The child's fifth digit can provide an estimate of the size of the endotracheal tube. Alternatively, the formula $(\text{age} + 16)/4$ may be used. It is preferable to use uncuffed endotracheal tubes in children younger than 8 years to minimize tracheal trauma. After evaluation of the airway, breathing is assessed. It is important to consider that gastric distention from aerophagia can severely compromise respirations. A nasogastric tube should therefore be placed early in the resuscitation. Pneumothorax or hemothorax should be treated promptly. When evaluating the circulation, it is important to recognize that tachycardia is usually the earliest measurable response to hypovolemia. Other signs of impending hypovolemic shock in children include changes in mentation, delayed capillary refill, skin pallor, and hypothermia. Intravenous access should be rapidly obtained once the patient arrives in the trauma bay. The first approach should be to use the antecubital fossae. If this is not possible, a cut-down onto the saphenous at the groin can be performed quickly and safely. Intraosseous cannulation can provide temporary access in infants until intravenous access is established. Percutaneous neck lines should be generally avoided. Blood is drawn for cross-match and evaluation of liver enzymes, lipase, amylase and hematologic profile after the intravenous lines are placed.

In patients who show signs of volume depletion, a 20 mL/kg bolus of saline or lactated Ringer should be promptly given. If the patient does not respond to three boluses, blood should be transfused (10 mL/kg). The source of bleeding should be established. Common sites include the chest, abdomen, pelvis, extremity fractures or large scalp wounds. These should be carefully sought. Care is taken to avoid hypothermia, by infusing warmed fluids and by using external warming devices.

Evaluation of Injury

All patients should receive a radiograph of the c-spine, chest, and abdomen with pelvis. All extremities that are suspicious for fracture should also be evaluated by radiograph. Screening blood work that includes AST, ALT, and amylase/lipase is useful for the evaluation of liver and pancreatic injuries. Significant elevation in these tests require further evaluation by CT scanning. The child with significant abdominal tenderness and a mechanism of injury that could cause intraabdominal injury should undergo abdominal CT scanning using intravenous and oral contrast in all cases. There is a limited role for diagnostic peritoneal lavage (DPL) in children as a screening test. However, this can be very useful in the child that is brought emergently to the operating room for management of significant intracranial hemorrhage. At the time of craniotomy, a DPL can be performed concurrently, to identify abdominal bleeding. Although abdominal ultrasound is extremely useful in the evaluation of adult abdominal trauma, it has not been widely accepted in the management of pediatric injury. In part this relates to the widespread use of nonoperative treatment for most solid-organ injuries, which would result in a positive abdominal ultrasound scan.

Thoracic Injuries

The pediatric thorax is pliable because of incomplete calcification of the ribs and cartilages. As a result, blunt chest injury commonly results in pulmonary contusion, although rib fractures are infrequent. Diagnosis is made by chest radiograph and may be associated with severe hypoxia requiring mechanical ventilation. Pulmonary contusion usually resolves with careful ventilator management and judicious volume resuscitation. Children who have sustained massive blunt thoracic injury may develop traumatic asphyxia. This is characterized by cervical and facial petechial hemorrhages or cyanosis associated with vascular engorgement and subconjunctival hemorrhage. Management includes ventilation and treatment of coexisting central nervous system (CNS) or abdominal injuries. Penetrating thoracic injuries may result in damage to the lung, or to major disruption of the bronchi or great vessels.

Abdominal Injuries

In children, the small rib cage and minimal muscular coverage of the abdomen can result in significant injury after seemingly minor trauma. The liver and spleen in particular are relatively unprotected, and are often injured after direct abdominal trauma. Duodenal injuries are usually the result of blunt trauma, which may arise from child abuse or injury from a bicycle handlebar. Duodenal hematomas usually resolve without surgery. Small intestinal injury usually occurs in the jejunum in the area of fixation by the ligament of Treitz. These injuries are usually caused by rapid deceleration in the setting of a lap belt. There may be a hematoma on the anterior abdominal wall caused by a lap belt, the so-called "seat belt sign." This finding should alert the caregiver to the

possibility of an underlying small bowel injury, and a lumbar spine fracture (Chance fracture).

The spleen is injured relatively commonly after blunt abdominal trauma in children. The extent of injury to the spleen is graded, and the management is governed by the injury grade. Current treatment involves a nonoperative approach in most cases, even for grade 4 injuries, provided that the patient is hemodynamically stable. This approach avoids surgery in most cases. All patients should be placed in a monitored unit, and type specific blood should be available for transfusion. When nonoperative management is successful, as it is in most cases, an extended period of bed rest is prescribed. This optimizes the chance for healing, and minimizes the likelihood of re-injury. A typical guideline is to keep the children on restricted activity for two weeks longer than the grade of spleen injury (i.e., a child with a grade 4 spleen injury receives 6 weeks of restricted activity). In children that have an ongoing fluid requirement, or when a blood transfusion is required, exploration should not be delayed. At surgery, the spleen can often be salvaged. If a splenectomy is performed, prophylactic antibiotics and immunizations should be administered to protect against overwhelming postsplenectomy sepsis. The liver is also commonly injured after blunt abdominal trauma. A grading system is used to characterize hepatic injuries, and nonoperative management is usually successful. Recent data have shown that associated injuries are more significant predictors of outcome in children with liver injuries rather than the actual injury grade. Criteria for surgery are similar to those for splenic injury, and primarily involve hemodynamic instability. The intraoperative considerations in the management of massive hepatic injury are similar in children and adults. Renal contusions may occur after significant blunt abdominal trauma. Nonoperative management is usually successful, unless patients are unstable because of active renal bleeding. It is important to confirm the presence of a normal contralateral kidney at the time of surgery.

ANATOMY**The Kidney and Ureter**

The organs of the urinary system, which include the kidney, ureter, and bladder, are located in the retroperitoneum. The kidneys are paired organs surrounded by perirenal fat and the Gerota fascia. The superior aspect of the kidney is contained within the lower thoracic cavity at the level of the tenth rib.

The blood supply to the kidney comes from the renal artery. The right and left renal arteries come off the aorta just inferior to the takeoff of the superior mesenteric artery. The renal veins are anterior to the renal arteries and drain into the inferior vena cava. In the kidney, the arteries are end-arteries, although the veins anastomose freely. The left adrenal vein and left gonadal vein drain into the left renal vein, although on the right, these same vessels drain directly into the vena cava.

Adrenal Gland

The adrenal glands are endocrine organs that lie superomedial to the kidneys. They are surrounded by the perirenal fat and contained within the Gerota fascia. The right adrenal gland is positioned posterolateral to the inferior vena cava and tends to be more superior in relation to the left adrenal gland. The arterial blood supply to the adrenal glands is provided primarily by the inferior phrenic artery. On the right, the primary venous drainage is directly to the inferior vena cava. On the left, the primary venous drainage is to the left renal vein.

Bladder and Urethra

The bladder is a hollow, muscular organ adapted for storing and expelling urine. When it is empty, it lies posterior to the pubic symphysis in the pelvis and is extraperitoneal. The dome of the bladder is covered with peritoneum, and when the bladder is full, it can rise into the abdomen and is palpable on physical examination. The normal bladder can store approximately 350–450 mL. The arterial blood supply to the bladder comes from the superior, middle, and inferior vesical arteries, which are all branches of the internal iliac artery. The venous return from the bladder drains into the internal iliac vein.

Prostate and Seminal Vesicle

The prostate gland and the seminal vesicles are part of the male reproductive system. Secretions from these two organs make up part of the male semen. The prostate surrounds the proximal urethra. The gland can be divided into several zones. Most prostate cancers form in the peripheral zone. The central zone surrounds the ejaculatory ducts as they empty into the urethra at the verumontanum. Benign prostatic hyperplasia (BPH) is caused by enlargement of the transition zone surrounding the urethra. BPH, which is common in the older adult population, can lead to increased urinary resistance and voiding symptoms.

Testis

The volume of an average testis is approximately 20 mL. The testicles have two important functions: androgen and sperm production. The Leydig cells in the testis produce testosterone. The Sertoli cells support the maturation of spermatogenic cells into sperm. The Sertoli cells also are responsible for establishing a blood–testis barrier.

The testicles are surrounded by several fascial layers that are embryologically derived from the same layers comprising the anterior abdominal wall. The external spermatic fascia is analogous to the external oblique. The cremasteric muscle envelops the spermatic cord and is analogous to the internal oblique and transversus abdominis. The internal spermatic fascia is analogous to the transversalis fascia. The visceral and parietal layers of the tunica vaginalis testis represent peritoneum that surrounded the testicle during its descent into the scrotum.

The blood supply to the testicles is provided by three arteries: gonadal, cremasteric, and vasal. The gonadal artery branches directly from the aorta. The cremasteric artery branches from the inferior epigastric artery, and the vasal artery branches from the superior vesical artery. The venous drainage from the testicles forms the pampiniform plexus at the level of the spermatic cord. At the internal inguinal ring, the pampiniform plexus coalesces to form the gonadal vein, which drains into the inferior vena cava on the right and into the renal vein on the left.

Penis

The penis is formed by three corpora bodies: two corpora cavernosa and a corpus spongiosum. The corpus spongiosum surrounds the male urethra. The three corpora bodies are covered by the tunica albuginea. The common penile artery is the terminal branch of the internal pudendal artery. It divides into three branches that supply blood to the penis. Venous drainage from the penis is provided by the dorsal and cavernous veins, which join to form the internal pudendal vein. Sensory innervation is carried by the dorsal nerves that run with the dorsal vessels. Autonomic innervation is provided by the cavernous nerves that pierce the tunica albuginea to innervate the smooth muscles found in the corpora cavernosa.

SIGNS AND SYMPTOMS

Symptoms Related to Voiding

Symptoms related to voiding can be broadly categorized as irritative or obstructive. Specific irritative symptoms include dysuria, frequency, and urgency. These symptoms generally imply inflammation of the urethra, prostate, or bladder. Although irritative voiding symptoms are commonly caused by infection, they also can be caused by malignancy, and in patients with symptoms that persist after treatment with appropriate antibiotics, malignant processes such as transitional cell carcinoma must be ruled out.

Specific obstructive voiding symptoms include a weak urinary stream, urgency, frequency, hesitancy, intermittency, nocturia, and sense of incomplete emptying. The most common cause of obstructive voiding in men is benign prostatic hyperplasia. Urethral strictures may also obstruct the bladder outlet and often are secondary to trauma, urethritis, or previous instrumentation of the bladder.

Urinary Incontinence

Urinary incontinence can be categorized as stress, urge, total, and overflow. Stress incontinence refers to incontinence associated with an increase in intraabdominal pressure. Patients often report leakage of urine when coughing, laughing, or during physical exertion. Urge incontinence is secondary to an involuntary contraction of the bladder and is accompanied by a sudden sense of needing to void. Urge incontinence may be secondary to inflammation and irritation of the bladder, or it may result from neurologic disorders such as a stroke or spinal cord injury.

Total incontinence refers to a continuous leakage of urine and implies a fistula between the skin or vagina and the urinary tract, proximal to the sphincter mechanism. Overflow incontinence is secondary to an obstruction of the lower urinary tract. As urine builds up in the bladder, the intravesical pressure increases and overcomes the resistance provided by the urinary sphincter. All patients at risk for urinary tract obstruction who develop new-onset incontinence should be checked for urinary retention by postvoid bladder ultrasound or catheterization of the bladder.

Hematuria

Patients with gross or microscopic hematuria, in the absence of obvious evidence of a urinary tract infection, need to be evaluated with upper and lower tract studies. On microscopic examination of the urine, more than five red blood cells per high power field in spun urine or more than two red blood cells per high power field in unspun urine is considered significant microscopic hematuria. Because hematuria can be intermittent, even a single documented episode of significant microscopic hematuria warrants a complete evaluation. The upper tract, which includes the kidney and ureter, should be evaluated with an intravenous pyelogram, computed tomography (CT) scan, or retrograde pyelogram. The CT scan should be performed with intravenous contrast and delayed images should be obtained once the excreted contrast has filled the upper tract collecting system. The lower tract, which includes the bladder and urethra, should be evaluated by cystoscopy.

The differential diagnosis for hematuria includes malignancies, infections, kidney stones, and trauma. Malignancies of the kidney and bladder classically present with painless hematuria. Patients with gross painless hematuria should be considered to have a urinary tract malignancy until proven otherwise. Infections involving the bladder or urethra generally are associated with symptoms of irritative voiding. Pyelonephritis is a clinical diagnosis based on findings of irritative voiding symptoms, fever, and flank pain. Kidney stones are associated with a colicky pain. The localization of the pain depends on the level of obstruction by the stone. An obstruction at the ureteropelvic junction will cause flank pain while obstruction of the lower ureter can produce colicky pain referred to the lower abdomen or groin.

LABORATORY EXAMINATION

Examination of the Urine

The complete urinalysis includes testing with a dipstick impregnated with an array of chemical reagents and a microscopic examination of urinary sediments obtained by centrifugation. Most standard dipsticks will test for urinary pH, specific gravity, protein, glucose, ketones, bilirubin, urobilinogen, hemoglobin,

leukocytes, and nitrites. Usually the urine pH will reflect the pH of the serum. Exceptions to this rule occur in patients with renal tubular acidosis or a urinary tract infection involving a urea-splitting organism.

The specific gravity of the urine reflects the hydration status of the patient and the concentrating ability of the kidney. Proteinuria detected on dipstick may indicate intrinsic renal pathology or the presence of excess protein in the serum. Persistent proteinuria determined using a dipstick should be confirmed by a 24-h urine collection for protein. Testing for urinary glucose and ketones is useful in screening for diabetes. Urinary glucose usually will be detected when serum glucose levels are greater than 180 mg/dL. A small amount of urobilinogen can normally be detected in the urine. However, a positive test for bilirubin and high levels of urobilinogen may indicate liver disease or hemolysis. Presence of hemoglobin, myoglobin, and red blood cells in the urine can produce a positive result on dipstick tests for blood. Therefore, a positive dipstick test should be confirmed by microscopy.

A positive urinalysis for leukocytes and nitrites suggests inflammation, which most commonly is caused by a bacterial infection. The dipstick tests for leukocyte esterase, which is an enzyme found in neutrophils. The urine may be positive for leukocytes in the presence of both hematuria and pyuria. Therefore, suspected pyuria should be confirmed by microscopic examination of the urine. Normal urine does not contain nitrites. However, in the presence of urea-splitting organisms, urinary nitrates are converted to nitrites, which can be detected by the dipstick test. Urea-splitting bacteria include the *Proteus*, *Klebsiella*, *Pseudomonas*, *Enterococcus*, and *Morganella* species. It should be noted that this list does not include *Escherichia*, which is the most common cause of urinary infections.

Urine Culture

It is important to keep in mind that the urinalysis results may be normal in patients with a urinary tract infection. A urine culture is the most definitive test for symptomatic patients. Greater than 105 organisms/mL of urine is consistent with a urinary tract infection. However, in patients who have irritative voiding symptoms, such as frequency and dysuria, 100 organisms/mL of a known urinary pathogen is sufficient evidence of a bacterial infection.

Tests of Kidney Function

Several simple tests can be used to estimate kidney function. Urine-specific gravity can be measured in the office by using a dipstick. As renal function decreases, the ability of the kidney to concentrate urine decreases. This is reflected by a proportional change in specific gravity. Serum creatinine level is a better approximation of kidney function. Creatinine is an end-product of muscle creatine metabolism and is excreted by the kidney. Serum creatinine levels are less affected by hydration status. However, creatinine does not reflect early loss of renal function, as serum creatinine levels remain in the normal range until approximately 50 percent of the kidney function is lost.

The best measure of kidney function that does not involve infusion of exogenous substances is the endogenous creatinine clearance rate. Creatinine clearance is defined as the volume of plasma from which creatinine is completely removed per unit of time and is a clinical approximation of the glomerular

filtration rate (GFR) and renal function. Creatinine clearance is calculated from a 24-h urine collection according to the following formula:

$$\text{Clearance} = UV/P$$

In this formula, U and P represent the urine and plasma concentrations of creatinine, respectively, and V represents the urine flow rate. Normal creatinine clearance is 90–110 mL/min.

The gold standard for measuring GFR involves infusing and measuring the clearance of inulin. Inulin is an ideal substance for measuring GFR because it is completely filtered by the kidney without being secreted or reabsorbed by the tubules. In contrast, creatinine is secreted in small amounts by the proximal tubule. Therefore, creatinine clearance will slightly overestimate GFR at all levels of kidney function.

RADIOLOGIC STUDIES OF THE URINARY SYSTEM

Imaging of Kidney and Ureter

With recent improvements in CT technology, CT scans have become the study of choice for general imaging of the kidney and ureter. On a CT scan, kidney stones that are radiolucent on plain radiograph are readily visible. Uptake of contrast by the renal parenchyma during the nephrogram phase of the CT scan provides a rough estimate of the kidney function. After the contrast is excreted by the kidney into the collecting system, the collecting system can be evaluated for subtle filling defects and hydronephrosis.

CT scans are useful when renal or ureteral malignancy is suspected. When a CT scan is performed for evaluation of hematuria, the study should be performed with and without intravenous (IV) contrast, and delayed images should be obtained after the contrast has been excreted into the renal pelvis and ureter. Renal cell carcinomas classically appear as solid, enhancing masses. The degree of enhancement can be determined by comparing the images with and without contrast. Transitional cell tumors of the renal pelvis and ureter often present as filling defects on delayed images.

Although CT scan is the study of choice in most settings, an intravenous pyelogram (IVP) is a better test when the primary goal is to evaluate the collecting system. To obtain an IVP, radiologic contrast is infused and a series of plain radiographs are taken of the abdomen and pelvis. When an IVP is not diagnostic, or if the patient is allergic to IV contrast, a retrograde pyelogram can be performed. A magnetic resonance image (MRI) obtained with contrast medium such as gadolinium generally can be used in place of a CT scan when renal insufficiency or contrast allergy prohibits the use of CT contrast.

The least-invasive imaging modality for the kidney is a renal ultrasound. Many common renal pathologies have a characteristic appearance on ultrasound. Kidney stones are identified as a hyperechoic lesion associated with hypoechoic “shadowing” behind the stone. On ultrasound, fluid is hypoechoic, therefore renal cysts and hydronephrosis are readily identified. Renal masses appear as hyperechoic lesions and generally warrant further evaluation with a CT scan. In the pediatric population, a renal ultrasound is the first screening test obtained when a congenital abnormality of the urinary system is suspected.

Imaging of the Bladder and Urethra

A urethrogram should be performed when a urethral stricture or a traumatic urethral disruption is suspected. A Foley catheter is inserted just beyond the tip of the meatus and the catheter balloon is inflated with approximately 0.5 mL of fluid. Radiologic contrast is injected in a retrograde fashion and a plain radiograph is taken. Alternatively, the urethra is visualized during the injection using fluoroscopy.

An antegrade urethrogram also can be performed during a voiding cystourethrogram (VCUG). For a VCUG, a small-diameter catheter is inserted into the bladder and a cystogram is obtained. The patient is then asked to void the contrast and a urethrogram is taken. In the pediatric population, a VCUG is most commonly performed to rule out ureteral reflux or a posterior urethral valve.

Testicular Ultrasound

A testicular ultrasound most commonly is performed to evaluate testicular pain or a palpable lesion noted on physical examination. On Doppler ultrasound, the absence of blood flow is consistent with a testicular torsion, although increased blood flow suggests epididymal orchitis. Solid masses in the testicle or in the epididymis should be considered a malignancy until proven otherwise and an orchiectomy should be performed to make a definitive diagnosis.

Renal Scan

A renal scan is a nuclear medicine study used to determine renal function and evaluate drainage of the renal pelvis and ureter. An agent such as technetium-99m mercaptoacetyltriglycine (MAG-3) is administered intravenously, and is both filtered by the glomeruli and secreted by the tubules. Therefore, it is well suited for imaging the renal cortex, estimating differential renal function, and evaluating drainage of the renal pelvis.

BENIGN PROSTATIC HYPERPLASIA

Etiology

Benign prostatic hyperplasia (BPH) refers to the stromal and epithelial proliferation in the prostate gland that may eventually result in voiding symptoms. BPH occurs primarily in the transition zone of the prostate gland.

Natural History

Patients with BPH can present with both obstructive and irritative voiding symptoms, which often are referred to collectively as lower urinary tract symptoms (LUTS). Patients may complain of a decreased urinary stream, frequency, nocturia, urgency, hesitancy, intermittency, and a sense of incomplete emptying.

Medical Therapy

BPH is not always progressive. Patients with mild symptoms can be managed by watchful waiting. Patients with more severe symptoms should be treated based on the degree of bother. Absolute indications for treatment include urinary retention, bladder stones, upper tract dilation, and renal failure. Relative

indications for treatment include large postvoid residuals, hematuria, and recurrent urinary tract infections.

The smooth muscles at the bladder outlet are under α_1 -adrenergic innervation. The first line therapy for BPH is an α blocker. Tamsulosin is an example of a selective alpha blocker that targets the α_1 -adrenoceptor subtype, which is predominately found in the prostate. Patients in urinary retention require emergent catheterization and the catheter should be left in place for at least 24 h to allow the acutely distended bladder to remain decompressed.

Surgical Management

Surgery should be recommended for patients who continue to be bothered by their symptoms or who experience urinary retention despite medical therapy. Surgery also should be recommended for patients with upper tract dilation, renal insufficiency secondary to BPH, or bladder stones. Surgery for BPH most commonly is performed endoscopically; however, if the prostate gland is greater than 80–100 g, an open prostatectomy should be performed.

The standard endoscopic procedure for BPH is a transurethral resection (TUR) of the prostate. TUR is performed with a nonhemolytic fluid such as 1.5 percent glycine. Saline cannot be used because electrolytes in the irrigation fluid will dissipate the electric current used to resect the prostate. During the resection some of the irrigation fluid is absorbed through venous channels in the prostate. If enough fluid is absorbed, TUR syndrome may develop from the resulting hypervolemia and dilutional hyponatremia. Patients with TUR syndrome may experience hypertension, bradycardia, nausea, vomiting, visual disturbance, mental status changes, and even seizures. Patients with evidence of TUR syndrome should be treated with diuretics, and electrolyte imbalances should be corrected.

UROLOGIC ONCOLOGY

Renal Cell Carcinoma

Epidemiology

Each year more than 30,000 new cases of renal cell carcinoma are diagnosed in the United States, resulting in approximately 12,000 deaths. With the increased use of ultrasonography and CT scanning, incidental detection of early renal cell carcinoma has accounted, at least in part, for a 3 percent increase in incidence each year since the 1970s. However, the mortality rate for renal cell carcinoma also has been increasing, suggesting that other factors are involved. Currently, renal cell carcinoma represents approximately 3 percent of all malignancies. The male-to-female ratio is approximately 3:2. At the time of diagnosis, approximately one third of patients have metastatic disease.

Presentation and Prognosis

Before the widespread use of radiologic studies, patients often presented with advanced disease with findings of a palpable mass, flank pain, and hematuria. Today, most renal tumors are incidentally discovered on ultrasounds and CT scans performed for unrelated disorders. Patients with renal cell carcinoma also can present with paraneoplastic manifestations such as anemia, hepatic dysfunction (Stauffer syndrome), cachexia, polycythemia, and hypercalcemia. Paraneoplastic findings result from soluble substances released by the tumor

or by immune cells in response to the tumor. Paraneoplastic findings resulting from localized disease resolve following a nephrectomy.

Work-Up

All patients with a history of gross or microscopic hematuria should undergo a cystoscopy and an upper tract imaging study such as a CT scan, MRI, or renal ultrasound. A solid, enhancing mass in the kidney has a 90 percent chance of being a renal cell carcinoma. Except in select cases, a renal biopsy is unnecessary. A renal biopsy is associated with a high false-negative rate because of potential sampling error and difficulty interpreting the pathology from a biopsy sample. Therefore, a negative or nondiagnostic biopsy does not obviate the need for surgical removal of the mass. A biopsy may be helpful in patients with a history of another primary malignancy or in patients with metastatic disease in whom the primary site is unknown. In these patients, a biopsy is performed to determine whether the renal mass is a primary tumor or a metastatic deposit.

A simple cyst in the kidney is a common, benign finding. However, a complex cyst may harbor a malignant tumor. Several features of a renal cyst are suggestive of a malignant component. These features include multiple septations, irregular cyst wall, calcifications, and wall or septations that enhance with IV contrast on CT or MRI.

The most common benign tumors in the kidney are oncocytomas and angiomyolipomas. Oncocytomas do not have a characteristic radiologic appearance and the diagnosis is made histologically following a nephrectomy. Angiomyolipomas are benign lesions common in patients with tuberous sclerosis. They have a characteristic appearance on CT scan, and nephrectomy is generally not necessary to confirm the diagnosis. Large angiomyolipomas, however, have a high risk of bleeding and embolization should be considered for lesions larger than 4 cm.

Several histologic subtypes of renal cell carcinoma have been defined. Approximately 80 percent of renal cell carcinomas are clear cell tumors and approximately 75 percent of sporadic clear cell tumors have a mutation of the von Hippel-Lindau (VHL) gene found on chromosome 3. The papillary subtype represents 10–15 percent of renal cell carcinomas and is associated with activation of the MET proto-oncogene or cytogenetic abnormalities involving chromosomes 7 and 17.

All patients with a renal mass should undergo a metastatic work-up that includes a check of serum electrolyte levels, liver function tests, chest radiograph, and imaging of the abdomen and pelvis with a CT scan or MRI. The CT scan or MRI should be performed with and without IV contrast. If there is any suspicion of renal vein or inferior vena cava involvement by a tumor thrombus, a vena cavagram or MR angiogram with coronal sections should be performed to evaluate the extent of caval involvement. Patients with metastatic lesions on imaging of the chest, abdomen, and pelvis should undergo a bone scan and a head CT as well.

Treatment

The standard treatment for localized renal cell carcinoma remains a radical nephrectomy. The classic radical nephrectomy involves removal of the kidney, the ipsilateral adrenal gland, and all the fat contained within the Gerota fascia. However, it has been shown that if there is no evidence of adrenal involvement by the tumor on the CT scan, the adrenal gland can be spared. A

radical nephrectomy can be performed using either an open or a laparoscopic approach. The laparoscopic approach is associated with less postoperative pain and a more rapid return to normal activities.

Metastatic renal cell carcinoma is resistant to radiation and standard chemotherapies. There are several important principles to guide the treatment of metastatic disease. Any metastatic lesion to the central nervous system can become rapidly symptomatic and should be addressed by the radiation oncologist and neurosurgeon prior to initiating any further treatment. Patients with a relatively good prognosis, as determined by a good performance status and a limited number of metastatic sites, are candidates for a cytoreductive nephrectomy and interleukin-2 or interferon-based immunotherapy. The combination of neoadjuvant nephrectomy and immunotherapy represents the current standard of care for patients with metastatic renal cell carcinoma.

Bladder Cancer

Epidemiology

In the United States, approximately 56,000 new cases of bladder cancer are diagnosed each year, resulting in approximately 13,000 deaths. Bladder cancer represents 7 percent of all newly diagnosed cancers in men and 2 percent of all newly diagnosed cancers in women. The majority of patients with bladder cancer have superficial disease, which is associated with long-term survival. Therefore, there is a cohort of 300,000–400,000 patients with bladder cancer in the United States at all times.

In Western countries, more than 90 percent of bladder cancers are transitional cell carcinomas (TCCa), approximately 5 percent are squamous cell carcinomas, and less than 2 percent are adenocarcinomas. In the developing countries, 75 percent of bladder cancers are squamous cell carcinomas and most of these are secondary to *Schistosoma haematobium* infection. TCCa is strongly linked to environmental exposures. Smoking accounts for more than 50 percent of bladder cancers, and 2-naphthylamine and 4-aminobiphenyl are likely the most significant carcinogens found in cigarette smoke that lead to TCCa. The development of bladder cancer also has been associated with industrial exposure to aromatic amines in dyes, paints, solvents, leather dust, inks, combustion products, rubber, and textile. Prior radiation treatments to the pelvis and acrolein, a urinary metabolite of cyclophosphamide, increase the risk of bladder cancer.

Presentation

The classic presentation of bladder cancer is painless hematuria. Eighty-five percent of patients with bladder cancer present with hematuria. Hematuria, whether gross or microscopic, requires a urologic evaluation. Microscopic hematuria as a result of bladder cancer may be intermittent, therefore, bladder cancer cannot be ruled out with a repeat negative urinalysis. Persistent, irritative voiding symptoms may be a result of carcinoma in situ (CIS) or muscle-invasive bladder cancer. Therefore, irritative voiding symptoms that do not resolve with treatment for a urinary tract infection require further evaluation. A urologic work-up for hematuria includes cystoscopy and radiographic imaging of the upper urinary tract as previously discussed.

Work-Up

At the time of clinic cystoscopy, a bladder wash for cytology can be sent. Bladder cytology is 95 percent accurate for diagnosing high-grade tumors and CIS, however, its accuracy for diagnosing low-grade carcinoma is only 10–50 percent. Newer assays for the detection and surveillance of TCCa in voided urine include the BTA-Stat, NMP-22, and FDP tests. However, because of high false-positive rates and high false-negative rates, it is unlikely that these tests will obviate the need for cystoscopy. Patients with an abnormal cystoscopic exam or suspicious bladder wash cytology should be further evaluated with an operating room cystoscopy. In the operating room, all suspicious lesions should be endoscopically biopsied. Blood effluxing from either ureteral orifice should be further investigated with a retrograde pyelogram and possibly ureteroscopy.

Both tumor grade and stage correlate independently with prognosis. Transitional cell cancer most commonly is graded on a scale between 1 and 3, representing well, moderate, and poorly differentiated tumors. The TNM system, developed by the International Union Against Cancer and the American Joint Committee on Cancer Staging, is used to stage bladder cancer. Tumors that involve the bladder mucosa (Ta and CIS) or lamina propria (T1) are considered superficial cancers. CIS is a unique designation that signifies a flat, high-grade tumor confined to the mucosa, and CIS generally implies a higher risk of recurrence following treatment. Tumors that invade the muscular layer of the bladder wall (T2) or beyond (T3 and T4) are considered muscle invasive.

Approximately 25 percent of patients with bladder cancer have muscle-invasive disease at the time of diagnosis. Patients with muscle-invasive bladder cancer should undergo a metastatic work-up, which includes a CT scan of the abdomen and pelvis, chest radiograph, serum chemistries, and liver function tests. If the patients are asymptomatic with normal calcium and alkaline phosphatase, bone scans are unnecessary. Approximately 15 percent of all patients have metastatic disease at the time of initial presentation. The life expectancy for most patients with overt metastatic disease is less than 2 years; however, approximately 25 percent of patients with only limited regional lymph node metastases discovered during cystectomy and pelvic lymph node dissection may survive beyond 5 years.

Treatment of Superficial Bladder Cancer (Ta, T1, CIS)

Most superficial bladder cancers are adequately treated by endoscopic resection and fulguration of the bladder tumor. No further metastatic work-up is indicated if the pathology confirms a low-grade, superficial TCCa. However, bladder cancer is considered a polyclonal, field-change defect and continued surveillance is mandatory. In other words, the underlying genetic changes that resulted in the bladder cancer have occurred in the entire urothelium, making the entire urothelium susceptible to future tumor formation. The risk of recurrence following the treatment of superficial bladder cancer is approximately 70 percent within 5 years.

The risk of disease progression, defined as a subsequent increase in tumor grade or stage, depends on the initial tumor grade. The risk of progression for TCCa grades I, II, and III is 10–20 percent, 19–37 percent, and 33–67 percent, respectively. Carcinoma in situ alone or in association with Ta or T1 papillary tumor carries a poorer prognosis, with a recurrence rate of 63–92 percent. Patients with a history of superficial TCCa should undergo surveillance with cystoscopy and bladder wash cytology every 3 months for 2 years. If they

are disease free during this period, the follow-up intervals can be gradually increased.

Intravesical therapy is effective for patients with high-risk, superficial TCCa in reducing the risk of recurrence. The most effective intravesical therapy is bacille Calmette-Guérin (BCG), which is a live, attenuated strain of *Mycobacterium bovis*. BCG is recommended for carcinoma in situ, T1 tumors, and high-risk Ta tumors (large, high-grade, recurrent, or multifocal tumors). The beneficial effects of intravesical BCG is thought to be mediated by a nonspecific immune cytokine response. Because BCG is a live, attenuated organism, it can cause tuberculosis-like symptoms if it is absorbed into the blood stream. Contraindications for BCG treatment include active hematuria, immunodeficiency, and active urinary tract infection. BCG therapy reduces recurrence and some studies suggest it may reduce the risk of progression as well.

Treatment of Muscle-Invasive Bladder Cancer (T2, T3, T4)

The gold standard for organ-confined, muscle-invasive bladder cancer (T2 and T3) is radical cystoprostatectomy in men and anterior pelvic exenteration in women. In men, radical cystectomy involves the removal of the bladder, prostate, and pelvic lymph nodes. A total urethrectomy also is performed if the urethral margin is positive. In women, a classic anterior pelvic exenteration includes the removal of the bladder, urethra, uterus, ovaries, and anterior vaginal wall. However, in a female patient, if the bladder neck margin is negative, the urethra and anterior vaginal wall may be spared. With treatment, the 5-year survival rates for pathologic T2, T3, T4a, and N + tumors are 63–80 percent, 19–57 percent, 0–36 percent, and 15–44 percent, respectively.

After cystectomy, the urine is diverted using segments of bowel. The various types of urinary diversions can be separated into continent and incontinent diversions. The most commonly performed incontinent diversion is the ileal conduit. A small segment of ileum is taken out of continuity with the GI tract while maintaining its mesenteric blood supply. The ureters are anastomosed to one end of the conduit and the other end is brought out to the abdominal wall as a stoma. The urine continuously collects in an external collection device worn over the stoma.

There are two commonly performed continent urinary diversions. An Indiana pouch is a urinary reservoir created from detubularized right colon and an adjacent limb of terminal ileum. The terminal ileum is plicated and brought to the abdominal wall, creating a catheterizable stoma. The native ileocecal valve provides the continence mechanism. The Indiana pouch is emptied by clean intermittent catheterization of the stoma 4–6 times per day. An orthotopic neobladder is a similar reservoir that is connected to the urethra. Various segments of intestine, including small and large bowel, may be used in constructing the orthotopic neobladder. The orthotopic neobladder most closely restores the natural storage and voiding function of the native bladder. Patients have volitional control of urination and void by Valsalva maneuver.

Prostate Cancer

Epidemiology

Prostate cancer is the most common cancer in men and the second most common cause of cancer-related death in the United States. Each year, approximately 189,000 cancers are diagnosed, representing approximately 30 percent of all cancers diagnosed in men, and approximately 30,000 deaths results from

prostate cancer. It is estimated that in the United States, one in six men will be diagnosed with prostate cancer during their lifetime. Because the widespread use of screening prostate-specific antigen (PSA) in the late 1980s, the incidence of prostate cancer has dramatically increased; however, after about 1990, the death rate from prostate cancer has been declining. It often is suggested that this decline in prostate cancer mortality has resulted from increased screening and early detection of prostate cancer.

Family history, race, and environmental factors determine the risk of prostate cancer. The risk of prostate cancer is directly related to the number of affected family members and if three first-degree relatives are affected, the relative risk may be as high as 11. In the United States, the risk of prostate cancer also is related to race. African Americans have a higher incidence of prostate cancer than do whites, although Hispanics and Asians have a lower incidence than whites. Environmental factors also affect the risk of prostate cancer. There is scientific evidence suggesting that the risk of prostate cancer can be lowered by a low-fat diet, and by various nutritional supplements including lycopene, vitamin E, and selenium.

Prostate Cancer Screening

Until prostate cancer metastasizes or becomes locally advanced, it does not generally cause symptoms. Most prostate cancers are diagnosed based on an elevated PSA or an abnormal digital rectal examination (DRE) of the prostate. PSA is a serine protease that is synthesized by the prostate epithelium and is elevated in prostate cancer. A PSA greater than 4 ng/mL is considered abnormal. Approximately 25 percent of patients with a PSA greater than 4 ng/mL will have a positive prostate biopsy, which establishes the diagnosis of prostate cancer. Approximately 50 percent of patients with both an elevated PSA and an abnormal DRE will have a biopsy positive for prostate cancer.

The American Cancer Society recommends offering annual prostate cancer screening to men starting at 50 years of age who have at least a 10-year life expectancy. Additionally, the society recommends offering PSA screening at 45 years of age in African American men and in men with a family history of prostate cancer. However, the value of screening is debated within the medical community, and this debate is reflected by the conflicting guidelines published by various medical and health care organizations.

Work-Up

Despite the controversy surrounding prostate cancer screening, it is important to point out that most cancers detected as a result of an elevated PSA or abnormal DRE are clinically significant cancers that should be treated in men with at least a 10-year life expectancy. The diagnosis of prostate cancer is made by biopsy. Using transrectal ultrasound guidance, the biopsy needles are directed at the peripheral zones in which prostate cancer tends to develop. Prostate cancer is graded by the pathologist using the Gleason system. The two most predominant histologic patterns of the prostate cancer are assigned a Gleason grade, on a scale from 1–5. The two Gleason grades are added to give a Gleason score, on a scale from 2–10.

Tumors with Gleason scores of 8–10 are considered high-grade tumors, and tumors with Gleason scores of 5–7 are considered intermediate-grade tumors. High-grade prostatic intraepithelial neoplasia (PIN) is considered a premalignant lesion that may indicate the presence of adjacent cancer. Given the possibility for sampling error, the presence of PIN in a biopsy that is negative

for prostate cancer is an indication for repeating the biopsy; a repeat biopsy will be positive for prostate cancer in approximately 40 percent of cases.

Prostate cancer is most commonly staged using the TNM system. The most common sites of metastasis for prostate cancer are the axial bones and pelvic lymph nodes. For the majority of patients diagnosed with prostate cancers, no formal metastatic work-up is necessary. However, a PSA greater than 20 ng/mL or a PSA greater than 10 ng/mL in a patient with a Gleason score 8–10 tumor is associated with an increased risk of metastatic disease, and a bone scan and pelvic CT scan should be performed. Additionally, any patient complaining of bone pain should undergo a bone scan.

Treatment

Localized prostate cancer. Prostate cancer tends to progress slowly and have a long, natural history. Therefore, treatment for localized prostate cancer generally is offered to patients with at least a 10-year life expectancy. Patients with high-grade tumors (Gleason score of 8–10) may represent an exception to this rule; without treatment, they are at a significantly higher risk of developing symptomatic disease and dying from their disease. Therefore, in these patients, curative therapy should be considered regardless of life expectancy. The treatment options for localized prostate cancer can be broadly categorized as involving surgery or radiation therapy.

The most commonly performed surgical procedure is a radical retropubic prostatectomy (RRP). A pelvic lymph node dissection is generally performed for staging purposes at the time of surgery. The most significant complications associated with surgery are urinary incontinence and erectile dysfunction, which occur in approximately 5–10 percent and 14–30 percent of cases, respectively. During RRP, care should be taken to avoid injuring the urinary sphincter located just distal to the apex of the prostate. The neurovascular bundles that run along the posterolateral border of the prostate contain the cavernous nerves, which are responsible for erectile function. Care should be taken to separate the neurovascular bundle from the prostate and preserve it during surgery.

Options for radiation therapy include external radiation therapy (XRT) and brachytherapy. With most XRT protocols, 60–80 Gy is delivered by conformal radiotherapy. The primary genitourinary side effects following XRT include frequency, dysuria, hematuria, and decreased bladder capacity. The primary gastrointestinal side effects include diarrhea, rectal pain, and rectal bleeding. The sexual dysfunction following XRT develops gradually and 40–50 percent of previously potent men are impotent 5 years following treatment. Brachytherapy involves the percutaneous placement of radioactive seeds into the prostate. Although the side effects associated with brachytherapy are generally less severe than those associated with XRT, brachytherapy is less effective than XRT for treatment of high-risk prostate cancer.

Metastatic prostate cancer. The first-line therapy for metastatic prostate cancer is androgen-ablative hormone therapy. Since Charles Huggins won the Nobel Prize in 1966 for discovering the therapeutic effects of androgen ablation on metastatic prostate cancer, the fundamental principles for treating metastatic prostate cancer have not changed. Androgen-ablation is accomplished by performing bilateral orchiectomies or by administering gonadotropin-releasing hormone (GnRH) agonist. Testosterone synthesis by the Leydig cell in the testicles is stimulated by luteinizing hormone (LH) from the pituitary. The

release of LH requires a pulsatile discharge of GnRH. Therefore, a constant GnRH stimulation paradoxically results in inhibition of LH and testosterone. Nonsteroidal antiandrogens such as flutamide and bicalutamide often are added to block the low levels of androgens produced by the adrenal medulla.

Testis Cancer

Testicular cancer is the most common cancer in men between the ages of 20 and 35 years. There are approximately 7000 new cases and 400 deaths related to testis cancer per year. For more than 90 percent of patients, testicular cancer is curable. Any patient with a solid testicular mass, which has been confirmed on ultrasound, is considered to have testicular cancer until proven otherwise, and should undergo a radical orchiectomy to make a definitive diagnosis. Prior to surgery, serum markers for testicular cancer should be obtained. The two markers used in routine clinical practice are human chorionic gonadotropin (hCG) and follicle-stimulating hormone (FSH).

When performing a radical orchiectomy, the surgery should be performed by an inguinal approach rather than a scrotal approach. The metastatic spread of testicular cancer is ordered and predictable. The primary metastatic landing sites for left and right testicular cancers are the para-aortic and the interaortocaval nodes in the retroperitoneum, respectively. The lymphatic drainage of the scrotum, on the other hand, is to the inguinal nodes. If the scrotum is surgically violated by performing a scrotal orchiectomy, metastatic spread to both the retroperitoneal and the inguinal nodes becomes possible.

Penile Cancer

Penile cancer is rare in the United States, representing less than 1 percent of all tumors in men. However, in certain regions of Africa and South America, penile cancer represents 10–20 percent of all malignancies. The majority of penile malignancies are squamous cell carcinomas. The diagnosis is made on biopsy. The primary lesion should be completely resected, whenever possible, to prevent the morbidities associated with local invasion.

UROLOGIC INFECTIONS

Cystitis

Cystitis is inflammation of the bladder mucosa and usually is caused by bacterial organisms. *Escherichia coli* is the most common cause of urinary tract infection (UTI), including cystitis. Other common causative organisms include *Proteus*, *Klebsiella*, *Enterococcus*, and *Staphylococcus saprophyticus*. Women are at a higher risk for UTI than men because their urethra is shorter. Fecal flora contaminating the vaginal mucosa can ascend through the female urethra. Certain bacterial factors, such as type 1 pili found on some strains of *E. coli*, mediate adhesion and are more likely to cause UTI. Additionally, certain host factors such as vaginal pH, can promote vaginal colonization and UTI.

Symptoms of cystitis include urinary frequency, urgency, and dysuria. Uncomplicated cystitis generally does not cause fevers or leukocytosis. Patients with voiding symptoms can be worked up with a urinalysis. However, a urine culture provides a more definitive diagnosis of a UTI than a urinalysis. Important considerations when obtaining a urine culture have been previously discussed in this chapter. Bacterial UTI in women should be

treated with 3 days of antibiotics. In men, bacterial UTI should be treated with 7 days of antibiotics and younger men should be evaluated for correctable structural anomalies with an IVP or CT scan with IV contrast, and a cystoscopy.

Asymptomatic bacteriuria occurs in approximately 30 percent of older adult nursing home residents and in 5 percent of sexually active women. Asymptomatic bacteriuria is the rule in patients with chronic indwelling Foley catheters. Most asymptomatic bacteriuria does not need to be treated. However, asymptomatic patients with urea-splitting organisms should be treated with antibiotics. Pregnant women with bacteriuria should also be treated as they are at an increased risk for developing pyelonephritis.

Pyelonephritis

Pyelonephritis refers to inflammation of the renal parenchyma and collecting system. It is a clinical diagnosis that is made based on the presence of fever, flank pain, and infected urine. Older patients and young children may present with less-specific symptoms such as mental status changes, abdominal discomfort, and low-grade fevers. The most common causative agents are gram-negative bacteria such as *E. coli*, *Proteus*, *Pseudomonas*, and *Klebsiella*. Most bacterial agents gain access to the urinary system through the urethra and ascend to the kidney. Therefore, women generally are more susceptible to UTI and pyelonephritis because of the shorter urethra in females compared to males.

Patients presenting with signs and symptoms of pyelonephritis should have a urine culture and serial blood cultures. The results of the urine culture may not be available for 48 h; therefore, a urinalysis can be used to support a presumptive diagnosis of pyelonephritis. Healthy adults with no significant comorbidities can be treated as an outpatient; however, most patients diagnosed with pyelonephritis are admitted to the hospital. Broad-spectrum IV antibiotics, such as ampicillin and gentamicin, should be started until the results of the urine culture are available and a more selective antibiotic can be identified. When patients are afebrile, they can be discharged on oral antibiotics. Uncomplicated pyelonephritis should be treated for a total of 14 days while pyelonephritis associated with structural or functional abnormalities should be treated for 21 days.

In select patients with pyelonephritis, the upper tracts should be imaged at the time of presentation. In selecting patients for early radiologic study, the most important principle to keep in mind is that an obstructed and infected urinary system is a surgical emergency that requires prompt intervention to establish drainage. Therefore, the upper tracts should be studied in any patient with a history of kidney stones, anatomic abnormalities such as a ureteropelvic junction obstruction, or malignancies that may cause extrinsic compression of the urinary system. Options for emergently draining an obstructed kidney include percutaneous nephrostomy tube placement and cystoscopic placement of a ureteral stent. Bladder outlet obstruction causing bilateral hydronephrosis can be relieved by the placement of a Foley catheter.

Other findings on CT scan and MRI may require surgical intervention. Small renal and perirenal abscesses can be conservatively managed with antibiotics in clinically stable patients. However, if there is inadequate clinical improvement or if the abscess is large, the infectious collection should be immediately drained. Drainage is preferably accomplished percutaneously.

Emphysematous pyelonephritis often is seen in older diabetic patients and represents a medical emergency. Air bubbles produced by gas-forming organisms can be seen in the renal parenchyma on radiograph or CT scan. Emphysematous pyelonephritis should be promptly treated with percutaneous drainage; if there is no evidence of clinical improvement, an urgent nephrectomy should be performed.

In adult patients, there is no permanent sequela following successful treatment of pyelonephritis. However, pyelonephritis in an infant kidney that is still developing can be devastating. Pyelonephritis can lead to permanent parenchymal scarring and loss of renal function. The most common abnormality resulting in pyelonephritis in infants and children is ureteral reflux. Ureteral reflux can carry an infectious organism from the bladder to the kidney, and severe reflux can cause hydronephrosis and urinary stasis. Therefore, pediatric patients with cystitis or pyelonephritis should be worked up with a renal ultrasound and a voiding cystourethrogram. Any pediatric patient at risk for pyelonephritis should be treated with long-term antibiotic prophylaxis.

TRAUMA

Kidney and Ureter

Approximately 10 percent of traumas involve the urologic system, most commonly the kidneys. The best study for evaluating the kidneys is a helical abdominal CT scan with IV contrast. A CT scan should be performed for all penetrating traumas. For adult patients with blunt trauma, a CT scan should be obtained in patients with gross hematuria, or with microscopic hematuria and systolic blood pressure less than 90 mmHg at any point during the transport and resuscitation. Approximately one third of renovascular injuries present with complete absence of hematuria, and, therefore, mechanism of injury and associated clinical findings, such as flank contusions and lower rib fractures, should also prompt a CT scan. Pediatric patients are able to maintain blood pressure despite an almost 50 percent loss of circulating volume. Therefore, hypotension is a poor indicator for radiologic work-up. All pediatric patients with gross hematuria should have a CT scan, and all pediatric patients with microscopic hematuria and potential renal trauma based on the mechanism of injury should have a CT scan.

The most commonly applied staging system for renal injury was developed by the American Association for the Surgery of Trauma (Table 39-1). Approximately 95 percent of renal traumas are grade 1. Approximately 98 percent of renal injuries can be managed nonoperatively. The only absolute indications for surgical management of a renal injury are persistent bleeding resulting in hemodynamic instability or an expanding perirenal hematoma. Relative indications for surgical management include major urinary extravasation, vascular injury, and devitalized parenchymal tissue. Studies show that even large urinary extravasations will resolve with conservative management. Smaller vascular injuries resulting in devitalized tissue also can be managed without surgery; however, if the amount of devitalized tissue exceeds 20 percent of the renal tissue, surgical management leads to quicker resolution of the injury and to fewer subsequent complications.

Patients managed nonoperatively should be placed on bedrest until resolution of gross hematuria. After resuming ambulation, the patient should be carefully monitored for recurrence of gross hematuria, which requires reinstitution of bedrest. Surgical exploration should be performed following CT

TABLE 39-1 Staging System for Renal Injury Developed by the American Association for the Surgery of Trauma

Grade	Description of Injury
1	Contusion or nonexpanding subcapsular hematoma No laceration
2	Nonexpanding perirenal hematoma Cortical laceration <1 cm deep without extravasation
3	Cortical laceration >1 cm without urinary extravasation
4	Laceration: through corticomedullary junction into collecting system or Vascular: segmental renal artery or vein injury with contained hematoma
5	Laceration: shattered kidney or Vascular: renal pedicle injury or avulsion

Source: From Moore EE, Shackford SR, Pachter HL, et al: Organ & injury scaling: Spleen, liver, and kidney. *J Trauma* 29:1664, 1989.

staging when possible. If the patient requires immediate exploration for hemodynamic instability and a CT scan cannot be performed, a one-shot intravenous pyelogram (1 mL/kg of body weight of 30 percent contrast administered 10 min before radiograph) should be performed intraoperatively to evaluate the kidneys and confirm the presence of a functioning contralateral kidney. If surgical exploration of a kidney is required, the presence of a contralateral kidney should be confirmed. Surgical exploration should be performed through a midline approach. The renal vessels should be identified and controlled prior to opening the Gerota fascia, to allow the vessels to be rapidly occluded if massive bleeding is encountered. Injuries to the collecting system should be repaired by a watertight closure. Devitalized tissue should be excised and meticulous hemostasis should be obtained by ligating open segmental vessels. If bleeding cannot be controlled or only minimal vitalized tissue remains, a nephrectomy should be performed.

Ureteral injuries are rare, with the majority of injuries resulting from penetrating trauma. The diagnosis of ureteral injuries can be challenging as they often present without hematuria. Ureteral injuries often are discovered during radiographic work-up or abdominal exploration for related injuries. If a ureteral injury is suspected, an intravenous pyelogram, a retrograde pyelogram, or a contrast CT scan should be obtained. When performing a CT scan, delayed images should be obtained after the contrast has entered the collecting system. Surgical repair depends on the level of injury and the length of the injured segment. Important principles for surgical repair include a tension-free, water-tight closure after widely débriding the injured segment. For coverage of large ureteral defects, interposition of intestinal segments or bladder flaps may be required to achieve a tension-free repair. The adventitia surrounding the ureter should be carefully preserved to maintain the tenuous, ureteral blood supply.

Bladder

Hematuria, gross or microscopic, is the hallmark of bladder injury. The vast majority of bladder injuries are found in patients with pelvic fractures. More

than 90 percent of patients diagnosed with bladder injury have a pelvic fracture and approximately 10 percent of pelvic fractures are associated with bladder ruptures. Therefore, radiographic imaging should be obtained in all patients with hematuria and pelvic fractures, or in patients with penetrating trauma to the pelvis and lower abdomen. Rarely, bladder injury can occur in the absence of a pelvic fracture. Therefore, radiographic imaging also should be considered if pelvic contusions or urethral injuries are present.

A retrograde cystogram is the most accurate test for ruling out a bladder rupture. When performing a retrograde cystogram, it is critical to adequately distend the bladder (400 mL or 40 cm H₂O) and obtain a postdrainage film to look for extravasation of contrast. An alternative study is a CT cystogram, which can be obtained at the same time the abdomen and pelvis are imaged for related injuries. The management of bladder injury depends on the site of rupture. Extraperitoneal ruptures usually can be managed conservatively with prolonged catheter drainage; however, intraperitoneal ruptures should be explored and surgically repaired.

Urethra

Patients with urethral injury resulting from trauma classically present with blood at the meatus and inability to void. Other potential findings include a perineal hematoma and a “high-riding” prostate on digital rectal exam. If any of these findings are present, a retrograde urethrogram should be performed before attempting to catheterize the bladder. To perform a retrograde urethrogram, a small Foley catheter is placed just inside the meatus and the Foley balloon is inflated with 1–2 mL of water. Lateral decubitus films are taken while 30–50 mL of radiographic contrast is gently injected through the catheter. When feasible, performing the study under fluoroscopy is preferred. Urethral injuries are categorized as posterior or anterior injuries.

Posterior Urethra

Trauma to the posterior urethral, which includes the prostatic and membranous urethra, occurs in the context of pelvic fractures. The statistics are similar to that of bladder trauma. More than 90 percent of posterior urethral injuries occur in patients with a pelvic fracture and approximately 10 percent of pelvic fractures are associated with urethral injuries. Although a suprapubic tube provides effective urinary drainage without risking further disruption of the urethra, a urethral Foley catheter should be placed across the injury when possible.

The anterior urethra includes the bulbous and penile urethral. Anterior urethral traumas usually are isolated injuries that most commonly result from a straddle injury. Anterior urethral injury also can occur as a result of direct trauma to the penis. Pelvic fractures are rare in patients with anterior urethral injuries. More distal injuries are contained by the Buck fascia and resulting hematomas dissect along the penile shaft. More proximal injuries to the anterior urethra may be contained by the Colles fascia and produce a perineal hematoma.

The treatment of choice for most blunt and penetrating injuries is immediate exploration, débridement, and direct repair. An exception is an anterior urethral injury resulting from a high-velocity gunshot, which should be managed with a suprapubic cystostomy and delayed repair after clear demarcation of injured tissues. Proximal injuries to the anterior urethra can be approached through

a perineal incision, and more distal injuries can be approached by making a circumferential, subcoronal incision and degloving the penis.

Penis

Penetrating injuries to the penis are rare. Injuries to the penile corporal should be repaired by closing ruptures of the tunica albuginea. Blunt or penetrating penile injuries resulting from an accident should be evaluated with a urethrogram. Urethral injuries should be managed as described in the section on urethral trauma.

Testis

The most common causes of testicular injury are assaults and sports injuries. Blunt trauma to the scrotum can disrupt the vessels surrounding the testicles and result in a hematocele. Small traumatic hematoceles do not require surgical intervention. An ultrasound should be performed to confirm that the testicles are intact. Rupture of the testicle itself is rare and requires immediate exploration and surgical repair. The testicles should be immediately explored with no need for an ultrasound if physical findings such as a large hematocele, large hematoma, or gross disruption of the testicular wall are found, suggesting testicular rupture. At the time of surgery, the hematoma should be evacuated and the tunica albuginea should be closed. Penetrating scrotal injuries should be explored, and amputated testicles often can be successfully reimplanted when warm ischemia time is less than 6 h.

STONE DISEASE

Etiology

Stone disease is one of the most common urologic diseases, affecting one in eight white men by age 70 years. Stone disease is most common in 20–40-year-olds and is three times more common in men than in women. The prevalence of urinary tract stone disease has been estimated at 2–3 percent. For patients developing a stone, the risk of recurrent stone formation within 5 years may be as high as 50 percent. Therefore, successful treatment of stone disease not only involves management of the acute stone, but also long-term medical management to prevent future stone formation.

Acute Kidney Stone

Presentation

An acute stone is defined as a urinary stone obstructing the kidney or ureter, and causing symptoms. The classic symptoms of an obstructing kidney stone include colicky flank pain and hematuria, often accompanied by nausea and vomiting. If the stone moves down the ureter, the pain may localize to the ipsilateral lower abdomen. A stone impacted in the distal, intramural ureter may produce pain referred to the inguinal and perineal areas. On physical exam, costovertebral angle tenderness usually can be appreciated. The hematuria accompanying stone disease may be microscopic or gross. However, approximately 15 percent of acute renal stones present without hematuria. Patients with a superimposed urinary tract infection may present with fever and irritative voiding symptoms. Patients with an infected urinary system and

a completely impacted stone may even present with signs and symptoms of sepsis.

Radiologic Work-Up

The diagnosis of a urinary stone can be confirmed radiologically. A plain radiograph of the abdomen and pelvis is the simplest test to obtain; however, radiolucent stones, such as uric acid stones and cystine stones, may not be visualized, and stool in the colon may make it difficult to identify smaller stones in the ureter. The test of choice at most centers for diagnosing an acute stone is a noncontrast, helical CT scan. All stones, regardless of composition, are visualized on CT scan with the exception of a small percentage of indinavir stones. Indinavir stones form in human immunodeficiency virus (HIV)-positive patients treated with the protease inhibitor indinavir sulfate.

Management

The majority of renal stones will pass spontaneously. Only 10 percent of patients presenting with an acute renal stone require hospital admission. Patients with any of the following presentations should be managed as an inpatient: intractable pain, severe nausea with inability to tolerate oral intake, urinary infection, or renal insufficiency. All other patients can be managed on an outpatient basis.

Patients with obstructing stones and no evidence of urinary infection can safely be given up to 4 weeks to spontaneously pass their stone. No detectable renal damage occurs within 4 weeks of even complete ureteral obstruction. However, in the presence of a urinary infection, emergent intervention is indicated. A percutaneous nephrostomy tube or a ureteral stent should be placed to establish drainage of the obstructed urinary system. Following treatment of the urinary infection, the stone can be treated electively. Stones 4–5 mm in diameter have at least a 40–50 percent chance of passing spontaneously; however, stones greater than 6 mm in diameter have less than 5 percent chance of passing. Therefore, patients with larger stones should be considered for early intervention.

Surgical management. The least-invasive treatment option for renal stones is extracorporeal shock wave lithotripsy (ESWL). Shock waves are generated outside the body and focused on the stone. The shock waves harmlessly propagate through intervening tissue and attain sufficient intensity to fragment the stone only when it reaches the calculus. The stone is placed in the focal point of the shock waves by using ultrasound or fluoroscopy.

Endoscopic options for the surgical treatment of upper tract stone disease include retrograde ureteroscopy and percutaneous nephroscopy. Selection of the specific approach depends on the size and location of the stone. For example, a large stone filling multiple renal calyces is best treated using a percutaneous approach to directly access the kidney through the flank.

Once the stone is endoscopically visualized through a nephroscope or a ureteroscope, small stones can be snared and removed with a number of specialized instruments, such as a stone basket or a three-prong grasper. Larger stones can be fragmented intracorporeally by using a variety of energies, including laser, ultrasound, or mechanical force. Energy is applied to the stone through the working port of the scope and the stone is fragmented under direct vision.

SEXUAL DYSFUNCTION

Priapism

Priapism refers to an erection that is unrelated to sexual activity or persists beyond sexual activity. Priapism can be classified as low-flow (ischemic) or high-flow (nonischemic). The two forms of priapism can be distinguished by assessing the blood gas drawn from the penile corpora. The blood gas from a normal penis that is erect or a penis affected by high-flow priapism is similar to an arterial blood gas. However, in low-flow priapism, the blood gas will be similar to that of venous blood. Low-flow priapism results from venous occlusion. It is associated with severe pain. It is essentially a compartment syndrome of the penis and should be treated as a medical emergency. Most priapisms are idiopathic; however, specific causes of low-flow priapism include sickle cell disease, pelvic tumors, leukemia, spinal cord injury, penile injections for erectile dysfunction, antidepressants, and antipsychotics, especially chlorpromazine.

The management of low-flow priapism should be dictated by the duration of the priapism. Within 36 h of onset of low-flow priapism, intracorporal irrigation with an alpha-adrenergic agonist may be effective. A variety of protocols exist. One example of a protocol for intracorporal irrigation involves diluting 5 mg of phenylephrine in 500 mL of normal saline and repeatedly aspirating 20 mL of blood and injecting 20–30 mL of the phenylephrine solution through a 21-gauge butterfly needle.

If this is ineffective, or if the priapism has been present for more than 36 h, a distal shunt should be performed under anesthesia. A commonly performed distal shunt is the Winter shunt, in which a biopsy needle is inserted through the penile glans into the corpora cavernosa to create a shunt. If this procedure is unsuccessful, a more proximal shunting procedure, between the corpora cavernosum and the corpora spongiosum, should be performed. The rationale for these shunting procedures is that the glans of the penis and the corporal spongiosum are flaccid during priapism and unaffected by the veno-occlusive process. Therefore, a shunt will allow the occluded blood in the corpora cavernosa to drain.

Priapism resulting from sickle cell disease or leukemia should initially be managed medically. Patients with sickle cell disease tend to have recurrence of priapism, and, therefore, a trial of conservative therapy directed at preventing additional sickling is warranted. Medical therapy should include hydration, oxygenation, and alkalinization. Transfusions or exchange transfusions should be considered. Patients with leukemia should be promptly treated with chemotherapy rather than surgery.

High-flow priapism generally is painless, and because tissue ischemia is not a feature, treatment is less urgent. Nonischemic priapism results from an arterial-venous fistula that is most commonly secondary to trauma. The diagnosis of high-flow priapism can be confirmed by color Doppler ultrasound. The arterial-venous fistula can be identified by angiography and selectively embolized. If this fails, the fistula can be surgically ligated.

PEDIATRIC UROLOGY

Hydronephrosis

Hydronephrosis, or dilation of the upper urinary tract, may signify a congenital anomaly with the potential for adversely impacting renal function. Fetal

hydronephrosis is diagnosed in 1 of 500 routine prenatal ultrasounds. The majority of fetal hydronephrosis resolves by birth or within the first year of life. Fetal intervention rarely is necessary, and should only be considered in cases of bilateral hydronephrosis and severe oligohydramnios. Following birth, severe hydronephrosis may be appreciated as a palpable abdominal mass.

In cases of bilateral hydronephrosis, a renal ultrasound and a VCUG should be obtained shortly after birth. For unilateral hydronephrosis, both studies can be obtained electively at approximately 1 month of life. Because neonates with hydronephrosis are at a higher risk for pyelonephritis, all neonates diagnosed with unilateral or bilateral hydronephrosis should be started on antibiotic prophylaxis (i.e., amoxicillin, 10 mg/kg per 24 h). Pyelonephritis during the first year of life, when the kidney is still immature, leads to permanent deterioration in renal function.

Ureteropelvic Junction Obstruction

Ureteropelvic junction (UPJ) obstruction is the most common cause of hydronephrosis in neonates. The precise etiology is poorly defined. UPJ obstructions may result from abnormal development of the smooth muscle at the UPJ. In some cases, an aberrant lower pole vessel crosses the UPJ, possibly resulting in extrinsic compression. Most neonates are asymptomatic, whereas older children often present with symptoms, such as flank or abdominal pain.

Initial evaluation should include a renal ultrasound and a VCUG to rule out coexisting reflux. If a UPJ obstruction is suspected, a nuclear renal scan should be performed to assess differential function in the right and left kidneys, and to assess renal pelvic drainage by timing the washout of nuclear isotope following Lasix administration. Mild to moderate hydronephrosis resulting from a UPJ obstruction can be safely observed and usually will resolve by 2 years of age. Antibiotic prophylaxis should be continued until the UPJ obstruction resolves completely.

Surgical repair should be performed for a UPJ obstruction associated with severe hydronephrosis, diminished renal function, high-grade obstruction or breakthrough infections while on antibiotic prophylaxis. The most commonly performed surgical repair is a dismembered pyeloplasty. The dyskinetic segment of the collecting system at the UPJ is resected, and the ureter and renal pelvis are brought over any crossing vessels that may be present and then anastomosed. The ureter in older patients may readily accommodate endoscopic instruments and a UPJ obstruction may be incised using either a percutaneous or a ureteroscopic approach. Kidneys with minimal function may best be treated with a simple nephrectomy.

Vesicoureteral Reflux

Vesicoureteral reflux is the second most common cause of hydronephrosis and may be found in as many as 70 percent of infants presenting with a urinary tract infection. For vesicoureteral reflux detected after birth, there is a female preponderance, with 85 percent of cases diagnosed in females. Vesicoureteral reflux is often an inherited anomaly. It is ten times more common in whites than in blacks and up to 45 percent of siblings of children with reflux also have reflux. Primary reflux is a congenital anomaly caused by a deficiency of the longitudinal bladder muscle surrounding the intramural portion of the ureter. Secondary reflux results from bladder outlet obstruction and an increase in intravesical pressure. Secondary reflux is corrected by addressing the underlying bladder outlet obstruction.

Vesicoureteral reflux is diagnosed by demonstrating ureteral reflux on VCUG. The degree of reflux can be graded according to the International Classification System devised in 1981 by the International Reflux Study Committee. As the infant bladder grows and the bladder wall thickens, most low-grade refluxes resolve. Approximately 85 percent of all grades I and II reflux will spontaneously resolve, although 30–40 percent of grades III and IV reflux and 9 percent of grade V reflux will resolve. Given that some high-grade reflux will eventually resolve, it is reasonable to conservatively follow children with reflux, regardless of the grade. However, it is critical that patients managed conservatively are maintained on antibiotic prophylaxis.

Surgical repair should be performed in all patients with a breakthrough infection while on antibiotic prophylaxis. Although there is some controversy surrounding this issue, most practitioners recommend surgical correction before the onset of puberty for girls with persistent reflux. The rationale for this recommendation is based on the observation that after the cessation of longitudinal growth, the likelihood of spontaneous resolution of reflux is small, and during pregnancy, reflux places women at a higher risk of pyelonephritis and miscarriage. Boys are at a lower risk of infection secondary to reflux. Therefore, most practitioners recommend stopping antibiotic prophylaxis after early childhood and continuing to observe persistent reflux.

Ureterocele

A ureterocele is a cystic dilation of the distal ureter associated with a stenotic ureteral opening. Ureteroceles occur four times more frequently in girls than in boys and occur almost exclusively in whites. Approximately 80 percent are associated with the upper-pole moiety of a duplicated ureter.

Posterior Urethral Valve

Posterior urethral valves are obstructive urethra lesions usually diagnosed in male newborns and infants. The valves are thin, membranous folds located in the prostatic urethra. Posterior urethra valves are the most common cause of bilateral hydronephrosis detected on prenatal ultrasound.

The Penis

Hypospadias

Hypospadias results from incomplete fusion of the urethral plate during development of the male penis. Hypospadias occurs in 1 in 300 males. The risk for hypospadias is increased by history of maternal estrogen or progestin use during pregnancy. Hypospadias are classified by the location of the urethral opening. Approximately 70 percent of hypospadias occur on the corona or distal shaft of the penis. Neonates with a hypospadias are not at increased risk for having other congenital abnormalities of the urinary tract.

For psychologic reasons, the hypospadias should be repaired before 2 years of age. Newborns diagnosed with a hypospadias should not be circumcised. The foreskin may be needed for future corrective surgery. The goals of surgical treatment include correction of any penile curvature, moving the urethral opening to the tip of the glans, and producing a cosmetically satisfactory result.

Phimosis

Phimosis is the inability to retract the foreskin past the glans of the penis. In most neonates, a physiologic phimosis exists. By 3 years of age, 90 percent of males are able to retract their foreskin.

Paraphimosis

Paraphimosis occurs when the foreskin that has been retracted past the glans of the penis cannot be reduced to its normal position. Constriction of the distal penis by the foreskin leads to venous congestion and swelling, making reduction of the foreskin even more difficult. As swelling and edema worsen, arterial supply to the glans may be compromised, resulting in ischemia, and even necrosis of the glans. Paraphimosis should be reduced emergently.

The Testicle

Testicular Torsion

Testicular torsion occurs when the testicle rotates and strangulates its blood supply at the level of the spermatic cord. Testicular torsion is a medical emergency that requires prompt surgical attention. Torsion occurring in the neonatal and prenatal period is extravaginal—the testicle and both layers of the tunica vaginalis rotate. Testicular torsion in neonates may not produce symptoms and is usually only noted after the testicle has atrophied. Torsion in children and young adults is intravaginal—the testicle and the inner layer of the tunica vaginalis rotate.

Intravaginal torsion is most common in 12–18-year-olds, with peak incidence at age 13 years. Adolescents presenting with testicular torsion complain of severe pain. The differential diagnosis includes epididymo-orchitis and torsion of the appendix testis. Epididymo-orchitis is rare in adolescents and is accompanied by pyuria. When evaluating a patient with torsion, manual detorsion can be attempted. If this fails, the patient should be immediately taken to the operating room.

Surgery performed within 4–6 h of onset of pain has better than a 90 percent testicular salvage rate. Therefore, unless the evidence for a competing diagnosis is overwhelming, surgery should not be delayed by diagnostic studies. At the time of surgery, an orchiopexy should be performed by fixing the testicle to the scrotal wall at three different points. The anatomic predisposition to torsion affects both testicles; therefore, the contralateral testicle should be similarly repaired. In select cases in which the diagnosis is uncertain and testicular torsion is unlikely, Doppler ultrasound or nuclear scintigraphy can be performed to more definitively rule out testicular torsion.

Hydrocele

In infants, hydroceles are fluid collections within the tunica vaginalis or processus vaginalis. During development, the testicles are enveloped by a double layer of peritoneum, which becomes the tunica vaginalis. With normal development, the processus vaginalis, which connects the tunica vaginalis with the peritoneum, becomes obliterated. If the process vaginalis persists, peritoneal fluid can track into the space surrounding the testicles, creating a communicating hydrocele. If bowel tracks down the same space, an indirect inguinal hernia is the result. If the processus vaginalis obliterates and traps fluid in the tunica vaginalis, a noncommunicating hydrocele is the result.

DIAGNOSIS

Diagnostic Procedures

Cervical Cytology

An annual cervical cytology (Papanicolaou [Pap] smear) and pelvic examination should be scheduled for all women who are or who have been sexually active or who have reached 18 years of age. After a woman has had three or more consecutive, satisfactory, annual cytologic examinations with normal findings, the Pap test may be performed less frequently on a low-risk woman at the discretion of her physician (ACOG Committee Opinion Number 186, September 1997).

After removal of the uterus and cervix for benign disease, the Pap test is not required more often than every three years as a part of the periodic examination. The practitioner should expect a report from the laboratory in the format of the Bethesda classification (Table 40-1) for cervical cytologic reporting. The Bethesda system for reporting cervical cytologic diagnoses was developed in 1988 and improved in 1991; it replaced the original Papanicolaou reporting system and provides a uniform format for cytopathology reports.

Vaginal Discharge

The patient's complaint of abnormal vaginal discharge should be investigated. Vaginal fluid is prepared by placing a small amount of the saline suspension on a microscopic slide with a cover slip and examining it under magnification. The examiner may note motile trichomonads, indicative of *Trichomonas vaginalis*; characteristic "clue cells," indicative of bacterial vaginosis; or pus cells, which may be indicative of gonorrhea, chlamydial, or other bacterial infections.

Potassium hydroxide enables the practitioner to appreciate the presence of mycelia characteristic of *Candida vaginitis*.

Cultures

Vaginal and cervical cultures are most useful for the detection of sexually transmitted disease. Although the diagnosis of gonorrhea might be suspected when Gram-negative intracellular diplococci are found on a vaginal smear stained by Gram stain, culture should be obtained to prove the infection. Gonorrhea is cultured on a chocolate agar plate and incubated in a reduced oxygen atmosphere. Cultures are most conveniently collected on a Thayer-Martin medium in a bottle containing a carbon dioxide atmosphere.

Chlamydial infection is suggested by the finding of a characteristic thick, yellow mucus (mucopus) in the cervical canal. Mucopus should be collected with a calcium alginate-tipped swab and sent to the laboratory in transport media specifically designated for Chlamydia. Some laboratories are now offering urine tests for gonorrhea and Chlamydia using the ligase chain reaction (LCR).

TABLE 40-1 The Bethesda Classification for the Classification of Pap Smear Abnormalities

<i>Adequacy of the specimen</i>	<i>Epithelial cell abnormalities</i>
Satisfactory for evaluation	Squamous cell
Satisfactory for evaluation but limited by ... (specify)	Atypical squamous cells of undetermined significance
Unsatisfactory ... (specify)	Low-grade squamous intraepithelial lesion encompassing human papillomavirus
<i>General categorization</i>	High-grade squamous intraepithelial lesion encompassing moderate dysplasia, severe dysplasia, carcinoma in situ
Within normal limits	Squamous cell carcinoma
Benign cellular changes: see descriptive diagnosis	Glandular cell
Epithelial cell abnormality: see descriptive diagnosis	Endometrial cells, cytologically benign in postmenopause
<i>Descriptive diagnosis</i>	Atypical glandular cells of undetermined significance
Benign cellular changes	Endocervical adenocarcinoma
<i>Trichomonas vaginalis</i>	Endometrial adenocarcinoma
Fungus organisms	Extrauterine adenocarcinoma
Predominance of coccobacilli	
Consistent with <i>Actinomyces</i> sp.	<i>Adenocarcinoma, NOS</i>
Consistent with herpes simplex virus	<i>Other malignant neoplasms (specify)</i>
Reactive changes	<i>Hormonal evaluation (applies to vaginal smears only)</i>
Changes associated with inflammation	Hormonal pattern compatible with age and history
Atrophy with inflammation	Hormonal pattern incompatible with age and history
Radiation	Hormonal evaluation not possible due to ... (specify)
Intrauterine contraceptive device

Pregnancy Tests

These tests measure increased amounts of the beta subunit of human chorionic gonadotropin (hCG) in urine. These urine tests are very sensitive and specific, measuring hCG as low as 20 mIU/mL. Serum tests are more accurate and sensitive, and have an advantage in that they can be quantitated to give an hCG level. Serial hCG levels are helpful in circumstances in which it is important to determine that hCG levels are increasing or decreasing, such as in the management of threatened abortion, ectopic pregnancy, or trophoblastic disease.

Abnormal Bleeding

After the first menstrual period (menarche), cyclic bleeding is considered the norm but is subject to great variation. Menstrual interval varies from 21–45 days (time from the beginning of one menstrual period until the beginning of another). Menstrual duration varies from 1–7 days. The menstrual flow is a subjective assessment and varies from light to heavy. Some women experience bleeding at midcycle at the time of ovulation. Abnormal genital bleeding falls into six categories.

Bleeding Associated with Pregnancy

The availability of extremely sensitive pregnancy tests has made it possible to confirm pregnancy in the early days of gestation. Although bleeding can occur in up to 25 percent of all normally pregnant women, this symptom must be considered a threatened abortion until the bleeding is otherwise clarified. In the presence of threatened abortion, the pregnancy test is positive, the cervix is closed, and the uterus generally is consistent with the history of gestation. An abortion is considered inevitable when the cervix accommodates ring forceps and fetal tissue appears at the cervical os. Abortion is incomplete after a portion of the products of conception has been expelled; it is considered complete after all the products of conception have been expelled. Inevitable and incomplete abortion generally is treated by dilatation and curettage.

Ectopic pregnancy must be considered in any patient with a positive pregnancy test, pelvic pain, and abnormal uterine bleeding. Approximately 20 percent of patients with ectopic pregnancy have no bleeding, but others might complain of vaginal spotting or, occasionally, of hemorrhage.

Gestational trophoblastic disease also causes abnormal bleeding associated with a positive pregnancy test. Most gestational trophoblastic disease is represented by hydatidiform mole (see below).

Dysfunctional Uterine Bleeding

This type of bleeding abnormality is characterized by irregular menses with occasional extended intervals of amenorrhea. When bleeding does occur after one of these periods of amenorrhea, it tends to be extremely heavy. The combination of a period of amenorrhea and extremely heavy bleeding occasionally suggests spontaneous abortion. In the majority of instances, the problem is secondary to failure to ovulate. Evaluation of these patients should include a pregnancy test, which should be negative. Endometrial sampling usually reveals a nonsecretory or proliferative endometrium. In the presence of extremely heavy bleeding, dilatation and curettage is occasionally required, but in most instances, the condition can be managed with cyclic estrogen/progesterone treatment.

Trauma

The bleeding associated with genital trauma may be diagnosed secondary to a history of rape or genital injury. In the presence of genital bleeding secondary to trauma, the lesion must be evaluated carefully and repaired in the operating room under anesthesia if necessary.

In infants and premenarchal patients, the vaginal canal should be examined carefully for foreign bodies.

Bleeding Secondary to Neoplasm

Tumors, both benign and malignant, involving the genital tract from the vulva to the ovary, can produce abnormal bleeding.

The most common cause of abnormal bleeding in reproductive-age women is the presence of leiomyomas (fibroids). Leiomyomas are a common cause of heavy noncyclic bleeding (menometrorrhagia). Pelvic ultrasound is helpful in the diagnosis of uterine fundal tumors.

Pain

Pain associated with menses is the most common office complaint. Cyclic pain limited to that period just before or with the onset of menses is referred to as dysmenorrhea. Pain occurring without a demonstrable pathologic lesion is referred to as primary dysmenorrhea and is a common feature of ovulatory menstrual cycles. This condition is usually treated satisfactorily with nonsteroidal antiinflammatory analgesics. In some cases producing periodic disability, the use of ovarian suppression with oral contraceptives may be considered. Secondary dysmenorrhea commonly is associated with endometriosis, cervical stenosis, and pelvic inflammation. Acute pelvic pain may have its origin in abnormal pregnancy, benign or malignant neoplasia, or a variety of nongynecologic diseases. Pregnancy disorders include threatened abortion, inevitable abortion, incomplete abortion, and ectopic pregnancy.

Neoplasms cause acute pain through degeneration of a myoma or torsion of a myoma or ovarian neoplasm. The spontaneous rupture of an ovarian cyst can produce severe pelvic pain. Common causes of acute pain are salpingitis and endometriosis. Pain secondary to inflammatory conditions is associated with fever and other evidence of infection in most cases. Pelvic infection secondary to *C. trachomatis* is the exception to this rule. The possibility of a nongynecologic condition as the cause of pain must always be considered.

Pelvic Mass

The clinician must be aware that several physiologic conditions cause enlargement of pelvic organs. Pregnancy should be considered in all cases of uterine enlargement in reproductive-age women. Ovarian enlargement, as a result of ovulation and corpus luteum hematomas, produces masses that are easily palpable and that may persist for several weeks. In addition to a carefully performed pelvic examination, vaginal ultrasonography is a useful tool. Simple cysts associated with a normal CA125 are virtually never malignant.

Pelvic ultrasonography, computed tomography (CT), magnetic resonance (MR) and PET scanning all provide clues to the origin of pelvic tumors. Uterine enlargement may suggest pregnancy, uterine myomata, adenomyosis, or malignancy, such as endometrial cancer or sarcoma. Tubal tumors may represent a tubal pregnancy, inflammatory conditions of the tube and hydrosalpinx formation, or a primary fallopian tumor. Ovarian enlargement may suggest endometriosis, ectopic pregnancy, tuboovarian abscess, or benign or malignant tumor of the ovary. The decision to operate is predicated on the patient's age, clinical presentation, and character and clinical course of the mass. If the differential diagnosis points to a strong possibility of ovarian malignancy, the patient should be explored under conditions that will allow for the treatment of a pelvic cancer.

INFECTIONS

Vulvar and Vaginal Infections

Mycotic Infection

The most common cause of vulvar pruritus is candidal vulvovaginitis. The infection is most common in patients who are diabetic, pregnant, or on antibiotics. The majority of cases are caused by *C. albicans*, although other species

may be incriminated. Diagnosis is confirmed by examination of the vaginal secretions and recognition of the characteristic pseudomycelia. Systemic treatment is possible through the oral use of fluconazole 150-mg tablet in a single dose.

Parasitic Infections

Pin worms (*Enterobius vermicularis*), which are common in young girls, cause vulvitis. Diagnosis is made by finding the adult worms or recognizing the ova on microscopic examination of perianal material collected on adhesive tape. A number of antihelmintic agents are available; mebendazole therapy is commonly used.

Trichomonas vaginalis causes primarily a vaginal infection, but the copious vaginal discharge causes secondary vulvitis. Diagnosis is made by recognizing the motile flagellates on microscopic examination. Treatment consists of metronidazole 250 mg given three times daily for 7 days.

The vulvar skin is a frequent site for infestation by *Phthirus pubis* (crab lice) and *Sarcoptes scabiei* (scabies, itch mites). The primary symptom of both these infestations is severe pruritus. The adult and immature forms are recognized on close inspection of the skin. Treatment consists of Kwell. The use of this agent is contraindicated in pregnancy.

Bacterial Infections

Bacterial vaginosis is the most common bacterial pathogen. The vaginal discharge found with this condition is not unlike that found with trichomonal vaginitis. The discharge is thin and gray-green in color. Diagnosis is made by microscopic study of the vaginal secretions to identify characteristic "clue cells." The condition is treated with metronidazole orally or with metronidazole or clindamycin topical creams.

Viral Infections

A number of viral infections affect the vulva and vagina, the most common of these being condyloma acuminatum. The causative organism is the human papillomavirus. The lesions are characteristic wart-like growths that begin as single lesions but can grow to huge confluent lesions that distort the normal structures. The lesions enlarge rapidly in pregnancy. Diagnosis is suspected on the basis of appearance and may be confirmed by biopsy. Treatment depends on the destruction of the lesions with caustic agents, imiquimod, cryocautery, laser ablation, or electrocautery.

Herpes simplex infection causes painful vesicles followed by ulceration of the vulva, vagina, or cervix. Initial infection usually is widespread, but recurrent infection usually involves a single lesion. Cytologic evaluation of lesions in the vagina is helpful; culture is confirmatory for herpes infection. Once a patient is infected, there is a tendency for the lesions to recur at various intervals for the life of the patient. The attacks may be aborted and the interval between attacks lengthened through the use of acyclovir (400 mg orally three times daily for 7–10 days). Active infection in pregnancy carries the risk of newborn infection if the patient delivers vaginally. Cesarean section is recommended in patients in labor with vulvar or vaginal ulceration as a result of herpes simplex infection.

Molluscum contagiosum causes groups of small pruritic nodules with an umbilicated center. The lesions are treated by ablation by cautery, curettage, or corrosive medication.

Pelvic Inflammatory Disease

It is estimated that there are approximately 1.5 million cases of pelvic inflammatory disease in the United States each year. The condition might produce infertility in 10 percent of the cases that occur; 3 percent or more of patients will have ectopic pregnancy, and chronic pain is a problem in many others.

Several factors have been recognized as placing the patient at risk: age younger than 20 years, multiple sexual partners, nulliparity, and previous pelvic inflammatory disease.

Pelvic inflammatory disease is classified as acute or chronic. The most common organisms that produce the condition are *N. gonorrhoeae* and Chlamydia, but numerous other organisms have been incriminated. The classic signs include fever, lower abdominal pain with pelvic tenderness, and purulent vaginal discharge. Some patients, however, will have minimal or absent symptomatology, particularly in the presence of a chlamydial infection. In patients requiring further study, pelvic ultrasonography may be helpful in confirming a diagnosis. When pelvic inflammatory disease is present, laparoscopy will confirm it by finding tubal edema, erythema, and exudate. The presence of a tuboovarian abscess can be confirmed in this manner.

Treatment

Women with pelvic inflammatory disease with evidence of peritonitis, high fever, or suspected tuboovarian abscess should be admitted to the hospital for observation and intravenous antibiotics.

The Centers for Disease Control and Prevention (CDC) recommends one of the following oral regimens: ofloxacin 400 mg orally twice a day for 14 days or levofloxacin 500 mg orally once daily for 14 days with or without metronidazole 500 mg orally twice daily for 14 days.

Recommendations from the CDC for parenteral treatment include cefotetan 2.0 g intravenously (IV) every 12 h or ceftiofur 2 g IV every 6 h plus doxycycline 100 mg orally or IV every 12 h. This regimen is continued for at least 24 h after the patient shows clinical improvement. Doxycycline 100 mg orally twice daily is given to complete a total of 14 days of therapy. The use of broad-spectrum antibiotics, which must include an antibiotic with anaerobic activity, will result in cures of some pelvic abscesses.

Surgical Therapy

Surgery becomes necessary under the following conditions: (1) the intraperitoneal rupture of a tuboovarian abscess; (2) the persistence of a pelvic abscess despite antibiotic therapy; and (3) chronic pelvic pain.

In young women whose reproductive goals have not been achieved, especially in the presence of unilateral disease, a unilateral salpingo-oophorectomy may be more appropriate than total hysterectomy with removal of both ovaries and fallopian tubes.

The rupture of a tuboovarian abscess is a true surgical emergency. Rupture most frequently is associated with a sudden severe increase in abdominal pain. A shock-like state commonly accompanies rupture. Leukocyte counts are not necessarily increased, and some patients are afebrile. With prompt surgical intervention and intensive medical management, the mortality rate today is less than 5 percent.

The patient with a ruptured abscess must be explored promptly through an adequate incision. Hysterectomy and oophorectomy are commonly indicated.

Operation may be technically difficult because of the distortion and edema secondary to the inflammatory process. Before the extirpation of any pelvic organ, adhesions must be lysed and normal structures, such as ureters and the large and small bowel, identified. At the conclusion of the procedure, the abdomen should be liberally irrigated. If the uterus is removed, the vaginal cuff should be left open for drainage.

ENDOMETRIOSIS

It has been estimated that endometriosis will be demonstrated in approximately 20 percent of all women in the reproductive age group. Although the condition occurs in teenage women, it is found most often in the third and fourth decades of life.

The most common theory for endometriosis is that it is initiated by retrograde menstruation. The most common lesions of endometriosis can be recognized as bluish or black lesions, sometimes raised, sometimes puckered, giving them a "gunpowder burn" appearance. Although many patients are asymptomatic even with widespread endometriosis, others have severe pain, particularly dysmenorrhea, and dyspareunia. Other signs and symptoms depend on the location and depth of endometriotic implants. Infertility and abnormal bleeding are common problems.

Pain is associated most often with the menstrual period; deep pelvic dyspareunia is commonly associated with this disease, particularly in those individuals with implants involving the uterosacral ligaments or the rectovaginal septum.

The finding of a pelvic mass and tender nodularity of the uterosacral ligament strongly suggests endometriosis. The mass usually represents an ovarian endometrioma, often referred to as a "chocolate cyst" because of its dark-brown fluid contents.

Treatment

Patients with minimal endometriosis who are asymptomatic can be cared for through simple observation and management with cyclic oral contraceptives and simple analgesia.

Pseudomenopause is currently the most common medical treatment for endometriosis. The most common medications used today for this purpose are the gonadotropin-releasing hormone agonists (GnRHa).

Conservative surgical therapy for endometriosis has become much more common with the advancement of laparoscopic surgery. Until menopause, extirpative surgery is the only permanent cure for endometriosis.

ECTOPIC PREGNANCY

The most common complaint of patients with ectopic pregnancy is pain, frequently associated with irregular vaginal bleeding. Approximately 80 percent of affected women will recall a missed menstrual period. An adnexal mass may be palpated in approximately 50 percent of patients. As a result of the intraperitoneal bleeding, some patients present in shock.

Laboratory examination of β -hCG enables the surgeon to confirm the pregnant state in patients at risk for ectopic pregnancy. Once the physician is assured that the patient is pregnant, it must be determined that the pregnancy is in the uterus. Vaginal ultrasonography is important in differentiating uterine gestations from ectopic gestations.

In those patients who do not desire to continue the pregnancy, curettage of the uterus with examination of the tissue can be diagnostic. In the event that fetal tissue is not found, a diagnostic laparoscopy usually is required in the symptomatic patient for definitive diagnosis.

Treatment

Laparoscopic Procedures

Linear salpingostomy is the treatment of choice for ectopic pregnancies less than 4 cm in diameter that occur in the distal third (ampullary) segment of the tube. To aid in hemostasis, the mesentery below the involved tubal segment is infiltrated with a dilute vasopressin solution. The tube may then be opened in its long axis along the antimesenteric side with laser or a cutting cautery. The conceptus is then aspirated, and any bleeding is electrocoagulated. Partial or total salpingectomy is indicated when the pregnancy is located in the isthmic portion of the tube.

Medical Therapy

Conservative criteria for treatment of ectopic pregnancy with methotrexate include serum β -hCG levels less than 3500 IU/L and vaginal ultrasound that reveals the tubal pregnancy to be less than 3.5 cm in diameter with no visible fetal cardiac motion and no sign of hemoperitoneum. In this situation intramuscular methotrexate will result in complete resolution of the ectopic pregnancy in 96 percent of the cases. Subsequent tubal patency on the affected side can be documented in approximately 85 percent of the patients so treated. The risk of rupture and intraperitoneal hemorrhage must be made clear to the patient.

PELVIC FLOOR DYSFUNCTION

Pelvic Organ Prolapse

Female pelvic floor dysfunction is common. It includes many clinical conditions, the most prevalent of which are pelvic organ prolapse and urinary incontinence. Race, collagen metabolism, vaginal delivery, chronic constipation, chronic lung disease, and smoking are among the factors thought to be associated with the development of pelvic floor dysfunction (Bump).

Pelvic organ prolapse is the descent of the pelvic organs into or through the vagina because of deficient support of the vaginal walls. The standardization report of the International Continence Society in 1996 names "anterior vagina," "posterior vagina," and "vaginal apex" as reference points in the description of pelvic organ prolapse. This terminology, known as the Pelvic Organ Prolapse Quantification (POP-Q) system, quantifies prolapse according to the positions of those reference points relative to the hymen. The POP-Q has replaced the arbitrary grading systems that have been used in the past, improving the quality of description of the examination findings and facilitating communication among practitioners.

Patients with symptomatic pelvic organ prolapse report pelvic pressure and heaviness or a bulge protruding through the vagina. Patients may report difficulty with bowel or bladder emptying which requires them to push the prolapsed tissue back in manually. Obstructed voiding may occur, predisposing to urinary tract infection, urinary frequency and urgency, or, in rare cases, hydronephrosis. Because of shared risk factors, many patients

with prolapse also have urinary incontinence. However, the relationship between urinary incontinence and prolapse is complex. Advanced prolapse may be associated with paradoxical continence, in which kinking of the urethra by the prolapse masks symptoms of stress incontinence that would otherwise occur because of a defective urethral closure mechanism.

Reconstructive surgery is indicated for symptomatic pelvic organ prolapse. Symptoms requiring surgery may include discomfort, irritation, or disturbance of bowel and bladder function. It is important to carefully define which of the patient's symptoms can be reasonably expected to improve with an operation. A pessary trial may be recommended for patients who are not surgical candidates. The reconstructive pelvic surgeon must recognize pelvic organ prolapse as a quality-of-life issue. This means that surgical goals and outcomes are measured not only by restoration of anatomy, but by relief of the specific symptoms with which the patient presents.

Urinary Incontinence

Urinary incontinence is defined as involuntary leakage of urine. Stress urinary incontinence is leakage of urine on exertion or effort, or with sneezing or coughing, which can be objectively demonstrated. It results from a dynamic urethral closure mechanism which is insufficient to overcome increases in abdominal pressure. Urge incontinence is characterized by urine leakage which is accompanied or immediately preceded by urgency. Urge incontinence is thought to result from inappropriate activation of the micturition reflex ("overactive bladder"). Stress incontinence, but not urge incontinence, is amenable to surgical therapy.

A baseline physical examination for a patient complaining of urinary incontinence includes a standing stress (cough) test, pelvic examination—including prolapse staging and evaluation for pelvic mass—urinalysis, and post void residual determination. Urethral mobility may be evaluated using the cotton swab ("Q-tip") test. Urethral hypermobility often serves as a focus for repair in continence operations. It is important to note, however, that urethral hypermobility is not specific for, nor causative of, urinary incontinence.

A patient presenting with uncomplicated stress urinary incontinence may be a candidate for surgical therapy. Potential complicating factors include: history of previous incontinence or prolapse surgery; prolapse greater than Stage II; elevated postvoid residual or abnormal voiding function; urinary urgency, frequency, or symptoms of urge incontinence; hematuria; neurologic disease; and previous pelvic radiation or radical pelvic surgery. Such patients should undergo complex urodynamic studies and evaluation by a pelvic floor specialist prior to consideration of an incontinence operation.

Stress urinary incontinence may be treated conservatively or surgically. Commonly used conservative treatments include pelvic muscle rehabilitation and vaginal obstructive devices. Estrogen supplementation and α 1-adrenergic medications have been advocated for the treatment of stress incontinence, but their efficacy remains unproven.

Continence is a dynamic, complex function which surgery attempts to restore by unnatural means. The goal of a continence operation is to improve the ability of the urethra to close with increases in abdominal pressure, yet avoid interfering with voiding function. Surgical treatments for urinary incontinence have been performed since the beginning of the 20th century, pioneered by Howard Kelly and other gynecologic surgeons. Hundreds of different of

operations have been developed, a fact which testifies to the difficulty of consistently achieving satisfactory and long-lasting outcomes.

SURGERY FOR PELVIC ORGAN PROLAPSE

Many factors are important in determining which reconstructive operation is optimal for a given patient. Variations of operative techniques have been described. Surgical decisions often are based on case series and expert opinions which may not have universal applicability. The few controlled studies that have been published suggest that, in general, failure rates for vaginal procedures are higher than those for abdominal procedures. This difference may relate to the use of graft materials, a concept that has been well established in the general surgery literature regarding abdominal wall hernia repair.

Vaginal Procedures

Colporrhaphy

The oldest type of vaginal reconstructive operation is colporrhaphy. This type of procedure involves the destruction or excision of vaginal epithelium. Anterior colporrhaphy begins with incision of the anterior vaginal epithelium in a midline sagittal direction. The epithelium is sharply dissected away from the underlying vaginal muscularis. The vaginal muscularis is plicated with interrupted delayed absorbable stitches, following which the epithelium is trimmed and reapproximated. Posterior colporrhaphy is performed in a similar manner, often including the distal pubococcygeus muscles in the plication.

Sacrospinous fixation. The sacrospinous ligament may be used for suspension of the prolapsed vaginal vault. The procedure begins with entry into the rectovaginal space. The rectal pillar is penetrated to gain access to the pararectal space. Two nonabsorbable monofilament sutures are placed in the sacrospinous ligament, at least two fingerbreadths medial to the ischial spine. Structures at risk of injury in this area include the inferior gluteal neurovascular bundle, lumbosacral plexus, and sciatic nerve. The stitches are anchored to the vaginal apex and tied without suture bridging. The remainder of the epithelial incision is closed.

Uterosacral ligament suspension. This approach is based on the original description of posterior culdoplasty by McCall in 1957. The uterosacral ligaments are exposed with an intraperitoneal approach. Multiple delayed absorbable or permanent sutures are used to attach the lateral-most portion of the vaginal cuff to the distal-most portion of the ligament and the medial cuff to the proximal ligament. Intraoperative evaluation of the lower urinary tract is important to confirm the absence of ureteral compromise.

Colpocleisis. Colpocleisis is the term applied to a class of vaginal prolapse operations that involves removal of part or all of the vaginal epithelium. The main benefits of colpocleisis operations are their simplicity, speed, and—in the case of total colpocleisis—high efficacy.

The LeFort colpocleisis for complete uterovaginal prolapse requires preoperative screening of the cervix and endometrium for malignancy. The procedure involves denudation of a rectangular portion of vaginal epithelium on both the anterior and posterior vaginal walls, followed by suture reapproximation of the exposed submucosal surfaces. The uterus is left in situ. Lateral drainage canals remain for drainage of uterine secretions. Total colpocleisis involves

excision of the entire vaginal epithelium, followed by pursestring closure and inversion of the vaginal muscularis with complete obliteration of the vaginal vault.

Abdominal Procedures

Sacral Colpopexy

Pelvic reconstructive surgery by the abdominal approach allows for the use of graft material to support the vaginal apex. Suspension of the vaginal vault to the anterior surface of the sacrum using graft material was first reported in 1962. The procedure may be modified to include the anterior and posterior vaginal walls, and the perineal body, in the suspension.

Abdominal sacral colpoperineopexy begins with the attachment of graft material to the perineal body. The rectovaginal space is opened, and an allograft or xenograft is anchored to the levator ani muscles bilaterally and the perineal body distally using delayed absorbable or permanent monofilament suture in interrupted fashion. Laparotomy is then performed and the graft is retrieved. A strip of synthetic mesh is fixed to the remainder of the posterior vaginal wall directly and another to the anterior wall. The peritoneum overlying the presacral area is opened, and the anterior surface of the sacrum is skeletonized. Two to four permanent sutures are placed through the anterior longitudinal ligament. The sutures are passed through both leaves of the graft at the appropriate location which supports the vaginal vault under no tension. The peritoneum is then closed. The most dangerous potential complication of sacral colpopexy is life-threatening sacral hemorrhage.

SURGERY FOR STRESS URINARY INCONTINENCE

The choice of an incontinence operation for a given patient depends on many factors. Incontinence operations fall into three categories: needle suspension, retropubic urethropexy, and suburethral sling. Anterior vaginal wall plication, or anterior colporrhaphy, is no longer advocated for the surgical treatment of stress incontinence.

In cases of uncomplicated stress incontinence accompanied by urethral hypermobility, retropubic urethropexy most commonly is used. In the presence of intrinsic sphincter deficiency, success rates with colposuspension may be less than 50 percent. Therefore, intrinsic sphincter deficiency (ISD) with urethral hypermobility is best treated with suburethral sling procedures. ISD without urethral hypermobility is treated with suburethral slings, periurethral bulk injections, or rarely artificial sphincters.

Needle Suspension

Variations of this technique include the Pereyra, Stamey, Gittes, and Raz procedures. After an anterior colpotomy is made, the space of Retzius is entered bilaterally. Through a small transverse suprapubic incision, a long angled needle is passed through the space of Retzius to bring up the ends of a suture that has been secured to the periurethral vaginal muscularis. Variations exist regarding the way in which suture is attached to the periurethral tissue and the method of abdominal wall fixation. The utility of these procedures is limited by high long-term failure rates.

Retropubic Colposuspension

The first retropubic colposuspension was described in 1949 and modified in 1961.

Marshall-Marchetti-Krantz (MMK) procedure. Permanent suture is placed lateral to the urethra bilaterally and tied to the periosteum of the pubic ramus or perichondrium of the symphysis pubis. The surgical objective is to appose the urethra to the posterior surface of the symphysis pubis.

Burch procedure, Tanagho modification. Two pairs of large caliber delayed absorbable suture are placed through the periurethral vaginal wall, one pair at the midurethra and one at the urethrovesical junction. Each stitch is then anchored to the ipsilateral Cooper (iliopectineal) ligament. The sutures are tied to give preferential support to the urethrovesical junction relative to the anterior vaginal wall. Long-term outcome studies up to 10 years have shown cure rates of 80–85 percent for the Burch procedure.

Suburethral Sling

Suburethral sling procedures for stress incontinence have been in use since the beginning of the 20th century. Currently, the most commonly used sling materials include autografts (rectus fascia) and processed cadaveric allografts (fascia lata). The procedure is performed by a combined abdominovaginal approach, using a small transverse suprapubic skin incision. The anterior vaginal epithelium is incised and dissected from the underlying muscularis. The space of Retzius is entered. A Bozeman clamp or long angled ligature carrier is used to perforate the rectus fascia, passing it through the space of Retzius to retrieve the arms of the sling. The sling arms are fixed in place with suture. The base of the sling is positioned at the urethrovesical junction. Cure rates for the many different types of sling procedures described in the literature range from 75–95 percent.

Tensionless Sling

The tension free vaginal tape procedure was introduced in 1996. It is a modified sling using a strip of polypropylene mesh. Unlike traditional sling procedures, the mesh is positioned at the midurethra, not the urethrovesical junction, and is not sutured or otherwise fixed into place. Advantages of tension-free vaginal tape (TVT) include the ability to perform the procedure under local anesthesia and on an outpatient basis. Through an anterior vaginal wall incision, small subepithelial tunnels are made bilaterally to the descending pubic rami using sharp dissection. A specialized conical metal needle coupled to a handle is used to drive each end of the sling through the perineal membrane, space of Retzius, and suprapubic skin. The mesh is positioned at the midurethra without tension. The 7-year cure rate of TVT for stress incontinence is 82–85 percent.

Bulking Agent Injection

Glutaraldehyde cross-linked (GAX) bovine dermal collagen is currently the most widely used injectable. A transurethral or periurethral technique may be used, using a 30-degree operating female cystourethroscope to directly visualize the injection. The material is injected underneath the urethral mucosa at the bladder neck and proximal urethra, usually at the 4 and 8 o'clock positions, until mucosal apposition is seen. The long-term cure rate is 20–30 percent, with

an additional 50–60 percent of patients demonstrating improvement. Repeat injections are frequently necessary because of migration and dissolution of the collagen material.

Surgical Complications

The most common complication of incontinence surgery is voiding dysfunction. Complete urinary retention may be transient or permanent, depending on the procedure and the way it is performed. There is also a spectrum of voiding difficulties related to partial urethral obstruction. Because of the 1–3 percent risk of injury to bladder or ureters, intraoperative evaluation of the urinary tract is recommended whenever incontinence surgery is performed. Other potential complications include urinary tract infection, retropubic hemorrhage or abscess, intestinal tract injury, ilioinguinal or other nerve injury, enterocele formation, foreign body complications because of graft materials, and inflammatory or infectious processes involving the pubic bones.

BENIGN TUMORS

Ovarian Tumors

Nonneoplastic Cysts

By definition, a cystic enlargement of the ovary should be at least 2.5 cm in diameter to be termed a cyst.

Wolffian duct remnants. These are small unilocular cysts. They may enlarge or twist and infarct.

Müllerian duct remnants. These can appear as paraovarian cysts or as small cystic swellings at the fimbriated end of the fallopian tube (hydatids of Morgagni).

Nonfunctioning Tumors

Cystadenomas. Many fluid-containing cystic tumors of the ovary are also accompanied by papillary projections and are known as papillary serous cystadenomas or mucinous cystadenomas. Approximately 20 percent of the serous tumors and 5 percent of the mucinous tumors are bilateral.

Mature teratoma. The tumors often contain calcified masses, and, occasionally, either teeth or pieces of bone can be seen on abdominal radiographs. Mature teratomas occur at any age but are more frequent in patients between 20 and 40 years old. If a teratoma (dermoid) is encountered in a young woman, it is preferable to shell it out from the ovarian stroma, preserving functioning tissue in the affected ovary. The opposite ovary should be inspected, but no further operative procedure is performed if the opposite ovary appears normal. In approximately 12 percent of patients, these tumors are bilateral.

Meigs syndrome. This pertains to ascites with hydrothorax, seen in association with benign ovarian tumors with fibrous elements, usually fibromas. Meigs syndrome can be cured by excising the fibroma.

Functioning Tumors

Granulosa-theca cell tumor. Pure theca cell tumors (thecomas) are benign, but those with granulosa cell elements are low-grade malignancies. Usually,

granulosa cell tumors elaborate estrogen, but some of these tumors have no hormone production. In young girls, they are characteristically manifested by isosexual precocity, and in older adult women, they are sometimes associated with postmenopausal bleeding or endometrial carcinoma. The tumor can occur at all ages from childhood to the postmenopausal period, but it is most common in later life, with maximal occurrence between the ages of 40 and 60 years. If the tumor is discovered in the reproductive years and confined to one ovary without signs of surface spread or dissemination, a simple oophorectomy may be sufficient therapy. If it is discovered in later life, removal of both ovaries with the uterus is indicated. These tumors produce β inhibin, which may be measured in the peripheral circulation.

Struma ovarii. This term refers to the presence of grossly detectable thyroid tissue in the ovary, usually as the predominant element in dermoid cysts. This tissue occasionally may produce the clinical picture of hyperthyroidism and is rarely malignant.

Uterine Tumors

Leiomyomas

Uterine leiomyomas are the most common benign tumor in the female pelvis. It is estimated that up to 50 percent of all women at some time in their life have one or more of these tumors.

Treatment. Most symptomatic leiomyomata can be managed expectantly. When symptoms indicate surgical treatment, consideration must be given to the age of the patient, the number of children she desires, and her reaction to possible loss of reproductive and menstrual function. Surgery should be fitted to the needs and desires of the patient. Therapeutic options may include myomectomy, embolization, and hysterectomy.

Vulvar Lesions

In many instances, chronically irritated areas of the vulva will show sclerosing atrophy of the skin (lichen sclerosus). Lichen sclerosus is a pruritic lesion that does not appear to be premalignant. Hyperplastic lesions termed hypertrophic dystrophies are found that may be benign (epithelial hyperplasia) or that may show atypia, in which case dysplastic changes can be observed. The pruritic symptoms can be helped by topical application of testosterone, clobetasol or tacrolimus ointments.

MALIGNANT TUMORS

Ovarian Tumors

Ovarian Carcinoma

Ovarian carcinomas are divided histologically into epithelial, germ cell, and stromal malignancies. The majority of the 27,000 or more cases of ovarian cancer diagnosed annually in the United States are of the epithelial type. The median age at diagnosis for epithelial ovarian cancer is 61 years, and the overall 5-year survival rate for epithelial cancers is 37 percent. Approximately 15,000 women die of this disease in the United States annually.

Although the etiology of ovarian cancer is uncertain, approximately 10 percent of patients with epithelial tumors come from families in which one or more

first-degree relatives also have this disease or breast cancer. In such families, prophylactic oophorectomy may be considered at the completion of childbearing, especially if specific BRCA1 or BRCA2 mutations are identified. Testing for these mutations is now readily available in the United States. Primary peritoneal carcinomatosis has been reported in women who have undergone prophylactic surgery, however. Life-long screening with CA 125 levels, pelvic examination, and vaginal ultrasonography of women from affected families is important.

Table 40-2 outlines the International Federation of Gynecology and Obstetrics (FIGO) staging system for ovarian cancer. Early lesions are largely asymptomatic, and advanced tumors may produce only nonspecific symptoms such as early satiety, abdominal distention, and vague gastrointestinal symptoms. Although an annual pelvic examination is valuable in detecting early

TABLE 40-2 FIGO (1988) Staging System for Ovarian Cancer

Stage	Characteristic
I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites; no tumor on the external surfaces, capsule intact
IB	Growth limited to both ovaries; no ascites; no tumor on the external surfaces, capsule intact
IC	Tumor either stage IA or stage IB but with tumor on the surface of one or both ovaries, or with capsule ruptured, or with ascites containing malignant cells or with positive peritoneal washings
II	Growth involving one or both ovaries on pelvic extension
IIA	Extension or metastases to the uterus or tubes
IIB	Extension to other pelvic tissues
IIC	Tumor either stage IIA or IIB with tumor on the surface of one or both ovaries, or with capsule(s) ruptured, or with ascites containing malignant cells or with positive peritoneal washings
III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal nodes; superficial liver metastases equals stage III; tumor is limited to the true pelvis but with histologically verified malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
IIIB	Tumor of one or both ovaries; histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter; nodes negative
IIIC	Abdominal implants greater than 2 cm in diameter or positive retroperitoneal or inguinal nodes
IV	Growth involving one or both ovaries with distant metastases; if pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV; parenchymal liver metastases equals stage IV

ovarian cancer, efforts to establish other cost-effective screening programs using serum markers such as CA 125 and vaginal ultrasound examination are being developed. Vaginal ultrasound is a promising technology that is not presently cost-effective in mass screening programs, because the yield is no more than 1 ovarian cancer per 1000 asymptomatic postmenopausal women screened. Currently, more than 70 percent of women with epithelial cancer have stage III tumors at the time of diagnosis. Widespread peritoneal dissemination, omental involvement, and ascites are the rule, rather than the exception, in these women.

Treatment. In general, therapy for epithelial ovarian cancer consists of surgical resection and appropriate staging followed by adjuvant chemotherapy. Women with low-grade early stage (IA or IB) cancers who have undergone appropriate surgical staging may be treated with surgery without adjuvant therapy. If the lesion is bilateral (stage IB), abdominal hysterectomy and bilateral salpingo-oophorectomy are sufficient. It is in the limited group of patients with unilateral histologic grade 1 or 2 lesions that fertility can be preserved by performing adnexectomy and staging biopsies without removing the uterus or contralateral ovary and fallopian tube. In all other patients (stage IA, grade 3, and stage IC and above), appropriate initial surgery includes bilateral salpingo-oophorectomy, abdominal hysterectomy if the uterus has not been removed on a prior occasion, appropriate staging, and tumor resection.

Staging. Thorough staging is imperative in determining appropriate treatment for patients with ovarian cancer. Among patients whose cancer is confined to one or both ovaries at the time of gross inspection, occult metastases can be identified by careful surgical staging in one third. If staging is improperly performed and adjuvant therapy omitted in patients whose tumors are apparently confined to the ovary, 35 percent will suffer preventable relapse.

Epithelial ovarian cancers disseminate along peritoneal surfaces and by lymphatic channels. The first site of spread is the pelvic peritoneum. Later the abdominal peritoneal surfaces and diaphragms are involved. The omentum is a common site for metastases, as are both the para-aortic and pelvic lymph nodes. It is paramount that surgery for ovarian malignancies be performed through a full-length midline abdominal incision. After the peritoneal cavity is entered, the visceral and parietal surfaces are inspected for metastatic disease, and any suspicious areas are biopsied. If ascites is present, it should be aspirated and cytologic evaluation performed. If no ascites is found, peritoneal washings with balanced salt solution or lactated Ringer solution are obtained from the abdominal cavity and submitted for cytologic evaluation after centrifugation and fixation.

Appropriately staged patients with histologic grade 1 or grade 2 tumors confined to one or both ovaries (stage IA or IB) require no postoperative therapy. Five-year survival in this group of patients exceeds 90 percent.

Those patients who have stage I, grade 3 lesions, stage IC tumors (malignant peritoneal washings, rupture of tumor, surface excrescences, or ascites), or stage II cancers that are completely resected may be treated equally well with systemic chemotherapy, radiotherapy of the whole abdomen, or a single instillation of intraperitoneal radioactive chromic phosphate. Five-year survival approaches 75 percent in this group of patients.

Women with stages III and IV disease require systemic chemotherapy with cisplatin or carboplatin, generally in combination with a taxane such as

paclitaxel. Survival at 5 years in such patients may exceed 20 percent, although this rate drops as low as 10 percent at 10 years.

It is widely accepted that patients in whom little or no residual disease remains after initial operation, on average, live longer than those in whom a great deal of tumor remains unresected. Because of the survival advantage, every effort should be made to resect as much disease at the time of laparotomy as is possible. Because many patients with advanced ovarian cancer are older adults and nutritionally depleted, surgical enthusiasm must be tempered by proper preoperative evaluation and support with appropriate central monitoring and hyperalimentation when indicated. Occasionally, it is more prudent to obtain confirmation of the diagnosis, treat with neoadjuvant chemotherapy, and then perform definitive surgery when the tumor has diminished in size and the patient has been nutritionally resuscitated.

Resection of nodules involving the small or large bowel is warranted if it results in complete removal of all observed disease. Such procedures are probably not indicated if tumor remains at other sites. After surgical extirpation of the tumor, patients with ovarian cancers must be treated with chemotherapy. Approximately 80 percent of these tumors will respond to platinum-based combination therapy; 40 percent of all patients will experience a complete clinical response, or complete resolution of tumor identified on physical examination or radiographic or serologic study.

Disease on the right diaphragm may be resected by transecting the falciform ligament and retracting the liver inferiorly. If it serves to remove all remaining tumor, splenectomy may be performed. Resection of small and large bowel may be performed if the operation removes all residual disease. Use of the ultrasound aspirator and argon beam coagulator have resulted in an increased ability to completely remove tumors, including those that are implanted on the serosal surfaces and mesentery of the bowel. With diligence it often is possible to remove all appreciable disease with these instruments.

Palliative surgery. In most cases of advanced ovarian cancer, death is associated with bowel dysfunction or frank obstruction. Although invasion of the small bowel and colon is unusual, growth of the tumor adjacent to the bowel leads to mesenteric compromise and dysfunction usually heralded by distention, nausea, and vomiting. When bowel obstruction occurs early in the clinical course of ovarian cancer, particularly if it occurs before the administration of chemotherapy, surgical intervention is warranted and should be aggressive. Resection or bypass of the involved bowel is indicated; colonic resection also may be indicated. It is important to perform adequate radiographic studies preoperatively so that obstructed small bowel is not decompressed into a compromised colon.

When bowel obstruction occurs after chemotherapy, the prognosis is unfavorable. Women who develop such difficulties have a limited survival following surgical correction. Surgery is often difficult to perform because of extensive tumor. Laparotomy may be complicated by intestinal injury or fistula. Often the best approach in these patients is the use of a percutaneous or endoscopically positioned gastrostomy tube and intravenous fluids or conservative nutritional support. Such a procedure may limit the length of hospitalization and allow the patient to remain in a supportive home environment for a greater period of time.

Laparoscopy in ovarian cancer. At present, our ability to resect large ovarian cancers successfully using laparoscopic equipment is limited. Several

investigators have developed successful methods of performing both pelvic and para-aortic lymphadenectomies using endoscopic equipment. Additionally, ultrasonographic and serologic criteria are evolving that will allow the surgeon to more successfully distinguish between benign and malignant neoplasms of the ovary. Caution must be exercised when dealing with potentially malignant unresected ovarian tumors using the laparoscope.

Tumors of Low Malignant Potential

These are epithelial tumors of malignant potential intermediate between benign lesions and frank malignancies. Histologically, most are of the serous type. Although these tumors may be associated with epithelial budding, atypia, mitoses, and stratification, they are distinguished from invasive cancers microscopically by lack of stromal invasion. The median age of diagnosis is approximately 10 years younger than that of patients with epithelial cancers. The vast majority occur in stage I and have a favorable prognosis. Surgery should include abdominal hysterectomy and bilateral salpingo-oophorectomy unless fertility is to be preserved in patients with unilateral lesions. These patients may undergo unilateral salpingo-oophorectomy. Ovarian cystectomy or nonextirpative resections commonly result in recurrences.

Patients with stages III and IV lesions have 5-year survival rates that approach 85 percent after complete surgical resection. There is little evidence that either chemotherapy or radiotherapy administered after surgery improves survival; on the other hand, deaths from chemotherapy-induced leukemia are not uncommon.

Germ Cell Tumors

These tumors occur in women in the first three decades of life and typically grow rapidly, producing symptoms of distention and abdominal fullness. Torsion may occur, producing an acute abdomen. Most are unilateral, and all have a tendency to spread to the para-aortic lymph nodes, and throughout the peritoneal cavity. Although they are similar in many ways to testicular cancer in the male, there are some differences.

Dysgerminoma, the female equivalent of testicular seminoma, is composed of pure, undifferentiated germ cells. It is bilateral in 10–15 percent of patients and occasionally is associated with elevated levels of hCG or lactate dehydrogenase (LDH). It is the most common ovarian malignancy diagnosed during pregnancy. Patients bearing dysgerminomas should undergo appropriate staging at the time of the primary resection but need not undergo hysterectomy (if fertility is to be preserved) or removal of the opposite ovary if it is normal in appearance. Secondary operations solely for staging purposes are unwarranted. Adjuvant therapy is unnecessary unless there is evidence of extraovarian spread. Either radiotherapy encompassing the whole abdomen or systemic chemotherapy can be given to patients with metastases. This tumor is exquisitely sensitive to either type of treatment, and the cure rate exceeds 90 percent even in patients with metastases. Chemotherapy has the advantage of preserving ovarian function, whereas radiotherapy results in ovarian failure.

The other germ cell tumors, in order of frequency, are immature teratoma; endodermal sinus, or “yolk sac,” tumor; mixed tumors; embryonal carcinomas; and choriocarcinomas. The first may be associated with elevated levels of alpha-fetoprotein (AFP). Elevated AFP levels are found in all patients with endodermal sinus tumors and mixed tumors that contain this component.

Embryonal carcinomas are associated with abnormal levels of both AFP and hCG, and choriocarcinomas secrete hCG.

These tumors are invariably unilateral but may spread by peritoneal, hematogenous, or lymphatic routes. Surgical therapy involves unilateral oophorectomy and appropriate staging. Except for those with completely resected stage I, grade 1 immature teratomas and those with stage I dysgerminoma, all patients with germ cell tumors require systemic chemotherapy. Three courses of a platinum and etoposide-containing combination suffice in those patients whose tumors are completely resected. Cure rates in these patients approach 90 percent. In women with incompletely resected nondysgerminomatous germ cell tumors, cure may still be expected in more than 50 percent, but prolonged chemotherapy may be necessary. These tumors are not sensitive to radiotherapy.

Carcinoma of the Cervix

Carcinoma of the cervix accounts for about 16,000 cases and 5000 deaths annually in the United States. Risk factors include multiple sexual partners, early age at first intercourse, and early first pregnancy. Deoxyribonucleic acid (DNA) related to that found in the human papillomavirus has been identified in cervical dysplasia and carcinoma in situ, both precursor lesions, and in invasive cancers and lymph node metastases. Cigarette smoking is highly associated with an increased risk of cervical cancer and may impair the activity of T lymphocytes.

In no other cancer has widespread screening had as profound an impact on mortality as it has in carcinoma of the cervix. Georges Papanicolaou developed the cytologic smear that bears his name in 1943. Since then, screening programs have dramatically reduced the rate of invasive cervical cancer in countries in which this test is widely available. Use of the Pap smear has shifted the frequency of cervical abnormalities toward the premalignant intraepithelial diseases, dysplasia, and carcinoma in situ. Although there are histologic grades of dysplasia leading to carcinoma in situ, all intraepithelial lesions are noninvasive and can be treated successfully using conservative methods.

Eighty percent of all cervical cancers are squamous cell in type and arise from the squamocolumnar junction of the cervix. This epithelial transition zone is found on the face of the cervix or ectocervix in adolescence, and, through a process of squamous metaplasia, gradually moves into the endocervical canal as menopause is passed. Dysplasia represents a disordered metaplasia and gives rise to epithelial cells that contain increased mitotic rates and nuclear atypia and that lack appropriate maturation within the epithelium. Identification and eradication of intraepithelial lesions before invasion can occur are the goals of cervical cancer screening.

The remainder of cervical malignancies arise in the endocervical canal and are either adenocarcinomas or adenosquamous carcinomas. Although adenocarcinomas are very similar in their clinical behavior to squamous cancers, there is some evidence that adenosquamous cancers are more aggressive. Other rare histologic varieties associated with poor prognosis are neuroendocrine small cell carcinomas and clear cell cancers. The latter are frequently associated with maternal exposure to diethylstilbestrol.

Staging

Cervical cancers spread predominantly by lymphatic channels. The first lymph nodes involved are those in the tissues immediately lateral to the cervix. This

region is referred to as the paracervical or parametrial area. The next lymph nodes to be involved, in order, are those in the obturator fossa, the internal and external iliac chain, the common iliac chain, and the para-aortic lymph nodes. Direct vaginal extension may occur. The lymph nodes in the presacral area may be involved in early stage lesions, and the supraclavicular lymph nodes are the most common site of distant nodal metastases.

FIGO staging for cervical cancer is based on clinical examination, intravenous pyelography, and chest radiography. CT or MRI findings do not affect the clinical stage. Table 40-3 illustrates the FIGO staging system. Note that the presence of hydronephrosis connotes stage IIIB even if there is no clinical evidence of extracervical spread. Except for selected patients with stage IVA lesions and those with distant metastases, all patients with stage IIB cancer and above are treated primarily with radiotherapy in the United States.

TABLE 40-3 FIGO Staging System for Cervical Cancer

Stage	Characteristic
0	Carcinoma in situ
I	The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
IA	Preclinical carcinomas of the cervix; that is, those diagnosed only by microscopy
IA ₁	Minimal microscopically evident stromal invasion
IA ₂	Lesions detected microscopically that can be measured. The upper limit of the measurement should not show a depth of invasion of more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates, and a second dimension, the horizontal spread, must not exceed 7 mm. Larger lesions should be staged as IB
IB	Lesions of greater dimensions than Stage IA ₂ whether seen clinically or not. Preformed space involvement should not alter the staging but should be specifically recorded so as to determine whether it should affect treatment decisions in the future
IB ₁	Tumor size no greater than 4 cm
IB ₂	Tumor size greater than 4 cm
II	Involvement of the vagina but not the lower third, or infiltration of the parametria but not out to the sidewall
IIA	Involvement of the vagina but no evidence of parametrial involvement
IIB	Infiltration of the parametria but not out to the sidewall
III	Involvement of the lower third of the vagina or extension to the pelvic sidewall
IIIA	Involvement of the lower third of the vagina but not out to the pelvic sidewall if the parametria are involved
IIIB	Involvement of one or both parametria out to the sidewall
III (urinary)	Obstruction of one or both ureters on intravenous pyelogram (IVP) without the other criteria for stage III disease
IV	Extension outside the reproductive tract
IVA	Involvement of the mucosa of the bladder or rectum
IVB	Distant metastasis or disease outside the true pelvis

Treatment

Intraepithelial or preinvasive disease. Abnormal Pap smears must be evaluated by colposcopy and biopsy. Colposcopy is the examination of the cervix with a low-power (10–50 \times) microscope after application of dilute acetic acid to the cervix. The acid solution is mucolytic and serves to desiccate the epithelium, a process that brings out subtle epithelial patterns referred to as white epithelium, punctation, mosaicism, and abnormal vasculature. Abnormal areas must undergo mechanical biopsy or wide excision with a wire loop electrode and are examined histologically. If loop excision is not performed, the endocervical canal should be curetted to exclude epithelial abnormalities in this area, which is difficult to visualize colposcopically.

Once the diagnosis of an intraepithelial process is made and stromal invasion excluded, local therapy can be performed. If there are abnormal cells on the endocervical curettage specimen, a diagnostic cone biopsy or loop electro-surgical excision procedure (LEEP) is indicated to exclude the possibility of an invasive or microinvasive lesion in the endocervical canal.

Cervical intraepithelial neoplasia is treated in a number of ways. In general, the larger the lesion and the higher the grade of dysplasia, the greater the failure rate. Similarly, more aggressive therapy yields lower failure rates at increased risk of complications. The most definitive treatment for cervical intraepithelial neoplasia is vaginal or abdominal hysterectomy. This operation is associated with a rate of subsequent dysplasia at the vaginal apex of 1–2 percent. This major operation is usually reserved, however, for patients with extensive or high-grade lesions, those with recurrent disease after conservative treatment, those in whom adequate follow up is unlikely, and those with other indications for hysterectomy, such as prolapse, abnormal uterine bleeding, pain, or a pelvic mass. Cervical cone biopsy is curative in most cases of cervical intraepithelial neoplasia. In patients in whom the surgical margins of the cone specimen are uninvolved, the risk of recurrence is less than 5 percent. If the surgical margins are involved, half of such patients will develop recurrent disease. This is an outpatient procedure and is associated with few serious risks. It may, however, require general anesthesia.

More conservative methods of treating cervical intraepithelial neoplasia include wire loop excision, laser vaporization, and cryosurgery. Loop excision can be done under local anesthesia (paracervical block) in the outpatient setting. The advantage of loop excision is that it removes the diseased area and provides a diagnostic biopsy specimen. The main disadvantage is the relatively large amount of cervical stroma that is taken with the involved epithelium. In cases of cervical intraepithelial neoplasia confined to the ectocervix, such deep excision is probably unnecessary.

Laser vaporization usually is performed with a carbon dioxide laser, but other laser instruments may be used. The ectocervical transformation zone is ablated to a depth of about 7 mm to ensure the removal of endocervical glandular epithelium. This is a convenient outpatient procedure that results in a clearly visible squamocolumnar junction at the site of treatment. Risks of bleeding and infection are small. Cryotherapy is an inexpensive outpatient procedure that produces a frostbite injury to the ectocervical epithelium. When the cervix reepithelializes, the dysplasia generally does not recur. This is a simple technique that should not be applied to patients with endocervical lesions. The main disadvantage of cryotherapy is obliteration of the squamocolumnar junction, making subsequent colposcopic examination somewhat difficult.

In patients with very localized mild dysplasias or low-grade cervical intraepithelial neoplasia, local excision or electrocautery may be sufficient to eradicate the disease.

Microinvasive cervical cancer. FIGO (see Table 40-3) subdivides microinvasive cancers into those with “early” invasion (stage IA1) and those in which the tumor measurements are less than 5 mm in thickness and 7 mm in lateral extent (stage IA2). This aspect of the FIGO staging system for cervical cancer fails to distinguish adequately between stages IA2 and IB, however, because both may have occult lymph node metastases requiring regional therapy.

Many prefer the original system of the Society of Gynecologic Oncologists, in which stage IA (microinvasive) tumors may invade to no more than 3 mm and must lack capability of lymphatic space invasion. Stage IB includes all other cancers clinically confined to the cervix, even if they cannot be visualized on examination. The advantage of this system is that it clearly divides stage I cancer into two treatment groups. Few patients with stage IA cervical cancer have metastases to the lymph nodes. Simple, or extrafascial, hysterectomy without lymphadenectomy is therefore adequate therapy. Five-year survival rates approach 100 percent in these patients. In exceptional patients, cervical cone biopsy or electrosurgical excision may be sufficient treatment, provided close surveillance is possible.

Early invasive cervical cancer (stages IB and IIA). Stages IB and IIA tumors are associated with a risk of pelvic lymph node metastases of 10–15 percent and a risk of spread to the para-aortic nodes of about 5 percent. Treatment must include the regional lymph nodes in these patients. Radical hysterectomy with pelvic lymphadenectomy or definitive radiotherapy is effective treatment in this stage cancer. Prognosis with either modality depends on the size of the primary lesion, the presence or absence of lymph-vascular space involvement, spread to the regional lymph nodes, and status of the surgical margins.

Women with stage IB2 cervical cancers (exceeding 4 cm in diameter), especially those endocervical primaries that distend the cervix circumferentially, may require a combination of radiotherapy and surgery. These large endocervical tumors are referred to as “barrel” lesions and are refractory to surgery or radiotherapy alone. Isodose curves from cesium sources may not encompass the entire tumor. Cure rates with either treatment may be as low as 50 percent.

One current approach to these tumors is the administration of pelvic radiotherapy followed by a cesium implant and subsequent simple hysterectomy. This technique may reduce the number of patients who have persistent invasive cancer in the cervix after radiotherapy and consequently improve survival.

Stage IB1 lesions and early stage IIA cancers may be treated successfully with radical hysterectomy and pelvic lymphadenectomy. This operation was pioneered in the U.S. by John Clark in 1895. Radical surgery was transiently eclipsed by the first use of radium in the treatment of cervical cancer by Sjögren and Stenbeck in 1899, and subsequent establishment of the first radium hospital in Stockholm, Sweden, in 1910.

Radical surgery reemerged in the treatment of early carcinoma of the cervix with the advent of the Pap smear and increased diagnosis of early stage tumors in young women. Because early cervical cancer so rarely spreads to the ovaries, radical hysterectomy need not include oophorectomy. Ovarian preservation is one of the strongest arguments for the use of surgery over radiotherapy, because the latter inevitably results in the premature loss of ovarian function. Sexual function also is preserved.

Locally advanced carcinoma of the cervix (stages IIB–IVA). These cancers are treated primarily with radiotherapy, with cisplatin as a radiosensitizer. Treatment consists of a combination of external therapy to the pelvis (teletherapy) from a high-energy source such as a linear accelerator and a local dose delivered to the cervix and parametrial tissue (brachytherapy) using a cesium applicator such as a Fletcher-Suite tandem and ovoids. Combination therapy is essential because doses adequate to control cervical tumors exceeding about 1 cm in diameter cannot be given using teletherapy alone. Bladder and rectal tolerances are approximately 6000 rads; higher doses can only be attained by combination therapy. The addition of cisplatin as a weekly radiosensitizer has resulted in improved survival with no apparent increase in toxicity when compared with radiation alone.

Cure rates for stage IIB cervical cancers approach 70 percent, and those for stage IIIB approach 40 percent. Because the risk of pelvic sidewall lymph node involvement increases with advancing stage, the dose of radiotherapy to this area is advanced with increasing stage. When para-aortic metastases are present in either stage, survival is significantly impaired. Survival for patients with stage IIB carcinoma of the cervix and para-aortic metastases is poorer than that for those with stage IIIB disease and negative para-aortic lymph nodes. Gross para-aortic lymph node metastases may be detected by CT, MRI, lymphangiography, or PET scanning.

Microscopic nodal metastases are best detected by retroperitoneal common iliac and para-aortic lymphadenectomy, a relatively simple procedure performed through a “hockey stick” or paramedian incision. The fascial layers are divided, sparing the peritoneum, which is reflected medially to expose the lymph node-bearing areas overlying the major blood vessels. Laparoscopic staging and pelvic and para-aortic lymph node dissection may be used by appropriately trained surgeons.

The finding of metastases in the common iliac or para-aortic chain indicates the need for extended-field radiotherapy encompassing these areas in addition to the pelvis. Even with such therapy, 5-year survival rates are low, seldom exceeding 20 percent. Many consider the presence of para-aortic lymph node metastases to be an indicator of systemic disease, although supraclavicular metastases are present in fewer than 25 percent of such patients.

Recurrent cervical cancer. As a rule, patients who develop local recurrences after primary surgical therapy are treated most effectively with external and internal beam radiotherapy. Although those with lymph node failures may not be curable in this setting, those with vaginal recurrences often can be saved with such an approach. Patients who suffer recurrences at sites distant from the pelvis may be treated with palliative local radiotherapy or chemotherapy with limited success.

Women who develop recurrent cancer following primary radiotherapy are generally not candidates for curative therapy. If, however, recurrence is small, the interval to failure is a year or more, and the lesion is unaccompanied by symptoms such as back or leg pain or edema, surgical resection may be possible. Because radiotherapy results in fibrosis of the connective tissues surrounding the cervix, radical hysterectomy is impractical. The risk of vesicovaginal or rectovaginal fistulas approaches 50 percent. Additionally, surgical margins may be compromised by limited resection in such a situation.

Most gynecologic oncologists prefer to perform pelvic exenteration in such circumstances. Often, an anterior exenteration with en bloc removal of the

bladder, cervix, uterus, and upper vagina is feasible. These operations require urinary diversion. Because of radiation exposure, however, an ileal conduit may be associated with urinary leakage from ureteroileal anastomoses. The preferred method of diversion in these patients is the creation of a sigmoid urostomy or transverse colon conduit. Other surgical options include a Koch pouch or the Indiana reservoir, both of which provide a means of urinary continence without an external appliance.

In the case of extensive local recurrences, sigmoid resection may be required in addition to removal of the bladder. A total pelvic exenteration is performed. The sigmoid colon may be brought to the skin as a colostomy or reanastomosed to the rectal stump. Pelvic exenterations may be subclassified as supralelevator or infralevator depending on whether this muscular diaphragm is broached. Supralelevator exenterations generally are associated with less operative morbidity. An infralevator exenteration is required if the tumor involves the middle or lower third of the vagina or the vulva. Vaginal reconstruction in these extensive procedures with gracilis or rectus abdominis myocutaneous flaps is highly satisfactory.

In general, about half the patients thought to be candidates for pelvic exenteration are found to have intraperitoneal spread or nodal metastases at the time of exploratory laparotomy, and, in most centers, do not undergo resection. Laparoscopy may be a useful way of excluding such patients from laparotomy. Of the remaining patients in whom surgery is possible, 30–50 percent will develop a second, nearly always fatal, recurrence after surgery. This complex operation should thus be undertaken only in carefully selected patients.

Endometrial Cancer

Endometrial cancer is the most common female genital malignancy, accounting for 34,000 cases annually in the United States. It is a highly treatable cancer, with approximately only 6000 deaths reported each year.

Risk factors for endometrial cancer include obesity, diabetes mellitus, hypertension, low parity, early menarche, and late menopause. Prolonged or unopposed exposure to estrogens is implicated in the genesis of endometrial cancer and its precursor, endometrial hyperplasia. Women who take estrogens in the menopausal years are known to have a 6-fold increase in the risk of endometrial cancer if progestational agents are not taken as well. There is also an increase in the incidence of endometrial lesions in women with a history of chronic anovulation (Stein-Leventhal syndrome) and in those with estrogen-producing ovarian stromal neoplasms, such as granulosa cell tumors, and in those who take tamoxifen.

Endometrial hyperplasia may be divided into classifications of simple and complex, depending on the microscopic architecture, and into those with or without atypia. These hyperplasias are thought to be estrogen-dependent. Atypical complex hyperplasias are most likely to give rise to frank adenocarcinomas. They occur in women at an average age that is 5–10 years younger than those with frank carcinomas. Simple hysterectomy is the preferred method of treatment for the hyperplasias. In women with underlying health problems that preclude surgical therapy, therapy with progestational agents such as megestrol or medroxyprogesterone acetate may be used with success. Careful monitoring with endometrial biopsy or curettage or vaginal ultrasound is required in these patients, however.

Treatment

Endometrial cancer is staged according to the FIGO criteria detailed in Table 40-4. Many patients have stage I disease and can be managed successfully with abdominal hysterectomy and bilateral salpingo-oophorectomy. Adjuvant radiotherapy may be required, primarily to reduce the risk of vaginal recurrence. This can be given preoperatively with external therapy or a Fletcher-Suite implant or intrauterine packing (Heyman or Simon capsules).

TABLE 40-4 FIGO (1988) Staging System for Endometrial Cancer

Stages	Characteristics
IA G123	Tumor limited to endometrium
IB G123	Invasion to < 1/2 myometrium
IC G123	Invasion to > 1/2 myometrium
IIA G123	Endocervical glandular involvement only
IIB G123	Cervical stromal invasion
IIIA G123	Tumor invades serosa or adnexae or positive peritoneal cytology
IIIB G123	Vaginal metastases
IIIC G123	Metastases to pelvic or para-aortic lymph nodes
IVA G123	Tumor invasion bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal lymph node

Histopathology—Degree of Differentiation

Cases should be grouped by the degree of differentiation of the adenocarcinoma:

G1	5% or less of a nonsquamous or nonmorular solid growth pattern
G2	6%–50% of a nonsquamous or nonmorular solid growth pattern
G3	More than 50% of a nonsquamous or nonmorular solid growth pattern

Notes on Pathologic Grading

Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade I or grade II tumor by I.

In serous adenocarcinomas, clear cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

Rules Related to Staging

Because corpus cancer is now surgically staged, procedures previously used for determination of stages are no longer applicable, such as the finding of fractional D&C to differentiate between stage I and II. It is appreciated that there may be a small number of patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by FIGO in 1971 would still apply but designation of that staging system would be noted.

Ideally, width of the myometrium should be measured along with the width of tumor invasion.

Some clinicians prefer to deliver radiotherapy postoperatively after the uterus has been evaluated thoroughly. Either external beam therapy or vaginal cesium may be used.

Pelvic lymph node metastases occur in about 12 percent of patients with endometrial cancer apparently confined to the uterus. Lymph node metastases have a significant negative impact on survival. Risk factors associated with lymph node spread include high histologic grade (grade 2 or 3), low levels of progesterone receptor, deep myometrial or lymphatic channel invasion, spread to the adnexa, endocervical extension, and unusual histologic variants, such as papillary serous or clear cell carcinomas. Patients should have pelvic and para-aortic lymph nodes sampled at the time of hysterectomy. Therapeutic lymphadenectomy is advocated. Those with a high likelihood of spread to pelvic lymph nodes (grade 3, the outer one-third myometrial or uterine serosal involvement, and those with high-risk histologic subtypes) should undergo sampling of the common iliac and para-aortic lymph nodes, because these areas lie outside the usual fields of pelvic radiotherapy. Patients with papillary serous tumors may present with metastases in the abdominal cavity or omentum much as those with ovarian epithelial tumors; omentectomy, diaphragmatic, and peritoneal biopsies should be obtained.

Another important element of staging endometrial cancer is the evaluation of peritoneal lavage fluid for the presence of malignant cells. Approximately 12 percent of patients are found to have malignant peritoneal cytology; one half have other evidence of extrauterine spread of the disease, but the remainder have no other associated risk factors.

Vaginal hysterectomy occasionally is useful in patients with early endometrial cancer when lymph node metastases are thought to be unlikely. This operation is particularly well suited for massively obese parous patients in whom an abdominal incision would be prohibitive.

In patients with large stage IIB and III lesions, consideration generally is given to preoperative pelvic radiotherapy, because surgery may be otherwise difficult or impossible. These tumors should receive appropriate surgical staging or thorough radiographic evaluation if primary radiotherapy is used.

Radiotherapy alone may be the treatment of choice in patients at excessive risk for operative intervention. Radiotherapy alone produces results inferior to those of surgery or surgery and adjuvant radiotherapy; therefore patients treated without hysterectomy should be selected carefully. Advanced or recurrent endometrial cancer is responsive to progestin or tamoxifen therapy in 30 percent of unselected patients. Lesions that are well differentiated contain higher levels of progesterone receptor and respond more frequently. Only 10 percent of poorly differentiated cancers respond to hormonal treatment. Local radiotherapy or chemotherapy with paclitaxel, doxorubicin, topotecan, platinum compounds, or combinations may be of benefit in some cases as well.

Vulvar Cancer

Vulvar cancer accounts for approximately 5 percent of all gynecologic cancers. Although uncommon histologic types such as malignant melanoma and adenocarcinoma of the Bartholin's gland occur, more than 90 percent of vulvar malignancies are squamous carcinomas.

Although the etiology of this cancer is not well understood, it is likely that the human papillomavirus plays an important role, especially in younger women.

Spread of squamous carcinoma of the vulva is primarily via the lymphatics of the vulva. Lesions arising in the anterior aspect of the vulva drain preferentially to the inguinal lymph nodes, and posterior lesions may drain directly to the lymph nodes of the pelvis.

The 1988 FIGO staging system for vulvar cancer (Table 40-5) is currently accepted. This system requires surgical evaluation of the inguinal lymph nodes and provides a schema in which prognosis and therapy are closely linked with stage.

Treatment

Pelvic lymphadenectomy is probably not indicated in vulvar cancer except in those patients found to have grossly enlarged pelvic lymph nodes on preoperative CT or MRI. Patients with inguinal node metastases are best treated with inguinal and pelvic radiotherapy following resection of the inguinal lymph nodes. In the case of large vulvar primaries or suspicious inguinal lymph nodes, this approach yields better survival rates than those obtained when pelvic lymphadenectomy alone is performed.

Because extended radical vulvectomy is associated with long hospital stays and significant morbidity from wound breakdown and infectious complications, there has been a long-standing interest in more conservative surgery

TABLE 40-5 FIGO Staging of Vulvar Cancer

Stage 0	
Tis	Carcinoma in situ, intraepithelial carcinoma.
Stage I	
T1 N0 M0	Tumor confined to the vulva and/or perineum—2 cm or less in greatest dimension. No nodal metastasis.
Stage IA	≤ 1 mm invasion + other criteria
Stage IB	> 1 mm invasion + other criteria
Stage II	
T2 N0 M0	Tumor confined to the vulva and/or perineum—more than 2 cm in greatest dimension. No nodal metastasis.
Stage III	
T3 N0 M0	Tumor of any size with 1) adjacent spread to the lower urethra and/or the vagina, or the anus, and/or 2) unilateral regional lymph node metastasis.
T3 N1 M0	
T1 N1 M0	
T2 N1 M0	
Stage IV A	
T1 N2 M0	Tumor invades any of the following: Upper urethra, bladder mucosa, rectal mucosa, pelvic bone, and/or bilateral regional node metastasis.
T2 N2 M0	
T3 N2 M0	
T4 Any N M0	
Stage IV B	
Any T, Any N, M1	Any distant metastasis, including pelvic lymph nodes.

for early vulvar cancer. The first efforts to this end were made in the 1960s. Several investigators introduced the concept of radical vulvectomy and inguinal lymphadenectomy through separate incisions. This approach not only reduces hospital time but also results in fewer major wound complications. This approach, has been widely embraced by gynecologic oncologists. Because inguinal node metastases are the result of an embolic process rather than infiltration or direct extension, the approach is rational. Early concerns regarding recurrence in the skin bridge between the vulvar and groin incisions have been largely allayed by experience with this approach. Recurrence in the skin bridge usually is associated with preexisting large inguinal metastases.

Another area of progress in the surgical management of vulvar carcinoma has been the use of conservative surgery for early lesions of the vulva. Although specific criteria vary, most investigators recognize that squamous cancers of the vulva less than 2 cm in diameter and no more than 1 mm thick, and that are of histologic grade 1 or 2, are associated with a very small risk of inguinal metastases. Such lesions are adequately treated with deep, wide excision, provided skin margins of 8 mm are obtained and the dissection is carried to the level of the superficial transverse perineal muscles. Inguinal lymphadenectomy can be omitted in such patients.

In patients with intermediate lesions located on the labium minus or majus that do not cross the midline or involve midline structures such as the clitoris, perineal body, or perianal area, modified hemivulvectomy and ipsilateral inguinofemoral lymphadenectomy have been used successfully. This approach should be considered if the primary lesion is less than 2 cm in diameter and 5 mm or less in thickness. Lymph node metastases are uncommon in this group of patients and the groin nodes may be evaluated by frozen section at the time of surgery. Sentinel lymph node biopsy is being evaluated in vulvar cancer. Although it was once believed that superficial inguinal lymph nodes were "sentinel," it has been demonstrated that vulvar cancer often involves the deep femoral lymph nodes primarily as well. A conservative groin incision can also be used to sample these lymph nodes. If "sentinel" lymph nodes are free of tumor, the risk of involvement of other groin or pelvic lymph nodes is probably small. This excision site may be closed primarily with good results.

Another controversial area in the management of squamous carcinomas of the vulva is that of the patient with locally advanced disease. When extensive vulvar cancer involves more than the distal urethra, the vagina or rectovaginal septum, or the anal musculature, ultraradical surgery may be required. Anterior, posterior, or total pelvic exenteration may be necessary to resect such lesions successfully. The presence of fixed, matted, or ulcerating inguinal lymph nodes presents another problem that may require extensive surgical excision. Following such extirpative procedures, reconstruction of the vulva and groins is accomplished using myocutaneous flaps based on the gracilis, sartorius, or tensor fasciae latae muscles. Approximately 50 percent of patients are cured by such surgical procedures.

In recent years, such locally advanced lesions of the vulva also have been treated successfully with external beam radiotherapy combined with radiosensitizing drugs such as cisplatin. At the completion of combination therapy, the areas of involvement are excised widely or biopsied. This approach is associated with results as good as or better than those achieved with ultraradical surgery and generally results in less morbidity. The need for urinary and fecal diversion also is obviated.

Uncommon Vulvar Tumors

Melanoma. Traditional surgical therapy for malignant melanoma of the vulva has included en bloc radical vulvectomy and inguinofemoral lymphadenectomy. It is now known that lesions less than 1 mm thick or Clark level II lesions may be treated conservatively with wide local excision. The value of inguinofemoral lymphadenectomy is controversial in lesions of greater depth, although primary surgical cure occasionally is achieved in patients with microscopic nodal metastases. Melanomas of the urethra or vagina usually are diagnosed in advanced stages and may require pelvic exenteration for successful management.

Intraepithelial disease. Intraepithelial disease (Bowen disease, bowenoid papulosis, vulvar intraepithelial neoplasia, carcinoma in situ) may be treated successfully by removing the involved epithelium. Characteristically, this is a raised, velvety lesion with sharply demarcated borders that may contain gray, brown, or red pigmentation. Removal is accomplished by simple vulvectomy, where the plane of dissection is limited to the epithelium, or by wide excision. In the case of diffuse intraepithelial disease, a so-called skinning vulvectomy and split-thickness skin graft may be required. This approach is associated with prolonged hospital stays, however, and should be reserved for exceptional cases. Also effective in the treatment of intraepithelial disease are the carbon dioxide laser and the electrosurgical loop.

Paget disease is an unusual epithelial or invasive process characterized by the presence of distinct "Paget cells" in the involved epithelium. Grossly, the lesion is confluent, raised, red, and waxy in appearance. This lesion also can be excised widely, although the microscopic extent of the disease may exceed the visible margins. Intravenous fluorescein dye and ultraviolet light highlight areas that cannot be detected by the naked eye, and this assists in excision. Frozen-section examination of the surgical margins also is helpful but time-consuming. Paget disease occasionally is associated with an underlying invasive adenocarcinoma; careful pelvic examination and proctoscopy are indicated in patients with this process.

GYNECOLOGIC OPERATIONS

Dilatation and Curettage

The patient is placed on the operating table in a lithotomy position, and the vagina and cervix are prepared as for any vaginal operation. The cervix is grasped on the anterior lip with a tenaculum. The cervix is gently pulled toward the outlet of the vagina. Some traction on the cervix is necessary to reduce the angulation between the cervical canal and the uterine cavity. A sound is inserted into the uterine cavity, and the depth of the uterus is noted. The cervical canal is then systematically dilated beginning with a small cervical dilator. Most operations can be performed after the cervix is dilated to accommodate a number 8 or 9 Hegar dilator or its equivalent. Dilatation is accomplished by firm, constant pressure with a dilator directed in the axis of the uterus.

After the cervix is dilated to admit the curette, the endocervical canal should be curetted and the sample submitted separate from the endometrial curettings. The endometrial cavity is then systemically scraped with a uterine curette.

In recent years, suction curettage for incomplete abortion, hydatid mole, and therapeutic abortion has become popular. Suction machines fitted with

cannulas that vary from 4–12 mm in diameter evacuate the uterus in less time and with less blood loss.

Endoscopic Surgery

Endoscopic surgery, including both laparoscopy and hysteroscopy, has assumed a major role in gynecology. Although the limits of what is possible continue to be defined, the relative safety of some of these techniques in general use remains uncertain.

Laparoscopy

Tubal Sterilization Procedures

As in diagnostic laparoscopy, a one- or two-port technique can be used. Tubes are occluded in the mid-isthmic section (approximately 3 cm from the cornua) using clips, elastic bands, or bipolar electrosurgery. With electrosurgery, approximately 2 cm of tube should be desiccated. Pregnancy rates after any of these techniques have been reported in the range of 3 per 1000 women.

Fulguration of endometriosis. Conservative laparoscopic treatment of endometriosis increases fertility and often helps with pelvic pain. This condition and the various approaches to treatment were considered earlier in this chapter (see “Endometriosis”).

Treatment of ectopic pregnancy. Laparoscopy has established itself as the primary treatment approach for ectopic pregnancies, a condition considered earlier in this chapter (see “Ectopic Pregnancy, Treatment”).

Ovarian cystectomy. The laparoscopic removal of ovarian cysts less than 6 cm in diameter in premenopausal women has become common. Using a multiple-port technique, the peritoneal cavity is inspected for signs of malignancy, including ascites, peritoneal or diaphragmatic implants, and liver involvement. In the absence of signs of malignancy, pelvic washings are obtained, and the ovarian capsule is excised with scissors or a power instrument. The cyst is shelled out carefully and placed in a bag, intact if possible. The bag opening is brought through the lower port incision along with the 10-mm port. The cyst is then drained and the cyst wall removed. Hemostasis of the ovary is achieved with bipolar electrosurgery, but the ovary usually is not closed, because this may increase postoperative adhesion formation. Except in the obvious cases of simple cysts, endometriomas, or dermoid cysts, the cyst wall should be sent for frozen section to verify the absence of the malignancy. If malignancy is detected, immediate definitive surgery, usually by laparotomy, is recommended. All cyst walls are sent for permanent section and pathologic diagnosis.

In many cases the cyst will rupture prior to removal. This is always the case with an endometrioma that contains “chocolate” fluid. On rupture, the cyst contents are thoroughly aspirated, and the cyst wall is removed and sent for pathologic evaluation. The peritoneal cavity is copiously rinsed with Ringer lactate solution. This is especially important when a dermoid cyst is ruptured, because the sebaceous material can cause a chemical peritonitis unless all the visible oily substance is carefully removed.

Ovarian cysts larger than 6 cm and those discovered in postmenopausal women also can be removed laparoscopically. Because of the increased risk of malignancy associated with these situations, laparotomy is more commonly

used. Laparoscopy may be a reasonable alternative in select patients if standard methods for staging are used in conjunction with appropriate frozen-section evaluation and expedient definitive therapy when indicated.

Removal of adnexa. Occasionally, all or part of an adnexa must be removed. This may be the case with a large tubal pregnancy, a large hydrosalpinx, or when a small but growing cyst is found in a postmenopausal woman. Using a multiple-port technique, the vascular supply to the tissue is first desiccated with bipolar cautery and then divided with scissors. Alternatively, the ovarian vessels in the infundibulopelvic ligament can first be occluded with one of the techniques described earlier. Special care should be taken to identify and avoid the ureter, which lies retroperitoneally as it crosses the ovarian vessels and courses along the ovarian fossa.

Once the adnexa has been excised and hemostasis is achieved, attention is turned to removing the tissue from the peritoneal cavity. Small specimens can be removed using a retrieval bag via a 12-mm port. The port is removed with the sack, and the fascial incision is enlarged, if required.

For larger specimens, the opening of the sack is exposed outside the abdomen whereas the specimen remains in the abdomen. A cyst can be aspirated, and the remaining specimen can be removed piecemeal, taking care not to allow intraperitoneal spillage.

In difficult cases, the specimen can be removed via a colpotomy incision. For this procedure, a 12-mm port is placed through the posterior cul-de-sac under direct visualization. A retrieval sack is placed through the port, and the port and specimen in the sack are removed together. The distensible peritoneum and vaginal wall will allow the removal of a large specimen through a relatively small defect, which can then be closed with a running suture vaginally. Prophylactic antibiotics may decrease the risk of infection.

Myomectomy. Uterine leiomyomas often are approachable via the laparoscope. Hemostasis is assisted by intrauterine injection of dilute vasopressin (10 U in 50 mL) at the site of incision. Pedunculated leiomyomas can be excised at the base using scissors or a power instrument. Intramural leiomyomas require deep dissection into the uterine tissue, which must be closed subsequently with laparoscopic suturing techniques. Because myomectomies are associated with considerable postoperative adhesion formation, barrier techniques are used to decrease adhesion formation.

Removing the specimen can be difficult. In general, morcellation is required, and power morcellators have been developed that significantly expedite this technique.

Hysterectomy. Laparoscopy was first used to restore normal anatomy prior to vaginal hysterectomy. More recently, laparoscopy has been used to perform some or all of the actual hysterectomy to avoid laparotomy in patients with known pelvic adhesions, endometriosis, or in whom the uterus is enlarged by leiomyoma. Although multiple variations in technique exist, there are three basic laparoscopic approaches for hysterectomy: laparoscopic-assisted vaginal hysterectomy (LAVH), laparoscopic hysterectomy (LH), and laparoscopic supracervical hysterectomy (LSH). Although basic techniques for each of these methods have become somewhat standardized, the indications and relative risk for each remain controversial.

The most technically simple, and probably the most widely applied, is the LAVH. The round ligaments are occluded and divided, and the uterovesical

peritoneum is incised. Next, the proximal uterine blood supply is occluded and divided. When the ovaries are removed, the infundibulopelvic ligaments are divided. If the ovaries are conserved, the utero-ovarian ligament and blood vessels are divided and occluded. In some cases, the posterior cul-de-sac also is incised laparoscopically. The remainder of the case is performed vaginally, including dissection of the bladder from the anterior uterus, ligation of the uterine vessels, removal of the specimen, and closure of the vaginal cuff.

A LH differs from an LAVH in that almost the entire hysterectomy is performed laparoscopically. This procedure is used for the indications listed above and also when lack of uterine descent makes the vaginal approach impossible.

LH is begun in a manner identical to LAVH. But after the proximal uterine blood supply is divided, the bladder is dissected from the anterior uterus. This is followed by a retroperitoneal dissection in which the ureter is identified along its entire pelvic course and the uterine vessels are selectively occluded and divided. The uretero sacral ligaments are likewise divided and the posterior cul-de-sac incised. The specimen is removed vaginally, and the vaginal cuff is closed. The drawback to this approach is the reported increased risk of bladder and ureter injuries as compared to both abdominal and vaginal approach for hysterectomy.

The third common laparoscopic approach is the LSH. This procedure has been advocated for all benign indications for hysterectomy. Technically, it is begun in a manner identical to the first two approaches. However, after the proximal vessels are divided and the bladder is dissected from the anterior uterus, the ascending branches of the uterine arteries are occluded and the entire uterine fundus is removed from the cervix. The endocervix is either cauterized or cored out with a special instrument. The fundus is then morcellated and removed through a 12-mm abdominal port or through a special transcervical morcellator. The end result is an intact cervix and cuff, with no surgical dissection performed near the uterine artery and adjacent ureter. This approach avoids both a large abdominal incision and a vaginal incision. According to its advocates, this approach minimizes operating time, recovery time, and risk of both infection and ureteral injury. LSH has yet to be widely applied, in part out of concern for the subsequent risk of developing cancer in the residual cervical stump.

A guiding principle is that the same care must be rendered laparoscopically that would be performed by laparotomy with the same or less risk of complications. Until the relative risk of complications and effect on prognoses have been established for these approaches compared with laparotomy, application of the laparoscopic approach in gynecologic oncology will remain highly controversial.

Hysteroscopy

Hysteroscopy, like laparoscopy, has gained widespread support as a very useful technique for both diagnosis and treatment of intrauterine pathology and for ablation of the endometrium as an alternative to hysterectomy for the treatment of abnormal uterine bleeding.

General Hysteroscopic Techniques

Type of instruments. Hysteroscopes can be divided into the categories of diagnostic, operative, and hysteroscopes. The lens for all three is identical. This is usually a fiberoptic lens and light source with an outside diameter of

3 mm and an objective lens that is offset up to 30 degrees from the long axis of the instrument. In contrast, the sleeves for the three types of hysteroscopes vary considerably. The diagnostic sleeve usually has an external diameter of 5 mm and a single-direction flow. Because outflow is limited, bleeding may impede a clear intrauterine view.

The operative sleeve, with an external diameter usually less than 10 mm, has a flow-through design with separate channels for input and outflow of distention media. A separate channel is available for placement of fine operating instruments.

The final type of sleeve is the hysteroresectoscope. This is also of a flow-through design and has an integral unipolar resecting loop identical to a urologic resectoscope. The loop can be replaced with a roller bar for endometrial ablation.

Distention media and pumps. Several distention media have found widespread use for hysteroscopy. For diagnostic hysteroscopy, CO₂ gives excellent clarity. Although it is extremely safe in general use, fatal gas embolisms have been reported when CO₂ was used after cervical dilatation or intrauterine surgery. To minimize this risk, CO₂ should be used for diagnostic hysteroscopy only with specifically designed pumps that are relatively high pressure (80–90 mmHg) and low flow. More importantly, the use of CO₂ should be avoided after cervical dilatation or any uterine instrumentation.

For operative hysteroscopy, one of the first fluid media used was 32 percent dextran and 70 percent dextrose. This syrup-like substance is usually introduced by hand with a large syringe. The advantage is simplicity and low cost. The view is excellent in the absence of bleeding. The disadvantage is the difficulty in completely removing the substance from the instruments. If this solution is allowed to dry in critical movable points, the instrument may “freeze up,” and it is very difficult to remove. Additionally, intravascular intravasation can result in pulmonary edema.

More recently, aqueous solutions with pressure-controlled pumps have been used. For operative hysteroscopy, where electrosurgery is not being used, it is safest to use a balanced salt solution, such as Ringer lactate solution. Moderate fluid intravasation will be of no consequence in a healthy individual. However, intravasation of larger volumes can result in fluid overload, especially in a patient with any cardiac compromise. To minimize this risk, the use of a fluid-medium pump is recommended rather than gravity or a pressure cuff. This allows the maximal pressure to be limited to approximately 80 mmHg to prevent excess intravasation of distention media.

When electrosurgery is used for hysteroresectoscope excision of leiomyomas or roller-blade endometrial ablation, a nonconducting solution such as glycine must be used. Significant vascular intravasation can cause hyponatremia, potentially resulting in cerebral edema, coma, or even death. For this reason, protocols must be followed rigorously to detect and treat significant intravasation whenever these solutions are used. Intraoperatively, differences in distention medium input and output should be calculated every 15 min. If the difference is greater than 500 mL, a diuretic should be given. If the difference is greater than 1000 mL, the procedure also should be terminated. Whenever significant intravasation is suspected, serum sodium level should be checked immediately postoperatively and a few h later because later hyponatremia, presumably because of transperitoneal absorption, has been reported.

Hysteroscopic Procedures

Diagnostic hysteroscopy. This common procedure often is performed prior to uterine curettage to identify any focal abnormalities such as an endometrial polyp or a malignancy. This procedure usually is performed in the operating room with either general or regional anesthesia, although it has been performed by some as an office procedure with minimal analgesia.

After determining the position of the uterus, the anterior cervix is grasped with a tenaculum and traction placed to straighten the cervical canal. The lens and diagnostic sleeve are placed into the cervix, and distention medium is introduced with a pressure of 80–90 mmHg. The hysteroscope is advanced slowly and carefully toward the fundus, using tactile and visual cues to avoid perforation. The entire uterine cavity is inspected, and any abnormal anatomy is documented. As the hysteroscope is withdrawn, the uterocervical junction and the endocervix are examined.

Directed endometrial biopsy. If a focal abnormality of the endometrium is observed, directed biopsy may be more accurate than a simple uterine curettage. The cervix is dilated to allow passage of an 8–10-mm flow-through operating hysteroscope, and a balanced salt solution is used for distention. Once the hysteroscope is positioned in the uterine cavity, the area of interest is biopsied under direct visualization.

Polypectomy. If an intrauterine polyp is discovered, the base of the polyp is incised with hysteroscopic scissors, and the polyp is grasped with grasping forceps. The hysteroscope, sleeve, and polyp are removed simultaneously, because most polyps will not fit through the operating channel. Extremely large polyps may have to be removed piecemeal. Any residual base of the polyp may be removed with biopsy forceps.

Uterine septum resection. A septum may be resected with scissors, electro-surgery, or laser. Scissors are used most commonly in light of the minimal vascularity of septa and the decreased potential for bowel injury should inadvertent uterine perforation occur. An operating hysteroscope is placed into the uterine cavity, which will appear to be two tubular structures rather than the broad uterine fundus usually encountered. The septum is then evenly divided across the fundus. If scissors are used, rather than a power cutting instrument, the presence of bleeding indicates that the level of resection is shifting from the avascular septum to the vascular myometrium. After surgery, no special device is placed in the uterus because intrauterine synechiae formation is uncommon.

Removal of intrauterine synechiae. Intrauterine synechiae almost always are associated with previous uterine curettage, especially when performed in the immediate postpartum period. These synechiae may result in amenorrhea or infertility.

The removal of synechiae is performed in a manner similar to that described above for a uterine septum, with some differences. The first is that the anatomy, and thus the visual cues for location of normal uterine wall, are completely unpredictable from patient to patient. Preoperative hysterosalpingography usually is very helpful. Findings can vary from a few small synechiae to complete obliteration of the cavity.

In difficult cases, simultaneous transabdominal ultrasound is extremely helpful in guiding the direction and limits of hysteroscopic resection. Standby laparoscopy should be available in the event of perforation, which is a

significant risk in these patients. However, once pneumoperitoneum is achieved, abdominal ultrasound is no longer possible.

Following surgery, some type of intrauterine splint, such as an intrauterine device or a balloon catheter, often is placed to avoid synechia re-formation. Patients usually are placed on estrogen supplementation for a month and prophylactic antibiotics until the intrauterine splint is removed 1–2 weeks later.

Intrauterine myomectomy. Pedunculated or submucosal leiomyoma can be removed safely hysteroscopically with subsequent improvement in both abnormal uterine bleeding and infertility. Because myoma tissue is relatively dense, a power cutting instrument is required. The choices are either laser or, more commonly, electrosurgery. For argon or Nd-to-YAG laser, a fiber is placed through the operating channel of the operating hysteroscope, and a balanced salt solution is used for distention. When electrosurgery is used via a hysteroscopescope, an electrolyte-free solution, such as glycine or sorbitol, must be used because a balanced salt solution will dissipate the current and prevent cutting. Use of an electrolyte-free solution requires a thorough understanding of the potential risk and prevention of hyponatremia, because fatal complications have been reported with its use (see “Fluid Overload and Hyponatremia” below).

Both pedunculated and submucosal fibroids are shaved into small pieces with either the laser fiber or the hysteroscopescope. In the case of a pedunculated fibroid, the urge to simply transect the stalk as a first step should be resisted unless the fibroid is 10 mm or less in size. Fibroids that are larger than this are difficult to remove in one piece without excessive cervical dilatation. Morcellation is much easier when the stalk is still attached for stability.

When the field of view is obscured by multiple pieces of tissue, the hysteroscopescope is removed and the tissue collected in the urologic pouch. The hysteroscope is replaced in the uterus, and the procedure is repeated until the pedunculated fibroid and its stalk are completely removed, or the submucosal fibroid is shaved flush to the adjacent wall of the uterine cavity. After surgery, some gynecologists will treat the patient with estrogen or place an intrauterine splint as described above (see “Removal of Intrauterine Synechiae” above).

Risks of Hysteroscopy

Gas embolism. Gas embolism has been reported when using CO₂ for distention after intrauterine surgery. It is recommended that CO₂ not be used for any operative procedure or after significant dilation of the cervix. If symptoms of massive gas embolism occur during diagnostic hysteroscopy, the procedure should be stopped and the patient treated as described elsewhere.

Fluid overload and hyponatremia. During operative hysteroscopy, significant intravasation of distention medium can occur through venous channels opened during surgery or transperitoneally as a result of any fluid forced through the tubes. Symptomatic fluid overload has been reported with all fluid distention media, including 32 percent dextran 70 in dextrose. The volume of distention medium introduced through the operating hysteroscope or hysteroscopescope should always be compared with the volume retrieved using a urologic collection drape. When using a balanced salt solution (e.g., Ringer lactate solution), symptomatic fluid overload is treated effectively with diuretics.

When electrolyte-free solutions are used for electrosurgery, the potential exists for serious and even fatal hyponatremia, even without significant

fluid overload. Electrolyte-free solutions should not be used for hysteroscopy when electrosurgery is not required. When these solutions are used, careful monitoring of fluid balance should be performed every 15 min to detect intravasation.

Uterine perforation and bowel injury. Uterine perforation is a common risk of uterine dilation prior to hysteroscopy. If it is not possible to distend the uterine cavity when the hysteroscope is placed in the uterus, perforation should be suspected. If no sharp instrument or power source has been placed through the defect, expectant outpatient management is appropriate. Occasionally, perforation will occur during resection of a septum or leiomyoma or other operative procedures. If any chance of bowel injury exists, laparoscopy to evaluate contiguous bowel for injury is a reasonable precaution.

Intrauterine synechia. The formation of adhesions between the anterior and posterior uterine walls, referred to as synechiae, is an uncommon complication after intrauterine surgery. Although intrauterine devices, intrauterine catheters, and high-dose estrogen therapy have been advocated to decrease the risk of this complication, the efficacy of these treatments remains uncertain.

Abdominal Procedures

Incisions

There are several incisions used in pelvic surgery. The midline incision is the most useful. It is simple and tends to bleed less than incisions made off the midline. The midline incision provides excellent exposure of the pelvis, and, when necessary, the entire abdomen is accessible for operation. This incision is more susceptible to hernia formation and is somewhat more uncomfortable than the transverse incision. The resulting scar occasionally is thicker than incisions made along the Langer lines, resulting in a less-desirable cosmetic result.

Transverse incisions are used more often by a pelvic surgeon because the entire incision is centered over the area of operative interest. The incisions are more comfortable postoperatively and heal with a lower incidence of dehiscence or hernia formation. The most common transverse incision is the Pfannenstiel incision. The skin is incised transversely approximately 2 cm above the symphysis pubis, and the incision is taken down to the rectus fascia, which is entered transversely. The rectus fascia is dissected bluntly away from the underlying rectus muscles in both a superior and inferior direction. The rectus muscles are separated in the midline, and the peritoneum is opened in the vertical midline.

The Maylard incision carries with it the advantages of a transverse incision but affords more exposure of the pelvis than that provided by the Pfannenstiel. The skin is incised transversely approximately 4–6 cm above the symphysis pubis, and the rectus fascia is opened transversely but not separated from the underlying rectus muscles. The rectus muscles are cut directly under the fascial incision, and several small bleeders in the body of the rectus muscles are clamped and coagulated. The epigastric artery and vein located just below the lateral edge of the rectus muscles are ligated and cut; the peritoneum is then opened transversely to afford good visualization and access to the entire pelvis.

The Cherney incision provides the advantages of a transverse incision and all the visibility provided by the Maylard incision. The incision is made in

the transverse direction in the lower abdomen approximately 2 cm above the symphysis, the rectus fascia is opened transversely, the lower portion of the rectus sheath is dissected free of the rectus muscle, and the insertion of the rectus muscles on the symphysis pubis is visualized. The tendon of the rectus muscle is then cut free of the symphysis pubis, and the muscle is allowed to retract upward. The peritoneum is opened transversely. This incision is repaired by simply sewing the rectus tendon to the lower aspect of the rectus sheath just above the symphysis before closing the rectus sheath at the completion of the operation.

Hysterectomy for Benign Disease

The abdomen is entered through an appropriate incision. The upper abdomen is examined for evidence of extrapelvic disease, and a suitable retractor is placed in the abdominal wound. The bowel is packed out of the pelvis and held in place with a retractor. The uterus is grasped at either cornu and elevated. The round ligament is identified and suture ligated and cut or electrocauterized. If the ovaries are to be removed, the peritoneal incision is extended from the round ligament lateral to the infundibulopelvic ligament for approximately 2.5 cm. The retroperitoneal space is bluntly opened. The ureter is identified on the medial leaf of the broad ligament. The infundibulopelvic ligament is isolated, clamped, and cut, and ligated. A similar procedure is carried out on the opposite side.

In the event that the ovaries are not to be removed, after ligating the round ligament, an avascular area in the broad ligament is chosen and the broad ligament bluntly fractured with a finger, producing an opening below the ovarian ligament and fallopian tube. The fallopian tube and ovarian ligament are clamped, cut, and ligated.

Upward traction is placed on the uterus. The peritoneum in the anterior cul-de-sac is opened between the ligated round ligaments. The bladder is mobilized by sharply dissecting it free of the anterior surface of the uterus and cervix. The uterine vessels are skeletonized by transilluminating the fold of the broad ligament and dissecting the avascular tissue off the uterine vessels. The peritoneum on the posterior surface of the uterus is dissected free of the uterus and then cut. Clamps are placed on the uterine vessels at the cervicouterine junction. The vessels are cut and the clamps replaced with suture ligatures. The bladder is again examined to ensure that it has been mobilized sufficiently from the vagina near the cervix. The cardinal ligaments are clamped, cut, and ligated. Following division of the cardinal ligaments, the uterus is elevated and the vagina entered with scissors or a knife. The uterus and cervix are cut free of the vagina. Sutures are placed at each lateral angle of the vagina, and the cardinal ligament is sutured to either lateral vaginal angle. The central portion of the vagina is left open after repairing it with a running absorbable suture. Pelvic reperitonealization is not necessary. The rectosigmoid colon is allowed to return to the pelvis. The pelvic packs are removed and the small bowel is allowed to return to the pelvis. The omentum is placed over the bowel and under the abdominal wound. The abdominal wound is closed in an appropriate manner. In some circumstances, uterine myomata interfere with the operative procedure and myomectomy or supracervical hysterectomy might be accomplished before removing the cervix. Control of vascular pedicles may also be accomplished using linear stapling devices or bipolar cautery.

Myomectomy

Myomectomy should be performed through an incision that will allow good visibility of the pelvis. Hemostasis for the procedure is aided by the placement of a Penrose drain around the base of the uterus and pulled through small perforations in the broad ligament lateral to the uterine blood supply on either side. This "uterine tourniquet" is held in place with a clamp.

Further hemostasis may be obtained by placing bulldog or rubber-shod clamps on the infundibulopelvic ligament to control the utero-ovarian blood supply. When possible, the uterine incision should be made in the anterior surface of the uterus to reduce the incidence of postoperative adhesions. An incision is made through the uterine musculature into the myoma. The pseudocapsule surrounding the tumor is identified and the tumor is bluntly dissected out with scissors, a knife handle, or a finger. After the tumor is freed of its lateral attachments, it can be twisted to expose a pedicle that frequently contains its major blood supply. On occasion, several myomas may be removed through a single incision. The uterine wounds are closed with absorbable sutures to obliterate the dead space and provide hemostasis. The uterine serosa is closed with a 000 absorbable suture placed subserosally if possible. Adhesion barriers may be used.

Radical Hysterectomy (Modified from Okabayashi)

The patient is placed in a modified lithotomy position with legs in obstetric stirrups, hips abducted 45 degrees and flexed 15 degrees. The peritoneal cavity is entered through a Maylard incision after ligating and dividing the inferior epigastric vessels. The Maylard incision permits unequal exposure of structures on the lateral pelvic sidewall. Access to the retroperitoneum is obtained by dividing the round ligaments. A U-shaped incision is carried from one lateral abdominal gutter to the other, including the peritoneum of the bladder reflection. The pararectal and paravesical spaces are opened using blunt digital or instrument dissection, and narrow rigid retractors are placed to maintain exposure. Pelvic lymphadenectomy is performed by removing lymph nodes from the external, internal, and common iliac vessels, and the obturator fossa. If there are no pelvic lymph node metastases, para-aortic lymph node sampling is unnecessary. Isolation of the superior vesicle artery by lateral retraction of the obliterated umbilical artery brings the uterine artery into view; this vessel is skeletonized and clipped at its origin from the anterior division of the internal iliac artery. Next, the structures inferior to the uterine artery in the cardinal ligament are clamped and divided; freeing the cervix and upper vagina from the lateral pelvic sidewall. A linear stapling device may expedite this portion of the procedure.

At this point, the proper ovarian ligaments and the proximal fallopian tubes may be transected between clamps. After the ovarian vessels are mobilized, the ovaries may be marked with vascular clips and suspended in the lateral abdominal gutters above the pelvic brim. This measure protects the ovaries if postoperative pelvic radiotherapy is to be given. The ureters are carefully detached from the posterior leaves of the broad ligament for a short distance and retracted laterally before the posterior cul-de-sac is entered and the rectovaginal space developed bluntly; the uterosacral ligaments are divided. Upward traction on the uterus facilitates dissection of the bladder inferiorly away from the underlying cervix and upper vagina. The ureters are freed from their investment in the paracervical tissue, allowing the bladder and ureters to be

displaced inferolaterally, exposing the upper vagina and paravaginal tissues. The tissues are clamped and cut, taking care to remove a 3–4-cm margin of vagina with the cervix. The vagina is closed, a suprapubic catheter is inserted, and the abdominal incision is repaired.

Radical hysterectomy is associated with 85–90 percent cure rates in patients without lymph node, parametrial, or marginal involvement, and with 65–70 percent cure rates in those with spread to the regional nodes. The primary morbidity is bladder denervation, which occurs to some extent in almost all women undergoing this procedure. Generally, loss of bladder sensation is the only deficit, although inability to void is not uncommon in the immediate postoperative period. Rectal dysfunction may result in difficult defecation. Uterovaginal fistulas occur in approximately 1 percent of all patients in recent studies.

Postoperative external beam radiotherapy may be elected if nodal metastases, positive surgical margins, or parametrial tissue involvement is found. Because bladder and ureteral complications are more common in women undergoing postoperative radiotherapy, surgical candidates must be chosen with care.

Resection of Ovarian Cancer

Radical or modified radical hysterectomy is indicated in the treatment of epithelial ovarian cancer only if peritoneal tumor nodules obliterate the posterior cul-de-sac or extend to the retroperitoneal spaces. Generally, extrafascial (simple or conservative) hysterectomy suffices in the resection of these tumors.

When hysterectomy and salpingo-oophorectomy are completed, the omentum should be removed by reflecting the fatty organ superiorly, isolating and dividing the right and left gastroepiploic vessels, and dissecting through the avascular posterior leaf before isolating and dividing the vessels in the anterior leaf of the omentum. If the omentum contains a large amount of disease, the gastrocolic omentum should be removed by isolating and dividing the short gastric vessels along the greater curvature of the stomach. In cases of extensive omental involvement, care must be taken not to injure the spleen, stomach, or transverse colon. Generous peritoneal biopsies should be obtained from the right hemidiaphragm, both lateral abdominal gutters, and the anterior and posterior peritoneum of the pelvis.

If gross intraperitoneal tumor is completely resected, the lymph nodes should be evaluated. The left para-aortic lymph nodes may be exposed by reflecting the sigmoid colon medially. These lymph nodes should be liberally sampled, keeping in mind that the primary venous drainage of the left ovary is the left renal vein and that of the right ovary is the inferior vena cava at the level of the renal vein. Metastases are more common above than below the inferior mesenteric artery. The right para-aortic lymph nodes may be sampled transperitoneally or by mobilizing the ileocecal area and reflecting it superiorly.

Pelvic lymph node sampling is also an important aspect of surgical staging in ovarian cancer and is completed by removing lymph nodes from the distribution of the external and internal iliac vessels and obturator space above the level of the obturator nerve. This part of the staging procedure is facilitated by first opening the paravesical and pararectal spaces as described for radical hysterectomy above. Lymph node sampling is primarily a diagnostic procedure in the management of early ovarian cancers. Complete lymphadenectomy may extend disease-free interval, but does not affect survival in patients with advanced disease.

Vaginal Procedures

Hysterectomy

The removal of the uterus through the vagina is preferred in many cases of myoma, uterine prolapse, intraepithelial neoplasia, and uterine bleeding disorders. Patients are more comfortable and operative time, hospital stay, and recovery time are shorter than in cases of abdominal operation. Vaginal hysterectomy is an acceptable approach in those patients in whom the uterus descends, the bony pelvis allows vaginal operation, the uterine tumors are small enough to permit vaginal removal, and the patient is amenable to vaginal operation. The patient is placed in a high lithotomy position, and the pelvis is examined under anesthesia. This examination should confirm previous findings and provide assurance that the operation is possible through the vaginal route. The bladder is not catheterized before operation unless it is greatly distended. A weighted vaginal speculum is placed in the posterior vagina, and the cervix is grasped with a tenaculum and pulled in the axis of the vagina. The posterior cul-de-sac is identified and entered with scissors. Mayo scissors are used to circumcise the cervix, and the mucosa is cut down to the pubocervical-vesical fascia. The vaginal mucosa and the bladder are sharply and bluntly dissected free of the cervix and the lower portion of the uterus. When the peritoneum of the anterior cul-de-sac is identified, it is entered with the scissors, and a retractor is placed in the defect. The uterosacral ligaments are identified, doubly clamped, cut, and ligated. Serial clamps are placed on the parametrial structures above the uterosacral ligament; these pedicles are cut, and the clamps are replaced with ties. At the cornu of the uterus, the tube, round ligament, and suspensory ligament of the ovary are doubly clamped and cut. The procedure is carried out on the opposite side, and the uterus is removed. The first clamp is replaced with a free tie; the second clamp is replaced with a suture ligature that is transfixed. The second suture ligature is held long. The pelvis is inspected for hemostasis; all bleeding must be meticulously controlled at this point.

The pelvic peritoneum is closed with a running purse-string suture incorporating those pedicles which were held. This exteriorizes those areas which might tend to bleed. The sutures attached to the ovarian pedicles are cut. The vagina may be closed with interrupted mattress stitches, incorporating the uterosacral ligaments into the corner of the vagina with each lateral stitch. The vaginal cuff is inspected again for hemostasis. In most cases, no vaginal packing is required. A catheter is left in the bladder until the patient has fully awakened and is ambulatory.

On occasion, the uterus, which is initially too large to remove vaginally, may be reduced in size by morcellation. After the uterine vessels have been clamped and ligated, serial wedges are taken from the central portion of the uterus to reduce the uterine mass. This procedure will allow the vaginal delivery of even very large uterine leiomyomas.

Neurologic surgery is a discipline of medicine and the specialty of surgery that provides the operative and nonoperative management including prevention, diagnosis, evaluation, treatment, critical care, and rehabilitation of disorders of the central, peripheral, and autonomic nervous systems, including their supporting structures and vascular supply; the evaluation and treatment of pathologic processes that modify the function or activity of the nervous system, including the hypophysis; and the operative and nonoperative management of pain. As such, neurologic surgery encompasses the treatment of adult and pediatric patients with disorders of the nervous system. These disorders include those of the brain, meninges, skull and skull base, and their blood supply, including surgical and endovascular treatment of disorders of the intracranial and extracranial vasculature supplying the brain and spinal cord; disorders of the pituitary gland; disorders of the spinal cord, meninges, and vertebral column, including those that may require treatment by fusion, instrumentation, or endovascular techniques; and disorders of the cranial and spinal nerves throughout their distribution (courtesy of the American Board of Neurological Surgeons).

An accurate history is the first step toward neurologic diagnosis. A history of trauma or of neurologic symptoms is of obvious interest, but general constitutional symptoms also are important. Neurologic disease may have systemic effects, although diseases of other symptoms may affect neurologic function. The patient's general medical ability to withstand the physiologic stress of anesthesia and surgery should be understood. A detailed history from the patient and/or family, along with a reliable physical examination will clarify these issues.

NEUROANATOMY

The cerebral hemispheres consist of the cerebral cortex, underlying white matter, the basal ganglia, hippocampus, and amygdala. The cerebral cortex is the most recently evolved part of the nervous system. The frontal areas are involved in executive function, decision making, and restraint of emotions. The motor strip, or precentral gyrus, is the most posterior component of the frontal lobes, and is arranged along a homunculus with the head inferior and lateral to the lower extremities superiorly and medially. The motor speech area (Broca area) lies in the left posterior inferior frontal lobe in almost all right-handed people and in up to 90 percent of left-handed people. The parietal lobe lies between the central sulcus anteriorly and the occipital lobe posteriorly. The postcentral gyrus is the sensory strip, also arranged along a homunculus. The visual cortex is arrayed along the medial surfaces of the occipital lobes. The temporal lobes lie below the sylvian fissures. The hippocampus, amygdala, and lower optic radiations (Meyer loops) are important components of the temporal lobe.

Lying deep to the cerebral hemispheres the thalamus and hypothalamus. The thalamus is a key processor and relay circuit for most motor and sensory information going to or coming from the cortex. The hypothalamus, at the

base of the brain, is a key regulator of homeostasis, via the autonomic and neuroendocrine systems.

The brain stem consists of the midbrain, pons, and medulla. Longitudinal fibers run through the brain stem, carrying motor and sensory information between the cerebral hemispheres and the spinal cord. The nuclei of cranial nerves III through XII are also located within the brain stem. The cerebellum arises from the dorsal aspect of the brain stem.

The ventricular system is a cerebrospinal fluid (CSF)-containing contiguous space inside the brain, continuous with the subarachnoid space outside the brain. There are two lateral ventricles, and the third and fourth ventricle. Choroid plexus creates the CSF, mostly in the lateral ventricles. The average adult has an approximate CSF volume of 150 mL and creates approximately 500 mL per day.

The spinal cord starts at the bottom of the medulla and extends through the spinal canal down to approximately the first lumbar vertebra. It transmits motor (efferent) and sensory (afferent) information between the brain and the body. Paired nerves exit the spinal cord at each level. There are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The C5–T1 spinal nerves intersect in the brachial plexus and divide to form the main nerve branches to the arm, including the median, ulnar, and radial nerves. The L2–S4 spinal nerves intersect in the lumbosacral plexus and divide to form the main nerve branches to the leg, including the common peroneal, tibial, and femoral nerves.

The autonomic nervous system (ANS) carries messages for homeostasis and visceral regulation from the central nervous system (CNS) to target structures such as arteries, veins, the heart, sweat glands, and the digestive tract. The ANS is divided into the sympathetic, parasympathetic, and enteric systems. The sympathetic system drives the “fight or flight” response, and uses epinephrine to increase heart rate, blood pressure, blood glucose, and temperature, and to dilate the pupils. The parasympathetic system promotes the “rest and digest” state, and uses acetylcholine to maintain basal metabolic function under nonstressful circumstances. The enteric nervous system controls the synchronization of the digestive tract. It can run autonomously, but is under the regulation of the sympathetic and parasympathetic systems.

NEUROLOGIC EXAMINATION

Mental status is assessed first. A patient may be awake, lethargic, stuporous, or comatose. Cranial nerves may be thoroughly tested in the awake patient, but pupil reactivity, eye movement, facial symmetry, and gag are the most relevant when mental status is impaired. Motor testing is based on maximal effort of major muscle groups in those able to follow commands, although reaction to pain may be all that is possible for stuporous patients. Characteristic motor reactions to pain in patients with depressed mental status include withdrawal from stimulus, localization to stimulus, flexor (decorticate) posturing, extensor (decerebrate) posturing, or no reaction (in order of worsening pathology). Light touch, proprioception, temperature, and pain testing may be useful in awake patients. It is critical to document sensory patterns in spinal cord injury patients. Muscle stretch reflexes should be checked for symmetry and amplitude. Check for ankle-jerk clonus or up-going toes (the Babinski test). Presence of either is pathologic and signifies upper motor neuron disease.

Diagnostic Studies

Plain Films

Plain radiographs of the skull may demonstrate fractures, osteolytic or osteoblastic lesions, or pneumocephaly (air in the head). Plain spine films are used to assess for fracture, soft-tissue swelling, spinal deformities, osteolytic, or osteoblastic processes.

Computed Tomography (CT)

The noncontrast head CT scan of the head is useful in the setting of new focal neurologic deficit, decreased mental status, or trauma. It is very sensitive for hemorrhage. A contrast-enhanced CT scan will help show neoplastic or infectious processes. Spine CT scans are helpful for defining bony anatomy and pathology, and is usually done after an abnormality is seen on plain films. New high-speed scanners allow CT-angiography (CT-A). CT-A does not reliably detect lesions such as cerebral aneurysms less than 3 mm across, but can provide detailed morphologic data of larger lesions.

Magnetic Resonance Imaging (MR)

MRI provides better soft tissue imaging than does CT. Several MRI sequences are available. T1 with and without gadolinium are useful for detecting neoplastic and infectious processes. T2 sequences facilitate assessment of neural compression in the spine by the presence or absence of bright T2 CSF signals around the cord or nerve roots. Diffusion-weighted images (DWI) can detect ischemic stroke earlier than CT. Time-of-flight (TOF) images can be reformatted to build MR-angiograms (MR-A) and MRI-venograms (MR-V).

Angiography

Transarterial catheter-based angiography remains the standard criterion for evaluation of vascular pathology of the brain and spine because of its ability to detect smaller lesions and give dynamic flow information.

Electromyography and Nerve Conduction Studies (EMG/NCS)

These studies evaluate the function of peripheral nerves. EMG records muscle activity in response to stimulation of a motor nerve. NCS records the velocity and amplitude of the nerve action potential. EMG/NCS is typically performed 3–4 weeks after an acute injury.

Invasive Monitoring

Intracranial monitors are used in patients with intracranial pathology without a reliable neurologic exam.

External ventricular drain (EVD, ventriculosomy). A catheter is inserted into the frontal horn of the lateral ventricle. ICP can be transduced, and CSF drained to reduce ICP or for laboratory studies.

Intraparenchymal fiberoptic pressure transducer (“bolt”). It allows ICP monitoring, and is smaller and less invasive than a ventriculostomy.

Brain tissue oxygen sensors. Patients with brain trauma or aneurysmal hemorrhage may have insufficient brain oxygen tension with relatively normal ICPs. Oxygen sensors can provide additional management information.

NEUROLOGIC AND NEUROSURGICAL EMERGENCIES

Raised Intracranial Pressure

ICP normally varies between 4 and 14 mmHg. Sustained ICP levels above 20 mmHg can injure the brain. The Monro-Kellie doctrine states that the cranial vault is a rigid structure, and therefore the total volume of the contents determines ICP. The three normal contents of the cranial vault are brain, blood, and CSF. The brain can swell because of traumatic brain injury (TBI), stroke, or reactive edema. Intravascular (vasodilation) or extravascular (hematoma) blood volume can increase. CSF volume increases in the setting of hydrocephalus. Addition of a fourth element, such as a tumor or abscess, will also increase ICP.

Increased ICP often presents with headache, nausea, vomiting, and mental status decline. Cushing triad is the classic presentation of ICH: hypertension, bradycardia, and irregular respirations. This triad is usually a late manifestation. Patients with these symptoms should have an urgent head CT.

Brain Stem Compression

Mass effect in the posterior can rapidly kill by occluding the fourth ventricle causing acute obstructive hydrocephalus, or directly crushing the brain stem. Both cause rapid mental status decline and death but are treatable if caught immediately.

Stroke

Patients who present with acute focal neurologic deficits for whom the time of onset of symptoms can be clearly defined must be evaluated rapidly. A patient with a clinical diagnosis of acute stroke younger than 3 h old, without hemorrhage on CT, may be a candidate for thrombolytic therapy with tissue plasminogen activator (t-PA).

Seizure

Seizures may be because of a tumor, hematoma, or intrinsic brain disorder. A seizing patient is at risk for neurologic damage if the seizure is not stopped, and airway and ventilation problems. Any patient with new-onset seizure should have imaging of the brain, such as a head CT scan, after the seizure is controlled and the patient resuscitated.

TRAUMA

Trauma is a leading cause of death and disability in children and young adults. The three main areas of neurosurgic interest in trauma are traumatic brain injury (TBI), spine and spinal cord injury (SCI), and peripheral nerve injury.

Head Trauma

Glasgow Coma Scale (GCS) Score

Neurosurgical evaluation begins as part of “D” after “ABC” in the primary evaluation with assessment of the Glasgow Coma Scale. Table 41-1 describes how the GCS is determined.

TABLE 41-1 The Glasgow Coma Scale (GCS) Score^a

Motor response (M)		Verbal response (V)		Eye-opening response (E)	
Obeys commands	6	Oriented	5	Opens spontaneously	4
Localizes to pain	5	Confused	4	Opens to speech	3
Withdraws from pain	4	Inappropriate words	3	Opens to pain	2
Flexor posturing	3	Unintelligible sounds	2	No eye opening	1
Extensor posturing	2	No sounds	1		
No movement	1	Intubated	T		

^aAdd the three scores to obtain the Glasgow Coma Scale score, which can range from 3 to 15. Add "T" after the GCS if intubated and no verbal score is possible. For these patients, the GCS can range from 2T to 10T.

Scalp Injury

The scalp is densely vascularized and can contribute to significant blood loss. Lacerations should be irrigated and sutured closed, either in one layer if simple or two layers (galea and skin) if long and complex.

Skull Fractures

A closed fracture is covered by intact skin. A compound fracture is associated with open skin. The fracture lines may be single (linear), multiple and radiating from a point (stellate), multiple, creating fragments of bone (comminuted), or pushed into the brain (depressed). Closed skull fractures do not normally require specific treatment. Open fractures require repair of the scalp. Depressed fractures may require craniotomy to elevate the bone, evacuate associated blood clots, and stop bleeding.

Skull base fractures are common in TBI patients. They indicate significant impacts and are generally apparent on CT. If asymptomatic, they require no treatment. Symptoms from skull base fractures include cranial nerve deficits (anosmia, facial palsy) and CSF leaks (rhinorrhea, otorrhea). Many CSF leaks will heal with elevation of the head of the bed for several days although some require a lumbar drain or direct surgical repair. There is no proven efficacy of antibiotic coverage for preventing meningitis in patients with CSF leaks. Traumatic cranial neuropathies are generally followed conservatively. Steroids may help facial nerve palsies.

Closed Head Injury

Closed head injury (CHI) is the most common type of TBI. There are two components of CHI and TBI in general. The initial impact causes the primary injury, defined as the immediate injury to neurons from transmission of the force of impact. Prevention strategies, such as wearing helmets, remain the best means to decrease disability from primary injury. Subsequent neuronal damage because of hypotension, hypoxia, hematomas, or increased ICP is referred to as secondary injury.

Initial assessment. Hypoxia and hypotension worsen outcome in TBI (secondary injury), so cardiopulmonary stabilization is critical. Patients who cannot follow commands require intubation for airway protection and ventilatory control. Spontaneous movements and responsiveness to voice commands or pain gives an initial indication of severity of injury.

Medical management. Phenytoin prophylaxis may decrease the incidence of early post-TBI seizures. Blood glucose and body temperature should be kept normal. Peptic ulcers occurring in patients with head injury or high ICP are referred to as Cushing ulcers, and may be reduced with H₂-blockers. Compression stockings should be used when the patient cannot be mobilized rapidly.

Classification. TBI can be classified as mild (GCS 14–15), moderate (GCS 9–13), or severe (GCS 3–8).

TBI patients who are asymptomatic; have only headache, dizziness, or scalp lacerations or abrasions; or did not lose consciousness have a low risk for intracranial injury and may be discharged home without a head CT. Patients with a history of altered or lost consciousness, amnesia, progressive headache, skull or facial fracture, vomiting, or seizure have a moderate risk for intracranial injury and should undergo prompt head CT. If the CT is normal, and the neurologic exam has returned to baseline (excluding amnesia of the event), then the patient can be discharged to the care of a responsible adult.

Patients with depressed consciousness, focal neurologic deficits, penetrating injury, depressed skull fracture, or changing neurologic exam have a high risk for intracranial injury. These patients should undergo immediate head CT and admission for observation or intervention as needed.

Concussion. Temporary neuronal dysfunction after TBI. The CT is normal and deficits resolve over min to h. Amnesia is very common. The brain remains in a hypermetabolic state for up to a week after injury and is more susceptible to injury from even minor head trauma in the first 1–2 weeks after concussion (second-impact syndrome). Patients should be informed that even after mild head injury they may experience memory difficulties or persistent headaches.

Contusion. A contusion is a bruise of the brain, and occurs when the force from trauma is sufficient to cause breakdown of small vessels and extravasation of blood into the brain. The contused areas appear bright on CT scan. They may be under the area of impact (coup injury) or opposite the area of impact (contrecoup injury). They frequently do not require direct treatment unless they enlarge or hemorrhage and cause mass effect.

Diffuse axonal injury. Diffuse axonal injury is caused by damage to axons throughout the brain, because of rotational acceleration and then deceleration. Axons may be completely disrupted and then retract, forming axon balls. Small hemorrhages can be seen in more severe cases, especially on MRI. Hemorrhage is classically seen in the corpus callosum and the dorsolateral midbrain (Duret hemorrhage).

Penetrating injury. The two main subtypes are missile injury (e.g., bullets) and nonmissile injury (e.g., knives). Skull radiographs and CT scans are useful in assessing the nature of the injury. Cerebral angiography must be considered if the object passes near a major artery or dural venous sinus. Operative exploration is necessary to remove any object extending out of the cranium, and for débridement, irrigation, hemostasis, and definitive closure. Small objects contained within brain parenchyma often are left in place to avoid iatrogenic secondary brain injury.

Traumatic Intracranial Hematomas

The various traumatic intracranial hematomas contribute to death and disability secondary to head injury. Hematomas can expand rapidly and cause brain shifting and subsequent herniation.

Epidural hematoma (EDH). Tearing of the middle meningeal artery results in accumulation of blood between the skull and the dura. CT reveals a bright biconvex (lenticiform) clot. EDH has a classic three-stage clinical presentation with immediate loss of consciousness (concussion), a lucid interval, and then lethargy and herniation as the hematoma expands. This is probably seen in only 20 percent of cases. Treatment of symptomatic EDH is craniotomy.

Acute subdural hematoma (SDH). Tearing of a bridging vein from the cerebral cortex to the dural sinuses leads to subdural blood accumulation. CT reveals a bright crescent-shaped (lunate) clot. Craniotomy is indicated for any acute SDH more than 1 cm in thickness, or smaller hematomas that are symptomatic. Symptoms may be as subtle as a contralateral pronator drift, or as dramatic as coma. Smaller hematomas may stabilize and eventually reabsorb, or become chronic SDHs. The prognosis for functional recovery is significantly worse for acute SDH than EDH because it is associated with greater primary injury to brain parenchyma from high-energy impacts.

Chronic subdural hematoma. Small acute SDHs may not resorb and may evolve from blood clots to a dark motor-oil-like fluid that may expand and cause delayed symptoms. A chronic SDH thicker than 1 cm, or any symptomatic SDH should be surgically drained via a burr hole.

Intraparenchymal hemorrhage. Isolated hematomas within the brain parenchyma may be due TBI but hypertensive hemorrhage, arteriovenous malformations, or underlying tumors are more likely.

Vascular Injury

Trauma to the head or neck may cause dissection of the carotid or vertebrobasilar arteries. The newly created space within the vessel wall is referred to as the false lumen. Dissection can cause ischemia or thromboembolism in supplied tissues. Diagnosis is by four-vessel angiography, which may reveal stenosis of the true lumen, visible intimal flaps, or the appearance of contrast in the false lumen. Neurology may assist with antiplatelet or anticoagulation therapies. Endovascular options include vessel occlusion or stenting.

Carotid dissection. Carotid dissection may result from neck extension combined with lateral bending to the opposite side, or trauma from an incorrectly placed shoulder belt tightening across the neck in a motor vehicle accident. Symptoms of cervical carotid dissection include contralateral neurologic deficit from brain ischemia, headache, and ipsilateral Horner syndrome from disruption of the sympathetic tracts ascending from the stellate ganglion into the head on the surface of the carotid artery. Traumatic vessel wall injury to the portion of the carotid artery running through the cavernous sinus may result in a carotid-cavernous fistula (CCF). These present with pulsatile proptosis (the globe pulses outward with arterial pulsation), retro-orbital pain, and decreased visual acuity or loss of normal eye movement (because of damage to cranial nerves III, IV, and VI in the cavernous sinus). Symptomatic CCFs should be treated by balloon occlusion to preserve eye function.

Vertebrobasilar dissection. Vertebrobasilar dissection may result from sudden rotation or flexion/extension of the neck, chiropractic manipulation, or a direct blow to the neck. Common symptoms are neck pain, headache, brain stem stroke, or subarachnoid hemorrhage.

Brain Death

Brain death occurs when there is an absence of signs of brain stem function or motor response to deep central pain in the absence of pharmacologic or systemic medical conditions that could impair brain function.

Clinical examination. Two exams consistent with brain death 12 h apart, or one exam consistent with brain death followed by a consistent confirmatory study is generally sufficient to declare brain death. The patient must be normotensive, eutermic, oxygenating well, and not be under the effects of sedating or paralytic drugs.

Documentation of no brain stem function includes the following: nonreactive pupils; lack of corneal blink, oculoccephalic (doll's eyes), or oculovestibular (cold calorics) reflexes; and loss of drive to breathe (apnea test). The apnea test demonstrates failure of spontaneous breathing when $Paco_2$ is allowed to rise above 60 mmHg.

Deep central painful stimulus is provided by forceful twisting pinch of the sensitive skin above the clavicle. Pathologic responses such as flexor or extensor posturing are not compatible with brain death. Spinal reflexes to peripheral pain, such as triple flexion of the lower extremities, are compatible with brain death.

Confirmatory studies. Lack of cerebral blood flow consistent with brain death may be documented by cerebral angiography, technetium radionuclide study, and transcranial Doppler ultrasonography. An electroencephalogram (EEG) documenting electrical silence is not favored because there is often artifact or noise on the recording.

Spine Trauma

Damage to the bone or soft tissues of the spine can reduce its stability and its ability to protect the spinal cord and nerve roots. Spine trauma may occur with or without neurologic injury. Neurologic injury may be incomplete, if there is some residual motor or sensory neurologic function below the level of the lesion, or complete, if there is no residual neurologic function below the level of the lesion. A patient with 24 h of complete neurologic dysfunction has a low probability of return of function in the involved area.

The Mechanics of Spine Trauma

Flexion/extension. Bending the head and body forward into a fetal position flexes the spine. Arching the neck and back extends the spine. Extension loads the spine posteriorly and distracts the spine anteriorly.

Compression/distraction. Force applied along the spinal axis (axial loading) compresses the spine. A pulling force in line with the spinal axis distracts the spine.

Rotation. Force applied tangential to the spinal axis rotates the spine.

Patterns of Injury

Remember that a patient with a spine injury at one level is at significant risk for additional injuries at other levels.

Cervical. The cervical spine is more mobile than the thoracolumbar spine. Stability comes primarily from the multiple ligamentous connections of adjacent vertebral levels. Disruption of the cervical ligaments can lead to instability in the absence of fracture.

Jefferson fracture. Bursting fracture of the ring of C1 (the atlas) because of compression forces. There are usually two or more fractures through the ring of C1. The open-mouth odontoid view may show lateral dislocation of the lateral masses of C1. The rule of Spence states that 7 mm or greater combined dislocation indicates disruption of the transverse ligament and the potential need for surgical stabilization.

Odontoid fractures. The odontoid process, or dens, is the large ellipse of bone arising anteriorly from C2 (the axis) and projecting up through the ring of C1 (the atlas). Odontoid fractures usually result from flexion forces. Odontoid fractures are classified as type I, II, or III. A type I fracture involves the tip only. A type II fracture passes through the base of the odontoid process. A type III fracture passes through the body. Type II fractures are most likely to need surgery.

Hangman's fracture. Either hyperextension/distraction or hyperextension/compression. The part of C2 bridging C1–C3 is broken. Most hangman's fractures heal well with external immobilization.

Jumped facets. The facet joints of the cervical spine slope forward, and the facet from the level above can slide up and forward over the facet from the level below if the joint capsule is torn. Patients with a unilateral injury are usually neurologically intact, although those with bilateral injury usually have spinal cord compression.

Thoracolumbar. The thoracic spine is significantly stabilized by the rib cage. The lumbar spine has comparatively very large vertebrae. Thus the thoracolumbar spine has a higher threshold for injury than the cervical spine. The three-column model is useful for categorizing thoracolumbar injuries. The anterior longitudinal ligament and the anterior half of the vertebral body constitute the anterior column. The posterior half of the vertebral body and the posterior longitudinal ligament constitute the middle column. The pedicles, facet joints, laminae, spinous processes, and interspinous ligaments constitute the posterior column.

Compression fracture. Compression/flexion injury causing failure of the anterior column only. It is stable and not associated with neurologic deficit, although the patient may have significant pain.

Burst fracture. Axial compression injury causing failure of the anterior and middle columns. It is unstable, and perhaps patients may have neurologic deficit because of retropulsion of bone fragments.

Chance fracture. Flexion-distraction injury causing failure of the middle and posterior columns. It is unstable and is often associated with neurologic deficit.

Fracture-dislocation. Flexion/distraction, shear, or compression injuries causing failure of the anterior, middle, and posterior columns. They are unstable and often associated with neurologic deficit.

Initial Assessment and Management

The possibility of a spine injury must be considered in all trauma patients. A patient with no symptoms referable to neurologic injury, a normal neurologic exam, no neck or back pain, and a known mechanism of injury unlikely to cause spine injury is at minimal risk for significant injury to the spine. Victims of moderate or severe trauma, especially those with injuries to other organ systems, usually fail to meet these criteria or cannot be assessed adequately. The latter is often because of impaired sensorium or significant pain. Because of the potentially catastrophic consequences of failure to diagnose spine instability in a neurologically intact patient, spine precautions should be maintained until fully evaluated.

Studies

Plain radiographs provide initial assessment of spinal alignment but are often inadequate for full evaluation. CT and MR scans are useful adjuncts.

Definitive Management

Spinal-dose steroids. The National Acute Spinal Cord Injury Study (NASCIS) I and II papers provide controversial evidence of improved outcome in spinal cord injury patients if they are given high-dose methylprednisolone acutely.

Orthotic devices. External stabilization by decreasing range of motion and minimizing stress transmitted through the spine. Philadelphia and Miami-J hard collars stabilize the neck. Cervical collars are poor for C1, C2, or cervicothoracic instability. Halo-vest assemblies provide the most external cervical stabilization. Four pins driven into the skull lock the halo ring in position. Four posts arising from a tight-fitting rigid plastic vest immobilize the halo ring. Lumbar stabilization may be provided by thoracolumbosacral orthoses (TLSOs).

Surgery. Neurosurgical intervention has two goals. First is the decompression of the spinal cord or nerve roots in patients with incomplete neurologic deficits. These patients should be decompressed expeditiously if there is evidence of neurologic deterioration over time. Second is the stabilization of injuries judged too unstable to heal with external orthotics only. Surgical stabilization can allow early mobilization, aggressive nursing care, and physical therapy and may decrease the need for burdensome orthotics.

Continued Care

Regional spinal cord injury centers with nurses, respiratory therapists, pulmonologists, physical therapists, physiatrists, and neurosurgeons specifically trained in caring for these patients may improve outcomes. Acute issues include hypotension and aspiration pneumonia. Chronic issues include deep venous thrombosis, autonomic hyperreflexia, and decubitus ulcer formation. Patients should be transferred to spinal cord injury rehabilitation centers after stabilization of medical and surgical issues.

Peripheral Nerve Trauma

The peripheral nervous system extends throughout the body and is subject to injury from a wide variety of traumas. Peripheral nerves transmit motor and sensory information between the CNS and the body.

The four major mechanisms of injury to peripheral nerves are laceration (knives, bullets), stretch (hematomas, fracture), compression (casts, external blow), and contusion (shock wave from bullet).

The following four characteristics make a nerve segment more vulnerable to injury: proximity to a joint, superficial course, passage through a confined space, and fixed position.

The Seddon Classification

Neurapraxia. (Least severe) Temporary failure of nerve function without physical axonal disruption. Axon degeneration does not occur. Return of normal axonal function occurs over hours to months, often in the 2–4-week range.

Axonotmesis. Disruption of axons and myelin. The surrounding connective tissues, including endoneurium, are intact. The axons degenerate proximally and distally (Wallerian degeneration) from the area of injury. Axon regeneration within the connective tissue pathways can occur at a rate of 1 mm per day. Recovery may occur for up to 18 months. Scarring at the site of injury from connective tissue reaction can form a neuroma and interfere with regeneration.

Neurotmesis. (Most severe) Disruption of axons and endoneurial tubes. Peripheral collagenous components, such as the epineurium, may or may not be intact. Proximal and distal axonal degeneration occurs.

Management of Peripheral Nerve Injury

The sensory and motor deficits should be documented. Deficits are usually immediate. Clean and sharp or progressing injuries may benefit from early exploration and repair. Most other peripheral nerve injuries should be observed and be tested by EMG/NCS after 3–4 weeks if deficits persist. If there is no improvement over 3 months the injury should be explored. Surgical techniques include nerve grafting and neuroma excision. The tissue structure of the graft provides a pathway for axon regrowth.

Patterns of Injury

Brachial plexus. Susceptible to injury during parturition, falls, and motorcycle accidents by stretching or shoulder dislocation. A lung apex tumor, known as a Pancoast tumor, can cause compression injury to the plexus. Two well-known patterns of plexus injury are Erb palsy and Klumpke palsy. Injury high in the plexus to the C5 and C6 roots resulting from glenohumeral dislocation causes Erb palsy with the characteristic “bellhop’s tip” position. The arm hangs at the side, internally rotated. Hand movements are not affected. Injury low in the plexus, to the C8 and T1 roots, resulting from stretch or compression injury, causes Klumpke palsy with the characteristic “claw hand” deformity. There is weakness of the intrinsic hand muscles, similar to that seen with ulnar nerve injury.

Radial nerve. Susceptible to injury from improper crutch use, humerus fractures, or improper sleeping position (Saturday night palsy). The key finding is wrist drop (weakness of hand and finger extensors). Axillary (proximal) injury causes triceps weakness in addition to wrist drop.

Common peroneal nerve. Susceptible to injury from car bumpers in the lateral knee where it wraps superficially around the fibular neck. The key finding is foot drop (weakness of the tibialis anterior) and numbness over the anterolateral surface of the lower leg and dorsum of the foot.

CEREBROVASCULAR DISEASE

This is the most frequent cause of nontraumatic acute neurologic deficit. Common medical problems including diabetes, high cholesterol, hypertension, and smoking contribute to vascular disease by such mechanisms as atheroma deposition causing luminal stenosis, endothelial damage promoting thrombogenesis, and weakening of the vessel wall resulting in aneurysm formation or dissection. The most common cerebrovascular diseases are carotid stenosis, ischemic and hemorrhagic stroke, and aneurysm formation.

Ischemic Diseases

Ischemic stroke accounts for approximately 85 percent of acute cerebrovascular events. Arterial occlusion leads to ischemia in the neural tissues supplied by that vessel. This leads to immediate dysfunction and eventual tissue death. Symptoms depend on which area of the brain is ischemic. Collateral blood supply minimizes ischemia in some situations.

A transient ischemic attack (TIA) resolves within 24 h. A reversible ischemic neurologic deficit (RIND) resolves within one week. A stroke, i.e., a cerebrovascular accident, or CVA, indicates permanent neurologic deficit.

Thromboembolic Disease

Thrombi that form in the heart, aorta, or carotid arteries can break off and embolize to the brain, causing vessel blockage and tissue ischemia. Thrombosis also can completely occlude the carotid artery and cause ischemia without embolus.

Management

Thrombus formation can be treated medically with anticoagulation and antiplatelet agents. Chronic atrial fibrillation is an indication for coumadin therapy. Patients with symptomatic carotid stenosis with 70–99 percent occlusion should undergo carotid endarterectomy. Certain asymptomatic carotid lesions also should be considered for surgery.

Patients with suspected stroke should have an immediate head CT to evaluate for hemorrhage. Management of ischemic stroke includes maintaining good cerebral perfusion pressure, aspirin, hydration, and careful neurologic monitoring on the neurology service.

Common Types of Strokes

Anterior cerebral artery stroke. The ACA supplies the medial frontal and parietal lobes, including the motor strip, as it courses into the interhemispheric fissure. ACA stroke results in contralateral leg weakness.

Middle cerebral artery stroke. The MCA supplies the lateral frontal and parietal lobes and the temporal lobe. MCA stroke results in contralateral face and arm weakness. Dominant-hemisphere MCA stroke causes language deficits. Proximal MCA occlusion causing ischemia and swelling in the entire MCA

territory can lead to significant intracranial mass effect and midline shift and may benefit from decompressive hemicraniectomy (removing half of the skull).

Posterior cerebral artery stroke. The PCA supplies the occipital lobe. PCA stroke results in a contralateral homonymous hemianopsia.

Posterior inferior cerebellar artery stroke. The PICA supplies the lateral medulla and the inferior half of the cerebellar hemispheres. PICA stroke results in nausea, vomiting, nystagmus, dysphagia, ipsilateral Horner syndrome, and ipsilateral limb ataxia. The constellation of symptoms resulting from PICA occlusion is referred to as lateral medullary syndrome or Wallenberg's syndrome.

Hemorrhagic Diseases

Intracranial hemorrhage (ICH) from abnormal or diseased vascular structures accounts for approximately 15 percent of acute cerebrovascular events. Hypertension and amyloid angiopathy account for most intraparenchymal hemorrhages. Aneurysms and arteriovenous malformations (AVMs) are the most common causes of nontraumatic subarachnoid hemorrhage (SAH). Tumors and venous sinus thrombosis also can cause ICH.

Hypertension

Hypertension increases the relative risk of ICH by approximately 4-fold, likely because of chronic degenerative vasculopathy. Hypertensive hemorrhages often present in the basal ganglia, thalamus, or pons, and result from breakage of small perforating arteries that branch off of much larger parent vessels. Surgery often causes more injury than benefit.

Amyloid Angiopathy

Amyloid deposition in the media of small cortical vessels compromises vessel integrity and predisposes to more superficial (lobar) hemorrhages. Patients may have multiple hemorrhages over time. These occasionally benefit from surgery because they are more superficial than hypertensive hemorrhages.

Cerebral Aneurysm

Aneurysms are focal dilatation of the vessel wall that usually occur at branch points of major vessels. They may be saccular (balloon-like) or fusiform (elongated). They have thin, weakened walls and are prone to rupture, causing subarachnoid hemorrhage (SAH). Symptoms range from sudden "thunderclap" headache to coma or death. The Hunt-Hess grading system categorizes patients clinically (Table 41-2). Patients with suspected SAH should have a head CT immediately. If the CT is negative but clinical suspicion is high, a lumbar puncture should be performed to look for xanthochromia. If either is positive the patient should have a four-vessel cerebral angiography within 24 h to assess for aneurysms or other vascular malformations.

SAH patients should be resuscitated as needed and admitted to the neurologic ICU. Ruptured aneurysms require occlusion by surgical clipping or endovascular coiling according to the neurosurgeon's judgment. Certain aneurysms are more appropriate for one approach or the other. The International Subarachnoid Aneurysm Trial (ISAT) researchers suggested that endovascular occlusion resulted in better outcomes for certain types of cerebral aneurysms, however, this trial was marred by poor selection and randomization

TABLE 41-2 The Hunt-Hess Clinical Grading System for Subarachnoid Hemorrhage

Hunt-Hess grade	Clinical presentation
0	Unruptured aneurysm
1	Awake; asymptomatic or mild headache; mild nuchal rigidity
2	Awake; moderate to severe headache, cranial nerve palsy (e.g., CN III or IV), nuchal rigidity
3	Lethargic; mild focal neurologic deficit (e.g., pronator drift)
4	Stuporous; significant neurologic deficit (e.g., hemiplegia)
5	Comatose; posturing

techniques and the validity of its conclusions have been questioned. Debate also continues regarding optimal care for unruptured intracranial aneurysms.

SAH patients often require 1–3 weeks of ICU care after aneurysm occlusion for medical complications that accompany neurologic injury. In addition to routine ICU concerns, SAH patients also are at risk for cerebral vasospasm, which is pathologic vessel constriction 4–21 days after SAH, potentially causing ischemia and stroke.

Arteriovenous Malformations

AVMs are abnormal, dilated arteries and veins without an intervening capillary bed. They may bleed or cause seizures. AVMs hemorrhage at an average rate of 2–4 percent a year.

Three therapeutic modalities for AVMs are currently in common use: microsurgical excision, endovascular glue embolization, and stereotactic radiosurgery. Each has limitations so they are often used in combination.

TUMORS OF THE CENTRAL NERVOUS SYSTEM

A wide variety of tumors affect the brain and spine. Primary benign and malignant tumors arise from the various elements of the CNS, including neurons, glia, and meninges. Tumors metastasize to the CNS from many primary sources. Presentation and prognosis vary widely depending on location and histology.

Brain Tumors

Brain tumors may be clinically silent and found incidentally or cause symptoms from mass effect or seizures. Supratentorial tumors commonly present with focal neurologic deficit, such as contralateral limb weakness or visual field deficit, or headache or seizure. Infratentorial tumors often cause increased ICP because of hydrocephalus because of compression of the fourth ventricle, leading to headache, nausea, vomiting, or diplopia. Cerebellar hemisphere or brain stem dysfunction can lead to ataxia, nystagmus, or cranial nerve palsies. Infratentorial tumors rarely cause seizures. Patients with such symptoms should undergo head CT or brain MRI with contrast.

Metastatic Tumors

The sources of most cerebral metastases are (in decreasing frequency) the lung, breast, kidney, gastrointestinal (GI) tract, and melanoma. Lung and breast

cancers account for more than half of cerebral metastases. Metastases often are very well circumscribed, round, and multiple.

Craniotomy for resection of 1–3 metastases followed by whole brain radiation can improve survival. Stereotactic radiosurgery also is an option.

Glial Tumors

Glial cells provide the anatomic and physiologic support for neurons and their processes in the brain. The several types of glial cells (astrocytes, oligodendrocytes, ependymal and choroid cells) give rise to distinct primary CNS neoplasms.

Astrocytomas

Astrocytomas are the most common primary CNS neoplasm. They are graded from I–IV. Grades I and II are referred to as low-grade astrocytoma (LGA), grade III as anaplastic astrocytoma (AA), and grade IV as glioblastoma multiforme (GBM). Hypercellularity, nuclear atypia, neovascularity, and necrosis characterize higher grades. Median survival for LGA is 8 years, AA is 2–3 years, and GBM is 1 year. GBMs account for almost two-thirds of all astrocytomas, AAs account for two-thirds of the rest, and LGAs the remainder.

The treatment for GBMs and AAs is surgical resection followed by brain radiation. Management of LGAs is less clear and may involve stereotactic biopsy, resection, radiation, or observation. Adjuvant chemotherapy remains disappointing but clinical trials are ongoing. Brachytherapy with carmustine wafers provides a small increase in length of survival for GBMs.

Oligodendroglioma

These account for approximately 10 percent of gliomas. They often present with seizures and demonstrate calcifications and hemorrhage on CT. Oligodendrogliomas also are graded from I–IV; grade portends prognosis. Prognosis is slightly better overall than for astrocytomas. Median survival ranges from 2–7 years for highest and lowest grade tumors, respectively. Aggressive resection improves survival. Chemotherapy, and occasionally radiation, are adjuvants.

Ependymoma

The lining of the ventricular system consists of cuboidal/columnar ependymal cells from which ependymomas may arise. They arise from the lateral, third, and fourth ventricles and often cause symptomatic hydrocephalus. They may metastasize within the CNS. Two main histologic subtypes are papillary ependymomas and anaplastic ependymomas, with the latter characterized by increased mitotic activity and areas of necrosis. Gross total resection can result in cure. Radiation is usually administered postoperatively.

Choroid Plexus Papilloma and Carcinoma

The choroid plexus is composed of many small vascular tufts covered with cuboidal epithelium. Choroid plexus papillomas and carcinomas arise from these cells. They are uncommon. Papillomas are well circumscribed and vividly enhance because of extensive vasculature. They often present with hydrocephalus. Treatment is surgical excision; total surgical excision is curative.

Neural Tumors and Mixed Tumors

Neural and mixed tumors are a diverse group that includes tumors variously containing normal or abnormal neurons and/or normal or abnormal glial cells. Primitive neuroectodermal tumors (PNETs) arise from bipotential cells, capable of differentiating into neurons or glial cells.

Medulloblastoma

Medulloblastoma is the most common malignant pediatric brain tumor. They are usually midline in the posterior fossa and present with hydrocephalus. Histologic characteristics include densely packed small round cells with large nuclei and scant cytoplasm. They are generally not encapsulated, frequently disseminate within the CNS, and should undergo surgical resection followed by radiation therapy and chemotherapy.

Ganglioglioma

Ganglioglioma is a mixed tumor in which both neurons and glial cells are neoplastic. They present in the first three decades of life with seizures. They are usually circumscribed masses in the medial temporal lobe, often with cysts or calcium. Patients have a good prognosis after complete surgical resection.

Neural Crest Tumors

Multipotent neural crest cells develop into a variety of disparate cell types, including smooth muscle cells, sympathetic and parasympathetic neurons, melanocytes, Schwann cells, and arachnoid cap cells. They migrate in early development from the primitive neural tube throughout the body.

Miscellaneous Tumors

Meningioma

Meningiomas are derived from arachnoid cap cells of the arachnoid mater. They appear to arise from the dura mater grossly and on MRI, and so are commonly referred to as dural-based tumors. The most common intracranial locations are along the falx, the convexities (over the cerebral hemispheres), and the sphenoid wing. Less common locations include the foramen magnum, olfactory groove, and inside the lateral ventricle. Most are slow growing, encapsulated, benign tumors. Aggressive atypical or malignant meningiomas may invade adjacent bone or into the cortex. Previous cranial irradiation increases the incidence of meningiomas. Approximately 10 percent of patients with a meningioma have multiple meningiomas. Total resection is curative, although involvement with small perforating arteries or cranial nerves may make total resection of skull base tumors impossible without significant neurologic deficit. Small, asymptomatic meningiomas can be followed until symptoms present or growth is documented. Atypical and malignant meningiomas may require postoperative radiation. Patients may develop recurrences from the surgical bed or distant de novo tumors.

Vestibular Schwannoma (VS or Acoustic Neuroma)

VSs arise from the superior half of the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII). They present with progressive hearing loss, tinnitus, or balance difficulty. Large tumors may cause brain stem compression and obstructive hydrocephalus. Bilateral VSs are pathognomonic for

neurofibromatosis type 2, a syndrome resulting from chromosome 22 mutation associated with an increased incidence of meningiomas and gliomas.

Vestibular schwannomas may be treated with microsurgical resection or with stereotactic radiosurgery. The main complication of either treatment is damage to the facial nerve (cranial nerve VII), which runs through the internal auditory canal with the vestibulocochlear nerve. Risk of facial nerve dysfunction increases with increasing tumor diameter.

Pituitary Adenoma

Pituitary adenomas arise from the anterior pituitary gland. They are microadenomas if less than 1 cm in diameter, macroadenomas if larger, functional if they secrete endocrinologically active compounds, or nonfunctional (silent) if they do not. Functional tumors are often diagnosed when quite small because of endocrine symptoms. The most common endocrine syndromes are Cushing disease because of adrenocorticotrophic hormone (ACTH) secretion, Forbes-Albright syndrome because of prolactin secretion, and acromegaly because of growth hormone secretion. Nonfunctional tumors commonly present when larger because of mass effect (visual field deficits because of compression of the optic chiasm, panhypopituitarism because of compression of the gland). Pituitary apoplexy is hemorrhage into an adenoma causing abrupt headache, visual disturbance, decreased mental status, and endocrine dysfunction. It may require urgent decompressive surgery. Surgical resection is indicated to eliminate symptomatic mass effect or to attempt endocrine cure in medically refractory cases. Prolactinomas usually shrink with dopaminergic therapy. Most pituitary tumors are approached through the nose by the transsphenoidal approach. Endoscopic sinus surgery techniques may be helpful and are increasingly being used.

Hemangioblastoma

Hemangioblastomas occur almost exclusively in the posterior fossa. Twenty percent occur in patients with von Hippel-Lindau (vHL) disease, a multisystem neoplastic disorder associated with renal cell carcinoma, pheochromocytoma, and retinal angiomas. Many appear as cystic tumors with an enhancing mural (wall) nodule. Surgical resection of the nodule is curative for sporadic (non-vHL) tumors.

Lymphoma

CNS lymphoma may arise primarily in the CNS or secondary to systemic disease. Increasing incidence may be because of increasing numbers of immunocompromised people in the transplant and acquired immune deficiency syndrome (AIDS) populations. Presenting symptoms include mental status changes, headache because of increased ICP, and cranial nerve palsy because of lymphomatous meningitis (analogous to carcinomatous meningitis). Surgical excision has little role. Diagnosis often is made by stereotactic needle biopsy. Subsequent treatment includes steroids, whole brain radiation, and chemotherapy. Intrathecal methotrexate chemotherapy is an option.

Embryologic Tumors

Embryologic tumors result from embryonal remnants that fail to involute completely or differentiate properly during development.

Craniopharyngioma

Craniopharyngiomas are cystic, usually calcified lesions with bimodal incidence peaks in childhood and the fifth decade of life. Symptoms include visual field defects, endocrine dysfunction, or hydrocephalus from mass effect on the optic chiasm, pituitary, or third ventricle. Treatment is primarily surgical. These are histologically benign but clinically more malignant because of difficult resection frequently causing neurologic injury (visual loss, panhypopituitarism, diabetes insipidus, and cognitive impairment from basal frontal injury).

Epidermoid

These are cystic lesions with stratified squamous epithelial walls from trapped ectodermal cell rests that grow slowly and linearly by desquamation into the cyst cavity. The cysts contain keratin, cholesterol, and cellular debris. They occur most frequently in the cerebellopontine angle and may cause symptoms because of brain stem compression. Recurrent bouts of aseptic meningitis may occur because of release of irritating cyst contents into the subarachnoid space (Mollaret meningitis). Treatment is surgical drainage and removal of cyst wall. Intraoperative spillage of cyst contents leads to severe chemical meningitis and must be avoided by containment and aspiration.

Dermoid

Dermoids are less common than epidermoids. They contain hair follicles and sebaceous glands in addition to a squamous epithelium. Dermoids are more commonly midline structures and are associated with other anomalies than are epidermoids. They may be traumatic, as from a lumbar puncture that drags skin structures into the CNS. Bacterial meningitis may occur when associated with a dermal sinus tract to the skin. Treatment of symptomatic lesions is surgical resection, again with care to control cyst contents.

Teratoma

Teratomas are germ cell tumors that arise in the midline, often in the pineal region. They contain elements from all three embryonal layers: ectoderm, mesoderm, and endoderm. Teratomas may contain skin, cartilage, GI glands, and teeth. Teratomas with more primitive features are more malignant, although those with more differentiated tissues are more benign. Surgical excision may be attempted. Prognosis for malignant teratoma is very poor.

Spinal Tumors

A wide variety of tumors affect the spine. Approximately 20 percent of CNS tumors occur in the spine. The majority of spinal tumors are histologically benign. Understanding the concepts of spinal stability and neural compression facilitates understanding of the effects of spinal tumors. Destruction of bones or ligaments can cause spinal instability and lead to deformities such as kyphosis or subluxation and possible subsequent neural compression. Tumor growth in the spinal canal or neural foramina can cause direct compression of the spinal cord or nerve roots resulting in neurologic deficit.

Extradural Tumors

Extradural tumors comprise 55 percent of spinal tumors. This category includes tumors arising within the bony structures of the vertebrae and in the epidural

space. Destruction of the bone can lead to instability and fractures, leading to pain and/or deformity. Epidural expansion can lead to spinal cord or nerve root compression with myelopathy or radiculopathy, respectively.

Metastatic tumors. Metastatic tumors are the most common extradural tumors. Spinal metastases most commonly occur in the thoracic and lumbar vertebral bodies because the greatest volume of red bone marrow is found therein. The most common primary tumors are lymphoma, lung, breast, and prostate. Other sources include renal, colon, thyroid, sarcoma, and melanoma. Most spinal metastases create osteolytic lesions. Osteoblastic, sclerotic lesions suggest prostate cancer in men and breast cancer in women. Patients with progressing neurologic dysfunction or debilitating pain should undergo urgent surgery or radiation therapy. Preoperative neurologic function correlates with postoperative function. Patients may lose function over h. These patients should be given high-dose intravenous dexamethasone, taken immediately to MRI, and then to the operating room or radiation therapy suite, as appropriate.

Primary tumors. Hemangiomas are benign tumors found in 10 percent of people at autopsy. They occur in the vertebral bodies of the thoracolumbar spine and are frequently asymptomatic. They are often vascular and may hemorrhage, causing pain or neurologic deficit. Large hemangiomas can destabilize the body and predispose to fracture. Osteoblastic lesions include osteoid osteoma and osteoblastoma. The latter tends to be larger and more destructive. Aneurysmal bone cysts are nonneoplastic, expansile, lytic lesions containing thin-walled blood cavities that usually occur in the lamina or spinous processes of the cervicothoracic spine. They may cause pain or sufficiently weaken the bone to lead to fracture. Cancers arising primarily in the bony spine include Ewing sarcoma, osteosarcoma, chondrosarcoma, and plasmacytoma.

Intradural Extramedullary Tumors

Intradural extramedullary tumors comprise 40 percent of spinal tumors and arise from the meninges or nerve root elements. They may compress the spinal cord, causing myelopathy, or the nerve roots, causing radiculopathy. Most are benign, slow growing, and well circumscribed. Rare epidural masses include arachnoid cysts, dermoids, epidermoids, metastases, and gliomas.

Meningioma. Meningiomas arise from the arachnoid mater. They enhance on MRI, appear to have a “dural tail,” and are most frequent in the thoracic spine. Treatment is surgery.

Schwannoma. Schwannomas are derived from peripheral nerve sheath Schwann cells. They are benign, encapsulated, and tend to grow out of the parent nerve. Two-thirds are entirely intradural, one sixth are entirely extradural, and one sixth are intra- and extra-dural (“dumb-bell” shaped). Treatment is surgery to alleviate symptoms and rule-out malignant disease. Patients with multiple schwannomas likely have neurofibromatosis type 2 (NF-2).

Neurofibroma. Neurofibromas tend to be more fusiform and grow within the parent nerve, rather than forming an encapsulated mass off the nerve, as with schwannomas. They are benign but not encapsulated. Treatment is by surgery, but salvage of the parent nerve is more challenging than with schwannomas. Thoracic and high cervical nerve roots may be sacrificed, with no or minimal deficit, to improve likelihood of total resection. Patients with multiple neurofibromas likely have von Recklinghausen neurofibromatosis (NF-1).

Intramedullary Tumors

Intramedullary tumors comprise 5 percent of spinal tumors. They arise within the parenchyma of the spinal cord. Common presenting symptoms are local or radicular pain, sensory loss, weakness, or sphincter dysfunction. Patients with such symptoms should undergo MRI.

Ependymoma. Ependymomas are the most common intramedullary tumors in adults. There are several histologic variants. The myxopapillary type occurs in the conus medullaris and has a better prognosis. The cellular type occurs more frequently in the cervical cord. Many have cystic areas and may contain hemorrhage. They are more likely than astrocytomas to have a clean surgical margin. Treatment is surgery and adjuvant radiation.

Astrocytoma. Astrocytomas are the most common intramedullary tumors in children. They may be associated with a dilated central canal, referred to as syringomyelia (syrinx). They are most commonly in the cervical cord and are usually low grade. Treatment is surgery and radiation but complete excision is rarely possible because of the nonencapsulated, infiltrative nature of the tumor. As such, patients with astrocytomas fare worse overall than patients with ependymomas.

Other tumors. Other types of rare tumors include high-grade astrocytomas, dermoids, epidermoids, teratomas, hemangiomas, hemangioblastomas, and metastases. Patients usually present with pain. Prognosis depends generally on preoperative function and the histologic characteristics of the lesion.

SPINE

The spine is a complex structure subject to a wide variety of pathologic processes, including degeneration, inflammation, infection, neoplasia, and trauma. Please refer to the sections on trauma, tumor, and infection for discussions of how these processes impact the spine.

The spine consists of a series of stacked vertebrae, intervening discs, and longitudinal ligaments. The vertebrae consist of the vertebral body anteriorly and the pedicles, articular facets, laminae, and spinous processes posteriorly. The intervertebral discs are composed of the tough, fibrous outer ring (annulus fibrosus) and the spongy central material (nucleus pulposus). They cushion adjacent vertebral bodies, absorb forces transmitted to the spine, and allow some movement. The ligaments stabilize the spine by limiting the motion of adjacent vertebrae.

Two concepts critical to understanding the mechanics and pathologic processes affecting the spine are stability and neural compression.

Stability

The spinal column is the principal structural component of the axial spine. It bears significant load. The vertebrae increase in size from the top to the bottom of the spine, correlating with the increased loads the lower spine must bear. The cervical spine is the most mobile. Cervical stability depends greatly on the integrity of the ligaments that run from level to level. The thoracic spine is the least mobile, because of the rib cage. The lumbar spine has large vertebrae, supports heavy loads, and has intermediate mobility. The sacral spine (sacrum) is fused together and has no intrinsic mobility. The load borne by the lumbar spine is transmitted to the pelvis via the sacrum. The coccyx is the

inferiormost segment of the spine and does not contribute to load bearing or mobility.

A stable spine is one that can bear normal physiologic forces resulting from body mass, movement, and muscle contraction, although protecting the spinal cord and nerve roots by maintaining normal structure and alignment.

Radiographs and CT scans are good for detecting bony defects such as fractures or subluxation; MRI is better for detecting disruption of the ligaments and discs.

Neural Compression

Besides providing a stable central element of the body's support structure, the spine must also protect the spinal cord in the central canal and the nerve roots in the neural foramina. The spinal cord and nerve roots are normally suspended in CSF, free of mechanical compression. Degenerative disease, mass lesions, or traumatic movement can impinge on the CSF spaces and cause myelopathy (cord dysfunction,) or radiculopathy (nerve root dysfunction).

Myelopathy

Cord compression can lead to crush injury or ischemia because of reduced perfusion. Histopathologic changes can include edema, demyelination, gliosis (scarring), and necrosis, leading to impairments in motor, sensory, and/or autonomic function below the level of injury. Myelopathy leads to upper-motor neuron symptoms below the injury, including hyperreflexia and spasticity.

Radiculopathy

Nerve root compression causing radiculopathy can cause lower motor neuron signs (hyporeflexia, atrophy, and weakness) and sensory disturbances such as numbness, tingling sensations (paresthesias), burning sensations (dysesthesias), and shooting pain. Myelopathy and radiculopathy often present together in diseases that involve the central canal and the neural foramina. This can lead to lower motor neuron dysfunction at the level of disease, and upper motor neuron dysfunction below that level.

Patterns of Disease

Cervical Radiculopathy

The cervical nerve roots exit the central canal above the pedicle of the same-numbered vertebra and at the level of the higher adjacent intervertebral disc. Therefore a C5–C6 disc herniation will cause C6 radiculopathy. Most patients with acute disc herniations will improve without surgery. Progressive numbness, weakness, and/or refractory pain are indications for surgery. Nerves can be decompressed anteriorly by discectomy and fusion or posteriorly by hemilaminotomy.

Cervical Spondylotic Myelopathy

The term spondylosis refers to diffuse degenerative and hypertrophic changes of the discs, intervertebral joints, and ligaments. Spondylosis can cause myelopathy from cord compression, a syndrome called cervical spondylotic myelopathy (CSM). CSM presents with spasticity and hyperreflexia because of corticospinal tract dysfunction, upper extremity weakness and atrophy from degeneration of the motor neurons in the anterior horns of the spinal gray

matter, and loss of lower extremity proprioception because of dorsal column injury. Patients complain of difficulty ambulating and using buttons and utensils. Treatment is operative decompression by cervical laminectomy or anterior decompression and fusion. Patients may have significant recovery or only prevention of further worsening.

Care must be taken to avoid misdiagnosing amyotrophic lateral sclerosis (ALS, Lou Gehrig disease) as CSM because both have similar upper and lower motor neuron findings. Two findings help differentiate CSM from ALS: cranial nerve dysfunction such as dysphagia (not caused by cervical spine disease) and sensory disturbance (not found in ALS).

Thoracic Disc Herniation

Thoracic disc herniation accounts for less than 1 percent of herniated discs. They may present with radicular pain leg spasticity because of thoracic myelopathy. Discectomy often requires an anterior approach via thoracotomy.

Lumbar Radiculopathy

The anatomy of the lumbar spine is such that a disc herniation compresses the passing nerve root that exits at the next lower level. Therefore, an L4–L5 disc herniation compresses the exiting L5 nerve root. Herniated lumbar discs normally cause pain lancing down the leg (sciatica). Most improve without surgery. Lumbar discectomy is indicated for symptoms persisting more than 6–8 weeks, progressive motor deficit (e.g., foot drop), or for patients with incapacitating pain not manageable with analgesics. After lumbar discectomy, approximately two thirds of patients will have complete relief of pain, and up to 85 percent will have significant improvement.

Neurogenic Claudication

Neurogenic claudication is low back and leg pain that occurs while walking and is relieved by stopping, leaning forward, or sitting. It is caused by lumbar spinal stenosis. It must be distinguished from vascular claudication, which tends to resolve quickly with cessation of walking without need to change position, be in a stocking distribution rather than a dermatomal distribution, and be associated with cold, pale feet. Lumbar laminectomy is offered when the pain causes unacceptable functional impairment.

Cauda Equina Syndrome

Lumbar disc herniation, epidural hematoma, epidural abscess, tumor, or traumatic subluxation from trauma can cause compression of the cauda equina (the lumbar and sacral nerve roots in the thecal sac below the end of the spinal cord at L1–L2). Symptoms are urinary retention, saddle anesthesia (numbness in the perineum, genitals, inner thighs), or progressing leg weakness. The patient should have an urgent MRI and surgical decompression.

Spine Fusion Surgery

Patients who have unstable spines (because of disease or surgery) often need restabilization by fusion. Fusion occurs when a solid mass of bone grows from one vertebral body to the next. This is called arthrodesis and is the same process of bone growth and remodeling that occurs to heal a fractured bone. Movement across a spine fusion site hinders solid fusion. External orthotics (hard collars, braces) and internal fixation with wires, screws, rods, and hooks minimize

movement for the 2-4 months required for solid fusion. The arthodesis is the permanent cure; braces and fixation devices will all eventually fail if fusion does not occur.

PERIPHERAL NERVE

Common pathologic processes that compromise function of the peripheral nervous system include mechanical compression, ischemia, inflammation, and neoplasia.

Peripheral Nerve Tumors

Most peripheral nerve tumors are benign. Pain suggests malignancy. Treatment for peripheral nerve tumors is surgical resection to establish diagnosis and evaluate for signs of malignancy.

Schwannoma

Schwannomas are the most common peripheral nerve tumors. They arise from Schwann cells, which form myelin in peripheral nerves. They tend to grow slowly and eccentrically on the parent nerve and can usually be dissected free of the parent nerve for complete resection.

Neurofibroma

Neurofibromas arise within the nerve and tend to be fusiform masses. Neurofibromas are often difficult to resect completely without sacrifice of the parent nerve. Neurofibromas have a higher incidence of malignant transformation, so patients with known residual tumors require close observation.

Malignant Nerve Sheath Tumors

Patients with malignant peripheral nerve tumors typically complain of constant pain, rather than pain only on palpation, and are more likely to have motor and sensory deficits in the distribution of the parent nerve. Treatment for these tumors is radical excision, often requiring sacrifice of the parent nerve.

Entrapment Neuropathies

Neurologic dysfunction in nerves passing through a pathologically narrowed space. Typical symptoms are pain, numbness, and muscle atrophy.

Ulnar Neuropathy

The ulnar nerve is susceptible to injury in its passage posterior to the medial epicondyle in the elbow. Disease causes numbness/pain in the medial digits and intrinsic hand muscle weakness. If splinting and behavior modification fail the nerve should be surgically decompressed at the elbow.

Carpal Tunnel Syndrome

The median nerve is susceptible to injury in its passage through the carpal tunnel at the base of the palm. Disease causes numbness/pain in the lateral digits and thenar wasting. As with ulnar neuropathy, the patient should have surgical division of the flexor retinaculum if conservative measures fail.

INFECTION

Cranial

Osteomyelitis

The skull is highly vascular and resistant to infections. Paranasal sinus disease, craniotomy, or traumatic contamination can lead to osteomyelitis of the skull. *Staphylococcus aureus* and *epidermidis* are the most frequent organisms. Treatment is surgical débridement of involved bone followed by 2–4 months of antibiotics.

Subdural Empyema

Subdural empyema is a rapidly progressive pyogenic infection with fever and meningeal signs followed quickly by coma and death. Streptococci and staphylococci are the most frequently found organisms. Neurologic deficit results from inflammation of cortical blood vessels, leading to thrombosis and stroke. The treatment is urgent surgery, for lavage and microbiologic diagnosis, followed by culture-directed antibiotic therapy. Rapid intervention may minimize the chance of permanent neurologic deficit or death.

Brain Abscess

Bacteria may invade the brain by hematogenous (endocarditis) or local (sinus) routes. Cerebritis (infected brain tissue) evolves into a walled-off abscess. Typical therapy is open or needle aspiration followed by antibiotics.

Spine

Pyogenic Vertebral Osteomyelitis

Destructive bacterial infection of the vertebrae that can result from hematogenous spread or local extension. *Staphylococcus aureus* and *Enterobacter* spp. are the most frequent etiologic organisms. Patients usually present with fever and back pain. There is increased incidence in diabetics, intravenous (IV) drug abusers, and dialysis patients. Most cases can be treated successfully with antibiotics alone, although surgery may be indicated for diagnosis, medical failure, or spinal stabilization.

Tuberculous Vertebral Osteomyelitis (Pott disease)

Tuberculous vertebral osteomyelitis is a more indolent infection. It rarely involves the intervertebral disc space. Treatment is with long-term antibiotics. Again, surgery may be indicated for diagnosis or spinal stabilization.

Discitis

Discitis is most commonly a postoperative infection. Spontaneous discitis occurs more commonly in children. *S. epidermidis* and *S. aureus* account for most cases. Patients may have back pain and fevers. Persistent cases require antibiotics. Surgery is generally unnecessary.

Epidural Abscess

Epidural abscesses present with back pain, fever, and neurologic deficit. *S. aureus* and *Streptococcus* spp. are the most common organisms. The source may be hematogenous spread, local extension, or operative contamination.

Surgery is indicated for diagnosis and neural decompression. Antibiotics are then administered.

FUNCTIONAL NEUROSURGERY

Epilepsy Surgery

Patients with recurrent seizures (epilepsy) refractory to medical managements may be candidates for epilepsy surgery. Surgery can cure seizures or allow better seizure control with less and fewer medication. Epilepsy surgery may be underused, given the relatively low risk of the procedures and the crippling effects of poorly controlled epilepsy.

Anterior Temporal Lobectomy

This is preformed for complex partial seizures (CPS) originating in the medial temporal lobe. Many patients with CPS have poor seizure control on medications and can improve significantly after surgery. Risks include visual field deficit, language or memory problems, and depression, but many patients will recover.

Corpus Callosotomy

This procedure “splits” the brain and can prevent seizure activity in one hemisphere from spreading to the other. Loss of consciousness requires bilateral seizure activity. A common indication is atonic seizures with drop attacks. The posterior one-third of the callosum is spared to minimize disconnection syndrome, which is the inability to match objects in the opposite visual hemifields, to identify objects held in one hand with the other hemifield, to write with the left hand, or to name objects held in the left hand (in left hemisphere–dominant patients).

Hemispherectomy

Children with intractable epilepsy, structural anomalies in one hemisphere, and contralateral hemiplegia, may have improved seizure control after resection of the hemisphere (anatomic hemispherectomy) or disruption of all connections to the hemisphere (functional hemispherectomy).

Deep Brain Stimulators (DBS)

Fine electrical leads placed in deep brain structures can modify pathologic signals that contribute to abnormal motor activity. The stimulators are placed by MRI-guided stereotaxic systems involving fixing a rigid cage around the head with skull pins.

Essential Tremor

Essential tremors are action tremors of 4–8 Hz rhythmic oscillation that often affect one arm or the head, start in the third or fourth decade, and may respond to beta blockers. Placement of a DBS in the contralateral ventrointermediate nucleus (VIN) of the thalamus can dramatically help refractory cases.

Parkinson Disease (Paralysis Agitans)

Parkinson’s disease is a progressive disorder characterized by rigidity, bradykinesia, and resting tremor because of loss of dopamine-secreting neurons in the substantia nigra and locus ceruleus. Dopaminergic and anticholinergic agents

minimize symptoms. Refractory cases can benefit from DBSs in the subthalamic nuclei (STN) or globus pallidus pars interna (GPi) with durable symptom control and decreased medication use.

Trigeminal Neuralgia (Tic Douloureux)

This is a syndrome of repetitive, unilateral, sharp and lancinating pains in the distribution of one of the three branches of the trigeminal nerve (cranial nerve V). This seems to result from pulsatile irritation of the root entry zone by a loop of the superior cerebellar artery. The pain is excruciating and can be debilitating. Medical therapy, including carbamazepine and amitriptyline, may reduce the frequency of events. Options for medically refractory cases include percutaneous injection of glycerol into the path of the nerve, peripheral transection of the nerve branches, stereotactic radiosurgery, and microvascular decompression (MVD). MVD involves a craniotomy to move the artery away from the root entry zone of the nerve to relieve compression. It remains the first definitive management option because stereotactic radiosurgery is associated with a high incidence of facial numbness.

STEREOTACTIC RADIOSURGERY (SRS)

SRS refers to techniques that allow delivery of high-dose radiation that conforms to the shape of the target and has rapid isodose fall-off, minimizing damage to adjacent neural structures. The two most common devices for this are the LINAC (linear accelerator) and the gamma knife.

Arteriovenous Malformations

SRS is an effective therapy for AVMs up to 3 cm in diameter. SRS is best for lesions that are difficult to access surgically. SRS is not effective for lesions larger than 3 cm and is associated with a 2–4 percent hemorrhage risk per year in the 2 years it takes for AVM obliteration. There are reports of late AVM recanalization and hemorrhage. SRS may be used as an adjuvant in lesions that cannot be completely resected surgically.

Vestibular Schwannomas

SRS is an alternative to microsurgical resection for vestibular schwannomas up to 2.5 cm in maximum diameter. It seems to be associated with lower incidence of early postoperative facial nerve palsy but an increased incidence of delayed palsies. Long-term follow up is now becoming available on this modality to compare it with microsurgery.

Intracranial Metastases

Patients with solitary or multiple intracranial metastases may be treated primarily with SRS. SRS plus whole-brain radiation therapy (WBRT) seems to be similar to craniotomy plus WBRT. SRS is being explored as a treatment for multiple metastases (up to seven) because surgery is usually inappropriate for these patients. Patients with multiple intracranial metastases have almost zero long-term survival, and most will die of their intracranial disease. These patients live 3–6 months on average with medical care and WBRT. This can be extended to 9–16 months with SRS or surgery, depending on tumor type, age, and patient condition.

CONGENITAL AND DEVELOPMENTAL ANOMALIES

Dysraphism

Dysraphisms are defects of fusion of the neural tube in the spine or cranium involving the neural tube or overlying bone or skin. Neural tube defects are among the most common congenital abnormalities but can be reduced with prenatal vitamins.

Spina Bifida Occulta

Spina bifida occulta is the congenital absence of posterior vertebral elements, including the spinous processes and the laminae. Patients are neurologically normal. It is common (25 percent incidence), but asymptomatic.

Spina Bifida with Myelomeningocele

Spina bifida with myelomeningocele (MM) describes congenital absence of posterior vertebral elements with protrusion of the meninges through the defect, and underlying neural structural abnormalities. Common findings are weakness and atrophy of the lower extremities, gait disturbance, urinary incontinence, and deformities of the foot. MMs arising from the high lumbar cord usually cause total paralysis and incontinence, although those arising from the sacral cord may have only clawing of the foot and partial urinary function. MM patients always have Chiari II malformations (abnormal downward herniation of the cerebellum and brain stem through the foramen magnum) and frequently have hydrocephalus. Treatment is closure of dura, fascia and skin over the defect.

Encephalocele

Herniation of brain encased in meninges through the skull that forms an extracranial mass is referred to as encephalocele. Most occur over the convexity of the skull. Treatment is excision of the herniated tissue and closure of the defect. Most patients with encephaloceles and meningoceles have impaired cognitive development. Patients with greater amounts of herniated neural tissue tend to have more severe cognitive deficits.

Craniosynostosis

Craniosynostosis is the abnormal early fusion of a cranial suture line with resultant restriction of skull growth in the affected area and compensatory bulging at the other sutures. Skull growth occurs at the cranial sutures for the first 2 years of life, at the end of which the skull has achieved over 90 percent of its eventual adult size. Fusion may involve any of the various sutures individually or in combination and results in characteristic patterns of abnormal head shapes. Treatment involves resection of the fused sutures and cranial remodeling as needed.

Hydrocephalus

Excess CSF in the brain that results in enlarged ventricles is known as hydrocephalus (HCP). The adult forms approximately 500 mL of CSF per day. CSF flows from the lateral to third to fourth ventricles and then to the subarachnoid space, where it is absorbed into the venous blood through the arachnoid granulations. Treatment for symptomatic HCP is shunting the CSF to the peritoneum, pleura, or right atrium.

Communicating Hydrocephalus

Obstruction at the level of the arachnoid granulations causes communicating HCP. This usually causes dilation of the lateral, third, and fourth ventricles equally. The most common causes in adults are meningitis and subarachnoid hemorrhage.

Obstructive Hydrocephalus

Obstruction of CSF pathways is known as obstructive HCP. Ventricles proximal to the obstruction dilate, although those distal to the obstruction remain normal in size. It is frequently caused by periventricular tumors or cerebellar hemorrhage. Obstructive hydrocephalus may present precipitously and require urgent ventriculostomy to prevent herniation.

Chiari I Malformation

Chiari I malformation is the caudal displacement of the cerebellar tonsils below the foramen magnum. It is often asymptomatic and found incidentally. Symptomatic patients usually present with headache, neck pain, or symptoms of myelopathy, including numbness or weakness in the extremities. The brain stem and lower cranial nerves are usually normal in Chiari I malformations. Symptomatic patients may be treated with suboccipital craniectomy to remove the posterior arch of the foramen magnum and the posterior ring of C1. Removal of these bony structures relieves the compression of the cerebellar tonsils and cervicomedullary junction, and may allow reestablishment of normal CSF flow patterns.

SKELETAL GROWTH AND PHYSIOLOGY

The skeletal system is initially formed as cartilage with the exception of the craniofacial bones and clavicle. These bones do not have a cartilaginous analogue and are formed directly from membranous tissue. The process of bone formation without an intermediate cartilage form is called intramembranous bone formation. The majority of an adult's bone is formed by intramembranous bone formation because diaphyseal bone grows circumferentially by the apposition of bone by the surrounding periosteum without cartilage being produced. Endochondral ossifications is the formation of bone through the initial formation of a cartilage model that then becomes bone. The skeletal system is formed in utero as cartilage; however, prior to birth, some of these prebone structures are well on their way to bone formation. This happens first in the middle of the diaphysis, known as the primary center of ossification. Later, at the secondary ossification center, bone will begin to form at the ends of the prebone structures. The secondary center of ossification has articular cartilage surrounding it on the side facing the joint and epiphyseal cartilage on the side facing the primary ossification center. The bone grows in length through the epiphyseal growth plate, which produces cartilage that undergoes endochondral ossification.

The epiphyseal growth plate is made up of proliferating cartilage cells that eventually die. After the cartilage cells die, osteoblasts line the calcified cartilage matrix previously produced by the chondrocytes, thus forming bone. The epiphyseal growth plate is divided into zones. The number of zones often varies in the literature dependent on the author; however, a general consensus specifies five zones. The first zone is the resting or reserve zone, followed by the proliferative zone, the maturation zone, the degeneration zone, and the zone of calcification. The zones of maturation, degeneration, and calcification often are referred to as the hypertrophic zone. The initial bone formed consists of spicules of bone with a calcified cartilaginous core and is called the primary spongiosa. The calcified cartilage will be removed entirely as the bone continues to remodel. The area of the bone with the primary spongiosa is called the metaphysis. This bone remodels to become the narrower diaphysis. The initial bone formed during this process is referred to as woven bone. This bone is unorganized both grossly and microscopically. As it remodels and matures, it becomes lamellar bone. It can be either cortical bone with a blood supply and a Haversian system, or trabecular bone, which does not have a Haversian system.

Osteoporosis is defined as a loss of bone per unit of volume. A more strict definition is bone with a bone mineral density (BMD) as measured by a dual-energy x-ray absorptiometry (DEXA) scan of more than 2.5 below the norm. The norm is based on a series of bone mineral density analyses done on healthy women who were at the peak bone mass. Osteomalacia (disorder in adults) and rickets (disorder in children) are the inadequate mineralization of bone. Osteopenia is the term used to describe the radiographic appearance of a bone with less density than expected. Osteoporosis should be prevented by having young persons, especially women, take adequate amounts of calcium and vitamin D, and exercise to build their skeletal to its maximum. Osteomalacia is treated

by restoring a normal calcium metabolism. Abnormal calcium metabolism may be caused by a congenital disorder, dietary abnormalities, gastrointestinal disorders, by-pass surgery, parathyroid dysfunction, or renal disease.

JOINT ANATOMY AND PHYSIOLOGY

A diarthrodial joint is one in which a complete separation between the connecting parts is present. The diarthrodial joint contains synovial fluid, which lubricates the two articular cartilage-covered surfaces that rub against one another. The amount of articular cartilage achieved on completing growth (mid-teenage years) is the total amount a person will possess for the remainder of life. Once damaged, it cannot be replaced. Repair cartilage (fibrocartilage) can look similar and even have similar (not identical) properties, but does not have the mechanical properties to withstand the high demands placed on a joint surface. Articular cartilage is composed of hyaline cartilage, which is between 60 and 80 percent water. The remaining composition consists of macromolecules—collagen, proteoglycans, and noncollagenous proteins—which are all composed of amino acids and sugars. Type II collagen accounts for approximately 95 percent of the collagen in articular cartilage. Articular cartilage is organized into four zones or layers; superficial or gliding, middle or transitional, deep or radial, and calcified. Each has its own organization, collagen and proteoglycan contents, and function. Disruption of any layer causes the articular cartilage to malfunction. There are many other minor proteins in articular cartilage that are critical to the normal function of the cartilage.

Degenerative arthritis or osteoarthritis is the wearing away of articular cartilage. It can occur secondary to an injury, from malalignment leading to abnormal forces, from numerous conditions that interfere with the synovial lining from doing its job, or for no apparent reason. Idiopathic or osteoarthritis of old age is the most common form. The hallmark of degenerative arthritis is a loss of articular cartilage.

The synovium is critical to the normal function of the joint as it provides synovial fluid that surrounds the joint that is necessary to maintain the extremely low coefficient of friction between the articular surfaces. The synovial fluid also contains the nutrients needed for chondrocytes in the articular cartilage to survive. Normal synovial fluid is viscous, slightly yellow, and has no white blood cells, erythrocytes, or clotting factors. However, a traumatic or nonspecific reactive synovitis produces synovial fluid with decreased viscosity that can contain as many as 10,000 white blood cells. A synovitis associated with an inflammatory, noninfectious condition can have a white blood cell count of up to 50,000. Synovial fluid associated with an infectious process usually will have a white blood cell count of over 50,000 (Table 42-1).

Joints are stabilized by a combination of ligaments and muscles that cross the joint. These ligaments are subject to injury when stretched, resulting in a sprain. The degree of the injury is usually reflected in the severity of the local swelling and pain. Ligaments heal as does other collagenous tissue. Often the ligaments need surgical repair to assure that they are properly tensioned.

TUMORS OF THE MUSCULOSKELETAL SYSTEM

General Considerations

Primary tumors of the musculoskeletal system are rare. Most histogenetic tumor types have variable levels of aggressiveness and occur in benign and

TABLE 42-1 Synovial Fluid Analysis

Clinical example	Normal	Noninflammatory (osteoarthritis)	Inflammatory (rheumatoid)	Septic (bacterial)
Color	Clear	Clear yellow	Opalescent yellow	Turbid yellow to green
Viscosity	High	High	Low	Low
WBC/mm ³	200	200–2000	200–100,000	> 100,000
% PMM leukocytes	< 25%	< 25%	> 50%	> 75%
Culture	Negative	Negative	Negative	Positive
Mucin clot	Firm	Firm	Friable	Friable
Glucose (% of serum glucose)	100%	100%	50–75%	< 50%
Total protein	Normal	Normal	Elevated	Elevated

malignant forms. Table 42-2 illustrates the range of incidence and histogenesis of musculoskeletal neoplasms. The biologic behavior of tumors can vary, as reflected by the pathologic grade of the tumor. Although various grading systems exist for different tumors, in general the simplified system adopted by the Musculoskeletal Tumor Society reflects overall gross behavior differences, with benign, low-grade malignant, and high-grade malignant forms.

Characteristics. Musculoskeletal neoplasms are characterized by initial centrifugal growth from a single focus, pseudoencapsulation (formation of a zone of reactive tissue around the expanding lesion, which in malignant lesions can be focally invaded by the tumor), and a tendency to respect anatomic boundaries early in the evolution of the lesion. These tumors thus tend to spread along fascial planes and tend to remain contained in anatomic compartments, a crucial characteristic in strategies for staging and surgical treatment of these lesions.

Metastasis. Metastasis of malignant musculoskeletal neoplasms is associated with a poor prognosis. Metastases are most often pulmonary, although some tumors tend also to involve regional lymph nodes, and bony metastases also occur. Brain and visceral metastases are unusual, generally occurring only in terminal end-stage disseminated disease.

Staging. Table 42-3 shows the most widely used staging system for musculoskeletal neoplasms.

Clinical manifestations. Patients typically present with a history of pain that is often worse at night and usually is not activity related. A mass or swelling may be present, but constitutional symptoms (weight loss, fevers, night sweats, malaise) usually are absent, except in cases with disseminated disease. Lesions adjacent to joints can cause effusion, contractures, and pain with motion. Soft-tissue tumors often are painless unless there is involvement of neurovascular structures. Patients may also present with a pathologic fracture as a manifestation of benign or malignant intraosseous lesions, with bone destruction and subsequent mechanical failure.

Radiographic findings. The plain radiograph is the single most useful study in differential diagnosis of bone lesions. Considerations include the following:

TABLE 42-2 Incidence of Bone Tumors (After Dahlin)

Histology	Benign	% Cases	Malignant	% Cases
Hemopoietic (28%)			Myeloma	24.7
			Lymphoma	3.1
Chondrogenic (27%)	Osteochondroma	12.0	Primary chondrosarcoma	8.7
	Enchondroma	4.3		
	Chondroblastoma	0.7	Secondary chondrosarcoma	0.8
	Chondromyxoid fibroma	0.6		
Osteogenic (25%)	Osteoid osteoma	2.5	Osteosarcoma	9.9
	Osteoblastoma	0.7	Chondroblastic osteosarcoma	6.0
			Fibroblastic osteosarcoma	4.6
			Parosteal osteosarcoma	0.9
Unknown origin (12%)	Giant cell tumor	4.8	Ewing's sarcoma	6.2
			Giant cell tumor	0.5
			Adamantinoma	0.2
Fibrogenic (4%)	Fibroma	1.5	Fibrosarcoma	2.5
Notochordal (3.5%)			Chordoma	3.5
Vascular (0.8%)	Hemangioma	0.6	Hemangioen- dothelioma	0.1
	Hemangio- pericytoma	0.1		
Lipogenic (0.1%)	Lipoma	0.1		
Neurogenic (<1%)	Neurilemmoma	< 0.1		

1. Evidence of matrix production (bone formation, calcification)
2. Pattern of growth (permeative, geographic, moth-eaten, loculated, expansile, exophytic)
3. Presence of bony reaction to the lesion (periosteal reaction, sclerotic margination)
4. Zone of transition between the host bone and lesion (narrow or well margined versus wide or poorly defined)
5. Age of the patient
6. Bone involved (flat bone, long bone, skull, vertebrae, acral bone)
7. Location within the bone (epiphyseal, metaphyseal, diaphyseal)
8. Associated soft-tissue mass, clinical symptoms
9. Presence of solitary versus multiple lesions

Using these criteria, an accurate differential diagnosis can be formulated in most cases. Infection (osteomyelitis) must always be considered given its highly variable radiographic appearance. Metabolic, inflammatory, dysplastic, traumatic, congenital, and degenerative conditions also always are considered.

TABLE 42-3 Surgical Staging System for Musculoskeletal Tumors (After Enneking)

Stage	Characteristics	Metastases
Benign		
1	Latent	No
2	Active	No
3	Aggressive	No
Malignant		
IA	Low grade; intracompartmental	No
IB	Low grade; extracompartmental	No
IIA	High grade; intracompartmental	No
IIB	High grade; extracompartmental	No
III	Low or high grade; intra or extracompartmental	Yes

Source: Enneking WF: *Musculoskeletal tumor surgery*, London: Churchill-Livingston, 1983.

Soft-tissue lesions are better evaluated by magnetic resonance imaging (MRI) than any other type of radiographic study.

Diagnostic evaluation. Routine laboratory studies include complete blood count and differential; erythrocyte sedimentation rate; serum alkaline phosphatase, calcium, and phosphate levels, renal and liver function studies, and urinalysis. If multiple myeloma is within the differential diagnostic possibilities, determination of serum protein level or immunoelectrophoresis should also be performed.

Biopsy. For lesions with a radiographically benign appearance, imaging studies of the lesion usually are unnecessary, and the appropriate next step is tissue diagnosis by biopsy. For any potentially malignant lesion, three-dimensional imaging studies (computed tomography [CT] or, preferably, MRI) before biopsy are recommended to fully assess the extent of the lesion and to plan the biopsy procedure, minimizing potential contamination of compartments, which could compromise subsequent definitive surgery. Depending on the experience of the surgeon and pathologist, needle or trocar biopsy is appropriate for the majority of soft-tissue and bone tumors. General principles of the biopsy procedure include the following:

1. Biopsy incisions should always be longitudinal on extremities.
2. Needle biopsy tracts and incisional biopsy should be placed so that they can be excised en bloc at the time of resection.
3. Radiographic localization should be done to ensure accuracy.
4. Frozen-section examination should be done to be sure that adequate tissue has been obtained.
5. Cultures and appropriate microbiologic studies should be performed.
6. The bone biopsy cortical window should be as small as possible and oval in shape to minimize the risk of pathologic fracture.
7. Central or necrotic areas should be avoided; biopsy at the periphery of the lesion is most helpful.
8. Exposure of any major neurovascular structures should be avoided.
9. Hemostasis must be obtained to prevent hematoma, which could seed other compartments; for bone lesions suspected of malignancy, the biopsy site should be plugged with methacrylate cement to prevent hematoma.
10. Tourniquet use is helpful for intraoperative accuracy of dissection.

11. Use of a drain with its tract in line with the biopsy incision and near it will facilitate later en bloc resection.
12. Contamination of any uninvolved compartment must be avoided.
13. In general, the surgeon providing definitive treatment should also perform the biopsy whenever possible; this would usually involve a tertiary care referral center.

Treatment. In the treatment of benign and nonmetastatic malignant musculoskeletal tumors the primary goal is eradication of the disease; preservation of limb function is an important but secondary consideration. Long-term results have improved dramatically in the past two decades, and the treatment approach for malignant lesions has changed, with a shift away from amputations and toward limb salvage procedures. The specific treatment varies with the lesion but usually includes a combination of several modalities: surgery, chemotherapy, and radiotherapy.

Specific Musculoskeletal Tumors

Osteoid osteoma. This benign bone-forming lesion primarily affects patients under 30 years of age and has a male preponderance. Patients present with local pain, which can be quite severe and often is relieved by aspirin. Radiographically, a small (less than 1 cm) lucent lesion (nidus) is seen, typically surrounded by marked reactive sclerosis. Sometimes areas of radiodensity are seen within the lucent lesion, corresponding histologically to disorganized woven bone formation. The lesion gradually regresses over a period of 5–10 years, but most patients are unable to tolerate the symptoms and opt for surgical resection of the lesion, which usually is curative if the entire nidus is removed.

Osteosarcoma. Osteosarcoma is the most common primary bone malignancy apart from multiple myeloma, although it is nonetheless a rare disease (incidence 2.8/1,000,000). Patients 10–25 years of age most often are affected, and the most common sites are areas of maximal bone growth (distal femur—52 percent; proximal tibia—20 percent; proximal humerus—9 percent). Usually the lesions are metaphyseal. Although any bone can be involved, the disease seldom occurs in the small bones of the distal extremities and in the spine. This disease has a number of variants: (1) “classic” central or medullary high-grade osteosarcoma; (2) periosteal osteosarcoma; (3) parosteal osteosarcoma; (4) osteosarcoma secondary to malignant degeneration of Paget disease, fibrous dysplasia, or radiation; and (5) telangiectatic osteosarcoma.

Osteosarcoma exhibits a blastic radiographic appearance in most cases because of the neoplastic woven bone formation. The periosteum may be raised off the bone by the tumor mass, causing a fusiform swelling with reactive periosteal bone at the periosteal margins (Codman triangle). The malignant bone formation may have a sunburst appearance, with invasion into adjacent compartments. Pathologic fractures can occur but are unusual.

Histologically, the tumor consists of small pleomorphic spindle cells, with osteoid and woven bone formation, and there is often cartilage formation as well. Cartilage formation is a prominent feature of periosteal and parosteal variants of osteosarcoma. Telangiectatic variants are lytic and expansile, resembling an aneurysmal bone cyst, and have prominent vascular spaces and relatively sparse bone formation.

Patients present with pain that often is nocturnal and a mass or swelling. Metastatic spread usually is pulmonary, and evaluation of the chest by CT

is necessary. Serum alkaline phosphatase levels may be markedly elevated, but laboratory studies are otherwise usually negative. Evaluation also should include bone scan to rule out bone metastases, and CT or, preferably, MRI of the region for surgical planning. Most osteosarcomas present as stage IIB lesions.

Osteosarcoma is not particularly sensitive to radiation, but it does typically respond well to combination chemotherapy. Depending on the extent and location of the lesion, treatment typically involves wide surgical resection or amputation, usually after preoperative (neoadjuvant) chemotherapy. Bone resected in limb salvage operations can be reconstructed by custom prosthetic replacement, arthrodesis, or allografting. Results of combination chemotherapy with resection are better than even radical surgical amputation without adjuvant therapy, with 50–70 percent 5-year survival rates and usually better than 90 percent local control (compared with a 20 percent 5-year survival rate with radical surgery alone). Pathologic fracture, with contamination of all compartments, can preclude limb salvage surgery. Chemotherapy is continued after surgery for 1 year. Prosthetic designs that can be periodically lengthened by a minor surgical procedure allow limb salvage even in relatively young children with osteosarcoma, in whom progressive limb length discrepancy might otherwise be a severe problem. Preoperative intraarterial chemotherapy and radiotherapy have been used instead of neoadjuvant systemic chemotherapy, and results appear to be comparable.

Osteochondroma (exostosis). This lesion is a common exophytic benign lesion that occurs during childhood, usually in the metaphyses of the long bones. It is thought to result from an aberrant fragment of the growth plate that is left behind and undergoes spontaneous growth. The lesions have a bony base with a cartilaginous cap, from which the growth occurs as it does in normal growth plates during childhood. A multiple hereditary form occurs and was discussed earlier. There is a familial condition called multiple hereditary exostosis in which patients have many osteochondroma. It has a variable penetrance. The lesions may cause pain from impingement on tendons, nerves, or muscle and frequently require surgical excision. Growth of the lesion, although not of concern in children, may indicate malignant transformation in adults. A cartilaginous cap thickness of more than 1 cm (assessed by CT or MRI) should arouse suspicion of malignancy. In solitary lesions the risk of malignant degeneration is less than 1 percent, although in multiple lesions it may be as high as 15 percent. Marginal to wide excision of benign or malignant lesions usually is curative if all the cartilage is removed.

Enchondroma. Enchondromas are intramedullary cartilage lesions, often exhibiting calcification and expansion of the bone. The small bones of the hands and feet are commonly involved, but long bone involvement also occurs. The disease occurs in solitary and multiple forms. Patients may present with pain or pathologic fracture. The usual treatment is intralesional resection (curettage) and bone grafting. The most serious concern is the possibility of malignant degeneration, and careful sampling at the time of biopsy is necessary to exclude the possibility of chondrosarcoma.

Chondroblastoma. This is one of the few epiphyseal tumors and occurs most often in the first and second decades of life, when the growth plate is still open. Patients present with pain, joint effusions, or contractures, and radiographs show a lytic lesion with calcifications in the epiphysis. The lesion is composed

of chondroblasts, cartilage, giant cells, and vascular stroma. Treatment is by curettage and bone grafting and often is challenging because of the intraarticular location of the lesions. A rare malignant epiphyseal cartilage tumor in older adults, clear cell chondrosarcoma, probably represents the malignant degenerative counterpart of chondroblastoma.

Chondrosarcoma. Chondrosarcoma can be primary or secondary (as discussed above) and affects a broad age range (age 20–60 years). The pelvis, femur, tibia, and other long bones can be involved, and lesions closer to the axial skeleton are more likely to be malignant. Intramedullary calcifications are usually evident. Differential diagnosis includes bone infarction and enchondroma. Features of cortical destruction and pain are important indicators of possible malignancy. The tumors are graded as low, intermediate, or high grade of malignancy on the basis of cytologic features and presence of matrix production. Lower-grade lesions can be treated by wide resection, but with high-grade lesions metastatic disease is frequent and the prognosis is poor. Limb salvage surgery often is feasible, but adjuvant treatments are not particularly helpful because these lesions tend to be resistant to chemotherapy and radiotherapy.

Unicameral (solitary) bone cyst. This lesion occurs in children in the metaphysis of the long bones adjacent to the growth plate, most often the humerus or femur, although the radius, calcaneus, and tibia also can be affected. Usually the lesions are painless and may present with a pathologic fracture as the initial manifestation of the disease. The lesions are lytic, expansile, and well marginated, and may be found in the diaphysis in older children as a result of continued growth of the growth plate away from the lesion. In young children fractures heal, but the lesions usually recur, causing recurrent fractures during childhood. The cyst fluid contains high levels of bone resorptive cytokines, presumably produced by the living tissue and accounting for the aggressive bone resorption in these lesions. At skeletal maturity the cysts tend gradually to disappear. In older children and young adults, the lesions become latent (stage I) and do not progress. Recurrence rates in active (stage II) lesions in younger children after surgical treatment (curettage and bone grafting) average 50 percent. Partial or complete healing of the majority of these lesions has been obtained after intraosseous injection of methylprednisolone, currently the preferred treatment (70–90 percent effective with up to three sequential injections). In older children or adults with latent cysts, curettage and bone grafting is effective, and steroid injections appear to have little effect.

Aneurysmal bone cyst. This tumor, found most often in children or young adults, consists of a cystic lesion with large vascular spaces, characterized by aggressive, expansile lysis of bone. The tumor is composed of fibrous tissue, vascular spaces with a lining resembling endothelium, giant cells, and reactive bone formation at the periphery. Aneurysmal cysts can arise as a secondary degenerative vascular lesion within another primary benign or malignant bone tumor, such as giant cell tumor or chondroblastoma; however, about half are thought to represent primary lesions. Because recurrence is relatively frequent with simple curettage, local resection with bone grafting is preferable. Embolization has been used successfully in unresectable spinal or pelvic lesions, as has intermediate-dose radiation treatment. Preoperative embolization of large lesions is helpful in decreasing the risk of hemorrhage.

Round Cell Tumors

Ewing sarcoma. Ewing sarcoma is a highly malignant primary bone tumor of children (age range 5–15 years) that tends to arise in the diaphyses of long bones. The spine and pelvis also may be primary sites. The radiographic appearance usually is that of an aggressive lesion, with a permeative pattern of bone lysis and periosteal reaction. Often there is an associated large soft-tissue mass, and patients have systemic symptoms (fever, weight loss) in addition to local pain, which tends to be worse at night. A soft-tissue variant of Ewing sarcoma, primitive neuroectodermal tumor (PNET), occurs as well, usually exhibiting evidence of neural differentiation immunohistochemically. Differential diagnosis includes osteomyelitis, lymphoma, and eosinophilic granuloma. Diagnostic evaluation includes chest and abdominal CT scans and bone scan to rule out metastases. Treatment consists of a combination of local radiation therapy and systemic chemotherapy. Five-year survival rates with this approach are around 50 percent. A multimodality treatment that uses adjuvant surgery (wide or marginal resection) has resulted in 5-year survival rates of 75 percent. In young children amputation may be necessary because of the severe compromise of bone growth that can result from the effect of the required levels of radiation on the growth plates.

Giant cell tumor of bone. These tumors arise in the epiphyses of young adults, most commonly in the proximal tibia, distal femur, proximal femur, and distal radius. Characteristically the lesion is radiographically purely lytic, well circumscribed, and occasionally expansile with cortical destruction. The lesion often extends to the subchondral surface and can even invade the joint. Although usually benign, a malignant variant occurs in a small proportion of cases, and even the benign lesions are stage III tumors, with local aggressive behavior and a high tendency to recur after surgical treatment. Patients usually present with pain, and pathologic fracture may occur. The tumor consists of monocytic stromal cells, vascular tissue, and sheets of large, multi-nucleated osteoclast-like cells. The key feature in differentiating these tumors from other tumors that can contain large numbers of giant cells (eosinophilic granuloma, brown tumor of hyperparathyroidism, aneurysmal bone cyst, chondroblastoma, osteoblastoma, nonossifying fibroma) is that the oval nuclei of the monocytic stroma resemble those of the giant cells, suggesting a common origin. The most common cause of malignant giant cell tumors is prior radiation therapy for a benign giant cell tumor, which was a former mode of treatment and can be associated with malignant recurrence in up to 10 percent of cases. Because of this radiation is no longer used in the treatment of giant cell tumors except in dire circumstances (such as unresectable lesions in the spine with threat of neurologic deficit).

The most common treatment of a giant cell tumor, curettage of the lesion, is associated with recurrences in 25–50 percent of cases. Alternative treatments therefore have included wide resection (usually reserved for recurrent cases) and adjuvant local treatments such as cryotherapy with liquid nitrogen or phenol and, most recently, filling the defect with methyl methacrylate. The lowest recurrence rates have been with cryotherapy and methyl methacrylate cementation. Cementation causes a thermal kill of tissue within several millimeters of the margin in bone as a result of the exothermic reaction that occurs during polymerization of the cement. If local recurrence occurs after cementation, it is readily detectable radiographically as a lucency next to the cement. With bone grafting, remodeling changes in the graft can obscure signs of recurrence.

Because these are epiphyseal lesions, the presence of cement next to the articular cartilage may predispose to cartilage degeneration, and in young patients, some advise removal of the cement and bone grafting after 2 years if the patient remains free of recurrence. Given an incidence of joint degeneration of only 15–20 percent in long-term follow-up studies, the indications for cement removal are controversial. Control of the lesion with this treatment approach has been successful in 90 percent of cases.

Vascular Tumors

Metastatic Bone Tumors

Carcinomas often metastasize to the skeleton, and metastatic lesions are much more common than primary bone lesions in general orthopaedic practice. The five primary cancers with a strong propensity to metastasize to bone are those originating in the breast, prostate, lung, kidney, and thyroid. Multiple myeloma, although technically a primary bone tumor, also must be considered in this group because of its similar age distribution (patients over age 50 years), radiographic presentation, and orthopaedic problems and treatment (pathologic fractures). Over 90 percent of patients with metastatic breast or prostate carcinoma have at least microscopic bone involvement.

The axial skeleton, including the skull, thoracic spine, ribs, lumbar spine, and pelvis, is most commonly involved. The proximal long bones, particularly the humerus and femur, also are affected frequently. Acral (distal) metastases are uncommon and are almost always secondary to lung carcinoma when they do occur. The predilection of particular tumors for bone, and for particular regions of specific bones, is thought to be caused by cytokines, local growth factors, or matrix components that attract and support growth of these lesions in specific areas. Lesions can be blastic (breast, prostate), lytic (breast, lung, myeloma, kidney, thyroid), or mixed (breast, lung) in radiographic appearance. Blastic or sclerotic lesions are less prone to pathologic fractures.

EVALUATION OF THE MUSCULOSKELETAL SYSTEM

History and Physical Examination

Collecting a thorough history and performing a physical examination is the foremost priority when examining a patient who has a musculoskeletal condition. The physical examination is concentrated on the musculoskeletal system, including its neurologic aspects, but a complete general examination is also important. The patient's chief complaint should direct the nature of history taking. Because the most common complaint is pain, it is important to note its location, duration, its intensity, how long it lasts, what makes it worse, what makes it better, and what they do to relieve it. It is also important to know what past treatments have been employed and their results. In conjunction with a past medical and familial history, a social history is often important for conditions of the musculoskeletal system because many problematic musculoskeletal system conditions are a result of the patient's occupation or hobby. Additionally, decisions about treatment should take the patient's expectations and physical requirements into consideration.

The initial aspect of the physical examination is to observe the patient's general condition. The patient should be wearing a minimal amount of clothing. Observe how the patient moves about, examining their gait pattern. An antalgic gait indicates pain. Its feature is marked by a shortened period of time with

the extremity bearing weight. A Trendelenburg gait or gluteus medius limp is caused by malfunction of the hip abductor mechanism. A positive indicator for Trendelenburg sign is if the patient leans toward the affected side when the opposite extremity is raised off the floor. The following questions may help to elucidate additional musculoskeletal dysfunctions: Is the alignment of the lower extremities symmetric? Do the upper extremities move symmetrically? Does the patient stand straight? Additionally, the patient's range-of-motion (ROM) of all joints should be measured and areas of interest palpated. Joints should be inspected for effusion. A check of the vascular supply and a neurologic examination should also be performed.

Virtually all patients with musculoskeletal complaints should have plain radiographs. The minimum is two views taken perpendicular to one another. Once these have been examined, a differential diagnosis can be made which usually includes only a few conditions. Additional diagnostic tests may be needed before a treatment plan can be finalized.

The evaluation of a patient who has sustained acute trauma requires a slightly different approach, which involves collecting a detailed summary of the events of the injury. The following questions may be helpful in this effort: What was the patient doing when the patient was injured? Was the twist internal rotation or external rotation? Can the patient estimate the height from which the patient fell? Was the patient a pedestrian, cyclist, or passenger in or driver of an automobile? Was the patient wearing a seatbelt? Did the patient lose consciousness? Was the patient ejected from the vehicle? Answers to questions such as these can provide clues to the degree of injury and indicate possible associated injuries that should be looked for.

The measurement of joint motion is important and can be ascertained with the help of a goniometer. Comparing the affected side to the unaffected side is useful. In general, 0 degrees is the neutral anatomic position. Movements into the plane anterior to the body are flexion and movements into the plane posterior to the body are extension. Rotation (internal and external), abduction, and adduction are also important indicators to the measurement of motion. In general, flexion and extension are maintained longer than rotation, abduction, and adduction. Loss of motion can be from pathology intrinsic or extrinsic to the joint. For example, a patient with loss of flexion, rotation, and abduction in the hip might have degenerative disease of the hip joint or the patient might have muscular contractures. A careful analysis of the patient should distinguish between intrinsic and extrinsic causes.

Joint stability is important and ligaments are examined by stressing the joint in various directions. The knee, shoulder, elbow, and ankle are all joints commonly associated with injuries that lead to ligamentous disruption. The specifics for each of these joints are described in their respective sections.

The vascular supply to the extremity should be determined. If the patient has good pulses of the dorsalis pedis, posterior tibial, radial, and ulnar arteries, significant vascular injury or arterial disease is unlikely. Those patients without peripheral pulses should be examined more thoroughly to determine the status of the vascular supply. Edema should be noted if present.

After physical examination, plain radiographs are the single-most important diagnostic tool for evaluating a patient with a complaint related to the musculoskeletal system. Before obtaining a computerized tomography (CT scan) or an MRI, a plain radiograph should always be taken. A minimum of two views at right angles to one another should be obtained. Obliques are often useful to visualize certain aspects of the skeletal anatomy. The quality of the

radiograph is important; the bone should be clearly seen and the soft tissues, although visible, should not interfere with visualization of the bone.

Nuclear studies often are used to evaluate the skeletal system. Technetium-99 (99Tc) bone scans are the most commonly used study. The 99Tc is tagged to phosphorus, which attaches itself to the bone. The amount of 99Tc attached to the bone is directly related to bone formation. Therefore, any reactivity of the bone is seen as a "hot" spot. The patient is injected with the 99Tc and approximately 2 h later images are taken. The scan is sensitive but not specific. Indium (In) scans are used primarily to determine if there is an infection. White blood cells from the patient are tagged with Indium and injected into the patient. Because the tagged white blood cells concentrate at the site of an infection, the scan has a "hot" spot. Thallium scans also are occasionally used to identify soft-tissue inflammatory lesions.

Computed axial tomography (CAT) is the best method to use for visualizing the details of bone and calcifications. It is often used to evaluate fractures, especially comminuted ones and those involving an articular surface. Three-dimensional reconstructions can be done to better evaluate the injury. Computed tomography is useful in the evaluation of patients with suspected herniated nucleus pulposus, although MRI is probably better.

MRI is most valuable for the examination of soft tissues. It is particularly valuable in examining the soft tissue around joints. Torn ligaments and meniscus can usually be seen on an MRI. It is also an excellent means of examining the soft tissues of the extremities and the spine. The spinal canal is visible and damage to the spinal cord can be seen easily.

DISORDERS OF THE MUSCULOSKELETAL SYSTEM

Osteomyelitis

Osteomyelitis is an infection of the bone that most commonly occurs secondary to an open wound with an associated or compound fracture. However, osteomyelitis also can occur spontaneously, presumably as a consequence of circulating bacteria in the bloodstream, and is known as hematogenous osteomyelitis. Hematogenous osteomyelitis is an infection that predominantly occurs in children. The most common causative organism is *Staphylococcus*, but any bacteria can produce osteomyelitis. Less-common infectious agents include viruses, fungi, and mycobacteria. Osteomyelitis is divided into "acute" and "chronic" categories. Although the time limits delineating one category from the other are somewhat arbitrary, as a rule, infections up to 3 months' duration are termed acute, although those enduring longer than 3 months are termed chronic. In general, acute osteomyelitis is associated with systemic findings of an infection with fever, malaise, elevated white blood cell count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). The site of the infection is tender and the patient often does not want to move the extremity involved. Patients with chronic osteomyelitis usually are not systemically sick. They are more likely to have a draining sinus, necrotic bone (a sequestrum) surrounded by reactive bone (an involucrum).

Hematogenous osteomyelitis often is associated with an infection within a joint, or pyarthrosis. Joint infections also can occur without bone involvement and should be recognized and treated as soon as possible to reduce damage to the articular cartilage.

Arthritis

There are a variety of pathways by which a joint is transformed from an efficient, mobile, low-friction, shock-absorbing, and energy-conserving structure to one that is painful and stiff. One common pathway involves greater or lesser degrees of destruction of articular cartilage.

Osteoarthritis

Osteoarthritis (OA) is the most common form of arthritis, with up to 40 million people in the United States having been diagnosed with it. Also known as degenerative joint disease, OA generally has been considered to be non-inflammatory. Some prefer to refer to this disease as osteoarthrosis, changing the suffix -itis to -osis to emphasize the noninflammatory degenerative nature of this ailment. In fact, the same cytokines and interleukins seen in inflammatory arthritis also are seen in osteoarthritis, although in lesser quantity.

Typical findings on a radiographic examination reveal loss of articular cartilage, osteophytes, and subchondral cysts.

Physical examination reveals pain on walking (an antalgic gait pattern) or motion of the involved joint. Patients have some degree of limitation of motion, pain and/or crepitus with that motion. There usually is an effusion in the joint.

The initial treatment includes activity modification, weight reduction if indicated, the use of a cane for lower-extremity problems, and nonsteroidal anti-inflammatory and nonnarcotic analgesics medications if required. Patients should be encouraged to maintain their joint motion and muscular strength. If they cannot do this on their own, they should be referred to a physical therapist. Joint replacement is recommended to relieve pain and restore function to the arthritic joint for the patient whose symptoms persist despite nonoperative management.

Rheumatoid Arthritis

Rheumatoid arthritis is the most common form of inflammatory arthritis. It is an apparent autoimmune response that involves synovium, articular cartilage, and soft tissue. The joints of the hand are most commonly involved, but wrists, feet, knees, and hips are frequently affected. This disease is often symmetric, (i.e., both knees and both hands). Patients frequently suffer from morning stiffness. Subcutaneous nodules may be palpated, especially at the proximal ulna. The rheumatoid arthritis (RA) factor is positive in approximately 80 percent of patients.

Typical radiographs show loss of articular cartilage, osteopenia, and peri-articular erosions. A typical hip deformity of the femoral protruding medially into the pelvis (protrusio acetabulum) is not uncommon. These patients can have vasculitis, pericarditis, and pulmonary involvement.

Lyme disease is a tick-borne (deer tick, *Ixodes dammini*) illness caused by the spirochete *Borrelia burgdorferi*. Affected patients may have intermittent attacks of swelling in one or more large joints, accompanied by a characteristic skin rash (*erythema chronicum migrans*) that often precedes the arthritis. The knee is the most effected joint. A serum Lyme titer is diagnostic. Treatment includes tetracycline, penicillin, or erythromycin.

Gout results from abnormalities in the metabolism of urate that causes deposition of urate crystals in joints, kidneys, and musculoskeletal soft tissues.

When deposited in the synovium, the urate crystals may cause an acute inflammatory reaction. The patient often presents with acute onset of pain, swelling, and erythema of a single joint. The most commonly effected joint is the first metatarsophalangeal (MP) joint of the foot. The patient has elevated serum uric acid levels and urate crystals are seen on an analysis of the joint fluid. The crystals are long and thin. Colchicine has been used since the days of Hippocrates. A 0.65-mg dose is given orally every 1–2 h until the pain subsides or diarrhea begins. For less-painful episodes, nonsteroidal antiinflammatory medication can be used. Patients with gout should be treated to lower their serum urate levels.

Calcium pyrophosphate deposition disease (CPPD or pseudogout) is also an inflammatory synovial disorder caused by crystals. The crystals of CPPD are calcium pyrophosphate. The presentation is similar to gout but usually not as painful. Calcifications are often seen in the cartilage or meniscus. The crystals can be seen on analysis of the joint fluid. They are short and rectangular. Nonsteroidal antiinflammatory medication usually is sufficient treatment.

Infectious Arthritis

Infectious arthritis, also known as septic arthritis or pyarthrosis, is relatively uncommon. It most often is seen in patients younger than age 5 years or older than age 80 years. However, both morbidity and mortality rates can be relatively high. The knee and hip are the joints most typically infected. *Staphylococcus aureus*, streptococci, and gonococci are the organisms most typically involved. Viruses, mycobacteria, fungal agents, and Lyme disease are other causes. Early diagnosis and treatment limits joint destruction and preserves function. Early joint drainage and lavage are the mainstays of treatment, followed by intravenous antibiotics. Hematogenous seeding during a transient or persistent bacteremia is believed to be the most common mechanism in septic arthritis. The American College of Rheumatology defines septic arthritis as a synovial fluid aspirate that demonstrates a minimum of 50,000 white blood cells (WBC) per high-powered field and at least 80 percent neutrophils on differential count. In patients with previous total joint replacements, much lower counts can be diagnostic (see Table 42-1).

TRAUMA

Initial Assessment

The initial evaluation of the injured patient should be geared toward identifying life-threatening injuries. Injuries to the chest, head, abdomen, and major vessels may require emergent treatment and take precedence over most musculoskeletal injuries. Patients in shock must be treated aggressively with volume replacement. Unstable pelvic fractures often require some type of stabilization to control hemorrhage. Occult arterial bleeding requires emergency arteriography and embolization.

The trauma surgeon, in conjunction with the orthopaedic surgeon, should make the assessment of skeletal injuries. Evaluation of all open injuries, long-bone fractures, and spinal injuries is imperative. The patient should not be mobilized until appropriate radiographs of the spine have been taken and evaluated. Anterior and posterior radiographs of the cervical spine are the minimal requirement. The extremities need to be evaluated for neurovascular compromise, soft-tissue and bony injuries, and ligamentous injuries. Sensory and

motor examinations, including peripheral pulses and capillary refill, should be evaluated and carefully documented.

Injured extremities need to be splinted for soft-tissue management and mobilization of the patient. Skeletal traction should be considered for long-bone fractures when the patients are not going directly to the operating room, but femur fractures in multiply injured patients require stabilization as soon as possible.

An open fracture is defined as any fracture that is exposed to the outside environment. This can result from a penetrating injury that has caused a fracture or from a displaced fragment of bone that has violated the skin. Open fractures often are caused by high-energy injuries and associated injuries should be sought.

The early goals of treatment should include immediate irrigation and débridement combined with skeletal stabilization to prevent infection and to facilitate soft-tissue healing. Vascular injuries, larger wounds, greater comminution, and soft-tissue loss all are associated with increased risk of osteomyelitis. Once osteomyelitis has been established, it may be extremely difficult to eradicate. Therefore, early treatment should include aggressive and immediate débridement of the wound and fracture site in an operative environment and intravenous antibiotic therapy. Repeat intraoperative débridement is recommended when significant soft-tissue damage or contamination is present. Primary closure of wounds is controversial. Open wounds with fractures are classified to indicate the degree of damage and allow easy communication of injury level (Table 42-4). Low-grade, open wounds often are closed and sometimes not emergently débrided. This remains controversial and should not be the standard for surgeons inexperienced in dealing with open fractures. Higher-grade, open wounds will need surgical evaluation by a plastic surgeon as soon as possible. The orthopaedic surgeon and the plastic surgeon must work together to achieve soft-tissue closure, to prevent infection, and to achieve bony union. Ultimately, a prolonged course of rehabilitation will be necessary to ensure the best possible function for these patients.

The first principle of treatment involves reduction of the fracture. If a fracture is truly nondisplaced, then no reduction is necessary. For displaced fractures and dislocations, a reduction maneuver usually is performed. For extra-articular fractures, this often is unnecessary. Guidelines for determining what an adequate reduction is exist as a range of parameters; however, these parameters may differ among surgeons. In general, lower extremities require more precise reduction. Intraarticular fractures require an almost anatomic reduction. The second principle of treatment is to maintain the reduction. There is an arsenal of treatment methods available to the orthopaedic surgeon, including internal fixation and external fixation. External fixation includes casts or skeletal external fixation with percutaneous pins and external fixators. Internal fixation includes screw fixation, plate fixation, intramedullary fixation, and other types of metals or absorbable materials for fixation. In some cases,

TABLE 42-4 Grading of Open Wounds

Type I	Low energy, <1 cm
Type II	Modest energy, >1 cm
Type III	High energy, usually >10 cm
A	No vascular involvement
B	Vascular injury

a suture fixation is all that is necessary. Surgeons with different training can successfully treat the same fracture by totally different, but equally acceptable, methods. It is important to remember that the goal of treatment is function and how the reduction is maintained is simply a means to the end.

Terminology

It is useful for surgeons of all disciplines to understand some basic orthopaedic terminology. Orthopaedic surgeons use different terms to facilitate communication. Understanding these concepts and terms will help the physician communicate with the orthopaedist. A fracture is determined to be open when the fracture communicates with the outside environment. Fortunately, most fractures are closed and the soft-tissue envelope is intact. However, the internal soft-tissue injury can be quite variable and attempts have been made to classify the soft-tissue injury with closed fractures. The orthopaedic surgeon is aware that there are low-energy closed fractures and high-energy closed fractures. High-energy closed fractures generally are more difficult to treat because they tend to be more "displaced." Displacement is defined as fracture ends that are no longer contiguous. The authors describe displacement based on the distal segment. The distal segment can be medial or lateral on an anteroposterior radiograph. The distal segment can be anterior or posterior on a lateral radiograph.

Fractures are often "angulated." Angulation is described by the vertex of the angulation. The authors measure angulation by the deviation from normal alignment. If the vertex points anterior, then "anterior angulation" is present. Anterior and posterior angulation can be seen on lateral radiographs. Anterior/posterior radiographs can show "varus" or "valgus" angulation. If the fracture has a vertex that points medially, the fracture is in "valgus." If the vertex points laterally, the fracture is in "varus."

Rotational malalignment is sometimes difficult to determine on plain radiographs. Often this is quite evident by the clinical appearance of the extremity. If the distal portion of the extremity is rotated externally, then "external rotation" is present. Conversely, if the distal portion of the extremity is rotated internally, the fracture is described as being "internally rotated." Radiographically, a joint should be viewed from above and below to see the rotational alignment. This visualization of the joints, above and below the fracture, also is necessary to determine if there has been a joint injury associated with the fracture.

If a long bone is displaced 100 percent, it is said that "shortening" of the fracture has occurred. Shortening can be seen on either anteroposterior (AP) or lateral radiographs. The amount of shortening will not change from AP to lateral radiographs. However, two radiographs in planes 90 degrees to each other are necessary to visualize translation and angulation.

Pelvic Fractures

Injuries to the pelvic ring should be differentiated between the low-energy, stable fractures and the high-energy, life-threatening injuries. The former are commonly seen in older adult osteoporotic patients who may have sustained isolated fractures of the pubic rami or nondisplaced fractures of the acetabuli or sacrum from a fall. These fractures usually do not have disruption of the pelvic ring or weight-bearing segments and are considered stable.

High-energy injuries are the result of automobile collisions, pedestrians and cyclists being struck by motor vehicles, or falls from significant heights.

These injuries are caused by direct crush, either from the anterior or lateral direction or vertical shear, or combinations of rotational stress on the iliac wings. Initial evaluation of pelvic injuries includes an AP radiograph. Further imaging includes inlet and outlet views. Associated acetabular fractures and lumbar spine injuries require 45-degree oblique (Judet) views and AP and lateral radiographs of the lumbosacral spine. Most pelvic injuries will also need a CT scan with 3-mm cuts to evaluate a posterior injury to the pelvis. A CT scan is best used for evaluation of the sacrum and sacroiliac joints.

Continued, unexplained blood loss despite fracture stabilization and aggressive resuscitation is an indication for angiography. Early recognition of potential arterial bleeding should include early notification of the interventional radiology team. Angiography and embolization may be required in up to 20 percent of AP injuries, vertical shear injuries, and combined mechanical injuries.

Acetabular Fractures

Acetabular fractures are a subset of pelvic fractures that involve the acetabulum. These intraarticular fractures may result in posttraumatic arthritis of the hip and are sometimes associated with hip dislocations, which are discussed in the next section.

Thorough evaluation of acetabulum fractures requires 45-degree oblique views (Judet views) of the pelvis to assess the integrity of the anterior and posterior columns and the anterior and posterior walls. Additionally, CT scans are helpful in fully delineating fracture patterns and demonstrating the presence of intraarticular bony fragments. Nondisplaced or minimally displaced fractures are determined after complete evaluation of the radiographs and acetabular CT scans. Radiographs should be taken with traction removed and preferably with stress applied. Any degree of incongruence involving the weight-bearing surface of the acetabulum is unacceptable and is an indication for surgical treatment. Nondisplaced fractures may be treated with a period of traction followed by progressive weight bearing.

Hip Dislocation

Dislocation of the hip often is caused by a force applied to the femur and can be associated with fractures of the acetabulum or femoral head. The most common mechanism of injury is motor vehicles accidents. Force applied to an abducted hip can result in anterior dislocation, although striking the knee on a car dashboard with the hip flexed and adducted, results in posterior dislocations. Posterior dislocations often are associated with a fracture of the posterior wall of the acetabulum. Direct trauma to the greater trochanter from a lateral direction can result in medial wall fractures or central acetabular fractures/dislocations.

Thorough evaluation of hip dislocations often requires Judet radiographic views and additional CT scans. Similar to patients with pelvic fractures, these patients may have other major injuries and careful evaluation of the chest, abdomen, spine, and neurologic status is necessary. Prompt reduction of hip dislocations is essential in minimizing the incidence of osteonecrosis of the femoral head.

Femur Fractures

The mortality and morbidity of proximal femur fractures has significantly improved with modern methods of treatment. However, a proximal femur fracture still represents a major challenge to the health care system with the increasing age of our population. These fractures generally occur in the seventh and eighth decades of life. Femoral neck and intertrochanteric fractures occur with approximately equal frequency and similar epidemiology. Osteoporosis is a major contributing factor to hip fractures. An increasing awareness of this disease accompanied by new methods of treatment may facilitate the prevention of proximal femur fractures. This is extremely significant in light of the high mortality rate of hip fractures in older adults, which have been reported to be as high as 50 percent in the first year.

Femoral Neck Fractures

Femoral neck fractures most commonly are related to falls. The patient most often complains of pain in the groin or thigh and is unable to bear weight on the injured extremity. The lower extremity appears shortened and externally rotated. Most attempts at motion, especially rotational motion, cause severe pain. The diagnosis is confirmed by anteroposterior and lateral radiographs of the hip. The Garden classification is used to indicate the degree of displacement. A careful physical examination is necessary to rule out other injuries to the patient. Displaced femoral neck fractures can be treated with reduction and internal fixation. This method of treatment often is reserved for younger, active, individuals. The older adult patient is better treated with a hip replacement.

Intertrochanteric and Subtrochanteric Fractures

These fractures occur in older adults and are related to falls, and after significant trauma in younger individuals. Subtrochanteric femur fractures occur more distally below the level of the lesser trochanter. These fractures occur within 5 cm of the lesser trochanter. Below this level, the fracture is considered a femoral shaft fracture. The subtrochanteric region of the proximal femur is a high stress area. These fractures require strong implants to resist varus deformity and implant failure. Classically, the sliding hip screw with a side plate continues to be the preferred implant for most stable and unstable intertrochanteric hip fractures. More recently, fixed-angle sliding screws that incorporate an intramedullary nail to gain purchase to the shaft have been used to fix these fractures.

Fractures of the Femoral Shaft

Femoral shaft fractures may occur at any age from severe violence. However, these injuries may occur from less severe, direct torsional stress. Multiply injured trauma patients require evaluation of any associated injuries of the head, abdomen, and chest. These patients present with instability of the lower extremity, pain with motion, external rotational deformity, and shortening of the affected lower extremity. A complete neurovascular examination is essential because there may be injury to the sciatic or femoral nerve or femoral artery. Open femur fractures are associated with a 10 percent incidence of limb-threatening vascular injury. Associated femoral neck fractures or knee ligament injuries occur in approximately 5 percent of patients and must be intentionally looked for.

Femoral shaft fractures were historically treated in traction. This method had several disadvantages, such as shortening, rotational malunion, and knee stiffness. Traction is now mostly used as a temporizing measure until patients are stable enough to undergo definitive surgical stabilization. The gold standard of treatment of these fractures is reamed, locked, antegrade intramedullary nailing performed through a closed technique. Complications of treating femoral shaft fractures include infection (< 1 percent), delayed union, nonunion, malunion, compartment syndrome, neurologic injury, and heterotopic ossification. Nonunion is more common in patients with a history of smoking and diabetes.

Distal Femur Fractures

Distal femoral fractures occur in all age groups as a result of a variety of injuries. Older patients with osteoporotic bone may suffer this fracture from simple falls. Younger patients usually require higher-energy injuries, such as a motor vehicle accident, pedestrian injury, or falls from heights, to suffer supracondylar femur fractures. Patients usually present with pain, swelling, and deformity. Simple nondisplaced fractures may present only with a knee effusion. Supracondylar fractures are intraarticular fractures because of the large extension of the suprapatellar pouch of the knee. Even these fractures, which may be nonarticular, may result in scarring within the suprapatellar pouch and knee stiffness. Intracondylar fractures, by definition, involve the articular cartilage of the distal femur. Knee stiffness and posttraumatic arthritis is a major late complication of these fractures. Successful treatment of these fractures involves four major principles: (1) anatomic reduction of the fracture fragments, particularly intraarticular reduction; (2) preservation of the blood supply to the fracture fragments; (3) stable internal fixation; and (4) early, active, pain-free motion. Treatment is generally surgical for most of these fractures. Occasionally, a nondisplaced fracture is stable enough to be treated nonoperatively in a cast-brace. The majority of displaced fractures, including nondisplaced intraarticular fractures are treated with surgery.

In a patient with an open growth plate fractures that involve the growth plate may cause growth abnormalities. Absolute anatomic reductions are valuable in reducing this complication. Salter and Harris group fractures through the growth plate into five types. Type I is through the growth plate; type II is through the growth plate with extension into the metaphysis; type III is through the growth plate with extension into the epiphysis; type IV crosses the growth plate; and type V is a crush of the growth plate. The higher the type, the greater the risk of a growth abnormality. All growth plates can sustain fractures, but the most common site is the distal femur.

Patella Fractures

Patella fractures usually are caused by direct trauma to the patella but may also occur as a result of avulsion forces on the patella. This happens when the knee experiences sudden forced flexion while the quadriceps muscle is actively contracting. Fractures are classified by their geometry and location. The more common fractures are transverse secondary to avulsion forces; comminuted or stellate fractures may be caused by direct trauma. The patella functions as an integral part of the extensor mechanism and displacement of the patella usually is an indication that the extensor retinaculum has been interrupted. Disruption of the extensor retinaculum will make active extension of the knee impossible. Similar soft-tissue disruptions of either the quadriceps tendon or

patellar tendon may result from a similar mechanism of injury and present with lack of active extension. These injuries usually present with tenderness and a palpable defect over the ruptured tendon. The treatment of the soft-tissue injuries is surgical repair. The treatment of patella fractures is to restore the extensor mechanism and reconstruct the articular surface of the patella.

Nondisplaced fractures of the patella require immobilization in extension. This can be accomplished with a plaster cylinder cast or knee immobilizer. Immobilization of 6–8 weeks should allow healing and prevent separation of the fragments. Displaced fractures require open reduction and internal fixation. The goal of treatment is to restore the articular surface and repair the fragments securely enough to start early ROM therapy.

Tibial Plateau Fractures

Tibial plateau fractures involve the articular surface of the proximal tibia. These fractures occur when the knee experiences a varus or valgus force, with or without a combined action or compression force. The force causes failure of the bone or ligaments, but rarely both within the same compartment. Lateral plateau fractures are the most common followed by bicondylar and finally medial fractures. Lateral plateau fractures usually occur from a force directed from the lateral side with a resultant valgus force. The amount of force and degree of osteopenia determines the magnitude of depression, displacement, and combination. Typically, younger patients have split-type fractures. Older adult patients with osteopenia usually have split-depression fractures.

The principles of treatment are to restore the articular surface, maintain alignment of the articular surface with the rest of the leg, and to resume early ROM exercise. These goals are best accomplished with internal fixation of the fracture. The challenge for the orthopaedic surgeon is to achieve these goals with avoidance of the severe complications that can occur with this fracture. An articular step-off of greater than 3 mm or a widening of greater than 5 mm are indicators for surgery. Instability of greater than 5 degree or angulation of greater than 5 degrees should also be treated surgically. Any bony avulsions of the cruciate ligaments should be repaired at the time of internal fixation. The menisci should be repaired and saved whenever possible.

Tibial Shaft Fractures

Tibia shaft fractures result from direct traumas such as motor vehicle accidents, sport injuries, and falls. All age groups are affected and approximately 30 percent of fractures are open injuries. The high incidence of open fractures is a result of the subcutaneous position of the bone. Nondisplaced fractures may present with localized pain and swelling, and an inability to bear weight, but lack obvious deformity. Displaced or angulated fractures are easily diagnosed on physical examination. The physician must perform a careful neurovascular examination of the extremity with a special concern to any signs or symptoms of compartment syndrome. There is no significant difference in the rate of healing of tibial fractures according to the location of the fracture, plane of the fracture, or treatment of the fracture. Rate of healing appears to be more a relationship with the severity of the trauma. Fractures caused by high-energy trauma with open wounds, such as those associated with automobile accidents, have the longest rate of healing.

Treatment options vary widely and should be discussed regarding open versus closed injuries. Closed tibia fractures, in general, can be treated

successfully with closed reduction and cast immobilization. The indications for surgical treatment of closed tibia fractures remain relative and generally are at the discretion of the treating orthopaedic surgeon. Surgical treatment consists of reamed or nonreamed nailing of the fracture. Management of open tibia fractures remains a challenge to the orthopaedic surgeon. These fractures are usually the result of high-energy, direct trauma and there may be associated trauma elsewhere in the body. In some cases, the limb is so severely traumatized that salvage of the limb may be impossible.

Ankle Injury

Injuries to the ankle are common. The majority are ankle sprains that need temporary rest and completely heal with no residual consequences. There are more significant ligament injuries that occur to the ankle that can present like a simple ankle sprain. These more significant ligament injuries need to be treated with at least immobilization in a cast, and sometimes with surgery to allow maximum recovery. The patients with ankle fractures can be treated with a reduction and cast immobilization or open reduction and internal fixation. The patients also should have physical therapy after their injury has healed to regain their motion, strength, and ankle proprioception.

Depending on the degree of injury, the patient can sustain a strain, sprain, or complete disruption of the lateral ligaments. The degree of swelling and ecchymosis is directly correlated with the degree of ligamentous injury and is a simple means of determining the significance of the injury. If there is concern that the ligaments are completely torn and that the ankle is unstable, stress radiographs can be taken to evaluate the stability of the ankle. When the degree of the ligamentous injury is in question the initial management should be immobilization in a cast with a reassessment after the swelling and acute pain has subsided.

In general, ankle fractures that can be easily reduced and held with the foot in an anatomic position can be treated with a closed procedure. The patient is initially placed in a long-leg cast. This can be shortened to a well-molded short-leg cast after 3–4 weeks. Patients whose fracture cannot be reduced, or cannot be held reduced without placing the foot in an extreme position, should have open reduction and internal fixation.

The fibular is most often internally fixed with a plate, although the medial malleolus is held with one or two screws. If the deltoid ligament is torn but the talus reduces anatomically with reduction and fixation of the lateral malleolus, no surgery treatment of the deltoid is needed. If the reduction of the talus within the ankle mortis is not anatomic, the medial side of the ankle should be opened to remove any tissue that is preventing the reduction.

Talus

The most common fracture location is through the neck of the talus. The degree of displacement is both prognostically important and indicates the best treatment. Displaced fractures need reduction and internal fixation. Osteonecrosis of the proximal talus is a risk.

Calcaneus

Fractures of the calcaneus are common. They usually are caused by falls from heights. They may be associated with a lumbar fracture. The treatment depends

on the amount of displacement and the expectations of the patient. Those with minimal displacement are treated closed. Involvement of the subtalar joint needs to be assessed and as close to an anatomic reduction of any intraarticular component is critical. Böhler angle is a radiographic measurement indicating the amount of displacement.

Midfoot Injury

Dislocations between the tarsal bones and proximal metatarsals are a more common injury than is realized. They often are seen after what seems to be a minor injury. The patient complains of pain in the midfoot and there is swelling. The plain radiographic findings are subtle and one has to suspect the injury to make the diagnosis. Often, it can be treated closed, but open reduction and internal fixation is indicated if the closed reduction is not anatomic or cannot be held reduced.

Metatarsal Fractures

Fractures of the metatarsals are usually a result of direct trauma (e.g., dropping a heavy object on the dorsum of the foot). These are easily treated by non-weight-bearing for 4–6 weeks, followed by gradual resumption of activities.

An exception is the base of the fifth metatarsal. There are two types of fractures at this site. Avulsion injuries occur when the peroneus brevis muscle pulls off the bone with a fragment of the bone. This can be treated closed and will be healed within 6 weeks. Bone union is not necessary for normal function. A Jones fracture is a fracture to the proximal fifth metatarsal through the metaphysis or proximal diaphysis. This injury has an increased risk of delayed union or nonunion. Often, internal fixation is recommended immediately and should be used if the bone is not united within 3 months.

Toes

Fractures of the phalanges of the toes are very common. Treatment is almost always only taping to the adjacent toe. If the great toe has a displaced fracture, pin fixation may be indicated.

Clavicle

More than 80 percent of fractures of the clavicle occur in the middle third of the clavicle, and almost all of the remainder occur in the distal third of the clavicle. The most common causes are a direct blow to the clavicle, a fall on the shoulder, or a fall on an outstretched arm. Clavicle fractures often are seen in patients with multiple injuries and should be specifically looked for in this situation because they can be easily missed. Swelling and tenderness are usually found at the fracture site and pain is associated with shoulder motion. Associated neurovascular injuries can occur, but are uncommon.

Fractures that occur in the middle third of the clavicle are treated by placing the injured arm in a sling. The patient should start to move the shoulder as soon as pain allows, usually within a few days to a week, to reduce the risk of developing restricted shoulder motion. Healing usually occurs in about 6–8 weeks with return to full function in about 3 months. Children will heal the fracture faster and start using their arm earlier than an adult. Nonunion is rare.

Distal-third clavicle fractures are less common and require more care. When there is minimal displacement nonoperative treatment is advised. When

there is more than 100 percent displacement surgical treatment should be considered.

Acromioclavicular Separation

The mechanism of injury of the acromioclavicular (AC) joint is usually direct trauma to the acromion with a fall onto the shoulder. The patient presents with pain, swelling, and tenderness at the AC joint. Shoulder motion also causes pain. Direct pressure on the distal clavicle often demonstrates the instability of the joint. All AC joint separations can be treated nonoperatively. The more active the patient and the more displaced the more likely the patient will benefit from an open reduction and internal fixation. Those patients with persistent pain are operated on later.

Anterior Shoulder Dislocation

The glenohumeral joint is the most commonly dislocated large joint in the body. The humerus can dislocate anteriorly, posteriorly, or inferiorly relative to the glenoid. Anterior dislocations are by far the most common, accounting for more than 95 percent of cases. They generally occur after an indirect trauma with the arm abducted, externally rotated, and extended. Anterior dislocations often cause a tear in the glenoid labrum (Bankart lesion) and also can cause a compression fracture of the posterolateral aspect of the humeral head by the glenoid rim (Hill-Sachs lesion). When one of these occur, the patient usually develops recurrent dislocations of their shoulder.

Patients present with a painful shoulder held in slight external rotation and abduction. Physical examination may show squaring off of the shoulder with loss of the deltoid prominence, and fullness anteriorly, where the humeral head is situated. There is minimal active motion of the shoulder. A neurovascular exam should be performed. Sensation over the lateral deltoid region must be assessed, because the axillary nerve is the most common nerve injured. Anteroposterior, scapular Y, and axillary radiographs are obtained. Radiographs will demonstrate the anterior dislocation and any associated fractures of the proximal humerus or glenoid.

Reduction of the dislocated shoulder should be performed expeditiously. Narcotic analgesics and sedatives are usually necessary to facilitate reduction. Numerous reduction maneuvers have been described, but two of the more commonly used are the Stimson technique and the Hippocratic technique. The Stimson technique involves placing the patient prone with the involved arm hanging off the side of the table. Traction is applied by hanging weights from the patient's wrist. The patient must relax. Usually the shoulder reduces quickly, but it may take 15 min before the tensed shoulder muscles fatigue and allow the shoulder to reduce. In the Hippocratic technique, longitudinal traction is applied with the arm slightly abducted. Countertraction is applied in the axillary region, either with one's foot as originally described by Hippocrates or by an assistant holding onto a sheet wrapped around the patient's chest. Older patients are prone to develop shoulder stiffness so passive ROM, along with isometric exercises, is begun in 1–2 weeks. Rotator cuff tears are a common associated injury after shoulder dislocation in older adult patients. Slow progress with rehabilitation in this group should prompt one to evaluate for a cuff tear, because surgical cuff repair may be beneficial. Young patients are at risk for redislocation so they are kept immobilized from 3–4 weeks. Redislocation is the most common complication after shoulder dislocation. The age of the

patient is the most important factor, with recurrence rates as high as 80–90 percent in patients younger than age 20 years, and as low as 10–15 percent in patients older than age 40 years.

If a shoulder joint has been dislocated for a few days, it becomes much harder to reduce by closed techniques. Open reduction is the only means to reduce the shoulder joint in this circumstance.

Posterior Shoulder Dislocation

Posterior shoulder dislocations most often are due to seizures or electric shock. Patients present with pain, the shoulder held in internal rotation, and adduction. The injury frequently is not recognized in the emergency room. Physical findings include a prominent coracoid process, fullness of the posterior shoulder, and limited external rotation and elevation of the shoulder. Anteroposterior, scapular Y, and axillary radiographs are obtained. The dislocation may be missed on the anteroposterior radiograph because the findings are subtle.

Proximal Humerus Fractures

Proximal humerus fractures are common in the older adult population and generally occur from a fall on an outstretched hand. They occur less commonly in young adults, but are often more serious with associated injuries such as shoulder dislocation because of the higher forces required to fracture nonosteoporotic bone. Patients present with pain, swelling, and tenderness about the shoulder and have difficulty with active motion. Three orthogonal radiographic views of the shoulder best demonstrate the displacement of the fracture. These consist of an anteroposterior view, a scapular Y view, and axillary view. The location(s) of the fracture can be categorized as anatomic neck, surgical neck, greater tuberosity, and lesser tuberosity. Displacement of the fracture fragments can be explained by the muscular forces that are applied to them. In surgical neck fractures, the shaft tends to displace anteromedially because of the pull of the pectoralis major. Greater tuberosity fractures are displaced superiorly and posteriorly by the attached supraspinatus, infraspinatus, and teres minor. Lesser tuberosity fragments are displaced medially by the subscapularis.

Minimally displaced fractures are treated with immobilization followed by early ROM. Closed reduction is attempted on displaced two-part surgical neck fractures, but if an adequate reduction cannot be obtained or maintained, surgical reduction and fixation is performed. Displaced greater tuberosity fractures usually require surgery as they may impinge on the undersurface of the acromion when the shoulder is elevated and block elevation and external rotation. Displaced three-part fractures usually are treated with closed reduction and percutaneous pin fixation, although four-part fractures often are treated with humeral head prostheses because of the high incidence of osteonecrosis of the humeral head. To minimize shoulder stiffness, early postoperative passive ROM exercise is begun if adequate stability was obtained with surgery.

Humeral Shaft Fractures

Fractures of the humeral shaft can be the result of either direct or indirect trauma. Patients present with pain, swelling, and difficulty moving the shoulder and elbow. Examination reveals swelling and tenderness of the arm with crepitus and motion at the fracture site. Radial nerve palsies are

commonly associated injuries, particularly with fractures of the middle third of the humerus. Most of these are neurapraxias that resolve spontaneously within 3 to 4 months and therefore do not require operative nerve exploration.

A vast majority of humeral shaft fractures can be treated nonoperatively. A U-shaped plaster coaptation splint is commonly used initially. This is frequently converted to a humeral functional brace after 1–2 weeks, allowing better early ROM exercises of the shoulder and elbow. Operative stabilization of humeral shaft fractures is recommended in certain cases including inability to obtain an adequate alignment with a splint or brace, open fracture, floating elbow (fractures of humerus and radius/ulna), fracture with vascular injury, polytrauma, and pathologic fracture. Fracture fixation can be done with compression plate, intramedullary rod, or external fixation.

Elbow Fractures

Olecranon and distal humerus fractures are generally pure bone injuries with intact ligaments, barring iatrogenic injury. Open reduction and rigid internal fixation is recommended in the adult.

Supracondylar fractures are common in children and if minimally displaced, can be treated with a closed reduction and cast. A forearm compartment syndrome is not an uncommon complication. If displaced closed reduction and pin fixation most often is performed.

Forearm Fractures

The radius and ulna are the two bones of the forearm. Motor vehicle accidents, sports injuries, falls, or direct blows to the forearm may cause a fracture to one or both of these bones. The fracture may or may not have a significant associated soft-tissue or joint injury. Fractures of both bones of the forearm are described by their location (proximal, midshaft, or distal), by the amount of displacement (minimal, moderate, or complete), the degree of angulation, the extent of comminution, and whether the fracture is open (compound) or closed.

A fracture of the ulna with an associated dislocation of the radial head is known as a Monteggia fracture. A fracture in the distal third of the radius with an associated dislocation of the distal radioulnar joint is called a Galeazzi fracture. An isolated fracture of the ulna is called a “nightstick” fracture because being hit by a nightstick was a common mechanism of injury.

Recognizing a dislocation of the radial head from its normal articulation with the humeral capitellum can be difficult. A line perpendicular to the articular surface and through the central position of the radial head should bisect the capitellum. This relationship should be seen on all projections if the radial head is anatomically located. Generally, forearm fractures are treated with a closed manipulation and cast immobilization for children and open reduction and internal fixation in adults.

Distal Radius Fracture

Fractures of the distal radius are among the most common fractures encountered in children and in adults. There is a bimodal peak of incidence occurring in later childhood and after the sixth decade of life. Fractures in males contribute a greater number to the earlier peak, although fractures in females predominate in the later years. The most common mechanism of injury in both children

and adults is a lower-energy fall from ground level onto an outstretched hand with the wrist extended. Fractures that do occur from higher-energy injuries have varying degrees of comminution, may occur in any age group, and have a higher incidence of associated injuries. Anteroposterior, lateral, and possibly oblique radiographs are usually all that are needed to assess distal radius fractures. In the presence of comminution and intraarticular involvement, a CT scan may be of use to assess the status of the radiocarpal, and especially the radioulnar, joints. Patients with distal radius fractures present with pain, swelling, and deformity. Examination must include a neurologic assessment prior to and after reduction of the fracture.

In children, the distal radius fractures are grouped into metaphyseal (more common) and physeal fractures. The metaphyseal fractures may be complete or incomplete (buckle or torus fracture). The physeal fractures are described according to the Salter-Harris classification. The majority of these fractures in children are treated by closed means. Buckle fractures are treated in plaster for 4 weeks. Angulated and/or displaced fractures are manipulated and kept in a cast for 6 weeks. If at least 2 years of growth remain, up to 20 degrees of angulation may be accepted because remodeling will occur. Physeal injuries are reduced by gentle distraction and manipulation avoiding repeated attempts and possible further physeal injury. The aim of treatment of distal radius fractures in adults is to restore the general alignment of the distal radius and ulna, avoiding radial shortening of greater than 3–5 mm, residual angulation greater than 10–15 degrees, and articular incongruity of greater than 2–3 mm. The degree of residual deformity accepted will depend on the age and functional needs of the individual patient. The majority of these fractures are extra-articular or have a minimally displaced, intraarticular component, and are treated successfully by closed reduction followed by 6 weeks of protection in a cast, splint, or brace. Closed reduction is obtained by finger-trap traction followed by manipulation and application of the splint of choice, usually under hematoma-block local anesthesia. Fractures with severe shortening, angulation, and comminution are usually unstable and require some form of fixation.

Spinal Injuries

Injuries to the spinal column are potentially the most devastating of orthopaedic injuries. They occur most often after high-energy trauma such as motor vehicle accidents and falls from significant heights. Initial stabilization of potential spinal injuries at the scene of the accident is done with rigid backboard to protect the thoracic and lumbar spine and with a rigid cervical collar to immobilize the cervical spine. All patients with high-energy injuries should be presumed to have spine injuries until proven otherwise.

Spine fractures, dislocations, and fracture/dislocations are caused by falls, major trauma, and diving accidents. The location of the fracture can be predicted by the mechanism of the injury. Diving accidents cause injuries to the cervical spine. This is one of the most common causes of paralysis. Often, patients present with a history of diving into water that was too shallow. Injuries to the thoracic spine, especially to the lower thoracic/upper lumbar spine, are usually a result of major trauma from an automobile accident or when a pedestrian is struck by a car. Lower lumbar injuries are more likely a result of a fall, with the patient landing on their feet or buttocks. Common combinations of injuries are calcaneal fractures with a lumbar burst fracture.

There are general categories of fractures. The most important initial differential is whether the patient has or does not have neurologic injury. The next differential is whether the spine is stable or unstable. Any neurologic injury indicates that the spine is unstable. All patients should be carefully log-rolled and the spinous processes along the entire spine palpated for tenderness. A rapid, but thorough neurologic examination should be performed. In patients with severe spinal cord injuries, it is important to determine whether the injury is complete (with total motor and sensory loss) or incomplete. The prognosis for complete spinal cord injuries is worse, with no return of functional strength below the level of injury. The presence of rectal tone, perianal sensation, or great toe flexor activity indicates that the injury is incomplete with sacral sparing and that the prognosis for recovery of nerve function is better. An absent bulbocavernosus reflex (anal sphincter contraction after pressure is applied to the glans penis or the clitoris or after gently tugging on the Foley catheter) indicates that spinal shock is present. Determination of whether a seemingly complete neurologic deficit is actually so cannot be made until spinal shock has resolved, which nearly always occurs within 24 h.

A lateral cervical spine radiograph is part of the initial "trauma series" that is obtained on all multitrauma patients. The radiograph must include the entire cervical spine from the occiput to the first thoracic vertebra. Inability to obtain a proper lateral radiograph necessitates additional views, such as swimmer's view, to visualize the lower cervical spine or a CT scan. Other views of the cervical spine that should be obtained after the patient is sufficiently resuscitated and stabilized are the AP and open-mouth odontoid views. Anteroposterior, lateral thoracic spine, and lumbar spine radiographs are obtained in all unconscious or mentally impaired patients, and in conscious, alert patients with pain and/or tenderness in those regions.

Patients with neurologic injuries seen within 24 h of their injury are started on 30 mg/kg methylprednisolone, then 5.4 mg/kg per h for 24 h. Although there is some controversy regarding its efficacy, most believe the steroid improves the chance of recovery. Patients with spinal cord injuries may also have neurogenic shock with hypotension and bradycardia secondary to disruption of sympathetic outflow.

Cervical Spine

Stable injuries without nerve deficit can generally be treated with a cervical orthosis or a halo vest. The halo vest provides better immobilization than a cervical orthosis and is therefore preferred when there is a risk of instability. However, the halo vest does not completely restrict cervical motion and thus is not sufficient in patients with grossly unstable injuries. These types of patients require operative internal stabilization.

The presence of spinal cord compression with incomplete nerve injury generally necessitates operative decompression of the spine to facilitate recovery and prevent further damage to the cord. Most injuries are adequately seen on plain radiographs, but CT scans often are used to better appreciate the details of the bone fragments. For patients with neurologic injury an MRI is useful because the spinal cord and soft tissues within the canal can be visualized.

JOINT REPLACEMENT SURGERY

Total Hip Replacement

Pain and progressive disability in the face of failed conservative measures constitute the primary indication for total hip replacement. Total hip replacement is indicated in patients with deterioration of the hip joint, which may result from a number of causes, including degenerative arthritis, rheumatoid arthritis, osteonecrosis, ankylosing spondylitis, postinfectious arthritis, benign and malignant bone tumors of the hip joint, and hip fractures. Active infection, abductor muscle loss, progressive neurologic disease, and neurotrophic joints are specific contraindications to total hip replacement. Two types of fixation are employed: cement (polymethylmethacrylate, PMMA) and cementless. Cementless fixation is based on the use of a porous material that allows bone grow into the prosthesis. Roughened surfaces and biologically active coatings promote ingrowth of bone as a fixation method. For fixation of the acetabular component, cementless fixation is used in most healthy patients undergoing primary total hip replacement. Cemented fixation is used primarily in older adult patients (currently those older than 70 years of age), and in patients in which ingrowth is unlikely, such as those with significant prior irradiation to the pelvis. For fixation of the femoral component, both cemented and cementless stems are employed.

The major complications associated with total hip arthroplasty include infection, thromboembolism, heterotopic ossification, and dislocation. Infection is the most devastating consequence after total hip arthroplasty. The incidence of infection is 0.5–1 percent for primary total hip replacement. Thromboembolism is the most common complication following total hip arthroplasty and the leading cause of postoperative morbidity. The incidence of deep venous thrombosis, depending on how hard one looks, ranges from 8–70 percent with the occurrence of fatal pulmonary embolus, and from 1–2 percent in patients who are not given prophylaxis for thromboembolism. Multiple methods of postoperative prophylaxis (aspirin, warfarin, heparin, support hose, and sequential compression devices) are employed to lessen the incidence of deep vein thrombosis and pulmonary embolism. Despite the success of total hip arthroplasty, relatively short-term implant survival rates in active, young patients and in heavy laborers make its use in these groups problematic. As previously stated, the presence of an active infection is a contraindication to total hip arthroplasty. For patients in these situations, alternatives to hip arthroplasty include hip arthrodesis, hip osteotomies, and resection arthroplasty.

Total Knee Replacement

A total knee replacement resurfaces the distal femur with a metal prosthesis that articulates with a polyethylene surface that is attached to the tibia. Most commonly, the patella is also resurfaced with a dome-shaped implant made of high-density polyethylene. Fixation of the implants to the bone surfaces is either achieved with acrylic bone cement or by bone ingrowth into a roughened or coated prosthesis. Today, cemented knee replacements are the most commonly performed because of the excellent results achieved in long-term clinical studies.

As in other types of joint replacement, infection and deep venous thrombosis are significant systemic complications. Infection rates have been reported at 1–2 percent. Despite the indicated successes of total knee arthroplasty, younger

patients continue to present a difficult challenge and often require alternate treatments. Osteotomy of the tibia or femur often is used to transfer weight-bearing load to an uninvolved tibiofemoral joint surface when there is unicompartmental disease. This procedure is most commonly done at the proximal tibia for medial compartmental disease but may also be performed at the distal femur in lateral compartment disease. Arthrodesis provides another surgical alternative for the management of young patients with unstable degenerative knees, the management of septic arthritis with extensive destruction of the joint, and in neuropathic joints. Arthrodesis and resection arthroplasty may be employed in patients with failed total knee replacement in which prosthetic implantation is not an option.

SHOULDER DISORDERS

Rotator Cuff and Biceps Tendon

The rotator cuff consists of four muscles: the supraspinatus, infraspinatus, teres minor, and subscapularis. All insert onto the tuberosities of the humeral head. The primary function of the rotator cuff is to provide dynamic stabilization of the glenohumeral joint by depressing the humeral head into the glenoid cavity. The rotator cuff separates the subacromial bursa from the glenohumeral joint. The acromion covers the bursa and can contribute to local problems. Tears of the rotator cuff, either partial or complete, are common in individuals older than age 40 years and increase with each subsequent decade. Patients with rotator cuff pathology present with pain (especially at night), weakness, and difficulties with the activities of daily living, particularly overhead motions. On physical examination, they have limited shoulder abduction because of pain. It is important to rule out referred pain from cervical spine pathology. Plain radiographs are indicated, but MRI is the most useful means of evaluating the rotator cuff.

The biceps muscle has two heads—a long and short. The long head tendon is intraarticular. It originates on the supraglenoid tubercle of the glenoid and lies between the lesser and greater tuberosities of the humeral head. The long head can be inflamed and can be a source of shoulder pain. Rupture of the long head of the biceps can lead to the characteristic “Popeye” deformity of the arm. This is caused by the muscle bunching in the upper arm. This is treated in young, active patients, but not in older patients.

Frozen Shoulder

Patients with adhesive capsulitis or “frozen section” present with shoulder pain and limited motion. Because the scapula moves on the chest wall, patients often do not appreciate how limited their motion is. Careful examination reveals complete loss of motion at the glenohumeral joint. Most often this occurs after a short period of immobilization of the shoulder. Other patients have no inciting event. Diabetics have a higher incidence of adhesive capsulitis than nondiabetics. Physical therapy is the mainstay of treatment and it often takes up to 1 year to regain full motion. Rarely is surgical intervention necessary.

Glenohumeral Instability

Glenohumeral instability is a spectrum of disorders, which can vary in severity (subluxation to complete dislocation), direction (anterior, posterior, or multidirectional), and duration (acute, recurrent, or chronic). An acute, traumatic,

anterior dislocation is the most common instability situation. The risk of developing recurrent subluxation or dislocations is inversely proportional to age, with those patients who have their first acute dislocation before they are 20 years of age having more than an 80 percent incidence of recurrence. Recurrent instability most often is caused by a tear of the anterior labrum off the anterior glenoid; the so-called Bankart lesion. Most patients who have repeated dislocations of their shoulder require surgical repair. Posterior dislocations more often are caused by a seizure or a fall in an older adult patient. This dislocation is often missed by the unsuspecting physician.

Glenohumeral Arthritis

Arthritis of the shoulder joint occurs less often than arthritis of the hip or knee. Idiopathic osteoarthritis is the most common cause of shoulder degeneration; however, other arthritic conditions can produce shoulder damage (e.g., rheumatoid, septic, posttraumatic, and rotator cuff deficiency arthropathy). Pain, weakness, limited motion in all planes of motion, and crepitus are common complaints. If conservative measures such as heat, activity modifications, and nonsteroidal antiinflammatory medications (NSAIDs) do not produce relief, total shoulder arthroplasty may be indicated.

ELBOW DISORDERS

Epicondylitis most often affects the lateral epicondyle; however, the incidence of medial epicondylitis has increased with the popularity of golf. Another common, nontraumatic elbow condition is ulnar nerve compression (cubital tunnel syndrome), which is caused by compression of the ulnar nerve in the cubital tunnel or proximal flexor carpi ulnaris muscle, and causes pain and dysesthesias in the little and ulnar border of the ring fingers. Compression of the radial nerve or posterior interosseous nerve beneath the supinator muscle is much less common than ulnar nerve compression. The vague forearm aching and pain associated with this syndrome may respond to neurolysis, but electrodiagnostic studies, unlike cubital tunnel syndrome, are not diagnostic.

Rupture of the distal biceps tendon attachment to the bicipital tuberosity of the proximal radius may occur as a consequence of a chronic, degenerative tendinopathy. Treatment may be conservative or surgical repair may be performed. If treated conservatively, the patient can expect good flexion strength, but notable weakness of supination and aching with heavy use.

SPINE DISORDERS

Low Back Pain

Pain in the lumbar area and buttock is one of the most common complaints heard in medicine. The majority of adults will have at least one episode of low back pain during their life, and many adults have recurrent episodes. Most instances of low back pain will not have a specific diagnosis and the cause is generally muscular strain and spasm. More significant abnormalities need to be excluded when a patient with low back pain is evaluated. The most important spinal diagnosis to exclude is a neoplasia; however, it is also the least likely cause. Patients with aortic aneurysms and pancreatic cancer can present with low back pain and these diagnoses must be considered. Degenerative arthritis is a more common cause of low back pain, but a delay in making this diagnosis is not significant. Herniated disc with nerve compression is a relatively common

cause of back pain associated with leg pain and should be recognized from the patient's history and physical examination.

The initial evaluation includes the taking of a history to determine how the pain started, how long it has persisted, how severe it is, what makes it worse, and what makes it better. The abdomen should be examined. The patient's back is examined for tenderness, masses, muscular spasm, alignment, and motion. A neurologic examination should be done and a rectal examination is recommended. If no abnormalities are noted, except decreased motion and muscular spasm, the patient can be treated with a few days of rest and mild pain medication. If pain persists, a more complete evaluation is indicated.

Patients with a herniated disc without compression of a nerve root do not need specific treatment. They present with low back pain and virtually all will improve with nonoperative care. Those with compression of a nerve root will have pain that is distributed in the dermatome of the compressed nerve root. The patient usually has a positive straight-leg-raise test. Initially, nonoperative treatment is recommended, and most patients will have relief. Those with persistent pain or recurrent pain should undergo disc removal.

Discitis is an infection of the disc. This is not uncommon in children but is unusual in adults unless they are immunosuppressed or IV drug users. These patients will have unremitting back pain. On a radiograph there will be a loss of disc height; however, this may not be apparent until sometime after the patient has sought medical treatment.

Degenerative arthritis occurs in older adults, and typically can be managed with physical therapy and anti-inflammatory medication. Some patients will develop spinal stenosis as a result of compromise of the spinal canal. These patients may require decompression.

Another common cause of back pain, although usually seen more in the mid-back than in the lower back, is a compression fracture. Most compression fractures occur in osteoporotic bone and are caused by minimal trauma. Compression fractures can occur in patients with normal bone and are usually caused by significant trauma. However, the most common scenario is an older adult female who complains of acute onset back pain after a minor fall or automobile accident. There will be anterior wedging of a mid-thoracic vertebra. These patients are treated nonoperatively, usually with an extension brace.

Neck Pain

Like low back pain, neck pain is common. Usually it occurs after a minor injury and often is referred to as "whiplash." The usual patient has pain in the neck without a radicular component, loss of motion, and muscular spasm.

MUSCLE AND TENDON INJURIES

The most commonly injured muscles in the lower extremity are the hamstrings, quadriceps, and gastrocnemius. Injuries to these muscles either originate from a direct blow or, more typically, from a sudden eccentric contraction (acute lengthening of muscle as it is trying to shorten). This, in turn, ruptures muscle fibers. In severe cases, a defect in the muscle can be palpated; however, in most cases there is no gross defect. A well-defined sequence of events then occurs: bleeding, damage to muscle cells, and an inflammatory response that leads to a repair. Scar tissue then forms, ultimately leaving the muscle stiffer (less elastic) and more prone to re-injury. Treatment, therefore, involves controlling the pain

and inflammation acutely and stretching as the muscle heals to try to keep it at its normal resting length. In severe cases in which there is a disruption in the muscle tissue, both remodeled muscle tissue and postinjury muscle strength are improved by suturing the torn muscle tissue together.

Another sequence of events that can be spawned from a quadriceps contusion is myositis ossificans (MO). Myositis ossificans also is called heterotopic bone formation. The majority of patients with MO will recover full function and can be successfully treated nonoperatively. Rarely, a patient will have persistent loss of motion and need the ectopic bone removed. This should not be done until 1 year or more after the injury. A careful history should be taken with someone who has ossification within a muscle, because MO histologically resembles osteosarcoma, and an incorrect diagnosis either way can be disastrous.

Tendinitis and bursitis are commonly caused by overuse, trauma, or through compensation for another injured area. The presence of a bursa is a normal. It is a thin fluid-filled sac with a lining of blood vessels and nerve endings. Bursa occur in any area that has soft tissue repetitively rubbing over a bony prominence. Once irritated, they swell and become painful. The most common sites to develop bursitis around the knee are overlying the patella and the patella tendon (prepatella bursitis), at the anteromedial aspect of the proximal tibia in which the pes anserine tendons (sartorius, gracilis, and semitendinosus) insert (pes anserine bursitis), and at the posteromedial corner of the tibia in which the semimembranosus inserts (semimembranosus bursitis). Other common sites of bursitis are the bursa inferior to the acromion (subacromial bursa), the bursa over the greater trochanter of the femur (greater trochanter bursa), and the bursa over the olecranon (olecranon bursa).

Initial treatment involves decreasing the inflammation through icing, anti-inflammatory medication, and removing the offending insult. With the patella, in particular, it is important to avoid pressure through kneeling or bumping the knee. If this fails, the next step is to use a cortisone injection, aspirating the bursa first, if necessary. Finally, if conservative treatment fails, an excision of the bursa can be performed.

Tendinitis typically occurs from overuse. Endurance sports, such as running and cycling and power sports such as basketball, volleyball, and racquet sports are most frequently involved. The tendons are injured by cumulative micro-trauma in which there is a failed adaptation of the cells and extracellular matrix to repetitive activities at submaximal load. Essentially the micro-injuries are unable to heal themselves quickly enough, leading to fatigue of the tendon and, finally, to symptomatic injury. At the knee, the hamstring tendons are most commonly involved and iliotibial band friction syndrome is the most common cause of lateral-based knee pain in runners. The iliotibial band repetitively rubs over the lateral femoral epicondyle, causing both a bursitis and a tendinitis. Other common sites for tendinitis are the biceps tendon (both proximal and distal), common wrist extensors (tennis elbow), the abductor pollicis longus (de Quervain disease), Achilles tendon, and posterior tibial tendon.

Treatment is focused on calming the inflammation and pain. Ice and rest are the initial modalities. Antiinflammatory medications are usually prescribed. As the pain subsides, stretching of all tight structures and the use of modalities such as ultrasound and electrical stimulation may be beneficial. Rarely is surgical intervention required. When needed, surgical procedures include tendon sheath débridement (for tenosynovitis), tendon-relaxing incisions or lengthening, or tendon advancement.

THE ATHLETIC KNEE

Meniscal Injuries

Each knee has a medial and lateral meniscus. These are C-shaped fibrocartilage rings, triangular in cross-section, that serve as shock absorbers and secondary restraints to the ligaments. The lateral meniscus is more circular than the medial meniscus, but less-well attached to the capsule, particularly posteriorly. Because the medial meniscus is more constrained, it is subjected to higher forces and tears more frequently than the lateral meniscus. The peripheral 25 percent of the meniscus is vascularized, thus making it amenable to repair. The inner 75 percent has no blood supply, will not repair a tear, and requires resection if torn and symptomatic. A twisting or hyperflexion event is the usual cause of tears in the athletic population; however, in older individuals, tears may occur without a defined moment, presumably via a cumulative microtraumatic degenerative mechanism.

People with symptomatic tears may recall hearing a pop or tear and then the development of swelling. They complain of pain at the involved joint line, a sense of catching or locking, and often have difficulty with deep flexion. Typically, they cannot squat. On exam there is tenderness over the joint line, particularly posteromedially or laterally, there is pain with hyperflexion. Further confirmation of a tear can be made with greater than 90 percent accuracy with an MRI. Occasionally, a meniscus will tear peripherally and the central torn segment will flip over and stick in the notch of the knee. This is called a bucket-handle tear. The bucket handle often “locks” the knee, preventing extension. This is considered a semi-urgent situation requiring surgery. An arthroscopic repair or trimming is the treatment of choice for symptomatic meniscal tears.

Ligament Injuries

The ACL and posterior cruciate ligament (PCL) are the central pivots to the knee. The ACL provides anterior translation restraint and anterolateral rotatory stability, although the PCL provides mostly posterior translation restraint. They also act as secondary restraints for the collateral ligaments (medial collateral ligament [MCL] and lateral collateral ligament [LCL]), which provide valgus and varus control.

A patient presenting with knee pain after a twisting injury or a varus or valgus torque to their knee with immediate swelling and who reports hearing a pop should be evaluated for a ligament tear. The knee should be examined for instability. The medical collateral ligament and anterior cruciate ligament are the most commonly injured ligaments.

The Dislocated Knee

This condition can be a limb-threatening injury. It usually occurs with high-speed vehicular trauma or with a fall from heights, but can also happen in sporting activities, typically a contact sport. Usually the ACL, PCL, and one of the collateral ligaments are disrupted. There is a high incidence of popliteal artery, tibial nerve, and peroneal nerve injury; therefore, close attention should be paid to the neurovascular status during evaluation of a dislocated knee.

Articular Cartilage Injuries

Articular cartilage does not repair itself. For this reason, it is always best to save as much articular cartilage possible. Whenever possible, any cartilaginous body that has been knocked loose should be replaced into the defect.

FOOT AND ANKLE DISORDERS

Complaints concerning the foot and ankle are common. Ankle injuries are common. Patients with these complaints are some of the most appreciative patients once their condition has been improved.

Tendon Disorders

Tendon disorders of the foot and ankle are common problems, with chronic tendinosis, tendinitis, and frank rupture of the Achilles tendon constituting the majority. The Achilles tendon is the most commonly affected and tendinosis, or a chronic partial tear of the Achilles tendon, presents with thickening of the tendon and pain with palpation. MRI shows degeneration within the tendon and thickening. Tendinitis of the Achilles tendon also presents with pain and inflammation around the tendon. MRI shows fluid around the tendon within the paratenon surrounding the tendon. Tendinosis and tendinitis are treated nonsurgically with NSAIDs, gentle stretching, bracing, and a heel lift. Steroid injections should be avoided in this area because of the risk of rupture of the tendon.

History and physical examination easily diagnose complete rupture of the tendon. Patients report a feeling of being struck in the back of the leg and an inability to ambulate following the injury. It is unusual for a patient with a ruptured Achilles tendon to have had tendinitis of the Achilles tendon. The Thompson test is useful in diagnosing a complete Achilles tendon rupture. This is performed with the patient prone and knees flexed to 90 degrees. The calf is then squeezed on both the affected and normal leg. The normal side will show plantar flexion of the foot with calf compression, although the affected side will not. Absence of plantar flexion is a positive indicator for a disrupted tendon. Nonsurgical treatment of a ruptured Achilles tendon consists of casting the ankle in slight plantar flexion or functional bracing. Surgery often is recommended to repair the ruptured tendon, however, wound complications are common.

Peroneal tendinitis is a common cause of lateral ankle pain following an inversion injury. Symptoms include lateral ankle swelling and pain with resisted eversion of the ankle. Tenderness to palpation is seen over the area just posterior to the distal fibula, and pain may be elicited with passive inversion. MRI often is helpful in imaging the peroneal tendons. Nonsurgical treatment includes rest, a stirrup ankle support, NSAIDs, and physical therapy. Surgery may include direct repair of the tendon and tenodesis to the adjacent peroneal tendon, and tendon transfer.

Posterior tibial tendon insufficiency, often referred to as the adult acquired flat foot, has three distinct stages and presents with pain along the medial side of the ankle and progressive flattening of the longitudinal arch. In stage I, there is swelling and pain along the medial side of the ankle; however, the foot alignment remains normal. In stage II, the posterior tibial tendon and the ligaments supporting the arch begin to stretch, allowing lowering of the longitudinal arch. The heel drifts into valgus and the forefoot abducts; however,

the deformity is still flexible. In stage III of posterior tibial tendon insufficiency, arthritis of the hindfoot develops and the hindfoot remains fixed in valgus. At this stage, patients often report pain on the lateral aspect of the ankle, which is caused by impingement between the calcaneus and fibula. Stage IV occurs with long-standing deformity and consists of tilting of the talus within the mortise of the ankle. Radiographs are useful in assessing the position of the foot and ankle and determining the presence of arthritic changes. MRI is very helpful in assessment of the integrity of the posterior tibial tendon. Nonsurgical treatment consists of braces and orthoses, NSAIDs, and cast immobilization. Physical therapy does not usually help in this condition. Surgical treatment consists of tendon transfer with calcaneal osteotomy or lateral column lengthening. Often, an Achilles tendon lengthening is combined with these procedures. For patients with arthritic changes, selective arthrodesis of the hindfoot is necessary.

Heel Pain

Plantar heel pain, most often caused by plantar fasciitis, is one of the most common problems seen in the foot. Patients report severe pain with the first step after arising from sleep or after prolonged periods of sitting. The pain usually subsides after a few min of walking and often recurs later in the day after prolonged standing or walking. Usually plantar fasciitis is atraumatic in onset. Examination reveals point tenderness along the medial origin of the plantar fascia on the calcaneus. Heel cord contracture often is present. Approximately 40 percent of patients with plantar fasciitis also will have evidence of compression of the first branch of the lateral plantar nerve. Imaging studies should be used to eliminate other causes of heel pain such as a calcaneal stress fracture or insertional Achilles tendinitis. Treatment consists of plantar fascia and heel cord stretching, padding, custom-molded orthoses, NSAIDs, and a night splint to maintain passive stretch on the Achilles tendon and fascia. Cortisone injection can help relieve pain and inflammation. Surgery rarely is necessary and consists of releasing a portion of the plantar fascia along with decompression of the lateral plantar nerve.

Hallux Valgus

Hallux valgus is commonly known as a bunion. The great toe is deviated toward the second toe. The angle between the first metatarsal and proximal phalanges of the great toe is a valgus angle. The common causes of hallux valgus are genetic predisposition combined with improper shoes. Many patients will not have symptoms and do not need treatment. Others complain of pain over the medial eminence and difficulty fitting shoes. Lesser toe deformities often accompany hallux valgus as the migration of the great toe pushes the lateral toes out of proper alignment.

Stress Fractures

Stress fracture, or fatigue fracture of the metatarsals, is a common cause of forefoot pain. Most commonly affected are the second and third metatarsals. Athletes and dancers commonly suffer this problem, along with patients with underlying bone disorders. Symptoms consist of swelling and warmth in the foot, with point tenderness over the affected metatarsal. Radiographs

are often negative initially; however, the healing fracture usually is evident by the third week of symptoms. Treatment consists of supportive shoes and temporary cessation of the activity that led to the fatigue fracture. Surgery rarely is necessary.

Ankle Instability

Fifteen percent of patients with an ankle sprain will develop chronic instability of the ankle requiring treatment. Usually an inversion injury causes damage to the lateral ligament complex, including the anterior talofibular and calcaneofibular ligaments. Patients report pain and swelling on the lateral aspect of the ankle, often associated with feelings of “giving way” or weakness of the ankle. Physical examination consists of the anterior drawer test and inversion stress test. Stress radiographs help confirm the diagnosis.

Diabetic Foot

Diabetes commonly affects the foot and can lead to devastating complications, including amputation. Diabetes is the most common cause of neuropathy leading to loss of protective sensation on the plantar aspect of the foot. Charcot arthropathy is a form of arthritis seen in the neuropathic foot and leads to severe deformity. The combination of deformity with a lack of protective sensation leads to pressure ulceration and infection. This can develop into osteomyelitis, and often requires bony resection or amputation. Patients with neuropathy as a consequence of diabetes should be treated with protective shoes consisting of a soft orthoses and accommodative shoes with a soft, leather upper. Pressure relief may be obtained with bracing and shoe modifications. In those patients with deformity not treatable with shoe modifications, surgery is necessary. The goals of surgery are resection of bony prominences, and restoration of normal foot architecture. Surgical débridement should remove all necrotic tissue while producing a stable, plantigrade foot. Correction of the deformity can be successful given the patient has adequate circulation. Preoperative vascular evaluation is often necessary. Adequate glucose control promotes healing of ulcerations, and surgical wounds.

Interdigital Neuroma

Interdigital neuroma often is called a Morton neuroma. The patient's symptoms are a burning or tingling in the plantar aspect of the forefoot radiating into the toes. It most often occurs in the third web space and may be seen between the second and third toes.

Tarsal Tunnel Syndrome

Tarsal tunnel syndrome occurs with compression of the tibial nerve as it passes beneath the flexor retinaculum of the ankle. Patients present with vague symptoms, usually consisting of numbness and tingling on the plantar aspect of the foot. A positive Tinel sign is present over the tibial nerve; however, sensation usually is preserved. Examination should also include the lower spine to rule out a radiculopathy as the source for the symptoms. MRI often is helpful to rule out a space-occupying lesion within the tarsal canal causing compression of the nerve.

PEDIATRIC DISORDERS

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) is a spectrum of disorders involving degrees of instability of the hip and underdevelopment of the acetabulum (socket). The term used in the past was congenital dislocation of the hip, but this is currently out of favor. The disorder is usually diagnosed shortly after birth because all newborns are screened for the condition by physical examination and, in some areas, by ultrasonography. DDH can present in the toddler, although controversy exists regarding whether these cases represent missed diagnoses.

The physical examination consists of two provocative maneuvers: the Ortolani test and the Barlow test. The Ortolani maneuver attempts to relocate a dislocated or subluxed hip. The Barlow maneuver attempts to dislocate or subluxate a reduced, but unstable hip.

Slipped Capital Femoral Epiphysis

A slipped capital femoral epiphysis (SCFE) is a developmental disorder in which there is dissociation between the epiphysis and metaphysis of the proximal femur. The term is a misnomer because the epiphysis is fixed in the acetabulum and it is the metaphysis, along with the rest of the femur, which slips. In the vast majority of slips, the epiphysis is posteromedial with respect to the metaphysis. A SCFE usually occurs during the adolescent growth spurt and is bilateral in about one third of cases. Sixty to 65 percent of patients are above the 90th percentile for weight. Patients usually present with pain and a limp. The extremity usually is rotated externally and the time spent on the leg is less than the unaffected leg.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease (LCP) is defined as idiopathic osteonecrosis of the proximal femoral epiphysis. It occurs between the ages of 2 and 12 years with a peak incidence between 5 and 7 years of age. This corresponds to the period when the blood supply to the epiphysis is discreet. LCP is 3–5 times more common in males than in females, and is bilateral in 10–20 percent of cases. Patients with LCP present with pain in the groin, thigh, or knee. They may have an antalgic or a Trendelenburg gait. Plain radiographs and MRI help to classify the degree of head involvement, which has prognostic significance.

Talipes Equinovarus

Talipes equinovarus (TEV) is referred to as “clubfoot.” TEV is an idiopathic congenital deformity of the foot in which there is equinus at the ankle joint, varus and medial rotation at the subtalar joint, and adduction of the midfoot and forefoot. It occurs in 1–2 individuals per 1000 live births and is bilateral in 50 percent of cases.

Metatarsus Adductus

Metatarsus adductus (MA) is differentiated from talipes equinovarus because these patients have a normal midfoot and hindfoot. Ordinarily, the lateral border

of the foot is straight; in MA, the lateral border curves inward at the tarsal-metatarsal joints, producing a bean-shaped foot.

Tarsal Coalition

A tarsal coalition is an abnormal congenital connection between two or more tarsal bones. The calcaneonavicular and talocalcaneal joints most commonly are affected. Tarsal coalition is bilateral in 50–60 percent of patients. The cause is a failure of differentiation and segmentation during embryogenesis and is likely to be genetic. Tarsal coalition is estimated to occur in 1–3 percent of the population, and can be asymptomatic. When symptoms occur, they usually do so in early adolescence, when the coalition begins to ossify. Symptoms consist of activity-related foot and ankle pain associated with a fairly inflexible flat foot.

Plain radiographs may be sufficient to visualize the coalition, particularly when special oblique projections are used. When plain radiographs are not diagnostic, CT and MRI can be used. CT is best for bony coalitions and MRI is best for cartilaginous or fibrous coalitions.

Blount Disease

Infantile Blount disease is a disorder of toddlers in which the physiologic genu varum becomes progressive, damaging the anteromedial physis of the proximal tibia. As the bowing continues, increasing pressure on the anteromedial physis inhibits growth medially, which perpetuates the bowing.

Infantile Blount disease is diagnosed between the ages of 18 and 24 months. Affected children are generally early walkers who are above the 80th percentile for weight. Clinically, patients present with increasingly bowed legs and lateral instability of the knee evidenced by a thrust during single-leg stance of gait. Because the anterior portion of the medial physis is more affected than the posterior portion, these patients tend also to have increased internal tibial torsion.

Radiographs are used to measure the metaphyseal–diaphyseal angle (MDA) of Drennan. A measurement of greater than 11–16 degrees in the 18–24-month-old infant is predictive of progression. Classification systems of severity exist and depend on the extent of medial depression of the physis.

Patients with significant genu varum but a normal MDA are simply observed at 6–8-week intervals. Patients with an abnormal MDA and lateral instability are treated with bracing. The brace is designed to apply three-point pressure to the extremity to provide a valgus force, which unloads the medial physis. Controversy exists regarding whether the brace should be worn full-time, only during weight bearing, or while sleeping. Bracing is effective in reversing the progression in approximately 50 percent of cases, which reversal can be observed within 3 to 6 months.

Patients who either progress despite brace treatment or recur following treatment should have a proximal tibial osteotomy to restore the physiologic valgus alignment. An oblique osteotomy is made in the proximal metaphysis. Rotation at the osteotomy site corrects both the varus and torsion.

Adolescent Blount disease is a similar entity that occurs during the adolescent growth spurt. The MDA as an indicator of the significance of the genu valgum in adolescents has not been established. Adolescent Blount disease does not respond to bracing. The treatment is a proximal tibial osteotomy to

realign the mechanical axis of the knee. These osteotomies are stabilized with an external fixator to accommodate the generally large size of the patient.

Osgood-Schlatter Disease

Growth cartilage that serves as the origin or insertion of a tendon is called an apophysis. If the muscle associated with the tendon becomes tight, the tendon pulls with excessive force on the apophysis, which becomes inflamed. This condition is known as traction apophysitis. Traction apophysitis can occur at virtually any apophysis and affects different apophyses at different ages. The most common location is the tibial tubercle in which the condition is known by the eponym Osgood-Schlatter disease (OSD).

OSD is caused by a tight quadriceps and typically is seen in patients 12–14 years old. Patients with OSD complain of activity related pain very specifically at the tibial tubercle. The pain can be severe and may also occur after prolonged sitting. On physical exam, the tubercle is prominent and tender and the quadriceps are tight. Stretching of the quadriceps generally reproduces the pain. In unilateral cases, radiographs should be obtained to rule out occult lesions. The treatment is activity modification as dictated by the symptoms and physical therapy to stretch the quadriceps.

Other areas of traction apophysitis include, but are not limited to, the calcaneus (Sever disease), inferior pole of the patella (Sinding-Larsen-Johansson disease), anterior inferior iliac spine, and base of the fifth metatarsal.

Plastic and Reconstructive Surgery

*Saleh M. Shenaq, John Y. S. Kim, Alan Bienstock,
Forrest S. Roth, and Eser Yuksel*

HISTORY

Plastic surgery is derived from the Greek word, “plastikos,” meaning to mold. The unifying objective of all plastic surgeons is the ability to improve or restore form and function through the possibilities inherent in the manipulation and remodeling of tissue. Historically, the premise for plastic surgery dates back several millennia to the Egyptian, “Edwin Smith papyrus,” believed to be written in 1700 BC, which heralds modern fastidiousness with wound care, emphasizing the importance of débridement and meticulous surgical technique. During World Wars I and II, plastic surgery as a specialty evolved as surgeons were confronted with complex, massive, traumatic defects of the maxillofacial region and extremities. The reconstructive challenge crossed traditional boundaries of all other surgical specialties. In 1937, the American Board of Plastic Surgery was founded and plastic surgery was truly recognized as a distinct surgical specialty. As medical and technologic innovation resulted in the development of novel and advanced surgical techniques, subspecialization in plastic surgery developed, particularly in craniofacial, hand, aesthetic, and microsurgery. In 1962, Cronin and Gerow introduced the breast implant that sparked a heightened interest in aesthetic and reconstructive breast surgery and a general interest in applying alloplastic materials to plastic surgery.

WOUND HEALING

There are three general types of wound healing: primary, delayed primary and secondary. Primary wound healing is characterized by the physical opposition of wound edges. Delayed primary wound healing occurs when wound margins are intentionally left unopposed in face of presumed infection. If the signs of infection resolve, the wound may then be closed primarily at that time. Secondary wound healing occurs by granulation and wound contraction.

Paramount to wound healing are angiogenesis and the inflammatory reaction created by cells such as polymorphonuclear neutrophils, macrophages, lymphocytes, fibroblasts, and the cytokines they release. The fundamental limiting step to both wound healing and tissue reconstruction is adequate vascularity.

Impaired Wound Healing

Radiation is often an issue for reconstruction of ablative defects. Among other effects, radiation may result in ischemia via microangiopathic damage. Diabetic patients also experience impaired wound healing.

Dysfunctional healing may manifest as abnormal scars. Hypertrophic scars and keloids are manifestations of altered collagen deposition and breakdown. Hypertrophic scars are raised, collagen-rich lesions that do not extend beyond the initial boundaries of injury, whereas keloids are scars that have progressed beyond these margins.

Treatment of scars includes pressure, silicone sheets and gels, intralesional corticosteroids, and topical vitamins A and E. For recalcitrant keloid formation, radiation therapy and surgical excision may be required.

Basic Technique of Skin Closure

The choice of suture material may vary from monofilament to polyfilament and absorbable to nonabsorbable. Minimizing skin tension is essential to maintaining wound closure and preventing excessive scar formation. Techniques to minimize tension include multilayered closures and placement of skin incisions along relaxed-skin tension lines.

Suture Technique

Cutaneous sutures generally are placed through the epidermis and into the deep dermis approximately 2 mm from the skin edge and 7–10 mm apart. Care is taken with any suture placement to ensure that the needle enters the skin as nearly perpendicular as possible. Slight eversion of the skin edges facilitates maximal dermal opposition and closure without contracting depression of the scar.

Vertical and horizontal mattress sutures may yield a more substantial eversion. However, there is a greater theoretical concern of local tissue ischemia and inhibition of tissue healing. Simple or mattress sutures are usually constructed with nonabsorbable material and should be removed as expeditiously as possible to prevent scarring. The buried dermal and fascial sutures should provide the majority of strength of deeper wounds.

Subcuticular sutures are running, superficial dermal sutures that avoid the external scar of cutaneous sutures. However, they should not be relied on to provide the strength of a closure. Simple running cutaneous sutures allow for rapid closure of tissue with some element of hemostasis, especially if performed in a “locking” fashion. Staples also may be used for cutaneous closure. In combination with deeper sutures they may augment the strength of the closure. In general, sutures should not be left in longer than 1 week to avoid unsightly scars. Biosynthetic tissue adhesives such as cyanoacrylate are advantageous when tensionless closure has been accomplished with deeper sutures. They also may obviate the need for local anesthetic. Steri-Strips and other tapes may similarly be used when simple apposition of the superficial skin is required.

Reconstruction of more complex defects may require the recruitment of local or distant tissue. The “reconstructive ladder” algorithm for reconstruction of a given defect are primary closure, skin grafts, skin flaps, tissue expansion, local muscle flaps and free flaps.

SOFT TISSUE RECONSTRUCTION

Skin Grafts

The term graft indicates that the vascular supply has been severed during the procurement of the tissue. Graft survival depends on three sequential events: (1) imbibition—the absorption of nutrients from recipient capillary beds during the first 24 h; (2) inosculation—the alignment of donor and recipient vessels during the 24–72-hour period; and (3) angiogenesis—ingrowth of vessels from the recipient bed into the graft after 72 h. Factors that may interrupt this process include fluid collection under the graft or mechanical shear forces. This is in

contradistinction to a flap in which the blood supply to the tissue remains at least partially intact.

The type of skin graft is described according to its thickness. A split-thickness skin graft is comprised of epidermis and a portion of the dermis. Split-thickness skin grafts may be harvested from various donor sites depending on the thickness, color, and quality of skin needed. They may then be meshed to expand the potential coverage area. However, the cosmetic appearance of meshed grafts is inferior and they have a propensity to contract. In patients with significant skin requirements or when there may be a relative paucity of donor sites, skin grafts may be used in conjunction with skin substitutes.

A full-thickness skin graft includes the full complement of the epidermis and dermis (Table 43-1). Thicker grafts have more difficulty with adherence and survival because of their greater demand on vascular ingrowth. However, the greater the thickness of dermis, the greater the inhibition of myofibroblast activation and graft contraction. The full-thickness skin graft may also retain functional hair follicles and sweat glands. Full-thickness skin grafts are taken from areas in which primary closure can be accomplished.

Skin grafts may be immobilized for five days with compressive dressings to prevent graft loss because of fluid accumulation and shear forces. Donor sites for split-thickness grafts are allowed to re-epithelialize under occlusive dressings (OpSite, Tegaderm), petroleum (Scarlet Red) or antibiotic impregnated gauze (Xeroform). Re-epithelialization typically occurs in 7–14 days.

Skin Flaps

A flap is a volume of tissue that can be translocated and survive in a new location on its native blood supply. A flap may consist of skin and subcutaneous tissue, muscle, or a composite of all three. The vessels supplying a random flap are smaller and more diffuse than those of an axial pattern flap, in which the tissue has a consistent pedicle.

A Z-plasty is a method of constructing adjacent skin flaps at specific angles to lengthen or reorient a scar. A W-plasty is a camouflaging technique used to disperse the continuity of a linear scar. A V-Y advancement flap is a method of recruiting tissue from a region of relative excess to a soft tissue defect. Skin flaps may also be rotated on a dermal or subdermal pedicle. If the tension is too great, a back cut known as a “Burow triangle” may be created to increase the arc of rotation. A bilobed flap is transposed in sequence via two flaps with the most distal flap donor site being closed primarily. An

TABLE 43-2 Mathes and Nahai Muscle Flap Vascular Anatomy Classification

Type I	One vascular pedicle
Type II	Dominant and minor pedicle
Type III	Two dominant pedicles
Type IV	Segmental pedicles
Type V	One dominant pedicle and segmental pedicle

island flap is one in which the vessel is isolated from surrounding tissue, over an intervening segment. A free flap is one in which the vascular supply and flap are severed to be reattached via microvascular technique at a distant location.

Muscle-Based Flaps

The Mathes and Nahai Classification describes muscle flaps according to their pattern of dominant, minor, and/or segmental vascular supply (Table 43-2). Wounds that are prone to infection or irradiated benefit from muscle flaps because of their rich vascularity which ameliorates the delivery of antibiotics and immunological cells.

The vascular supply of a muscle flap may be enhanced by selective surgical ligation of one or several of the dominant feeding arteries. This delay phenomenon occurs as the vessels which connect adjacent angiosomes known as choke vessels dilate followed by neoangiogenesis. The ischemic tissue then acclimates to relying on the nonoccluded arterial supply. After a period of 10–14 days, the flap may be safely transferred with decreased risk of ischemic complications.

Tissue Expansion

The viscoelastic properties of skin allow a significant degree of stretch to be applied to the skin and subcutaneous tissue without undue ischemia. Tissue expanders inflated at staged intervals generate and recruit tissue via a process known as biologic creep. Histologic analysis of expanded skin shows increased mitotic activity and angiogenesis. The epidermis thickens in contrast to dermal attenuation.

Free Flaps and Microsurgery

Microsurgery is the technique which makes possible neurovascular repair in tissues transferred to distant locations. Microscopes or high-magnification loupes are required to visualize the nerves, vessels, instruments, and sutures. Interrupted or continuous sutures may be used to accomplish tensionless vascular anastomosis or neural coaptation. The configuration of the repair may be in an end-to-end or end-to-side fashion.

The vessels must be handled meticulously and minimally to prevent vasospasm and intimal injury. Papaverine, lidocaine, and heparinized saline may be applied intraoperatively to ameliorate vasospasm. Free flap thrombosis is a surgical emergency and vascular flow must be restored within a finite period of time. Factors contributing to thrombosis include anticoagulant deficiency, smoking, caffeine, hypovolemia, hypothermia, and cardiovascular disease. Venous congestion is more common than arterial complications and often resolves with leach therapy.

PERIPHERAL NERVE SURGERY

Compressive neuropathies are encountered in areas such as the carpal, cubital, and tarsal tunnels. Motor function may be assessed by various objective scales including the British Medical Research Council Muscle Grading Scale. Electrodiagnostic tests, such as nerve conduction studies, needle electrode examination, and somatosensory evoked potentials, are useful in determining the magnitude, location, and prognosis of the lesion.

Nerve injuries generally are graded according to the Sunderland Classification. A first-degree injury or neurapraxia results in focal axonal demyelination and transient conduction block. A second-degree injury or axonotmesis occurs as axonal injury results in Wallerian degeneration. Both first- and second-degree injuries are self-limited and complete recovery may be anticipated within 3 months. The third and fourth types of injury occur as significant force is applied to the nerve to result in a neuroma-in-continuity. The third-degree injury results in partial endoneurial scarring and regenerating axons only are able to partially traverse the zone-of-injury. Recovery is generally incomplete. Fourth-degree injury results in complete obliteration of the nerve by scar tissue and axonal regeneration is not possible. Lastly, a fifth-degree injury or neurotmesis results from complete transection of a nerve. Microsurgical repair is required for fourth- and fifth-degree injuries within a finite period of time to prevent irreversible motor end-plate degeneration. Mackinnon described a sixth-degree injury in which variable degrees of injury occur at various segments of the injured nerve.

If signs and symptoms of nerve repair and regeneration are not present within three months, exploration and intraoperative nerve testing is warranted. Conduction distal to a partially conducting neuroma may be augmented by jump grafts in an side-to-side fashion, or excision of the neuroma followed by end-to-end cable grafts. If a proximal donor is not available as in the case of nerve root avulsions, adjacent nerve transfers may be performed to restore distal innervation.

CRANIOFACIAL SURGERY

Cleft Lip and Palate

In normal embryologic growth, five facial elements (the frontonasal, lateral maxillary, and mandibular segments) merge via mesenchymal migration. According to the classic theory of cleft lip embryogenesis, failure of fusion of the maxillary processes and frontonasal processes during this time interval yields a cleft of the primary palate. However, the mesodermal penetration theory describes palate closure as dependent on mesodermal penetration without which results in epithelial apoptosis and cleft formation.

The primary palate consists of the lip, alveolus, and hard palate anterior to the incisive foramen, although the secondary palate comprises the hard and soft palate structures posterior to the incisive foramen. Cleft lips are complete if the cleft extends in to the nostril floor and incomplete if a tissue bridge unites the lateral and central lip.

Incidence of cleft lip and palate is 46 percent versus 33 percent in patients with isolated cleft palates or 21 percent with isolated cleft lips. Unilateral left cleft lips occur more often than right-sided or bilateral cleft lips, 6:3:1 respectively. Furthermore, the ratio of incidence of cleft lip varies with ethnicity: 0.41:1000 in African Americans; 1:1000 in whites; and 2.1:1000 in Asians.

The etiology of cleft lip is multifactorial and potential risk factors include anticonvulsants, parental age, lower socioeconomic class, smoking, alcohol intake, prenatal nutrition, and family history. Families in which a parent or sibling has a cleft have a 4 percent risk of a subsequent child being born with cleft lip and/or palate.

Timing of surgical repair often is dictated by the rule of tens: 10 weeks of age, 10 lbs, and 10 mg of hemoglobin. A Latham appliance may be fitted intraorally prior to definitive surgical repair to facilitate alveolar segment alignment.

Cleft Palate

Palatal shelves develop as swellings of the medial maxillary prominences. After downward growth adjacent to the tongue, the shelves become horizontal and fuse at 12 weeks of gestation. Incomplete closure of these palatal shelves results in a cleft palate. A cleft palate is described as complete if there is extension into the nose or incomplete if a partition exists.

A submucous cleft palate is the most common type and is characterized by a bifid uvula, thin membranous central portion, and a posterior palpable notch. Cleft palates are associated with greater than 200 syndromes and malformations. Incidence is approximately 0.05 percent and associated risk factors include teratogens, alcohol, dietary deficiencies, and maternal epilepsy.

Approximately 5 percent of patients after cleft palate repair will have persistent velopharyngeal insufficiency. Consequently, incomplete oropharyngeal occlusion and abnormal intraoral pressures and ineffective sucking, feeding, facial growth disturbances, middle ear disease, and recurrent otitis media. Surgical management includes pharyngeal flap, pharyngoplasty, palatoplasty and intravelar veloplasty.

Hemangiomas and Vascular Malformations

Hemangiomas are common vascular tumors 30 percent of which are present at birth and 80 percent during the first month of life. Distinguished as a small red or deep bluish patch, they rapidly proliferate during the first 2 years. Following this proliferative phase, hemangiomas steadily involute and spontaneous resolution occurs in 50 percent of patients by 5 years of life and in 70 percent by 7 years of life. Females are more inclined to develop hemangiomas and the majority of such lesions reside in the head and neck.

Treatment is indicated in patients with visual or airway impairment, bleeding or ulceration, infection, Kasabach-Merritt syndrome, or congestive heart failure. Noninvasive modalities include systemic corticosteroids, intralesional corticosteroids, and subcutaneous interferon α -2a. More invasive techniques include surgical excision, laser or cryotherapy, and embolization.

Vascular malformations are structural abnormalities which arise as a consequence of embryogenic dysmorphogenesis. They are all present at birth and grow concurrently with the patient. They have no sexual predilection and do not display the typical rapid proliferation or regression phases of hemangiomas. They are classified as either slow-flow or fast-flow lesions. The former include capillary, lymphatic, or venous malformations, whereas the later comprise arterial aneurysms, arteriovenous fistulas, and arteriovenous malformations. Skeletal distortion or hypertrophy, increased skin temperature, bruit or thrill, high-output cardiac failure, bleeding or ulceration, pain, and tissue overgrowth may accompany vascular malformations. The more severe vascular malformations may have a propensity to bleed and have high morbidity

and mortality rates. Arteriography and superselective embolization followed by surgical resection remains the standard of care. Other treatment modalities include sclerotherapy, compression garments, laser thermolysis, and surgical excision.

Craniosynostosis

Craniosynostosis is defined as the premature closure of one or more cranial sutures. Based on the law of Virchow, premature closure results in limited skeletal growth perpendicular to the suture line and overgrowth parallel to the suture. The incidence of craniosynostosis is 0.1 percent and its etiology is multifactorial.

Craniosynostosis may interfere with brain growth and result in increased intracranial pressures. Craniosynostosis may be an isolated manifestation or associated with a craniofacial syndrome. Classification is described according to the calvarial sutures involved and subsequent malformation: frontal plagiocephaly occurs with coronal synostosis; scaphocephaly with sagittal synostosis; trigonocephaly with metopic synostosis; and brachiocephaly with bicoronal synostosis.

Craniosynostosis Syndromes

Crouzon syndrome is characterized by brachycephaly, mid-face hypoplasia, strabismus, exophoria, antimongoloid palpebral fissures, and exophthalmos. Apert syndrome is similar to Crouzon syndrome with the addition of ocular muscle palsies, hypertelorism, and syndactyly. Saethre-Chotzen syndrome is distinguished by brachycephaly, low hairline, and syndactyly. Lastly, Pfeiffer syndrome is typified by brachycephaly and is distinguished by broad thumbs and toes. Craniofacial reconstructive surgery entails decompression by craniotomy followed by cranial vault remodeling and fixation with absorbable plates between 6 and 12 months of age.

Laterofacial Microsomias

Patients with hemifacial microsomia, the most common craniofacial anomaly, presents with unilateral or bilateral microtia, macrostomia, dysplastic mandible, zygoma, maxilla, temporal bone, facial muscles, muscles of mastication, palatal muscles, tongue, parotid gland, macrostomia, and cranial nerve involvement. Treacher-Collins syndrome includes maxillary and zygomatic dysplasia, eyelid colobomas, antimongoloid slant, hypoplastic mandible and maxilla, macrostomia, and microtia.

Orthognathic Surgery

The mandible and/or maxilla may be disproportionate because of traumatic or congenital anomalies. Dental occlusive relationships are characterized by Angle classification of malocclusion. In Angle class I, or normal occlusion, the mesiobuccal cusp of the maxillary first molar articulates with the buccal groove of the lower first molar. In class II occlusion, the maxillary first molar articulates anterior to the buccal groove of the lower first molar, although in class III occlusion, the maxillary first molar articulates posterior to the mandibular first molar.

Cephalometric analysis will determine vertical face, horizontal midface, horizontal lower face, and dental relationships. The mandible and maxilla

may require advancement, division, or setback by LeFort osteotomies and genioplasty.

MAXILLOFACIAL TRAUMA

Most facial fractures occur during motor vehicle accidents or aggravated assault and 50–70 percent of patients with facial fractures/injuries will have concomitant injuries. Treatment may be emergent, early or delayed. Emergency treatment for life-threatening facial fractures includes respiratory obstruction, aspiration and hemorrhage. Facial fractures are suspected in patients with contusions, tenderness, lacerations, neurologic deficit, malocclusion, visual disturbances and facial asymmetry. Examination of the face should be carried out in an orderly, concise manner, proceeding from either superior to inferior or inferior to superior and should entail:

- Visual evaluation for asymmetry and deformity.
- Palpation of entire craniofacial skeleton for irregularities or crepitus.
- Trigeminal and facial nerve examination.
- Intranasal inspection for septal hematoma.
- Ophthalmologic examination for extraocular entrapment or optic nerve deficit.
- Intraoral examination for malocclusion, and fractured or missing teeth.

Mandibular Fractures

The mandible is the second most commonly injured facial bone and represents 10–25 percent of all facial fractures. The most common locations for fracture to occur are the body, the angle and condyle, and the ramus and symphysis, from most to least common, respectively. Mandibular fractures often are multiple and a thorough investigation for a second should always be undertaken.

The mandible has the potential for multiple vector displacements depending on the muscular attachments of the fracture fragments. Surgical management includes open versus closed reduction and intermaxillary fixation.

Frontal Sinus Fracture

Frontal sinus fractures should be suspect in patients with forehead trauma. They often are not associated with any acute signs or symptoms and may be evaluated by computed tomography.

Management includes palliative care, open reduction internal fixation of anterior wall fractures, and cranialization of posterior wall fractures. All patients should be evaluated over a period of time for sinus opacification indicative of nasofrontal duct obstruction.

Nasoethmoidal Orbital Fractures

Nasoethmoidal (NOE) fractures involve injuries to both the nose and frontal processes of the maxilla. These fractures may result in telecanthus if the medial canthal tendon is involved. NOE fractures should be suspected in patients with epistaxis, depressed or comminuted nasal fractures, maxillary frontal process tenderness and periorbital hematomas. Computerized tomography remains the standard for accurate diagnosis and treatment usually requires open reduction and interfragmentary fixation.

Orbital Fractures

The most frequent orbital fracture is the “blow-out fracture,” which pertains to the medial and lower medial orbital walls. Orbital floor blow-out fractures may result from direct blunt trauma to the orbit or by an acute increase in intraorbital pressure. Signs and symptoms include periorbital hematoma, subconjunctival hemorrhage, diplopia, infraorbital nerve injury, enophthalmos, and visual acuity changes. Ophthalmologic and forced duction tests should be performed.

Indications for operative exploration include symptomatic diplopia greater than 2 weeks, positive forced duction test, muscle entrapment, orbital content herniation, orbital floor defect, and enophthalmos. Goals of treatment are reduction of herniated contents and restoration of normal architecture and orbital volume. Surgical treatment includes rigid fixation with either autologous or alloplastic materials.

Nasal Fractures

The nose is the most commonly fractured bone in the face. The nose may be laterally or posteriorly displaced, and the fracture may involve the cartilaginous septum and/or the nasal bones. Patients commonly present with edema, deformity, epistaxis, septal deviation, and/or crepitus. Intranasal inspection for septal hematoma should be performed and drained immediately if present. Diagnosis by computed tomography (CT) scan is useful to rule out concomitant injuries. Treatment consists of fracture reduction and midline positioning of the septum followed by splinting. Residual deformities may require formal rhinoplasty after inflammation and edema have resolved.

Zygoma Fractures

Signs and symptoms of zygomatic fractures include diplopia, trismus, depressed malar eminence, subconjunctival hemorrhage, infraorbital nerve injury and epistaxis. On examination, there may be a step-off deformity or tenderness. Fractures may be confirmed by plain films or CT scan. Surgical management includes open reduction and fixation with wires or plates.

Midface Fractures

The LeFort Classification is commonly used to describe the three classical midface fractures. Symptoms found with maxillary fractures are periorbital hematoma, epistaxis, and mobile maxillary segments. Surgical management includes open reduction and fixation.

MAXILLOFACIAL RECONSTRUCTION

Ear

Surgery may be performed in children with microtia once the rib cartilage has reached an appropriate size for ear reconstruction at 6–8 years of life. A radiograph tracing is made of the normal ear if present. In the first stage, the helix and antihelix are constructed from the patients costal cartilage. This framework is then implanted underneath a retroauricular skin envelope. In subsequent stages, the lobule and tragus are reconstructed.

Common causes of prominent ears include conchal overdevelopment, underdeveloped antihelical folds, or both. Surgical management includes

imbrication of the conchal cartilage with mattress or Mustardé sutures, by excision of excess conchal cartilage, or by scoring of the anterior conchal cartilage. In infancy, prominent ears may be permanently corrected by taping and splinting.

Lip

The majority of lip defects are secondary to basal cell cancer of the upper lip and squamous cell carcinoma of the lower lip. Extirpation and/or radiotherapy are essential for possible cure. Goals of reconstruction are to maintain vermilion continuity, lip sensation and oral competence by reapproximation of the orbicularis oris. Upper and lower lip defects less than 30 percent may be repaired primarily. In defects greater than 30 percent, the Abbé flap or variations thereof may ameliorate reconstruction. Lower lip defects greater than 65 percent may be restored by Karapandzic or Webster-Bernard techniques. Larger lip/soft-tissue defects may require larger pedicle flaps or free tissue transfer.

Cheek

The cheek is divided into three esthetic units: zone I (suborbital), zone II (preauricular), and zone III (buccomandibular). If primary close or local flap coverage cannot be achieved, or if lower lid ectropion occurs, serial excision, full-thickness skin grafting, or tissue expansion may be considered. Otherwise, cervicofacial advancement, regional flaps, or even free tissue transfer may be required.

Nasal

The nose is divided into nine subunits based on surface, skin thickness, color, and texture. Reconstruction of each individual unit must achieve:

- Similar skin dimension and quality
- A cartilaginous framework to maintain shape and support
- Restoration of an adequate vascular supply

Reconstruction of nasal subunits may be achieved by secondary healing, skin grafting, or local flaps. Secondary healing is successful in a defect adjacent to a nonmobile unit where contraction will not cause distortion. Skin grafts are generally acceptable for the upper two thirds of the nose and local flaps for alar and tip defects.

The nasolabial flap based on the facial artery may be used to resurface the nasal ala. The paramedian forehead flap based on the supratrochlear-supraorbital vessels provides soft tissue coverage especially of the tip, dorsum, and areas of missing cartilage.

Eyelid

The goals of eyelid reconstruction are:

- Preservation and restoration of function
- Shape and symmetry
- Incisions within natural lid creases
- Aesthetic skin grafts and flaps

Primary closure may be achieved in defects that are less than one third the length of the lid margin. A lateral canthotomy with lateral advancement may

be performed in defects greater than 25 percent. When there is skin loss of the lower lid, skin grafts from the upper lid, supraclavicular or preauricular region are excellent donor sites. When a full-thickness defect is greater than 25 percent, the cartilage and conjunctival lining will require septal or conchal cartilage with either conjunctiva from another lid, oral or nasal mucosa or a composite graft.

In general, local flaps provide the best color and texture match. For full-thickness lower-lid defects, local flap options include the nasolabial flap, V-Y advancement, and Mustardé cheek flap. In upper lid defects, a temporal skin flap may be designed to reconstruct defects greater than one half of the lid. Cross-lid flaps (e.g. Cutler-Beard or Hughes flaps) may be performed to restore either upper or lower lid defects involving the tarsus greater than 25 percent. Medial canthopexy may be performed when repairing the inner canthus to prevent telecanthus, or a tarsal strip and lateral canthopexy may be performed to prevent ectropion.

Ptosis may be congenital or acquired. Congenital ptosis may be caused by lid anomalies, ophthalmoplegia, and synkinesis, although acquired ptosis may be neurogenic, myogenic, or traumatic. Horner syndrome is a form of neurogenic ptosis in which sympathetic disruption results in ptosis, miosis, anhydrosis, and enophthalmos.

In patients with absent levator function, a frontalis sling procedure may be performed. In more mild forms of ptosis, Mueller resection, Fasanella-Servat advancement, or levator resections may suffice.

Scalp

The scalp is composed of five layers: skin, subcutaneous tissue, galea, loose areolar tissue, and pericranium. Scalp defects are classified as partial or full thickness. In partial-thickness defects, local flap elevation and advancement scalp flaps or multiple axial flaps may achieve closure with donor-site skin grafting. Larger defects may require a full scalp flap based on either the superficial temporal or posterior auricular arteries, pericranial flaps with skin grafting, or microvascular flap coverage. In patients with alopecia, tissue expansion with local tissue advancement performed to restore hair-bearing tissue or hair transplantation may be performed.

In full-thickness defects, skin grafts can be administered to the calvarium after the outer calvarial table is removed and burred. Calvarial defects may be reconstructed with autogenous bone (e.g., split rib grafts or calvarial bone grafts). Alloplastic materials also are available such as methylmethacrylate, LactoSorb, and hydroxyapatite. However, they generally have a higher rate of infection and extrusion.

Facial Paralysis

Lesions resulting in facial paralysis may be classified as intracranial, intratemporal, and extracranial. Idiopathic or Bell palsy is the most common etiology and 70 percent of such patients spontaneously recover without neurologic deficit.

The goals of facial reanimation surgery are:

- Restoration of resting facial symmetry
- Spontaneous, symmetrical facial animation

- Corneal protection
- Oral competence

Reconstruction depends on the duration of facial nerve injury. After eighteen months, the facial muscles atrophy and the motor end plate density is insufficient for reinnervation. If reinnervation is achieved within 18 months, primary repair, nerve grafting, or nerve transfers may be performed. If tensionless nerve repair is not feasible, then a nerve graft (e.g., sural nerve) will be interposed in between the proximal trunk and distal branches. When a proximal nerve is not available, cross-facial nerve grafting from the contralateral facial nerve and/or neurotization from the ipsilateral motor branch to the masseter may be performed.

Static or dynamic slings and free muscle transfers may be performed to restore facial and oral motor function. Static slings (e.g., Gore-Tex, fascia, temporalis, or masseter muscle) may be attached to the oral commissure to achieve both smile and oral competence. Gold weights are often placed in the upper eyelids to ensure corneal protection. Facial reanimation may be achieved by free muscle flaps.

HEAD AND NECK ONCOLOGIC RECONSTRUCTION

Small floor-of-mouth and tongue tumors may be treated with a skin graft. Larger defects will require more pliable tissue for an intraoral lining and allow for tongue mobility such as a radial forearm flap. In the setting of maxillectomy and/or orbitectomy, the palate and oral contents must be separated from the midface. If the palate is resected, a palatal obturator may be applied, but adequate soft-tissue coverage (i.e., rectus abdominis or scapular flap) is required. When the orbital floor is resected but the orbital contents are preserved, a bone graft is frequently used for reconstruction. Nevertheless, local flaps such as the temporalis muscle or temporoparietal flap offer adequate soft-tissue coverage in these defects.

More advanced lip and/or oral cancers may invade the maxilla and mandible. If the mandibular defect is smaller than 6 cm, a nonvascularized bone graft may fill the defect. However, if the defect is larger than 6 cm or the ablative field is to be irradiated, a free vascularized bone flap is required for durable reconstruction. Options for vascularized bone flaps include the fibula, iliac crest, and the scapula. These bone flaps may be accompanied with skin and soft tissue to obviate any dead space and provide an epithelialized lining.

In the neck, complete esophageal defects may be reconstructed with a jejunal flap. Hypopharyngeal defects, either circumferential or partially circumferential, may also be reconstructed with a jejunal flap if circumferential. Other tubed fasciocutaneous free flaps and the anterolateral thigh flap are reasonable alternatives that have the added benefit of not having the morbidity associated with entering the abdominal cavity.

BREAST SURGERY

Breast Reconstruction

Breast reconstruction following mastectomy may be performed with autogenous tissue or alloplastic implants. Autogenous tissue reconstruction may be considered in patients who require radiation postoperatively, or in patients who understand the morbidity of the procedure but desire the aesthetic

benefits. Potential donor flaps include the transverse rectus abdominis myocutaneous (TRAM) flap, the latissimus dorsi flap, the superior inferior epigastric artery flap, gluteal flap, and the deep circumflex iliac artery flap (DIEP).

The pedicle TRAM flap is purported to have more fat necrosis and radiation-induced problems than the free TRAM. Additionally, smoking is a relative contraindication for a pedicle TRAM, but not for a free TRAM. The free TRAM has a slightly longer operative time and a failure rate of approximately 5 percent. Both of these types of breast reconstruction require sacrifice of the rectus muscle, and mesh reconstruction of the abdominal wall may be employed if the fascial defect is significant. Muscle-sparing techniques or intramuscular dissection of the perforating vessels (DIEP flap) may be preferable surgical techniques.

The choice of recipient vessels for microvascular anastomosis of these flaps includes the thoracodorsal and the internal mammary arteries and veins.

Tissue Expansion and Implant Reconstruction

The principal benefit of using tissue expansion and implants versus autologous tissue is lower complication and donor-site morbidity rates. However, the aesthetic result is often superior after autogenous reconstruction and the use of radiation may limit other techniques. Furthermore, most mastectomy defects result in a loss of skin and soft tissue, and expansion of the skin flaps over several months may be required prior to the definitive implant procedure.

Implants are available in a range of volumes and shapes and may be smooth or textured. The expander soft-tissue pocket generally is placed beneath the pectoralis and serratus muscle, which affords greater coverage of the implant and may soften the resultant contour.

Reduction Mammoplasty

Gigantomastia may result in significant morbidity including back and shoulder pain. Reconstruction is based on inferior, superior, or medial pedicle techniques. Occasionally, women with extremely large breasts may require a free nipple-areolar complex graft if the pedicle is too long to sustain adequate perfusion to the nipple.

A potential complication is the descent of the reduced breast volume below the nipple level or "bottoming out," hematoma, delayed wound healing, loss of nipple sensation, and impaired ability to breast-feed.

Mastopexy

The descent of breast tissue often occurring with age is known as ptosis. For mild ptosis, skin excision along a superior crescent or a periareolar "doughnut" mastopexy may be used. A subglandular augmentation may ameliorate lift of the breast in select patients. For more severe forms of ptosis, an inverted T-shaped incision may be necessary to achieve sufficient lift and projection to the breast.

Breast Augmentation

FDA-approved breast implants are saline filled with a silicone-based shell. The four most commonly used incisions for placement of the breast implants for

augmentation are inframammary, periareolar, axillary, and transumbilical. The implants may then be placed in a subglandular or subpectoral position.

Capsular contracture occurs in 8–38 percent of patients who undergo augmentation mammoplasty. If significant contracture occurs resulting in surface deformity, asymmetry, or pain, then capsulotomy or capsulectomy with implant exchange may be required. Other potential complications include leak, rupture, hematoma, seroma, infection, and hypertrophic scarring occurs in less than 5 percent of patients. A study surveying augmented and nonaugmented patients found no statistical difference in survival or detection of carcinoma between the two cohorts.

Gynecomastia

Excessive breast tissue in males, or gynecomastia, may be associated with liver dysfunction, endocrine abnormalities, Klinefelter syndrome, and renal disease. Oncologic etiologies include testicular tumors, adrenal or pituitary adenomas, pulmonary carcinomas, and male breast cancer. Pharmacologic causes include marijuana use, digoxin, spironolactone, cimetidine, theophylline, diazepam, and reserpine. Occasionally, patients may respond to testosterone, tamoxifen, or danazol. Surgical treatment includes mastectomy and/or liposuction. Although most gynecomastia is not associated with male breast cancer, those patients with Klinefelter syndrome are at a higher risk.

Congenital Reconstruction

Congenital deformities of the breast include amastia, hypomastia, tuberous breast, and Poland syndrome. These are relatively rare conditions that may have psychosocial sequelae. Amastia and hypomastia may be addressed by augmentation with tissue expanders or adjustable implants. Tuberous breast deformities often have a degree of ptosis and herniation of breast tissue which may improve with subglandular implant placement. Poland syndrome is characterized by hypoplasia or aplasia of chest and limb structures including the breast. Reconstruction often is achieved in these patients with a latissimus dorsi flap and submuscular implant.

TRUNK, ABDOMEN, AND GENITOURINARY RECONSTRUCTION

Chest Reconstruction

If a significant bony defect exists (> 5 cm or four or more resected ribs), then the reconstruction may require a bone graft, mesh, or muscle flap. In patients with sternal wound infections, aggressive débridement and removal of infected hardware is essential. Serial débridements and quantitative culture data may be performed prior to definitive closure. Unilateral or bilateral pectoralis, rectus abdominus, and latissimus flaps or omentum may be used to provide soft tissue coverage. Complications such as re-infection, dehiscence, flap loss, or failure are relatively low with the integrated management of flap reconstruction and culture specific antibiotic therapy.

Posterior and lateral chest wall defects, occurring secondary to trauma or oncologic ablation, may require concomitant bony reconstruction. Marlex mesh, methylmethacrylate, and bone grafts are used to bridge rib gaps. The

latissimus, trapezius, rectus, and pectoralis are all potential options for soft-tissue reconstruction.

Abdominal Wall Reconstruction

Component separation is a technique whereby differential release of the abdominal wall musculature allows for primary closure of moderately sized open defects. For larger fascial defects PTFE (Gore-Tex), polypropylene (Prolene), polyglactin (Vicryl), or polyester (Mersilene) may be used. PTFE may predispose to infection and seroma but provides strength with minimal adhesion formation. Polypropylene mesh provides strength but may also result in adhesion formation. Polyglactin mesh integrates readily with low infection rates but provides relatively less strength. Any type of alloplastic mesh should be covered with well perfused skin and soft tissue flaps. Occasionally, tissue expanders may be used to allow sufficient local tissue to be generated for primary closure.

The rectus abdominis, tensor fascia lata, rectus femoris, latissimus dorsi muscle, omentum, and anterolateral thigh flap are excellent potential local flaps. Vacuum-assisted coverage systems are particularly useful in patients with enterocutaneous fistulas.

Traumatic, oncological, or infected abdominal defect may not be able to be reconstructed immediately and a skin graft or dermal graft may be placed over viscera and allowed to heal. The fascial defect may then be repaired during a second stage procedure.

Genitourinary Reconstruction

The gracilis myocutaneous flap or the vertical rectus abdominis myocutaneous flap may provide durable soft-tissue in patients with vaginal cancer. For congenital defects of the vagina such as Mayer-Rokitansky-Küster syndrome (congenital absence of the vagina), variants of the McIndoe procedure can be applied. A judicious dissection of the potential vaginal vault space is followed by split-thickness grafting. A bolster expander is kept in place to maintain the space.

Hypospadias is an abnormality of male urethral development characterized by proximal urethral termination. Associated anomalies, such as inguinal hernias and undescended testes, occur in 9 percent of patients. The Mathieu procedure uses a ventral, meatal-based flap, whereas the meatal advancement and glanuloplasty techniques are ideal for distal hypospadias with a more compliant urethra. Proximal hypospadias may be repaired with preputial island flaps. Bladder exstrophy reconstruction is a multistage procedure in which the external genitalia is reconstructed with local flaps.

Traumatic or oncologic defects of the perineal region may be reconstructed with gracilis, rectus abdominis, tensor fascia lata or gluteal thigh flaps. Anal sphincter reconstruction may also be performed with local gracilis or gluteus maximus flaps. Avulsion injuries or Fournier's gangrene may result in full-thickness defects requiring skin grafting. Complete penile reconstruction is a complex problem that may be managed with tubed pedicle or free flaps, such as the radial forearm flap.

The cavernous nerves may be injured during radical prostatectomy. Grafting across the nerve defect with sural nerve grafts may be performed to restore erectile function.

PRESSURE ULCERS

Pressure ulcers occur when the external pressure, especially in the areas over bony prominences, exceeds capillary filling pressures (32 mmHg). Factors associated with pressure ulcers include tissue friction, moisture, nutritional status, and advanced age. Commonly affected areas include the sacrum, heel, ischium, and trochanters. A grading system for pressure ulcers has been developed.

Treatment of pressure ulcers must incorporate adequate débridement of infected and necrotic tissue, pressure relief, local wound care, and antibiotics.

A diagnostic evaluation for osteomyelitis may include plain film, bone scan, MRI, and bone biopsy. Leukocytosis and elevated erythrocyte sedimentation rates increase the predictive value of other digestive tests. Aggressive bony débridement, vascularized flap coverage, and treatment with intravenous antibiotics are essential to successful management.

Dressings for pressure ulcers include wet-to-dry saline dressings with or without antibiotics, and enzymatic débriding ointments. Povidone-iodine or hypochlorite combinations are often useful in infected ulcers. For stage I and II ulcers, hydrocolloid dressings promote reepithelialization by providing a moist environment. Calcium alginate dressings may help to absorb wound exudates. Growth factor and basic fibroblast growth factor may also ameliorate wound healing.

The principles of pressure ulcer management include prevention of fecal contamination with bowel preparations, postoperative pharmacologic constipation, and occasionally, colostomy. Sensate pedicle fasciocutaneous flaps may provide added protection for ulcer-prone areas. For the sacrum, fasciocutaneous advancement flaps or muscle-based flaps include one or both gluteus maximus flaps. Treatment of ischial ulcers often requires ostectomies and/or bursectomies and posterior thigh flaps. Alternatively, in nonambulatory patients, V-Y advancement quadriceps flaps provide durable coverage. Less commonly, the gracilis, gluteus maximus, or even rectus abdominis muscle-based flaps may be used. The treatment of trochanteric ulcers often includes concomitant ostectomy of the exposed femoral head. The tensor fascia lata flap, gluteus maximus, posterior thigh flap, and the vastus lateralis myocutaneous flap have all been used for coverage of this region.

Recurrence occurs in 50–80 percent of patients, with higher recurrence rates found in the paraplegic population. The use of air mattresses and positional changes are useful to relieve pressure on the flap reconstruction. A rare complication of pressure ulcers is the development of Marjolin carcinoma 15–20 years after ulcer formation.

LOWER-EXTREMITY RECONSTRUCTION

After a thorough primary and secondary survey, the multidisciplinary team must assess the trauma patient in regard to neurovascular status, soft-tissue defects, and fractures. The Gustillo classification is a useful method to grade patients with open fractures of the lower extremity. A Doppler exam or arteriogram may help identify any concomitant, vascular injury.

Split-thickness skin grafts are reasonable for coverage of exposed healthy muscle or soft tissue. Local flaps are used to cover small to moderate exposed bony defects of the lower or middle third of the leg. For larger, soft-tissue defects with bony exposure, particularly of the lower one third, free tissue transfer

may be required. If no recipient vessels are available, the plastic surgeon may use a cross-leg flap as a last alternative.

Chronic osteomyelitis may complicate lower extremity reconstruction. The treatment for chronic osteomyelitis includes intravenous antibiotics, débridement of necrotic tissues, and replacement with well-vascularized soft tissue.

Diabetic Foot Ulcers

The pathophysiology of diabetic foot ulceration is divided into three components: peripheral neuropathy, peripheral vascular disease, and immunodeficiency. Because of profound sensory neuropathy, profound pressures may result in ischemia and subsequent ulcer formation. In the setting of microvascular disease, the oxygen-carrying capacity of the site is reduced, which predisposes to ulceration and diminished wound-healing capabilities. Finally, the diabetic patient's immune system is altered in terms of chemotaxis, phagocytosis, and bactericidal capacity predisposing the patient to polymicrobial bacterial and fungal infections.

Blood sugar levels must be controlled for expedient and successful wound healing. Furthermore, radiographs, bone scans, or MRI must be acquired to assess if there is osteomyelitis. Finally, a thorough vascular exam must be performed, either by duplex scanning or angiography. If significant vascular disease is present, the patient may require lower-extremity bypass.

All gross infection or foci of osteomyelitis must be débrided. Newer agents and modalities have emerged to enhance granulation and wound healing such as Regranex and the vacuum-assisted closure device. In certain circumstances, a skin graft may be appropriate, but are frequently unsuccessful because of the shear forces, particularly in weight-bearing areas. Local flaps, such as the reverse sural artery or lateral calcaneal artery flap, or free tissue transfer may provide durable tissue in weight-bearing areas.

Lymphedema

Lymphedema is classified by etiology. Primary or idiopathic lymphedema implies includes: (1) Milroy disease which is a congenital lymphedema that has an X-linked inheritance pattern; (2) lymphedema praecox which appears after puberty but before 35 years of age; and (3) lymphedema tarda which appears after the age of 35 years. Secondary lymphedema results from the mechanical obstruction of lymphatic channels.

The pathophysiology of lymphedema is based on abnormal pressure gradients in lymphatic channels. Normally, the pressure in the lower-extremity lymphatic system is subatmospheric and results in afferent lymphatic flow. However, in patients with lymphedema, the lymph spills into the dermis and subcutaneous tissue. Clinically, this is manifested as firm, nonpitting edema. CT or MRI may be helpful in differentiating lymphedema from venous insufficiency or lipodystrophic edema. Lymphoscintigraphy is useful to determine the lymphatic anatomy and quantitate the lymphatic flow.

Treatment of lymphedema is generally conservative and includes the use of external compressive garments and devices. Careful hygiene must also be instituted to avoid cutaneous fungal infection. Surgical treatments include excision of skin, subcutaneous tissue, and fascia as in the Charles procedure; suction lipectomy; lymphatic anastomosis or bridging procedures. Especially

following oncologic ablation, the onset of lymphedema must be differentiated from neoplastic invasion of the lymphatics or lymphangiosarcoma.

AESTHETIC SURGERY

Body Contouring and Liposuction

The assessment of body contour deformities requires evaluation of skin excess, lipodystrophy, and musculoaponeurotic laxity. Suction assisted lipectomy (SAL) is a technique that allows subcutaneous fat to be aspirated. Lipodystrophy without significant skin excess or musculoaponeurotic laxity may be treated with liposuction alone. Tumescant fluid is first infiltrated subcutaneously with lidocaine and epinephrine for analgesia and vasoconstriction, respectively. Significant fluid shifts may occur when large amounts of fat is aspirated and careful monitoring of urine output, intravenous fluids, and hemodynamics are required to ensure patient safety.

When excess skin and subcutaneous tissue is present or when the skin tone is compromised by age or loss of intrinsic elasticity, then frank excision of the excess tissue and skin may be necessary. If this excess occurs in the abdominal region, then abdominoplasty is performed to excise excess skin and subcutaneous tissue and plication of the rectus fascia through a low transverse incision.

Lower-body lipodystrophy may be genetic or occur after significant weight loss. If the problem is recalcitrant lipodystrophy without significant skin excess, then liposuction alone may be sufficient. However, if redundancy occurs in both the skin and subcutaneous tissue, then a lower body lift may be necessary. The entire buttock and thigh region can be elevated and advanced over the fascia and then fixed into a more cephalad position. In the upper arm, brachioplasty entails excision of skin and subcutaneous tissue through an elliptical medial inner arm incision.

Blepharoplasty and Browlift

Excess skin in the upper eyelid or dermatochalasia may be approached through an elliptical incision. Careful markings of the degree of excess skin are required to prevent overresection of skin and resultant lagophthalmos. A strip of orbicularis muscle may be excised to accentuate the fold of the eyelid. Excess postseptal fat also is resected.

When there is ptosis of the brow, elevation of the forehead in a subperiosteal or subcutaneous plane may be performed. A coronal, mid-forehead, brow, anterior hairline, or endoscopic incision can be made followed by advancement and suspension with sutures or screws.

Rhytidectomy

Excess skin and musculoaponeurotic laxity of the face may be treated with elevation of skin flaps and skin excision. Preauricular incisions are extended superiorly into the temporal hairline and posteriorly to the retroauricular region. The superficial musculoaponeurotic system (SMAS) lies immediately deep to the skin and may be plicated or excised. Often, the cervical region also is included and treated concurrently.

Rhinoplasty

Nasal airway obstruction may occur from internal or external structural defects. A deviated septum may disrupt the airflow. Through the nasal canal, the internal nasal valve consists of the upper lateral cartilage and septum and is a common location for nasal airway obstruction. Improvement in airflow with lateral traction of the cheek (Cottle sign) is an indication that spreader graft placement may improve obstructive symptoms. Deformities of the internal valve or septum may be corrected by resection or manipulation of the nasal cartilages. Excessive dorsal hump and tip deformities may be corrected by open or closed techniques. Resection or rasping of cartilage often is combined with cartilage grafts placed in critical structural locations. Cartilage may be harvested from the septum, concha, or costal margin and placed in the columella, tip, dorsum, and ala. Internal sutures may also help alter the shape of cartilaginous structures. Osteotomies may improve the relation between the nasomaxillary bony structure and the reshaped nose. The interrelatedness of the nasal subunits must be observed during any manipulation of a single structure.

CONCLUSION

Plastic and reconstructive surgery continues to implement advances in technology and basic science into clinical practice. Permutations of older techniques have resulted in more precise and refined alternatives in reconstruction surgery. Ongoing research in tissue engineering, gene therapy, and alloplastic materials are evolving into novel treatments of defects and more durable reconstructions.

Surgical Considerations in Older Adults

Rosemarie E. Hardin and Michael E. Zenilman

GENERAL CONSIDERATIONS

It is estimated that by the year 2025, persons older than age 65 will constitute 25 percent of the United States population. This ever-growing older adult population will increasingly require surgical consultation and intervention. A 1996 review showed that more than 4 million patients older than 65 years of age underwent surgical procedures, with the most common interventions being coronary artery bypass grafting, orthopedic procedures, and cholecystectomy. Older adult surgical patients account for 50 percent of surgical emergencies and 75 percent of perioperative deaths.

Chronologic age is rarely an accurate predictor of morbidity and mortality from surgical interventions. It is, however, an accurate marker for declining physiologic reserve and the presence of multiple comorbid conditions. These, in turn, place older adult patients at higher risk because of depressed cardiac, pulmonary, renal, and neurologic reserves, thereby increasing the morbidity and mortality of surgical interventions.

PREOPERATIVE EVALUATION

Surgical risk increases with advancing age as a consequence of physiologic decline and the development of comorbid conditions leading to postoperative complications, which are poorly tolerated because of decreased reserve.

The higher prevalence of comorbid disease in older adult patients places them in a higher American Society of Anesthesiologists (ASA) class; with approximately 80 percent falling into ASA class 3 or higher (Table 44-1). This physiologic fact leads to higher complication and mortality rates in patients 65 years of age or older. Mortality rates of major surgical intervention in patients older than 65 years of age without comorbid disease is approximately 5 percent but rises to approximately 10 percent with the presence of three comorbid illnesses.

A particular problem encountered in the older adult population is potential delay in surgical intervention. This may be caused by misdiagnosis of urgent surgical disease because of atypical presentations leading to higher risk of complications. Elective procedures may be delayed because of provider misconception that older adult patients will suffer complications and poor outcomes. The two main predictors of postoperative morbidity and mortality are advancing age and its accompanying physiologic decline and comorbid disease and the emergent nature of surgical interventions.

An important variable in the proper perioperative evaluation of an older adult patient is nutritional status. Older adult patients may have poor nutritional status because of either poor intake or underlying illness and comorbidities. Protein calorie malnutrition can occur in nil per os (nothing by mouth [NPO]) patients with inadequate nutritional reserve. This may occur in a short period in the older adult, malnourished surgical patient in a hypermetabolic state

TABLE 44-1 American Society of Anesthesiologists' Physical Status Classification

ASA risk stratification for anesthetic/surgical risk	
Class 1	Healthy patient
Class 2	Mild systemic disease
Class 3	Severe (but not incapacitating) systemic disease
Class 4	Severe systemic disease posing a constant threat to life
Class 5	Moribund with life expectancy < 24 h, independent of operation
Class 6 (by definition)	Organ donor

Note: Suffix "e" is added to the class for emergency operations.

induced by stress of illness and surgery. Older adult patients, therefore, need accurate assessment of nutritional status and, if clinically indicated, immediate appropriate nutritional support to meet caloric requirements.

Cardiac complications are the leading cause of perioperative complications and death in surgical patients of all age groups, but particularly among the older adult who may have underlying cardiac disease in addition to normal physiologic decline. Myocardial infarction or congestive heart failure comprises one quarter of all cardiac complications and perioperative deaths in older adult patients. Therefore, identifying correctable and uncorrectable cardiovascular disease is critical prior to elective surgical intervention.

Pulmonary complications are a major source of morbidity and mortality in surgical patients, with the older adult at an even greater risk because of the increased possibility of underlying pulmonary disease and decreased reserve. Pulmonary complications account for up to 50 percent of postoperative complications and 20 percent of preventable deaths. However, age alone is a minimal factor when adjusted for comorbidities, leading to a twofold risk of pulmonary complications.

Older adult surgical patients also are at increased risk of renal compromise in the perioperative period. The physiologic changes in renal function in these patients increase the susceptibility to renal ischemia perioperatively and to nephrotoxic agents. This functional decline with age is caused by glomerular damage and sclerosis leading to a decreased glomerular filtration rate (GFR). The GFR decreases by approximately 1 mL/min for every year over the age of 40. The GFR for a healthy 80-year-old patient is one half to two thirds of the value at age 30 years.

Acute renal failure is proven to dramatically increase morbidity and mortality in older adult patients. The mortality of perioperative acute renal failure is 50 percent, and may be even higher in older adult patients. Therefore, careful management of fluid and electrolytes status is prudent to avoid imbalances and limit exposure to nephrotoxic diagnostic studies and medications in the perioperative management of older adult patients. Prompt recognition of renal compromise, marked by an elevation of blood urea nitrogen (BUN) or creatinine levels, or oliguria requires aggressive correction of underlying causes.

SPECIFIC CONSIDERATIONS

Minimal Access Laparoscopic Surgery

The increasing experience with laparoscopic techniques, combined with minimized pain, decreased length of hospital stay, and low morbidity and mortality rates, has led to the increased use in minimal-access procedures among the older adult.

Laparoscopic surgery reduces common postoperative complications such as decreased atelectasis, ileus, and wound infections. In older adult surgical patients, these complications easily progress to pneumonia, deep vein thrombosis (DVT), moderate metabolic and electrolyte disturbances, and even sepsis. Decreased postoperative pain from smaller incisions leads to a faster return to a preoperative level of functioning including early ambulation, which decreases complications from prolonged bed rest such as DVT and pneumonia from poor pulmonary mechanics.

The cardiopulmonary effects induced by pneumoperitoneum are secondary to carbon dioxide insufflation and the increased intraabdominal pressure. CO₂ insufflation is associated with hypercarbia and acidosis, both of which are proven direct myocardial depressants. Hypercarbia becomes especially problematic in patients with preexisting pulmonary disease with chronic carbon dioxide retention such as chronic obstructive cardiopulmonary disease (COPD). However, in patients without preexisting disease, these alterations can be minimized with increased minute ventilation. The increase in intraabdominal pressure during insufflation can lead to increased afterload, increased peripheral vascular resistance and mean systemic pressure, and decreased preload because of decreased venous return.

Maintenance of adequate preload using appropriate preoperative and intraoperative volume control and careful mechanical ventilation to control hypercarbia and acidosis are basic concepts that allow safe application of minimally invasive techniques in the older adult.

A particularly valuable application of minimally invasive techniques in the older adult population is the evaluation of acute abdominal pain and to rule out a surgical abdomen. Vague, poorly localized pain with several confounding comorbid conditions that obscure the diagnosis, the risk of general anesthesia, and negative exploratory laparotomy would be life-threatening for an older adult, critically ill patient.

Endocrine Surgery

Breast Surgery

In the United States, breast cancer incidence continues to rise with advancing age; approximately two thirds of newly diagnosed breast cancer patients are age 55 years or older. Additionally, 77 percent of deaths caused by breast cancer occur in patients older than 55 years of age. There also is an increase in mortality rates for each successive 5-year age group, with patients 85 years and older having the highest mortality rate, estimated at approximately 200 deaths per 100,000 population. However, older adult patients have not been shown to present at later stages nor do they suffer increased morbidity and mortality after standard therapies.

The estimated mortality for a patient 70 years of age or older undergoing a mastectomy is less than 1 percent. Older adult women should be offered, and typically prefer, breast-conserving surgery. It has been suggested

that older adult women have a low rate of recurrence after lumpectomy, axillary dissection, and radiotherapy, making this a viable option. Radiation therapy is well tolerated by older adult women, with a minimal increase in morbidity and mortality, when added to breast-conserving procedures.

Routine axillary lymph node dissection with breast-conserving surgery remains controversial in older adult patients. There has been a trend toward providing adjuvant therapy with tamoxifen to patients with node-positive and node-negative disease, making axillary lymph node dissection (ALND) unnecessary. Furthermore, because ALND is associated with some morbidity, older adult women are considered at greater risk of chronic lymph edema and decreased shoulder mobility. In patients with clinically node-negative status, the axillary field also can be added to the radiation port to provide local control rates equivalent to those achieved with axillary dissection. However, ALND remains necessary in patients with clinically palpable axillary lymph nodes for adequate local control.

Older adult women with multiple comorbid conditions that lack the physiologic reserve to undergo the stress of surgical intervention should be offered conservative management with tamoxifen as the sole treatment. Adequate response rates have been observed and range from 10–50 percent, with failure rates ranging between 33 and 58 percent.

Thyroid Surgery

The prevalence of thyroid disease increases with advancing age. The etiologies, risk factors, and presentations of thyroid disease are similar across all ages and, therefore, are not discussed in detail. Of note, however, is that older adult patients more often present with cardiac manifestations of hyperthyroidism such as atrial fibrillation than do their younger counterparts. A common finding requiring evaluation in older adult patients is the presence of a thyroid nodule, usually detected by physical examination. These nodules are usually single and are four times more common in women, making them a particular concern for postmenopausal older adult women. Indications for surgical intervention for thyroid nodules are dependent on the characteristics of the nodule (i.e., whether it is benign or malignant, or whether the patient is euthyroid or thyrotoxic). Additionally, surgical intervention becomes necessary if the nodule enlarges, producing compressive symptoms.

Papillary carcinoma in older adult patients tends to be sporadic with a bell-shape distribution of age at presentation, occurring primarily in patients age 30–59 years. The incidence of papillary carcinoma decreases in patients older than 60 years of age. However, patients older than 60 years of age have increased risk of local recurrence and for the development of distant metastases. Metastatic disease may be more common in this population secondary to delayed referral for surgical intervention because of the misconception that the surgeon will be unwilling to operate on an older adult patient with thyroid disease. Age is also a prognostic indicator for patients with follicular carcinoma. There is a 2.2 times increased risk of mortality from follicular carcinoma per 20 years of increasing age. Therefore, prognosis for older adult patients with differentiated thyroid carcinomas is worse when compared to younger counterparts. The higher prevalence of vascular invasion and extracapsular extension among older patients is in part responsible for the poorer prognosis in geriatric patients. Advancing age leads to increased mortality risk for patients with thyroid cancer and is demonstrated by the AMES (age, metastases, extent of primary tumor,

TABLE 44-2 AMES Classification of Thyroid Cancers

	Low Mortality Risk	High Mortality Risk
A: Age	Men: < 41 y of age Women: < 51 y of age	Men: > 41 y of age Women: > 51 y of age
M: Metastases	Absence of distant metastases	Presence of distant metastases
E: Extent of primary tumor	Intrathyroidal papillary cancer (confined to thyroid) Follicular cancer with minor capsular involvement	Extrathyroidal papillary cancer Follicular cancer with major capsular involvement
S: Size of tumor	Primary tumor < 5 cm in diameter	Primary tumor \geq 5 cm in diameter (regardless of extent of disease)

Note: Older patients (men > 41 years of age and women > 51 y of age) one included in the low-risk group if tumors are less than 5 cm, intrathyroidal, or follicular with minor capsular involvement.

Source: Adapted from Sanders LE, Cady B: Differentiated thyroid cancer. *Arch Surg* 133:419,1998.

and size of tumor) classification system developed by the Lahey Clinic (Table 44-2).

Anaplastic carcinoma is a highly aggressive form of thyroid carcinoma with a dismal prognosis. It accounts for approximately 1 percent of all thyroid malignancies; however, it occurs primarily in older adult patients. This poorly differentiated tumor rapidly invades local structures, leading to clinical deterioration and eventually tracheal obstruction. These patients may present with a painful, rapidly enlarging neck mass accompanied by dysphagia and cervical tenderness. This leads to respiratory compromise and impingement of the airway. Unfortunately, because of the aggressive nature of the disease and the dismal prognosis, surgical resection of the tumor is not attempted for cure. Furthermore, radiation therapy and chemotherapy offer little benefit. Airway blockage, however, may necessitate surgical palliation or permanent tracheostomy to alleviate symptoms of respiratory distress.

Parathyroid Surgery

Approximately 2 percent of the geriatric population, including 3 percent of women 75 years of age or older, will develop primary hyperparathyroidism. Geriatric patients are usually referred to surgery only when advanced disease is present because of concerns regarding the risks of surgery, but low morbidity and negligible mortality rates combined with high cure rates of approximately 95–98 percent make parathyroidectomy safe and effective.

Limited parathyroidectomies with minimal dissection in geriatric patients are an effective alternative. This is a viable option in patients with multiple comorbid conditions in whom the increased risk of surgical intervention or general anesthesia remains a concern. One study demonstrated that preoperative localization of the hyperfunctioning gland with the aid of ^{99m}Tc -sestamibi nuclear scanning, and intraoperative parathyroid hormone (PTH) assays to rapidly confirm that all hypersecreting glands have been removed, allows limited parathyroidectomy to be performed with accuracy in older adult patients.

This procedure is described as “limited” because bilateral neck dissection for identification and biopsy of the remaining glands in order to determine if they are hypersecreting becomes unnecessary.

Cardiothoracic Surgery

Coronary Artery Bypass Grafting

There has been a significant trend in providing definitive operative intervention to older adult patients requiring coronary artery bypass grafting (CABG). Although older patients have higher morbidity and mortality rates after cardiac surgery than do younger patients, these rates are decreasing significantly over time. This decline in morbidity and mortality rates among older adult patients undergoing cardiac surgery reflects better preoperative assessment and patient selection. Older adult patients are more likely to have significant triple-vessel disease accompanied by poor ejection fraction, left ventricular hypertrophy, significant valvular disease, and previous history of myocardial infarction than are younger patients. Older adult patients also are more likely to be classified at New York Heart Association (NYHA) functional class III or higher and are more likely to present on an emergent basis. Despite the increased risk of morbidity and mortality compared to younger patients, older adult patients, including those older than age 80 years, can undergo CABG with acceptable mortality risk. The overall mortality rate is approximately 7–12 percent for older adult patients, including cases performed under emergency conditions. This figure decreases to approximately 2.8 percent when CABG is performed electively with careful preoperative evaluation.

Valve Replacement

There also is an increasing percentage of the geriatric population presenting with symptomatic valvular disease requiring intervention. The most common valvular abnormality present in older adult patients is calcific aortic stenosis, which can lead to angina and syncope. The operative mortality from aortic valve replacement is estimated to be between 3 and 10 percent, with an average of approximately 7.7 percent. If aortic stenosis is allowed to progress without operative intervention, congestive heart failure will ensue. The average survival of these patients is approximately 1.5–2 years. Older adult patients require surgery for mitral valve disease when ischemic regurgitation is present. Surgery for mitral valve disease carries a higher morbidity and mortality than for aortic intervention, with an estimated mortality rate as high as 20 percent. Left ventricular function is usually compromised in patients requiring intervention, leading to a poorer outcome in these patients. The surgical outcome for mitral valve procedures depends on the extent of the disease, age of the patient, presence of pulmonary hypertension, and extent of coronary artery disease.

Another concern regarding older adult patients who require surgery for valve disease is the additional requirement for coronary revascularization. This increases the morbidity and mortality from surgical intervention. An older adult patient with many comorbid conditions in need of a combined procedure should only have critically stenosed vessels bypassed.

An important consideration in valve replacement procedures in older adult patients is the type of prosthesis to be used. Older adult patients are at increased risk from bleeding-associated anticoagulation complications. This is especially significant in patients who have experienced falls and minor trauma

that have resulted in significant intracranial hemorrhage. To avoid the life-long requirement for anticoagulants, bioprosthetic valves should be used in place of mechanical valves whenever possible.

Trauma

Geriatric patients older than 65 years of age currently account for approximately 23 percent of total hospital trauma admissions—many of which are multisystem and life-threatening. This percentage is expected to rise to as high as 40 percent, making this a growing concern for potential long-term morbidity, mortality, rehabilitation, and cost. Trauma is the sixth most common cause of death in patients 65–74 years of age. Older adult patients are particularly susceptible to trauma because of changes that occur with aging, such as gait instability, decreased hearing and visual acuity, presence of confusion and dementia, or underlying disease. The presence of preexisting comorbid conditions increases the odds of an older adult patient experiencing a complication by a factor of three.

It is crucial to determine the medication regimen of older adult trauma patients. Medication such as beta blockers, calcium channel blockers, diuretics, and afterload reducers may impair augmentation of myocardial function in trauma patients, especially if they are hypovolemic.

Not only are older patients at increased risk of death from trauma, there is also an increased occurrence of delayed death when compared to younger patients. Preexisting cardiovascular or liver disease and the development of cardiac, renal, or infectious complications are independent predictors of delayed mortality.

The most common mechanism for injuries in the older adult is from falls, which account for approximately 20 percent of severe injuries. Many underlying chronic and acute diseases common to older adult patients place them at increased risk for falls. These diseases include postural hypotension leading to syncope “drop attacks,” dysrhythmia from sick sinus syndrome, autonomic dysfunction from polypharmacy with improper dosage of antihypertensive or oral hypoglycemic agents resulting in hypotension, and hypoglycemia.

Blunt thoracic trauma accounts for approximately 25 percent of all trauma deaths in North America. Rib fractures occur in up to two thirds of all cases of chest trauma and are associated with pulmonary complications in approximately 35 percent of cases. More than 50 percent of patients older than age 65 years sustain rib fractures from falls from less than 6 feet, which includes falls from the standing position. This injury in particular leads to morbidity and mortality for older adult patients as a consequence of the increased risk of development of pulmonary contusions and subsequent pneumonia, the latter of which occurs in 27 percent of older patients, as compared to 13 percent of younger patients.

In addition to higher mortality, older adult patients suffer from poorer functional recovery from trauma despite survival of injury, with approximately 20–25 percent of patients requiring discharge to a skilled nursing facility for long-term care and rehabilitation.

Kidney Transplantation

A new trend provides older adult patients with an increasing opportunity for organ donation and receipt, which increases the pool of potential organ donors. According to the United Network of Organ Sharing (UNOS) data, the

percentage of older adult organ donors increased from 2–24 percent between 1982 and 1995. In 1997, 44 percent of cadaveric renal transplant donors were older than 50 years of age. This trend is expected to increase given the expanding older adult population in the United States.

In the 1970s, experience with kidney transplantation in older patients was associated with poor prognosis. It was estimated that the 1-year patient and graft survival rates for patients older than age 45 years was 40 and 20 percent, respectively. This was thought to be a result of the decline in renal function and changes within the kidney as a result of damage from the aging process. It was therefore adopted that cadaveric transplants were not to be given to patients older than 45 years of age. However, advancements in immunosuppression have significantly improved quality of life off dialysis and have improved survival in this population. The significance of better survival outcomes in older patients receiving transplantation today is that older adult patients have the potential for prolonged life expectancy. The importance of this advancement is evident in the fact that in 2000, approximately 60 percent of end-stage renal disease (ESRD) patients were older than 65 years of age, and approximately 50 percent of newly diagnosed patients with ESRD belong to older age cohorts.

Older adult patients have better graft function, with decreased incidence of delayed graft function and fewer episodes of acute rejection, than do younger patients. This may be the result of decreased immune competence with aging. With the lower occurrence of both acute and chronic rejection in older adult patients, it has been suggested that older adult patients would benefit from lower doses of immunosuppressive agents. However, this decreased competence is balanced by the increased incidence of infections from viruses such as herpes, cytomegalovirus (CMV), and Epstein-Barr, and posttransplant neoplasia, including lymphoproliferative disorders.

The adoption of dual-kidney donation from older adult patients with depressed innate kidney function expanded the donor population to more than 75 years of age; greater than 15 percent of whom were glomerulosclerotic. The increased nephron mass achieved with dual-kidney transplantation compensated for the possible declining renal function with advanced age.

PALLIATIVE SURGERY

Palliative surgery is defined as surgical intervention targeted to alleviate a patient's symptoms, thus improving the patient's quality of life despite minimal impact on the patient's survival.

With an increasing number of aging surgical patients who often present with advanced disease, surgeons must be familiar with the concept of palliation to control disease. This concept focuses on providing the maximal benefit to the patient using the least-invasive intervention. Ultimately, this leads to symptom relief and preservation of the quality of life in terminal disease states.

There currently is no evidence to support that palliative surgery is less effective for older adult patients with surgically unresectable disease. Younger patients undergoing palliative interventions do not have a demonstrated improved outcome when compared to disease-matched older patients. Therefore, it is important to recognize that age is not a limitation to surgical intervention and that all interventions should be individualized based on the severity of symptoms and the predicted benefit.

Surgical palliative care can range from nonoperative management of malignant obstructions by percutaneous methods to laparoscopic surgery for the treatment of life-threatening illness by minimally invasive technique. An interesting challenge in palliative care is the determination of the actual cause of a patient's symptoms in order to offer the most beneficial, but least invasive, intervention.

Palliative intervention for symptom relief and prevention of complications can be demonstrated in the management of terminal pancreatic cancer and metastatic colorectal cancer. Two-thirds of patients with pancreatic cancer present with advanced disease, which is often diagnosed after evaluation of obstructive jaundice. Despite advanced disease, surgical intervention improves quality of life through relief of biliary obstruction. Percutaneous transhepatic stenting has emerged as a viable alternative to surgical bypass, achieving similar results and lowering mortality rates with the occurrence of fewer early complications. Endoscopic stenting is yet another option. If a patient does not have multiple comorbidities with good functional status, surgical intervention then can provide a definitive diagnosis and permanent biliary decompression and gastric drainage. Additionally, an important palliative intervention that can be provided to patients with the open procedure is chemical splanchnicectomy, which is infiltration of the celiac plexus with an agent such as alcohol for effective relief of intractable pain from tumor invasion of the celiac plexus. A gastroenterostomy drainage procedure is effective protection against gastric outlet obstruction, which inevitably develops in 30 percent of patients.

Palliative surgery for disseminated colorectal cancer should be aimed at the reduction of symptoms such as pain, obstruction, or hemorrhage. Bowel obstruction can be relieved with intestinal bypass or a diverting colostomy. The most common site of disseminated disease is the liver, and uncontrolled liver metastasis is responsible for pain, abdominal distention, jaundice, and inferior vena caval obstruction. Many patients with liver metastasis are not candidates for resection and therefore may be considered for ablation of the lesions by local destruction, cryotherapy, or radiofrequency ablation. More traditional means, such as chemotherapy, which can be administered via the hepatic artery, or radiation, also may be employed. Systemic corticosteroid therapy can be used in patients with advanced metastatic disease to reduce pain caused by swelling of the liver capsule. If bone metastases are present, pain may be controlled by irradiation, and prophylactic fixation of long bones may be considered to decrease pain and morbidity from pathologic fractures.

Specific Symptom Management

Gastrointestinal Disturbances

The distressing symptoms often faced by terminally ill patients either result from the disease process or as a side effect of treatment. The causes of nausea and vomiting in terminally ill patients are multifactorial and can be attributed to various medications or chemotherapy treatments, gastric stasis, obstruction of the gastrointestinal tract, mesenteric metastases, irritation of the gastrointestinal (GI) tract, raised intracranial pressure from cerebral metastasis, or anxiety-induced emesis. Treatment should be focused on prevention of dehydration and malnutrition from poor oral intake. Antiemetics may be administered for control of nausea and vomiting. The oral route of administration is the best option

for prophylaxis prior to chemotherapy treatments. However, other preparations, such as suppositories or injections, can be appropriate for patients who are unable to tolerate oral medications.

Diarrhea and constipation also are common GI disturbances in terminal patients. Constipation is particularly common in patients receiving chronic narcotic medications. Constipation also can be caused by such events as tumor invasion leading to intestinal obstruction, metabolic abnormalities such as hypercalcemia from metastatic disease, and dehydration. Because constipation may be worsened by dehydration, adequate fluid intake often helps to alleviate symptoms. Constipation can lead to fecal impaction, nausea, and colicky abdominal pain. If there is difficulty distinguishing between constipation and early bowel obstruction, diagnostic tests are useful, but should be kept to a minimum in terminal patients. Patients can be treated with stool softeners and stimulant agents. Laxatives with peristalsis-stimulating action such as senna or bisacodyl should be used with caution because of the potential for causing intestinal colic.

The occurrence of diarrhea also is multifactorial and can be caused by medications, overload incontinence with fecal impaction, from the disease process itself, malignant bowel obstruction, or improper laxative therapy. Radiation therapy can cause diarrhea by damage of the intestinal mucosa, which results in the release of prostaglandins and the malabsorption of bile salts that increases peristalsis. Once the underlying causes are identified and appropriately managed, patients can be given bulk-forming agents and opiate derivatives to aid in symptomatic improvement.

Cachexia and Anorexia

Cachexia refers to catabolic changes associated with progressive wasting that is present in patients with advanced illness; prominent symptoms include anorexia, weight loss, and asthenia. A subsequent loss of muscle and fat leading to anemia, hypoalbuminemia, and hypoproteinemia also is common. This is a chronic form of malnutrition and is not reversible with short-term nutritional support and hyperalimentation. Malnourished cancer patients with cachexia have reduced response to antineoplastic medications, radiation, and chemotherapy, and decreased survival rates. The mechanism of cachexia is poorly understood, but hypotheses include actions of interleukin-6, tumor necrosis factor, and interferon-mediating metabolic changes in chronic illness.

Management of cachexia begins with the identification of correctable causes. Patients may have underlying metabolic derangements, and dehydration, that must be appropriately treated. Poorly controlled pain, anemia, and sleep disturbances also may exacerbate symptoms of cachexia, leading to malnutrition and wasting. Patients with terminal disease additionally often suffer from gastrointestinal disturbances, such as constipation and nausea, which may lead to anorexia. Malabsorption is common in patients with pancreatic cancer, and supplementation of pancreatic enzymes may improve absorption and help to improve nutritional status. Nausea and vomiting should be appropriately managed. It is important to rule out mechanical causes of malnutrition that can effectively be treated with nonoperative management such as bowel rest and nasogastric tube compression or operative intervention.

If no underlying correctable abnormalities are identified, patients may benefit from pharmacologic intervention with dexamethasone and prednisone,

which increase appetites in patients with advanced cancer, leading to improved quality of life. Other agents, such as progestational drugs, namely megestrol acetate (Megace), also stimulate appetite and cause weight gain in cachexia patients.

Malignant Bowel Obstruction

Patients with malignant bowel obstruction typically present with cramping abdominal pain, nausea, and vomiting, which may be a common complication of advanced terminal disease secondary to gastrointestinal malignancy or from extrinsic compression of bowel loops from progressive tumor burden. Conservative management can be effective and includes NPO, intravenous hydration, and nasogastric decompression. Medical management with pharmacologic agents such as somatostatin analogues to decrease gastrointestinal output may also be considered for symptom alleviation along with analgesics and antiemetics. However, surgical palliation via bypass procedures, decompressing, or diverting ostomies may be required.

Surgical intervention may provide permanent alleviation of obstruction and eliminate the need for repeated nasogastric decompressions that can limit patient comfort. This must be balanced against the risk of perioperative mortality from surgical intervention, which ranges from approximately 12–20 percent, and the potential for mortality from wound infection, poor wound healing, and fistula formation. Patients in whom the risk of surgical intervention outweighs the benefit of palliation include patients who have ascites or multiple sites of obstruction accompanied by poor functional status and poor nutrition with serum albumin levels less than 3 g/dL. Should conservative management fail in a patient who is unfit to undergo surgical intervention, alternatives include a venting gastrostomy or jejunostomy, which can be inserted percutaneously.

ETHICAL CONSIDERATIONS

Ethical considerations and end-of-life care dilemmas have gained prominent focus in the care of older adult patients, especially in the terminal stages of illness. This is a particularly important issue given the increasing effectiveness of modern therapies and sophisticated intensive care available to patients with the technical ability to sustain life indefinitely. It is therefore critical to begin to address these issues early in the course of disease to properly interact with patients and family members regarding prognosis, treatment options, alternatives, and plan of care in terminal stages. Development of a clear plan of care for a terminally ill patient eases the transition from curative therapy to palliation. Open discussions regarding end-of-life care, withholding or withdrawal of life support, and medical futility are critical issues for patients, family, and caregivers and should be held as soon as is appropriate.

Defining medical futility remains controversial in practical definitions and in clinical determinations. The American Thoracic Society has stated that “a life-sustaining intervention is futile if reasoning and experience indicate that the intervention would be highly unlikely to result in meaningful survival for the patient,” with attention paid to both the duration of survival and existing quality of life. In actual clinical practice, it is difficult to predict that a particular therapy will in fact be futile in a given patient. It is helpful to clarify a patient’s wishes regarding life-sustaining treatment via advance directives, living wills,

and do not resuscitate (DNR) orders to avoid unnecessary prolongation of futile treatment.

The governing principle in end-of-life decision making is patient autonomy, which takes precedence over physicians' judgment of what is most appropriate care. Patients have a right to refuse treatment, even if it delays appropriate treatment or results in the patient's death. However, these preferences need to be documented during a time of mental competency. Surrogate decision making is tantamount to patient's wishes, giving surrogates complete decision-making responsibilities.

Physicians are not required to provide futile care. The Patient Self-Determination Act allows a patient to document preferences for life-sustaining interventions and resuscitation before undergoing treatments in the form of advance directives and living wills. These documents define the patient's wishes regarding life support measures. Additionally, a surrogate for decision making can be appointed by the patient to make decisions regarding plan of care in the event the patient becomes mentally incapacitated. Unfortunately, most DNR orders are written only within days of a patient's death. This issue should always be addressed with patients prior to operative intervention.

Another important principle is open communication. Patients must be informed honestly of their diagnosis and prognosis, and of the risks and benefits of all treatment options. It can be difficult to accurately portray a patient's prognosis to either the patient or family members because it often is unclear. Although this may be impossible to predict with certainty, patients and their families can be given honest information based on a physician's prior clinical experience with similar patients.

One of the most difficult issues faced in palliative care is resolution of conflicts that arise between the physician and the patient's family. Withdrawal and withholding of life-sustaining therapies is often a source of conflict between the physician, patient, and family members. It has been demonstrated that the most frequently identified cause of conflict, accounting for approximately 63 percent of disputes, was in regard to decisions for withdrawal or withholding of treatment. Strategies to avoid conflict regarding termination of care or withholding further measures that are deemed futile is to identify a single decision maker early in the course of illness and to establish a clear line of communication between the physician and family members regarding diagnosis, treatment plans, and transition to palliative care. The easiest way of avoiding conflict is by maintaining a relationship with the patient and the patient's family throughout the course of hospitalization.

End-of-life decisions are considerably easier when a patient elects a surrogate decision maker to make all necessary decisions in event of incapacitation via written documentation prior to admission to the hospital. Additionally, continuity of care must be established with flexibility in treatment plans. One method is to establish limits to therapy prior to, and during, therapy. This is helpful in demonstrating whether a patient is likely to respond to therapy and helps to alleviate family doubt regarding the likelihood of the patient's recovery and can confirm the physician's assessment that further care would be futile. If conflicts continue, involvement of an ethical committee is the next appropriate step. It is important for a physician to alleviate the fear of legal liability for the family member or proxy responsible for making the decision to withdraw or withhold life-sustaining therapies.

The discipline of anesthesia embodies control of three great concerns of humankind: consciousness, pain, and movement. The field of anesthesiology combines the administration of anesthesia with the perioperative management of the patient's concerns, pain management, and critical illness. The fields of surgery and anesthesiology are truly collaborative and continue to evolve together, enabling the care of sicker patients and rapid recovery from outpatient and minimally invasive procedures.

BASIC PHARMACOLOGY

Pharmacokinetics "What the Body Does to the Drug"

Pharmacokinetics describes the relationship between the dose of a drug and its plasma or tissue concentration. It depends on absorption (into the bloodstream), distribution, and elimination. Route of administration, metabolism, protein binding, and tissue distribution all affect the pharmacokinetics of a particular drug.

Administration, Distribution, and Elimination

The route of administration of a drug affects its pharmacokinetics, as there will be different rates of drug entry into the circulation. For example, the oral and intravenous routes are subject to first-pass effect of the portal circulation; this can be bypassed with the nasal or sublingual route. Other routes of drug administration include transdermal, intramuscular, subcutaneous, or inhalation.

Distribution is the delivery of a drug from the systemic circulation to the tissues. Once a drug has entered the systemic circulation, the rate at which it will enter the tissues depends on several factors:

1. Molecular size of the drug, capillary permeability, polarity, and lipid solubility. Small molecules will pass more freely and quickly across cell membranes than large ones, but capillary permeability is variable and results in different diffusion rates. Renal glomerular capillaries are permeable to almost all non-protein-bound drugs; capillaries in the brain are fused (i.e., they have tight junctions) and are relatively impermeable to all but the tiniest molecules (the blood-brain barrier). Unionized molecules pass more easily across cell membranes than charged molecules; diffusibility also increases with increasing lipid solubility.
2. Plasma protein and tissue binding. Many drugs bind to circulating proteins like albumin, glycoproteins, and globulins. Disease, age, and the presence of other drugs will affect the amount of protein binding; drug distribution is affected because only the unbound free portion of the drug can pass across the cell membrane. Drugs also bind reversibly to body tissues; if they bind with high affinity they are said to be sequestered in that tissue (e.g., heavy metals are sequestered in bone).

The fluid volume in which a drug distributes is termed the volume of distribution (Vd). This mathematically derived value gives a rough estimation of the overall physical distribution of a drug in the body. A general rule for volume distribution is that the greater the Vd, the greater the diffusibility of the drug. Because drugs have variable ionization rates and bind differently to plasma proteins and tissues, the Vd is not a good predictor of the actual concentration of the drug after administration. Determining the apparent volume of distribution (dose/concentration) is an attempt to more accurately ascertain the drug dose administered and its final concentration. This in turn is complicated by the immediate elimination of a drug after administration.

Drug elimination varies widely; some drugs are excreted unchanged by the body, some decompose via plasma enzymes, and some are degraded by organ-based enzymes in the liver. Many drugs rely on multiple pathways for elimination (i.e., metabolized by liver enzymes then excreted by the kidney). When a drug is given orally, it reaches the liver via the portal circulation and is partially metabolized before reaching the systemic circulation. This is why an oral dose of a drug often must be much higher than an equally effective intravenous dose. Some drugs (e.g., nitroglycerin) are hydrolyzed presystemically in the gut wall and must be administered sublingually to achieve an effective concentration.

It is important to remember that the response to drugs varies widely. The disposition of drugs is affected by age; weight; sex; pregnancy; disease states; the concomitant use of alcohol, tobacco, and other licit and illicit drugs; and genetic factors. The most important monitor in the operating room is the anesthesiologist, who continuously assesses the patient's response and adjusts the doses of anesthetic agents to match the surgical stimulus.

Pharmacodynamics “What the Drug Does to the Body”

Pharmacodynamics, or how the plasma concentration of a drug translates into its effect on the body, depends on biologic variability, receptor physiology, and clinical evaluations of the actual drug. An agonist is a drug that causes a response. A full agonist produces the full tissue response, and a partial agonist provokes less than the maximum response induced by a full agonist. An antagonist is a drug that does not provoke a response itself, but blocks agonist-mediated responses. An additive effect means that a second drug acts with the first drug and will produce an effect that is equal to the algebraic summation of both drugs. A synergistic effect means that two drugs interact to produce an effect that is greater than expected from the two drugs' algebraic summation.

Hyporeactivity means a larger than expected dose is required to produce a response, and this effect is termed tolerance, desensitization, or tachyphylaxis. Tolerance usually results from chronic drug exposure, either through enzyme induction (e.g., alcohol) or depletion of neurotransmitters (e.g., cocaine).

Potency, Efficacy, Lethal Dose, and Therapeutic Index

The potency of a drug is the dose required to produce a given effect, such as pain relief or a change in heart rate. The average sensitivity to a particular drug can be expressed through the calculation of the effective dose; ED₅₀ would have the desired effect in 50 percent of the general population. The efficacy of any therapeutic agent is its power to produce a desired effect. Two drugs may have the same efficacy but different potencies. The difference in potency

of the two drugs is described by the ratio ED_{b50}/ED_{a50} in which *a* is the less potent drug. If the ED_{b50} equals 4 and the ED_{a50} equals 0.4, then drug *a* is 10 times as potent as drug *b*. For example, 10 mg of morphine produces analgesia equal to that of 1 mg of hydromorphone. They are equally effective, but hydromorphone is 10 times as potent as morphine.

The lethal dose (LD_{50}) of a drug produces death in 50 percent of animals to which it is given. The ratio of the lethal dose and effective dose, LD_{50}/ED_{50} , is the therapeutic index. A drug with a high therapeutic index is safer than a drug with a low or narrow therapeutic index.

ANESTHETIC AGENTS

Anesthesia can be local, regional, or general (Table 45-1).

Local anesthesia is accomplished using a local anesthetic drug that can be injected intradermally, and is used for the removal of small lesions or to repair traumatic injuries. Local anesthesia is the most frequent anesthetic administered by surgeons, and may be accompanied by intravenous sedation to improve patient comfort.

Local Anesthetics

Local anesthetics are divided into two groups based on their chemical structure: the amides and the esters. In general, the amides are metabolized in the liver and the esters are metabolized by plasma cholinesterases, which yield metabolites with slightly higher allergic potential than the amides.

Amides

The amide local anesthetics include lidocaine, bupivacaine, mepivacaine, prilocaine, and ropivacaine. Lidocaine has a more rapid onset and is shorter acting than bupivacaine; however, both are widely used for tissue infiltration, regional nerve blocks, and spinal and epidural anesthesia. Ropivacaine is the most recently introduced local anesthetic, clinically similar to bupivacaine with a slow onset and a long duration, but less cardiotoxic. All amides are 95 percent metabolized in the liver, with 5 percent excreted unchanged by the kidneys.

Esters

The ester local anesthetics include cocaine, procaine, chlorprocaine, tetracaine, and benzocaine. Unique among local anesthetics, cocaine occurs in nature, was the first used clinically, produces vasoconstriction (making it useful for topical application; e.g., for intranasal surgery), releases norepinephrine from nerve terminals resulting in hypertension, and is highly addictive. Cocaine is a Schedule II drug. Procaine, synthesized in 1905 as a nontoxic substitute for cocaine, has a short duration and is used for infiltration. Tetracaine has a long duration and is useful as a spinal anesthetic for lengthy operations. Benzocaine is for topical use only. The esters are hydrolyzed in the blood by pseudocholinesterase. Some of the metabolites have a greater allergic potential than the metabolites of the amide anesthetics, but true allergies to local anesthetics are rare.

The common characteristic of all local anesthetics is a reversible block of the transmission of neural impulses when placed on or near a nerve membrane. Local anesthetics block nerve conduction by stabilizing sodium channels in their closed state, preventing action potentials from propagating along the nerve. The individual local anesthetic agents have different recovery times

TABLE 45-1 Anesthetic Agents, Their Actions, and Their Clinical Uses

Effect	Monitor	Intravenous drugs	Potent gases	Weak gases	Local anesthetics	
Unconsciousness, amnesia, anxiolysis	<i>Eeg</i> ; clinical signs	<i>Benzodiazepines</i> Midazolam Diazepam Lorazepam <i>Barbiturates</i> <i>Propofol</i> <i>Etomidate</i> Ketamine ^a	Sevoflurane Desflurane Isoflurane Enflurane Halothane	Nitrous oxide		
Analgesia	Heart rate, blood pressure, respiratory rate, clinical signs	<i>Opioids</i> Morphine Meperidine Hydromorphone Fentanyl <i>NSAID</i> Ketorolac Parecoxib	Sevoflurane Desflurane Isoflurane Enflurane Halothane	Nitrous oxide	<i>Amides</i> Lidocaine Bupivacaine Mepivacaine Prilocaine Ropivacaine <i>Regional peripheral</i> Brachial plexus	<i>Esters</i> Cocaine Procaine Chloroprocaine Tetracaine Benzocaine
Muscle relaxation, paralysis	Nerve stimulator; clinical signs; tidal volume, hand grip; 5-second head lift	<i>Depolarizing agent</i> Succinylcholine <i>Nondepolarizing agents</i> Pancuronium Vecuronium Rocuronium Atracurium Cis-atracurium Mivacurium	Sevoflurane Desflurane Isoflurane Enflurane Halothane	—	Lower extremity Cervical plexus <i>Regional central</i> Spinal Epidural	

^aNote that the intravenous agents are quite specific in their effects, except for ketamine, which has both amnestic and analgesic qualities.

The potent inhalational anesthetics contribute to all three components of anesthesia, but nitrous oxide has weak amnestic and analgesic properties, and provides no muscle relaxation at all.

The local anesthetics produce excellent analgesia and muscle relaxation, but contribute nothing to amnesia or anxiolysis, these anesthetics must be supplemented with an intravenous sedative.

General anesthesia entails all three elements of anesthesia (amnesia, analgesic, and muscle relaxation).

based on lipid solubility and tissue binding, but return of neural function is spontaneous as the drug is metabolized or removed from the nerve by the vascular system.

Toxicity of local anesthetics results from absorption into the bloodstream or from inadvertent direct intravascular injection. Toxicity manifests first in the more sensitive central nervous system, and then the cardiovascular system.

Central nervous system. As plasma concentration of local anesthetic rises, symptoms progress from restlessness to complaints of tinnitus. Slurred speech, seizures, and unconsciousness follow. Cessation of the seizure via administration of a benzodiazepine or thiopental and maintenance of the airway is the immediate treatment. If the seizure persists, the trachea must be intubated with a cuffed endotracheal tube to guard against pulmonary aspiration of stomach contents.

Cardiovascular system. With increasingly elevated plasma levels of local anesthetics, progression to hypotension, increased P-R intervals, bradycardia, and cardiac arrest may occur. Bupivacaine is more cardiotoxic than other local anesthetics. It has a direct effect on ventricular muscle, and because it is more lipid soluble than lidocaine, it binds tightly to sodium channels (it is called the fast-in, slow-out local anesthetic). Patients who have received an inadvertent intravascular injection of bupivacaine have experienced profound hypotension, ventricular tachycardia and fibrillation, and complete atrioventricular heart block that is extremely refractory to treatment. The toxic dose of lidocaine is approximately 5 mg/kg; that of bupivacaine is approximately 3 mg/kg.

Calculation of the toxic dose before injection is imperative. It is helpful to remember that for any drug or solution, 1 percent = 10 mg/mL. For a 50-kg person, the toxic dose of bupivacaine is approximately 3 mg/kg, or $3 \times 50 = 150$ mg. A 0.5 percent solution of bupivacaine is 5 mg/mL, so $150 \text{ mg} / 5 \text{ mg/mL} = 30 \text{ mL}$ as the upper limit for infiltration. For lidocaine in the same patient, the calculation is $50 \text{ kg} \times 5 \text{ mg/mL} = 250 \text{ mg}$ toxic dose. If a 1 percent solution is used, the allowed amount would be $250 \text{ mg} / 10 \text{ mg/mL} = 25 \text{ mL}$.

Additives. Epinephrine has one physiologic and several clinical effects when added to local anesthetics. Epinephrine is a vasoconstrictor, and by reducing local bleeding, molecules of the local anesthetic remain in proximity to the nerve for a longer time period. Onset of the nerve block is faster, the quality of the block is improved, the duration is longer, and less local anesthetic will be absorbed into the blood stream, thereby reducing toxicity. Although epinephrine 1:200,000 (5 $\mu\text{g/mL}$) added to a local anesthetic for infiltration will greatly lengthen the time of analgesia, epinephrine-containing solutions should not be injected into body parts with end-arteries such as toes or fingers, as vasoconstriction may lead to ischemia or loss of a digit.

Regional Anesthesia

Peripheral

Local anesthetic can be injected peripherally, near a large nerve or plexus to provide anesthesia to a larger region of the body. Examples include the brachial plexus for surgery of the arm or hand, blockade of the femoral and sciatic nerves for surgery of the lower extremity, ankle block for surgery of the foot or toes, intercostal block for analgesia of the thorax postoperatively, or blockade of the cervical plexus, which is ideal for carotid endarterectomy. Risks of peripheral

regional nerve blocks are dependent on their location. For example, nerve blocks injected into the neck risk puncture of the carotid or vertebral arteries, intercostal nerves are in close proximity to the vascular bundle and have a high rate of absorption of local anesthetic, and nerve blocks of the thorax run the risk of causing pneumothorax. All peripheral nerve blocks may be supplemented intraoperatively with intravenous sedation and/or analgesics.

Central

Local anesthetic injected centrally near the spinal cord—spinal or epidural anesthesia—provides anesthesia for the lower half of the body. This is especially useful for genitourinary, gynecologic, inguinal hernia, or lower-extremity procedures. Spinal and epidural anesthesia block the spinal nerves as they exit the spinal cord. Spinal nerves are mixed nerves; they contain motor, sensory, and sympathetic components. The subsequent block will cause sensory anesthesia, loss of motor function, and blockade of the sympathetic nerves from the level of the anesthetic distally to the lower extremities. Subsequent vasodilation of the vasculature from sympathetic block may result in hypotension, which is treatable with intravenous fluids and/or pressors.

Spinal anesthesia. Local anesthetic is injected directly into the dural sac surrounding the spinal cord. The level of injection is usually below L1–L2, where the spinal cord ends in most adults. Because the local anesthetic is injected directly into the cerebrospinal fluid (CSF) surrounding the spinal cord, only a small dose is needed, the onset of anesthesia is rapid, and the blockade thorough. Lidocaine, bupivacaine, and tetracaine are commonly used agents of differing durations; the block wears off naturally via drug uptake by the CSF, blood stream, or diffusion into fat. Epinephrine as an additive to the local anesthetic will significantly prolong the blockade.

Possible complications include hypotension, especially if the patient is not adequately prehydrated; high spinal block requires immediate airway management; and postdural puncture headache sometimes occurs. Spinal headache is related to the diameter and configuration of the spinal needle, and can be reduced to approximately 1 percent with the use of a small, 25- or 27-gauge needle.

Cauda equina syndrome is injury to the nerves emanating distal to the spinal cord resulting in bowel and bladder dysfunction, and lower-extremity sensory and motor loss. It has mainly been seen in cases in which indwelling spinal microcatheters and high (5 percent) concentrations of lidocaine were used. Indwelling spinal catheters are no longer used.

Epidural anesthesia. Epidural anesthesia also could be called extradural anesthesia, because local anesthetics are injected into the epidural space surrounding the dural sac of the spinal cord. Much greater volumes of anesthetic are required than with spinal anesthesia, and the onset of the block is longer—10–15 min. As in spinal anesthesia, local anesthetic bathes the spinal nerves as they exit the dura; the patient achieves analgesia from the sensory block, muscle relaxation from blockade of the motor nerves, and hypotension from blockade of the sympathetic nerves as they exit the spinal cord. Note that regional anesthesia, whether peripheral or central, provides only two of the three major components of anesthesia—analgesia and muscle relaxation. Anxiolysis, amnesia, or sedation must be attained by supplemental intravenous administration of other drugs (e.g., the benzodiazepines or propofol infusion).

Complications are similar to those of spinal anesthesia. Inadvertent injection of local anesthetic into a dural tear will result in a high block, manifesting as unconsciousness, severe hypotension, and respiratory paralysis requiring immediate aggressive hemodynamic management and control of the airway. Indwelling catheters often are placed through introducers into the epidural space, allowing an intermittent or continuous technique, as opposed to the single-shot method of spinal anesthesia. By necessity, the epidural-introducing needles are of a much larger diameter (17- or 18-gauge) than spinal needles, and accidental dural puncture more often results in a severe headache that may last up to 10 days if left untreated.

General Anesthesia

General anesthesia incorporates a triad of three major and separate effects: unconsciousness (and amnesia), analgesia, and muscle relaxation (see Table 45-1). Intravenous drugs usually produce a single, discrete effect, although most inhaled anesthetics produce elements of all three. General anesthesia is achieved with a combination of intravenous and inhaled drugs, each used to its maximum benefit. The science and art of anesthesia is a dynamic process: as stimuli to the patient change during surgery, the patient's vital signs are used as a guide and the quantity of drugs is adjusted, maintaining an equilibrium between stimulus and dose. General anesthesia is what patients commonly think of when they are to be "put under," and can be a cause of considerable preoperative anxiety.

Intravenous Agents

Unconsciousness and amnesia. The intravenous agents that produce unconsciousness and amnesia are frequently used for the induction of general anesthesia. They include barbiturates, benzodiazepines, propofol, etomidate, and ketamine. Except for ketamine, the following agents have no analgesic properties, nor do they cause paralysis or muscle relaxation.

Barbiturates. The most common barbiturates are thiopental, thiamylal, and methohexital. The mechanism of action is at the gamma-aminobutyric acid (GABA) receptor, where they inhibit excitatory synaptic transmission. They produce a rapid, smooth induction within 60s, and wear off in about 5 min.

Propofol. Propofol is an alkylated phenol that inhibits synaptic transmission through its effects at the GABA receptor. With a short duration, rapid recovery, and low incidence of nausea and vomiting, it has emerged as the agent of choice for ambulatory and minor general surgery. Additionally, propofol has bronchodilatory properties which make its use attractive in asthmatic patients and smokers. Propofol may cause hypotension, and should be used cautiously in patients with suspected hypovolemia and/or coronary artery disease (CAD), the latter of which may not tolerate a sudden drop in blood pressure. It can be used as a continuous infusion for sedation in the intensive care unit setting. Propofol is an irritant and frequently causes pain on injection.

Benzodiazepines. The most important uses of the benzodiazepines are for reduction of anxiety and to produce amnesia. Frequently used intravenous benzodiazepines are diazepam, lorazepam, and midazolam. They all inhibit synaptic transmission at the GABA receptor, but have differing durations of action. The benzodiazepines can produce peripheral vasodilatation and hypotension, and have minimal effects on respiration when used alone. They

must be used with caution when given with opioids; a synergistic reaction causing respiratory depression is common. The benzodiazepines are excellent anticonvulsants, and only rarely cause allergic reactions.

Etomidate. Etomidate is an imidazole derivative used for intravenous induction. Its rapid and almost complete hydrolysis to inactive metabolites results in rapid awakening. Like the above intravenous agents, etomidate acts on the GABA receptor. It has little effect on cardiac output and heart rate, and induction doses usually produce less reduction in blood pressure than that seen with thiopental or propofol. Etomidate is associated with pain on injection and more nausea and vomiting than thiopental or propofol.

Ketamine. Ketamine differs from the above intravenous agents in that it produces analgesia and amnesia. Its principal action is on the N-methyl-D-aspartate (NMDA) receptor; it has no action on the GABA receptor. A dissociative anesthetic, it produces a cataleptic gaze and nystagmus. Patients may associate this with delirium and hallucinations while regaining consciousness; the addition of benzodiazepines has been shown to prevent these side effects. Ketamine can increase heart rate and blood pressure which may cause myocardial ischemia in patients with CAD. Ketamine is useful in acutely hypovolemic patients to maintain blood pressure via sympathetic stimulation, but is a direct myocardial depressant in patients who are catecholamine depleted. Ketamine is a bronchodilator, making it useful for asthmatic patients, and rarely is associated with allergic reactions.

Analgesia. The intravenous analgesics most frequently used in anesthesia today have little effect on consciousness, amnesia, or muscle relaxation. The most important class is the opioids, so called because they were first isolated from opium, with morphine, codeine, meperidine, hydromorphone, and the fentanyl family being the most common. The most important nonopioid analgesics are ketamine (discussed above) and ketorolac, an intravenous nonsteroidal antiinflammatory drug (NSAID).

Opioid analgesics. The commonly used opioids—morphine, codeine, oxycodone, meperidine, and the fentanyl-based compounds—act centrally on μ -receptors in the brain and spinal cord. The main side effects of opioids are euphoria, sedation, constipation, and respiratory depression, which also are mediated by the same μ -receptors in a dose-dependent fashion. Although opioids have differing potencies required for effective analgesia, equianalgesic doses of opioids result in equal degrees of respiratory depression. Thus there is no completely safe opioid analgesic. The synthetic opioids fentanyl, and its analogs sufentanil, alfentanil, and remifentanil, are commonly used in the operating room. They differ pharmacokinetically in their lipid solubility, tissue binding, and elimination profiles, and therefore have differing potencies and durations of action. Remifentanil is remarkable in that it undergoes rapid hydrolysis that is unaffected by sex, age, weight, or renal or hepatic function, even after prolonged infusion. Recovery is within min, but there is little residual postoperative analgesia.

Naloxone and the longer-acting naltrexone are pure opioid antagonists. They can be used to reverse the side effects of opioid overdose (e.g., respiratory depression), but the analgesic effects of the opioid also will be reversed.

Nonopioid analgesics. Ketamine, an NMDA receptor antagonist, is a potent analgesic, but is one of the few intravenous agents that also causes significant

sedation and amnesia. Unlike the μ -receptor agonists, ketamine stimulates respiration. It can be used in combination with opioids, but the dysphoric effects must be masked with the simultaneous use of sedatives, usually a benzodiazepine like midazolam.

Ketorolac is a parenteral NSAID that produces analgesia by reducing prostaglandin formation via inhibition of the enzyme cyclooxygenase (COX). Intraoperative use of ketorolac reduces postoperative need for opioids. Two forms of cyclooxygenase have been identified: COX-1 is responsible for the synthesis of several prostaglandins and prostacyclin (which protects gastric mucosa), and thromboxane, which supports platelet function. COX-2 is induced by inflammatory reactions to produce more prostaglandins. Ketorolac (and many oral NSAIDs, aspirin, and indomethacin) inhibits both COX-1 and COX-2, which causes the major side effects of gastric bleeding, platelet dysfunction, and hepatic and renal damage. Parecoxib is a parenteral COX-2 NSAID now being tested which would presumably produce analgesia and reduce inflammation with less gastrointestinal bleeding and platelet dysfunction.

Neuromuscular blocking agents. Neuromuscular blocking agents have no amnestic, hypnotic, or analgesic properties; patients must be properly anesthetized prior to and in addition to the administration of these agents. A paralyzed but unsedated patient will be aware, conscious, and in pain, yet be unable to communicate their predicament. Inappropriate administration of a neuromuscular blocking agent to an awake patient is one of the most traumatic experiences imaginable. Neuromuscular blockade is not a substitute for adequate anesthesia, but is rather an adjunct to the anesthetic. Depth of neuromuscular blockade is best monitored with a nerve stimulator to ensure patient immobility intraoperatively, and to confirm a lack of residual paralysis postoperatively.

Unlike the local anesthetics, which affect the ability of nerves to conduct impulses, the neuromuscular blockers have no effect on either nerves or muscles, but act primarily on the neuromuscular junction.

There is one commonly used depolarizing neuromuscular blocker—succinylcholine. This agent binds to acetylcholine receptors on the postjunctional membrane in the neuromuscular junction and causes depolarization of muscle fibers.

Although the rapid onset (< 60 s) and rapid offset (5–8 min) make succinylcholine ideal for management of the airway in certain situations, total body muscle fasciculations can cause postoperative aches and pains, an elevation in serum potassium levels, and an increase in intraocular and intragastric pressure. Its use in patients with burns or traumatic tissue injuries may result in a high enough rise in serum potassium levels to produce arrhythmias and cardiac arrest. Unlike other neuromuscular blocking agents, the effects of succinylcholine cannot be reversed. Succinylcholine is rapidly hydrolyzed by plasma cholinesterase, also referred to as pseudocholinesterase. Some patients have a genetic disorder manifesting as atypical plasma cholinesterase; the atypical enzyme has less-than-normal activity, and/or the patient has extremely low levels of the enzyme. The incidence of the homozygous form is approximately one in 3000; the effects of a single dose of succinylcholine may last several h instead of several min. Treatment is to keep the patient sedated and unaware he or she is paralyzed, continue mechanical ventilation, test the return of motor function with a peripheral nerve stimulator, and extubate the patient only after he or she has fully regained motor strength.

Two separate blood tests must be drawn: pseudocholinesterase level to determine the amount of enzyme present, and dibucaine number, which indicates the quality of the enzyme. Patients with laboratory-confirmed abnormal pseudocholinesterase levels and/or dibucaine numbers should be counseled to avoid succinylcholine (and mivacurium, which also is hydrolyzed by pseudocholinesterase). First-degree family members should also be tested. Succinylcholine is the only intravenous triggering agent of malignant hyperthermia (discussed below).

There are several competitive nondepolarizing agents available for clinical use. The longest-acting is pancuronium, which is excreted almost completely unchanged by the kidney. Intermediate-duration neuromuscular blockers include vecuronium and rocuronium, which are metabolized by both the kidneys and liver, and atracurium and cis-atracurium, which undergo breakdown in plasma known as Hofmann elimination. The agent with shortest duration is mivacurium, the only nondepolarizer that is metabolized by plasma cholinesterase, and like succinylcholine, is subject to the same prolonged blockade in patients with plasma cholinesterase deficiency. All nondepolarizers reversibly bind to the postsynaptic terminal in the neuromuscular junction and prevent acetylcholine from depolarizing the muscle. Muscle blockade occurs without fasciculation and without the subsequent side effects seen with succinylcholine. Table 45-2 lists the most commonly used agents of this type and their advantages and disadvantages.

The reversal of neuromuscular blockade is not a true reversal of the drug, as with protamine reversal of heparinized patients. Neuromuscular blocking reversal agents, usually neostigmine, edrophonium, or pyridostigmine, increase acetylcholine levels by inhibiting acetylcholinesterase, the enzyme that breaks down acetylcholine. The subsequently increased circulating levels of acetylcholine prevail in the competition for the postsynaptic receptor, and motor function returns. Use of the peripheral nerve stimulator is required to follow depth and reversal of motor blockade, but it is essential to correlate data from the nerve stimulator with clinical signs that indicate return of motor function, including tidal volume, vital capacity, hand grip, and 5-s sustained head lift.

TABLE 45-2 Advantages and Disadvantages to Common Nondepolarizing Neuromuscular Blocking Agents

Agent	Duration	Advantages	Disadvantages
Pancuronium	>1 h	No histamine release	Tachycardia; slow onset; long duration
Vecuronium	<1 h	No cardiovascular effects	Intermediate onset
Rocuronium	<1 h	Fast onset; no cardiovascular effects	
Mivacurium	<1 h	Fast onset; short duration	Histamine release

Inhalational Agents

Unlike the intravenous agents, the inhalational agents provide all three characteristics of general anesthesia: unconsciousness, analgesia, and muscle relaxation. It would be impractical to use an inhalation-only technique in larger surgical procedures, because the dose required would cause unacceptable side effects, so intravenous adjuncts such as opioid analgesics and neuromuscular blockers are added to optimize the anesthetic. All inhaled anesthetics display a dose-dependent reduction in mean arterial blood pressure except for nitrous oxide, which maintains or slightly raises the blood pressure. Nitrous oxide, although not potent enough to use alone, provides partial anesthesia and allows a second potent agent to be used in smaller doses.

Minimum alveolar concentration (MAC) is a measure of anesthetic potency. It is the ED₅₀ of an inhaled patient (i.e., the dose required to block a response to a painful stimulus in 50 percent of subjects). The higher the MAC, the less potent an agent is. The potency and speed of induction of inhaled agents correlates with their lipid solubility and is known as the Meyer-Overton rule. Nitrous oxide has a low solubility and is a weak anesthetic agent, but has the most rapid onset and offset. The “potent” gases (e.g., desflurane, sevoflurane, isoflurane, enflurane and halothane) are more soluble in blood than nitrous oxide and can be given in lower concentrations, but have longer induction and emergence characteristics.

Sevoflurane and desflurane are the two most recently introduced inhalational agents in common use. Because of their relatively lower tissue and blood solubility, induction and recovery are more rapid than with isoflurane or enflurane.

All of the potent inhalational agents (e.g., halothane, isoflurane, enflurane, sevoflurane, and desflurane), and the depolarizing agent succinylcholine, are triggering agents for malignant hyperthermia.

ANESTHETIC MANAGEMENT

Preoperative Evaluation and Preparation

The preoperative visit results in a summary of all pertinent medical findings, including a detailed history, current drug therapy, complete physical examination, and laboratory and specific testing results. Based on these findings, the anesthesiologist may find that the patient is not in optimal medical condition to undergo elective surgery. These findings and opinions are then discussed with the patient's primary physician and the surgery may be delayed or canceled until the patient's medical condition is further tested and optimized.

The detailed medical history obtained at the preoperative visit should include the patient's previous exposure and experience with anesthesia, and any family history of problems with anesthesia. History of atopy (medication, foods, or environmental) is an important aspect of this evaluation in that it may predispose patients to form antibodies against antigens that may be represented by agents administered during the perioperative period. A careful review of major organ systems and their function also should be performed.

The physical examination is targeted primarily at the central nervous system, cardiovascular system, lungs, and upper airway.

Concurrent medications that produce desired effects (i.e., β blockade, antihypertensive, and asthma medications) should be continued throughout the perioperative period; patients should be counseled to continue these medications up to and including the morning of surgery.

Preoperative laboratory data and specific testing for elective surgery should be patient- and situation-specific. For example, serum potassium if the patient is on diuretics, glucose in a diabetic patient, or hemoglobin concentration if the planned surgery has a high risk of blood loss. Coagulation tests are not necessary if the patient is not receiving anticoagulants or has no history, signs or symptoms of abnormal clotting. Otherwise healthy patients usually do not need preoperative laboratory testing, and tests performed within the previous 6 months usually are sufficient. Other tests that should be generated by history and physical exam include chest radiograph if there is evidence of chest disease, and pulmonary function tests in patients who are morbidly obese, severe asthmatics, or patients undergoing pulmonary resection surgery. An electrocardiogram (ECG) should be performed in all symptomatic patients, and in asymptomatic men age 45 years or older and asymptomatic women age 50 years or older. Urine pregnancy testing is recommended on the day of surgery in all menstruating females.

Risk Assessment

An integral part of the preoperative visit is for the anesthesiologist to assess patient risk. Risk assessment encompasses two major questions: (1) Is the patient in optimal medical condition for surgery? and (2) Are the anticipated benefits of surgery greater than the surgical and anesthetic risks associated with the procedure?

Originally designed as a simple classification of a patient's physical status immediately prior to surgery, the ASA physical status scale is one of the few prospective scales that correlate with the risk of anesthesia and surgery (Table 45-3).

Criticism of the ASA scale is primarily because of its exclusion of age and difficulty of intubation (discussed later in this chapter); the ASA scale remains useful and should be applied to all patients during the preoperative visit.

Evaluation of the Airway

The airway examination is employed to identify those patients in whom management of the airway and conventional endotracheal intubation may be difficult. It is vitally important to recognize such patients before administering medications that induce apnea.

Mallampati Classification

The amount of the posterior pharynx one can visualize preoperatively is important and correlates with the difficulty of intubation. A large tongue (relative to the size of the mouth) that also interferes with visualization of the larynx on laryngoscopy will obscure visualization of the pharynx. The Mallampati

TABLE 45-3 ASA Physical Status Classification System

P1	A normal healthy patient
P2	A patient with mild systemic disease
P3	A patient with severe systemic disease
P4	A patient with severe systemic disease that is a constant threat to life
P5	A moribund patient who is not expected to survive without the operation
P6	A declared brain-dead patient whose organs are being removed for donor purposes

classification is based on the structures visualized with maximal mouth opening and tongue protrusion in the sitting position.

Other predictors of difficult intubation include obesity, immobility of the neck, interincisor distance less than 4 cm in an adult, a large overbite, or the inability to shift the lower incisors in front of the upper incisors. The thyromental distance (i.e., the distance from the thyroid cartilage to the mentum [tip of the chin]) should be greater than 6.5–7 cm.

Consideration of Patients with Comorbidities

A thorough knowledge of the pathophysiology of concurrent medical conditions regardless of the reason for surgery is essential for optimal perioperative care. Optimal anesthesia extends beyond pharmacology and technical procedures. Specifically, ischemic heart disease, renal dysfunction, pulmonary disease, metabolic and endocrine disorders, central nervous system diseases, and diseases of the liver and biliary tract can have major impact on the management of anesthesia.

Ischemic Heart Disease

Ischemic heart disease is the result of the heart demanding more oxygen than its supply can provide. In the vast majority of cases, this is because of a reduction in the luminal area of coronary arteries secondary to atherosclerosis.

An estimated 14 million people in the United States have ischemic heart disease. Of these, as many as 4 million have few or no symptoms and are unaware that they are at risk for angina pectoris, myocardial infarction, or sudden death.

An important goal of the preoperative visit is for the anesthesiologist to ascertain the severity, functional limitations and possibility of previously undiagnosed ischemic heart disease. The risk of perioperative death because of myocardial infarction in patients without ischemic heart disease is approximately 1 percent. In contrast, the risk in patients with known or suspected ischemic heart disease is approximately 3 percent, and in patients undergoing surgery for peripheral vascular disease, the combined risk of death because of cardiac causes is 29 percent.

Major Risk Factors for Coronary Artery Disease

The risk of hypercholesterolemia is proportional to the increased serum level of low-density lipoprotein (LDL) cholesterol. Reduction achieved via decreased dietary fat or pharmacotherapy reduces risk.

Hyperlipidemia may be familial, and thus may account for the fact that a strong family history of premature CAD is a significant risk factor. High-density lipoprotein (HDL) cholesterol is protective.

Although definitely a risk factor, hypertension alone probably does not cause plaques. Rather, it may act synergistically with hypercholesterolemia by first causing mechanical wall stress and damage.

Smoking causes endothelial damage and therefore promotes plaque thrombosis. Cessation greatly reduces the risk of CAD.

Diabetes mellitus is a strong independent risk factor. A hypothesis is that glycosylation products cause release of growth factors that stimulate smooth muscle proliferation and blockage of coronary arteries.

Other risk factors. Hyperhomocysteinemia is becoming an established independent risk factor, but is still under evaluation. Reduction of levels by folate therapy may be beneficial.

Advanced age, male sex, obesity, and a sedentary lifestyle also can put a person at risk for developing ischemic heart disease.

Drugs used for the medical management of patients with ischemic heart disease and hypertension should be continued throughout the perioperative period.

Intraoperative anesthetic technique allows for the prompt control of hemodynamic variables; the maintenance of the balance between myocardial oxygen delivery and myocardial oxygen demand is probably the single most important factor in managing patients with ischemic heart disease. In patients with impaired left ventricular function, continued myocardial depression with volatile anesthetics may not be tolerated; the addition of short-acting opioids (e.g., fentanyl) is beneficial. In cardiac surgical patients, it is not uncommon for high-dose opioids to be used as the predominant anesthetic.

Pulmonary Disease

Chronic pulmonary disease has developed into a worldwide public health problem. Chronic obstructive pulmonary disease (COPD) is distinguished from asthma in that it is not reversible; it is a progressive disease that leads to the destruction of the lung parenchyma.

Infection, noxious particles, and gases can exacerbate COPD, but no specific parameters of lung function are predictive of postoperative lung complications. The highest predictive parameter found was upper abdominal surgery and thoracic surgery.

General anesthesia can be performed safely in patients with pulmonary disease; inhaled anesthetics often are used because of their bronchodilating properties.

Regional and local anesthesia has the benefit of avoiding tracheal irritation and stimulating bronchospasm. However, patients with COPD may become hypoxic while lying strictly supine, and sensory levels of anesthetic above T10 are associated with the impairment of respiratory muscle activity necessary for patients with COPD to maintain adequate ventilation.

Intraoperatively, mechanical ventilation using a slow breathing rate (8 breaths per min) should be used to allow for passive exhalation in the presence of increased airway resistance. This slow breathing, facilitated by high inspiratory flow rate, may allow for improved maintenance of normal P_{aO_2} and P_{aCO_2} levels. Patients should also be well hydrated during the procedure with adequate crystalloid/colloid volume therapy, which may allow for less viscous pulmonary secretions following surgery.

Renal Disease

Five percent of the adult population may have preexisting renal disease that could contribute to perioperative morbidity. Additionally, the risk of acute renal failure is increased by certain events or patient characteristics independent of preexisting renal disease, such as hypovolemia and obstructive vascular disease. Ischemic tubular damage (i.e., acute tubular necrosis) is the most likely cause of acute renal failure in the perioperative period, reflecting events that cause an imbalance of oxygen supply to oxygen demand in the medullary ascending tubular cells.

Virtually all anesthetic drugs and techniques are associated with decreases in renal blood flow, the glomerular filtration rate, and urine output, reflecting multiple mechanisms such as decreased cardiac output, altered autonomic nervous system activity, neuroendocrine changes, and positive pressure ventilation. Renal blood flow (15–25 percent of the cardiac output) far exceeds renal oxygen needs, but ensures optimal clearance of wastes and drugs. Prehydration and the depth of anesthesia may influence the renal response to anesthesia.

Management of anesthesia in patients with chronic renal disease requires attention to intraoperative fluid management and tight control of ventilation, as respiratory alkalosis will shift the oxyhemoglobin dissociation curve, and respiratory acidosis could raise serum potassium to dangerous levels. Because of decreased excretion by the kidney, doses of opioids and neuromuscular blocking agents must be attenuated.

Hepatobiliary Disease

Data from the 1970s suggested that approximately 1 in every 700 adult patients who are scheduled for elective surgical procedures has unknown liver disease or is in the prodromal phase of viral hepatitis. Severe hepatic necrosis following surgery and anesthesia most often is because of decreased hepatic oxygen delivery rather than the anesthetic.

Regional anesthesia may be useful in patients with advanced liver disease, assuming coagulation status is acceptable. When general anesthesia is selected, administration of modest doses of volatile anesthetics with or without nitrous oxide or fentanyl often is recommended. Selection of nondepolarizing muscle relaxants should consider clearance mechanisms for these drugs. For example, patients with hepatic cirrhosis may be hypersensitive to mivacurium because of the lowered plasma cholinesterase activity. Perfusion to the liver is maintained by administering fluids (guided by filling pressures) and maintaining adequate systemic pressure and cardiac output.

The coexisting presence of liver disease may influence the selection of volatile anesthetics. Halothane is the anesthetic most studied regarding possible hepatotoxicity. Halothane hepatitis occurs rarely (approximately 1:25,000 patients) and may have an immune-mediated mechanism stimulated by repeated exposures to halothane. Halothane, enflurane, isoflurane, and desflurane all yield a reactive oxidative trifluoroacetyl halide and may be cross-reactive, but the magnitude of metabolism of the volatile anesthetics is a probable factor in the ability to cause hepatitis. Halothane is metabolized 20 percent, enflurane 2 percent, isoflurane 0.2 percent, and desflurane 0.02 percent; desflurane probably has the least potential for liver injury. Sevoflurane does not yield any trifluoroacetylated metabolites and is unlikely to cause hepatitis.

An estimated 15–20 million adults in the United States have biliary tract disease. Treatment of gallbladder disease by open or laparoscopic cholecystectomy most often is performed with general anesthesia supplemented with muscle relaxants. Complete biliary tract obstruction could interfere with the clearance of some muscle relaxants dependent on liver metabolism, such as vecuronium and pancuronium. Anesthetic considerations for laparoscopic cholecystectomy are similar to those for other laparoscopic procedures. Insufflation of the abdominal cavity with carbon dioxide results in increased intraabdominal pressure that may interfere with the ease of ventilation and venous return. During laparoscopic cholecystectomy, placement of the patient in the reverse

Trendelenburg position favors movement of abdominal contents away from the operative site and may improve ventilation. However, this position may further interfere with venous return and reduce cardiac output, emphasizing the need to maintain intravascular fluid volume. Mechanical ventilation of the lungs is recommended to ensure adequate ventilation in the presence of increased intraabdominal pressure and to offset the effects of systemic absorption of carbon dioxide used during insufflation of the abdominal cavity. High intraabdominal pressure may increase the risk of passive reflux of gastric contents. Tracheal intubation with a cuffed tube is advised to minimize the risk of pulmonary aspiration.

Metabolic and Endocrine Disease

Metabolic and endocrine disorders encompass a wide range of diseases. These diseases may be the primary reason for surgery or can exist in patients requiring surgery for other unrelated disorders. Preoperative evaluation of endocrine function consists of relevant medical history, glucose or protein in the urine, vital signs, history of fluctuations in body weight, survey of sexual function, and concomitant medications. The three metabolic and endocrine conditions that are most prevalent in patients undergoing surgery are diabetes mellitus, hypothyroidism, and obesity. The prevalence of all three conditions, either alone or in combination, in the general population has been steadily rising throughout the world for the past 20–30 years.

Patients with diabetes are at an increased risk for perioperative myocardial ischemia, stroke, renal dysfunction or failure, and increased mortality. Increased wound infections and impairment of wound healing also is associated with the preexistence of diabetes in patients undergoing surgery.

The stress response to surgery is associated with hyperglycemia in nondiabetic patients because of increased secretion of catabolic hormones, and a combination of reduced insulin secretion and increased insulin resistance. Improved glycemic control in diabetic patients undergoing major surgery has been shown to improve perioperative morbidity and mortality; avoidance of hypoglycemia and hyperglycemic events is the standard of care in these patients.

Anesthetic techniques in the diabetic patient can modulate the secretion of catabolic hormones. There is no evidence that regional anesthesia or general anesthesia, either alone or in combination, offers any benefit to the diabetic surgical patient in terms of morbidity or mortality.

Hypothyroidism is a deficiency in the secretion of the thyroid hormones, thyroxine (T₄) and triiodothyronine (T₃), by the thyroid gland. Over 5 million Americans have this common medical condition, and as many as 10 percent of women may have some degree of thyroid hormone deficiency. Controlled clinical trials have not shown an increase in risk when patients with mild to moderate hypothyroidism undergo surgery. Nevertheless, close monitoring of these patients for adverse effects of anesthesia including delayed gastric emptying, adrenal insufficiency, and hypovolemia, is warranted.

The prevalence of significant obesity continues to rise both in developed and developing countries, and is associated with an increased incidence of a wide spectrum of medical and surgical pathologies. In the United States, one third of people have a body weight more than 20 percent above their ideal weight. Body mass index (BMI) is calculated by dividing the weight in kilograms by the square of the height in meters. In the United States, the prevalence of a

BMI greater than 25 kg/m² is 59.4 percent for men, 50.7 percent for women, and 54.9 percent for adults overall. Patients with a BMI greater than 28 have increased perioperative morbidity over the general population.

Anesthetic management of the obese patient is problematic, and tasks such as establishing intravenous access, applying monitoring equipment, managing the airway, and transporting the patient are more difficult. Ventilation may be a particular problem because of obstructive sleep apnea or because obesity itself imposes a restrictive ventilatory state with decreased expiratory reserve and vital capacity. Induction of anesthesia is particularly challenging in the obese patient, as there is increased risk of pulmonary aspiration, and the increased mass of soft tissue about the head and neck make establishing and maintaining a patent airway difficult.

The impact of obesity on the pharmacokinetics of anesthetic drugs is variable. For example, blood volume often is increased in obese patients, which can decrease predicted concentrations of drugs, but adipose tissue has low blood flow, which could elevate blood concentrations of these agents. It is prudent to calculate the first dose of anesthetic based on ideal body weight, and base subsequent dosages on the patient's responsiveness.

Central Nervous System Disease

Diseases of the central nervous system (CNS) present unique situations for the anesthesiologist, and require an understanding of the relationship between intracranial pressure (ICP), cerebral blood flow (CBF), and cerebral metabolic rate of oxygen consumption (CMRO₂). Preoperative assessment of ICP is difficult, as symptoms of headache, nausea, and vomiting are nonspecific, and signs of retinal changes do not occur acutely. A midline shift on computed tomography (CT) scanning or magnetic resonance imaging (MRI) may indicate an expanding lesion in the brain.

Provision of anesthesia for intracranial procedures must balance hemodynamic factors such as fluid volume, mean arterial pressure (MAP), ICP, and CBF. For intracranial tumors, the mass effect of the tumor makes control of ICP and CBF critical. In intracranial aneurysm surgery, the goal of the anesthetic is to prevent sudden increases in systemic blood pressure that could rupture the aneurysm, especially during the stress of laryngoscopy and endotracheal intubation.

The relationship between MAP, ICP, and CBF is affected by pharmacologic agents. Inhalational agents in high concentrations (>0.6 MAC) cause dilation of the cerebral vasculature, decreasing cerebral vascular resistance. Cerebral blood flow is therefore increased in a dose-dependent fashion, despite decreases in CMRO₂.

Propofol decreases CBF, ICP, and CMRO₂. Propofol may also decrease systemic blood pressure, resulting in a decrease in cerebral perfusion pressure; however, propofol does not alter the autoregulation of CBF. Etomidate is a potent cerebral vasoconstrictor that reduces CBF and ICP, and should be used with caution in patients with epilepsy because of its excitatory effects seen on electroencephalograms.

Opioids decrease cerebral blood flow and may also decrease ICP under certain conditions. However, Sperry and associates have reported increases in ICP with the administration of fentanyl in head trauma patients. Additionally, opioids have a depressant effect on consciousness and ventilation that may

increase ICP if accompanied by an increase in Paco_2 ; opioids should be used with caution in head trauma patients.

Regardless of the drugs or technique selected, maintenance of stable hemodynamics is optimal. Recovery from anesthesia should be smooth, avoiding pain, coughing, and straining, all of which can increase blood pressure and ICP, and cause bleeding at the surgical site.

Fluid therapy can increase cerebral edema and ICP when administered in large quantities, resulting in hypervolemia. Euvolemia should be the goal in head trauma patients, although hypervolemia may be beneficial for patients with intracranial aneurysms, to reduce vasospasm.

INTRAOPERATIVE MANAGEMENT

Induction of General Anesthesia

During induction of anesthesia, the patient becomes unconscious and rapidly apneic, myocardial function usually is depressed, and vascular tone abruptly changes. The induction of general anesthesia is the most critical component of practicing anesthesia, as the majority of catastrophic anesthetic complications occur during this phase. There are several different techniques used for the induction of general anesthesia, each with significant advantages and disadvantages. Each patient must be carefully evaluated during the preoperative period to ensure that the most efficacious and safe technique is used.

Intravenous induction, used primarily in adults, is smooth and is associated with a high level of patient satisfaction. The addition of opioids will blunt the response of laryngoscopy and intubation to avoid hypertension and tachycardia.

In a patient with a full stomach, the standard induction technique may result in vomiting and pulmonary aspiration of stomach contents. The goal of rapid sequence induction is to achieve secure protection of the airway with a cuffed endotracheal tube while preventing vomiting and aspiration.

Rapid sequence induction is performed as follows:

1. Proceed only after evaluation of the airway predicts an uncomplicated intubation,
2. Preoxygenate the patient,
3. Rapidly introduce an intravenous induction agent, (e.g., propofol),
4. An assistant to the anesthesiologist presses firmly down on the cricoid cartilage to block any gastric contents from being regurgitated into the trachea, and
5. A muscle relaxant is injected and the trachea is quickly intubated. The assistant is instructed not to release pressure on the cricoid cartilage until the cuff of the endotracheal tube is inflated and the position of the tube is confirmed.

Patients undergoing inhalation induction progress through three stages: (1) awake, (2) excitement, and (3) surgical level of anesthesia. Adult patients are not good candidates for this type of induction, as the smell of the inhalation agent is unpleasant and the excitement stage can last for several min, which may cause hypertension, tachycardia, laryngospasm, vomiting, and aspiration. Children, however, progress through stage 2 quickly, and are highly motivated for inhalation induction as an alternative to the intravenous route. The benefit of postinduction intravenous cannulation is the avoidance of many presurgical

anxieties, and inhalation induction is the most common technique for pediatric surgery.

Management of the Airway

After induction of anesthesia, the airway may be managed in several ways, including by face mask, with a laryngeal mask airway (LMA), or most definitively by endotracheal intubation with a cuffed endotracheal tube. Nasal and oral airways can help establish a patent airway in a patient being ventilated with a mask by creating an air passage behind the tongue.

The LMA is a cuffed oral airway that sits in the oropharynx. It is passed blindly and the cuff is inflated to push the soft tissues away from the laryngeal inlet. Because it does not pass through the vocal cords, it does not fully protect against aspiration. It should not be used in patients with a full stomach.

The accurate placement of an endotracheal tube requires skill, the proper equipment, and the proper conditions. Usually the patient is unconscious and immobile (including paralysis of the muscles of respiration). Intubation is typically performed under direct visualization by looking through the mouth with a laryngoscope directly at the vocal cords (direct laryngoscopy), and watching the endotracheal tube pass through the cords into the trachea. To obtain a direct line of sight, the patient is placed in the sniffing position. The neck is flexed at the lower cervical spine and extended at the atlanto-occipital joint. This flexion and extension is amplified during laryngoscopy. Laryngoscope handles contain batteries and can be fitted with curved (Macintosh) or straight (Miller) blades.

Some patients have physical characteristics or a history suggesting difficulty in placing an endotracheal tube. A short neck, limited neck mobility, small interincisor distance, short thyromental distance, and Mallampati class IV, may all represent a challenge to endotracheal intubation. Several devices have been developed to assist in management of the difficult airway. The Bullard rigid fiberoptic laryngoscope is a self-contained device that can be passed through a mouth with a narrow opening. The head and neck also can be kept in a neutral position, as a direct line of sight needed with a standard laryngoscope is not necessary.

The intubating laryngeal mask airway (ILMA) is an advanced form of laryngeal mask airway designed to maintain a patent airway and facilitate tracheal intubation with an endotracheal tube. The ILMA can be placed in anticipated or unexpectedly difficult airways as an airway rescue device and as a guide for intubating the trachea. An endotracheal tube can be passed blindly through the ILMA into the larynx, or the ILMA can be used as a conduit for a flexible fiberoptic scope.

The flexible fiberoptic intubation scope is the gold standard for difficult intubation. It is indicated in difficult or compromised airways in which neck extension is not desirable, or in cases with risk of dental damage. The scope is constructed of fiberoptic bundles and cables encased in a sheath. The cables permit manipulation of the tip of the scope by adjustments made at the operating end of the device. There is a port for suction and/or insufflation of oxygen. The scope gives excellent visualization of the airway with minimal hemodynamic stress when used properly. It can be used nasally or orally in an awake, spontaneously ventilating patient, whose airway has been treated with topical anesthetic. It requires skill for proper use, is expensive, and requires careful maintenance.

The ASA has developed algorithms for management of the difficult airway.

Fluid Therapy (See Chapter 2)

Transfusion of Red Blood Cells (See Chapter 3)

RECOVERY FROM ANESTHESIA

Reversal of Neuromuscular Blockade

The elimination of neuromuscular blocking agents from the body and subsequent resumption of neuromuscular transmission takes a considerable amount of time, therefore it has become routine to antagonize the neuromuscular block pharmacologically with the use of reversal agents. Reversal agents raise the concentration of the neurotransmitter acetylcholine to a higher level than that of the neuromuscular blocking agent. This is accomplished by the use of anticholinesterase agents, which reduce the breakdown of acetylcholine. The most commonly used agents are neostigmine, pyridostigmine, and edrophonium.

The common side effects of these three anticholinesterase agents are bradycardia, bronchial and intestinal smooth muscle contractions, and excessive secretions from salivary and bronchial glands. These effects are primarily mediated by effects on muscarinic receptors, which are effectively blocked by the concomitant use of antimuscarinic drugs such as atropine or glycopyrrolate. To ensure adequate ventilation postoperatively, it is important that the neuromuscular blocking agents are fully reversed, as assessed by monitoring twitch strength with a nerve stimulator and clinically correlating this with signs such as grip strength or 5-s head lift.

The Postanesthesia Care Unit

It is of primary importance that all patients awakening from anesthesia are followed in a recovery room, as approximately 10 percent of all anesthetic accidents occur in the recovery period. As more serious surgeries are performed on older and sicker patients, the number of patients requiring postoperative ventilation and medications to support their circulation increases with age. The new trend for postoperative pain control with continuous epidural administration of local anesthetics and narcotics demands close observation, because respiratory depression can occur. In most hospitals, the number of intensive care beds is too small to accommodate the increasing number of these patients. What originally began as the recovery room now must function as an intensive care unit setting for short stays. The name "recovery room" has been changed to "postanesthetic care unit" (PACU).

A variety of physiologic disorders that can affect different organ systems need to be diagnosed and treated in the PACU during emergence from anesthesia and surgery. Postoperative nausea and vomiting (PONV), airway support, and hypotension requiring pharmacologic support have been observed to be the most frequent complications in the PACU. However, abnormal bleeding, hypertension, dysrhythmia, myocardial infarction, and altered mental status are not uncommon.

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) typically occurs in 20–30 percent of surgical cases and generally is considered a transient, unpleasant event carrying little long-term morbidity; however, aspiration of emesis, gastric bleeding,

and wound hematomas may occur with protracted or vigorous retching or vomiting. Troublesome PONV can prolong recovery room stay and hospitalization, and is one of the most common causes of hospital admission following ambulatory surgery. Prophylactic administration of antiemetics is not cost-effective in the surgical setting. Recent consensus guidelines using data from systematic reviews, randomized trials and studies, and data from logistic regression models recently have been published.

Agents usually administered for PONV are the serotonin receptor antagonists ondansetron, dolasetron, granisetron, and tropisetron. The safety and efficacy of the compounds when given at the end of surgery are virtually identical. Metoclopramide, when used in the standard dose of 10 mg, is ineffective for PONV. Although some studies have shown higher doses (20 mg) to have some effect on PONV, most evidence suggests that the serotonin receptor antagonists are the most efficacious choice.

Pain: The Fifth Vital Sign

Analgesic research methodology has been enhanced since the 1960s through the use of graduated and visual analog scales, tools that permit the standardization of pain scores. One frequently used graduated scale is a four-point measure of pain intensity (0 = no pain, 1 = mild pain, 2 = moderate pain, and 3 = severe pain) and a five-point measure of relief (0 = no relief, 1 = a little relief, 2 = some relief, 3 = a lot of relief, and 4 = complete relief).

Acute postoperative pain and its treatment (or prophylaxis) is a significant challenge for the health care professional. Despite the recent development of new nonnarcotic analgesics, and a better understanding of the side effects associated with pain medication of all types, acute postoperative pain remains a significant concern for patients, and represents an extremely negative experience for patients undergoing surgery. Many patients experience pain in the postoperative period despite the use of potent techniques such as patient-controlled analgesia, epidural analgesia, and regional anesthesia. The culture of acceptance of postoperative pain is changing. The American Pain Society has advocated the assessment of pain as the fifth vital sign, along with temperature, pulse, blood pressure, and respiratory rate. The four vital signs provide a quick snapshot of a patient's general condition, but pain management advocates claim the picture is not complete without including pain as the fifth vital sign. This approach may improve the efficacy of pain treatment.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a life-threatening, acute disorder, developing during or after general anesthesia. The clinical incidence of malignant hyperthermia is about 1:12,000 in children and 1:40,000 in adults. A genetic predisposition and one or more triggering agents are necessary to evoke MH. Triggering agents include all volatile anesthetics (e.g., halothane, enflurane, isoflurane, sevoflurane, and desflurane), and the depolarizing muscle relaxant succinylcholine. Volatile anesthetics and/or succinylcholine cause a rise in the myoplasmic calcium concentration in susceptible patients, resulting in persistent muscle contraction. The classic MH crisis entails a hypermetabolic state, tachycardia, and the elevation of end-tidal CO_2 in the face of constant minute ventilation. Respiratory and metabolic acidosis and muscle rigidity follow, and rhabdomyolysis, arrhythmias, hyperkalemia, and sudden cardiac arrest. A rise in temperature is often a late sign of MH.

Treatment must be aggressive and begin as soon as a case of MH is suspected:

1. Call for help.
2. Stop all volatile anesthetics and give 100 percent oxygen.
3. Hyperventilate the patient up to three times the calculated minute volume.
4. Begin infusion of dantrolene sodium, 2.5 mg/kg IV. Repeat as necessary, titrating to clinical signs of MH. Continue dantrolene for at least 24 h after the episode begins.
5. Give bicarbonate to treat acidosis if dantrolene is ineffective.
6. Treat hyperkalemia with insulin, glucose, and calcium.
7. Avoid calcium channel blockers.
8. Continue to monitor core temperature.
9. Call the malignant hyperthermia hotline to report the case and get advice: 1-888-274-7899.

Medicine has undergone several important changes over the last decade. Technologic and molecular advances have fundamentally changed the way diseases are treated. Access to the internet has changed the way both physicians and patients learn about diseases. Political and economic pressures have changed the way society views and reimburses medical care. The end result is that access to medical care, access to information about medical care and the very nature of the doctor-patient relationship have changed. These changes in medicine have resulted in a need for new approaches to medical education as well. The Accreditation Council for Graduate Medical Education (ACGME) developed the core competencies as a way to articulate, and measure, the specific goals of medical education in the United States.

The core competencies offer an effective conceptual framework to train surgeons and are designed to ensure that surgical residents will learn the skills necessary to competently and compassionately treat patients as they enter practice. The six core competencies, as designated by the ACGME are: patient care, medical knowledge, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice. These are principles that should make up the basis of competent surgical practice in the 21st century. Articulating these competencies, and mandating documentation that they have been learned, should lead to greater and more universal compliance with these principles. Even though the ACGME has mandated that all residency programs must train their residents in the six core competencies there is enormous flexibility in how this is to be accomplished. Training surgical residents in the modern health care system is an especially challenging endeavor. Not only must educators impart the medical knowledge of caring for patients and new advances in patient care but they must also impart the technical skills necessary to perform complex surgical procedures. Furthermore, with the burgeoning field of genomics and molecular biology, the surgical trainee must become adept at understanding and applying the latest in molecular medicine. The challenge of the surgical educator is to develop innovative and focused learning techniques to accomplish all six core competency mandates within an 80-h work week.

CORE COMPETENCIES

The six core competencies include six specific areas that have been designated as critical for resident training. Each surgical training program should provide an environment that is conducive for training of these six core competencies and proper assessment of that training (Table 46-1). The areas of training include:

1. Patient care. Residents must be able to provide patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health.

TABLE 46-1 Accreditation Council for Graduate Medical Education Core Competencies [ACGME].

Core competency	Description
Patient Care	To be able to provide compassionate and effective health care in the modern day health care environment.
Medical Knowledge	To effectively apply current medical knowledge in patient care and to be able to use medical tools (e.g., PubMed) to stay current in medical education.
Practice-Based Learning and Improvement	To critically assimilate and evaluate information in a systematic manner to improve patient care practices.
Interpersonnel/Communication Skills	To demonstrate sufficient communication skills that allow for efficient information exchange in physician-patient interactions and as a member of a health care team.
Professionalism	To demonstrate the principles of ethical behavior (e.g., informed consent, patient confidentiality) and integrity that promotes the highest level of medical care.
Systems-Based Practice	To acknowledge and understand that each individual practice is part of a larger health care delivery and to be able to use the system to support patient care.

- a. Communicate effectively and compassionately with patients and patient family members.
 - b. Use the latest medical information to effectively formulate and implement a patient management plan.
 - c. Competently interpret diagnostic information and perform all diagnostic or therapeutic procedures essential for patient care.
 - d. Collaborate with other health care professionals to deliver excellent patient care.
2. Medical Knowledge. Residents must demonstrate knowledge about established and evolving biomedical, clinical, and cognate (e.g., epidemiological and social-behavioral) sciences and the application of this knowledge to patient care.
 - a. Understand and apply the basic and clinical sciences that are necessary for practice in the appropriate discipline.
 3. Practice-Based Learning and Improvement. Residents must be able to investigate and evaluate their patient care practices, appraise and assimilate scientific evidence, and improve their patient care practices.
 - a. Systematically appraise and analyze one's clinical practice and practice-based outcomes. Apply this information for improvement in patient care.
 - b. Understand the basics of statistical methodology and its application for the appraisal of clinical studies.
 - c. Apply information technology tools for efficient management of patient information, support of clinical care, and patient education.
 4. Interprofessional and Communication Skills. Residents must be able to demonstrate interpersonal and communication skills that result in effective

- information exchange and teaming with patients, patient families, and professional associates.
- a. Develop the skills necessary to lead a medical team that may consist of consultants and allied health care professionals.
 - b. Effectively elicit patient interaction and participation in their care through nonverbal communication skills.
 - c. Create a skill set that will allow trainees to sustain a healthy patient-physician relationship based on trust and integrity.
5. Professionalism. Residents must demonstrate a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population.
- a. Demonstrate the principles that are inherent for practice as a physician such as integrity, respect, and a responsiveness to patient care and society that may supersede self-interest.
 - b. Act responsibly with a commitment to excellent patient care.
 - c. Understand and practice the ethical obligations for patient confidentiality, informed consent, and business practice.
 - d. Awareness of a possible patient cultural difference and to be sensitive and respectful of these differences.
6. Systems-Based Practice. Residents must demonstrate an awareness of and responsiveness to the larger context and system of health care and the ability to effectively call on system resources to provide care that is of optimal value.
- a. Acknowledge the importance of understanding that each individual medical practice is a component of the entire health care system and that each individual practice impacts the overall delivery and access of health care.
 - b. Practice cost-efficient health care so that resources may be properly allocated and health-care costs controlled.
 - c. Advocate for the improvement in health care delivery, quality health care, and improvement of patient access.
 - d. Develop a knowledge base of how to partner with health care organizations and health care providers to improve health care access, delivery, and cost-control.

Patient Care

Patient care is the foundation for the practice of clinical medicine and must be addressed early and continuously during residency. In the past, patient care was taught by an apprenticeship model, in other words, spending time with attending physicians on the wards or in the operating room. This model, which started with true “house officers” (i.e., residents that lived full-time in the hospital), is inherently inefficient. The unnecessary time spent between times of real learning are an experience the former generation will not forget and the current generation cannot afford. Training surgeons involves not only imparting sufficient knowledge, but, much like training pilots, also requires “hours” of practice, to ensure mastery of the technical skills needed to competently practice the art of surgery. With the 80-h work week, residents and educators must become more focused and efficient to provide adequate time to learn complex procedures and complex issues of patient care. The application of resident time motion studies may aid in properly allocating time to high-yield patient care. For example, optimal teaching occurs when residents participate in educationally appropriate

operations with attending physicians that have a dedication to teaching. This ideal cannot always be met, but programs have to struggle with how to limit the time residents spend doing inherently simple problems and procedures to allow them to concentrate on more complex issues. Other methods of maximizing the resident educational experience include adding ancillary professionals (e.g., physician assistants or nurse practitioners) to help with the day-to-day simple necessities of patient care so that the surgical residents can spend more time on high-yield tasks. Other innovative educational philosophies and techniques also can be applied to surgical education to optimize resident training. For example, lessons learned in the training of pilots have direct applicability to the training of surgeons. The use of simulators, whether mechanical or “table simulators” (e.g., discussing the case before scrubbing) is one example of how these techniques can be applied to surgical training.

Medical Knowledge

The rapidly changing medical research environment also has created a responsibility among medical trainees to understand evolving research and its application to patient care. With this in mind, the ACGME has stated that “residents must demonstrate knowledge about established and evolving biomedical, clinical, and cognate (e.g., epidemiological and social-behavioral) sciences and the application of this knowledge to patient care.” Surgery has undergone an exponential growth in new procedures and technologies. With this explosion in medical innovation, surgical training programs are posed with the daunting task of teaching new and complex skills to surgical trainees. From laparoscopic procedures to endovascular stenting, the evolving indications and techniques for each new surgical procedure must be continuously taught to the residents. Furthermore, the field of molecular biology and its application to surgical diseases has mandated that surgeons understand the basic molecular mechanisms of each disease. “Molecular surgery” has become a term that can describe the training of future surgeons and the knowledge base that surgeons will need to function in the 21st century medical field. The new era of molecular biology requires understanding the complex science that will lead to such innovations as molecular fingerprinting techniques to tailor treatments that are specific for each individual patient. Other, more cognitive tools such as the ability to critically review literature and logically apply the relevance of a study must also be imparted to residents so that they can correctly apply the latest medical studies to each individual patient.

The ability of a surgical program to adequately meet this educational challenge can be improved by using innovative learning techniques. Educational systems such as the SQR system of studying, the Pimsleur model and Rosetta Stone learning techniques are all tools that can aid in the understanding and application of a rapidly advancing surgical field. Finally, it must be conveyed to surgical trainees that surgery is a life-long learning process and the ability to continue building on one’s medical knowledge is critical for a successful surgical career.

Practice-Based Learning and Improvement

The third ACGME mandate concerns the ability of the trainee to learn from real-life scenarios to improve their own performance and patient outcomes. The mandate states “residents must be able to investigate and evaluate their patient care practices, appraise and assimilate scientific evidence, and improve their patient care practices.” The goal of this mandate is to teach the surgical

trainee the ability to critically evaluate their practice patterns and outcomes in a systematic fashion. Currently, the simplest example of this mandate is the surgical morbidity and mortality conference. This conference allows for in-depth discussions on how to improve patient care and patient outcomes through review of weekly surgical cases. To further improve practice patterns the ACGME also has suggested that trainees should be trained on the use of information technology systems to manage patient information and support clinical care. As hospitals increasingly move toward computer-based patient information systems, surgical trainees must receive formal training on the use and application of these systems. One of the best examples of the use of information technology and computerized patient database systems is the Computerized Patient Record System (CPRS) that is employed by the Veterans Affairs (VA) Hospital System. This fully computerized patient database allows easy access to all patient clinical data, including lab tests, radiologic studies, physician notes, and appointment times. This central core information system has allowed the VA health system to develop the National Surgical Quality Improvement Program (NSQIP). Using information from CPRS, nurse reviewers are able to gather and input information into the NSQIP system. NSQIP has been the first prospective risk-adjusted outcome based program for comparing and improving surgical outcomes across multiple institutions. This program has revolutionized the reporting and quality control of surgical services within the VA system. With the VA system as an example of improvement in not only information technology management but also surgical outcomes monitoring, the surgical trainee will need to stay abreast of the changes in new information technology systems and its application to patient care.

Interprofessional and Communication Skills

Communication is essential to the successful and competent practice of medicine. Developing advanced communication skills not only improves patient-physician interaction but also improves interactions with physicians and other health-care professionals. To be an effective leader, which is necessary to achieve optimal patient care, surgical trainees must be taught to effectively communicate with patients, families, consultants and ancillary health care personnel. Formal leadership training has been shown to improve communication skills in surgical residents. After institution of a formal collaborative leadership training program, Awad and associates described a 12 percent increase in resident perceived communication skills. Other studies also have shown that formal physician leadership training improves communication and conflict resolution skills. The use of leadership training provides the tools necessary for successful team building. All of these components will allow the trainee to work effectively as a member or leader of a health care team.

Professionalism

The core competency of professionalism is expressed as follows: "residents must demonstrate a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population." The trainee should demonstrate respect, compassion, and integrity while involved in patient care. The adherence to the principles of patient confidentiality and informed consent also are involved in professionalism. Of all the core competencies, this one may be the most difficult to teach, and the one that relies the most on successful role models and mentors. However, with less time spent in the hospital, the ability to learn from real-life situations is decreased.

Therefore, these principles need to be creatively taught to the residents, either through didactic lectures or problem-based learning. As with communication, formal leadership training may be an effective method of teaching the basic principles of professionalism. In one study, residents increased their scores on the integrity section of an Internal Strength Scorecard Survey by 12 percent (p -value < 0.04) after completion of a formal leadership training program. Professionalism also can be taught with training in negotiating and problem-solving skills. Teaching residents how to navigate difficult situations can further promote an environment of integrity and mutual respect. Fisher and Ury have described five principles to successful conflict resolution: (1) maintain objectivity by not focusing on the participants but by focusing on the problem, (2) relinquish the position of power and inflexibility to focus more on individual interests, (3) create outcomes in which both parties will have gains, (4) make sure there are objective criteria for the negotiating process, and (5) maintain an open mind and dialogue, yielding to principles not pressure. These five principles can best be taught with role-playing and small group discussions and are essential skills for the surgical trainee. The role of the individual surgical educator in teaching professionalism cannot be overstated. The daily interaction of residents with their attending physicians is the single most important component of teaching professionalism. Therefore, it is the responsibility of each surgical educator to maintain the highest standards of integrity, for they are serving as role models for the next generation of surgeons.

Systems-Based Practice

With increasing health care costs and an aging population, surgical trainees need to recognize that they are part of a larger health care system which struggles to balance resources and principles. The ACGME has concluded it is important that "residents demonstrate an awareness of and responsiveness to the larger context and system of health care and the ability to effectively call on system resources to provide care that is of optimal value." In today's medical world, resources and finances are limited and each health care provider must understand that what they do impacts the greater health care system. Dimick and associates described a 1-year analysis of a private sector hospital participating in the private sector NSQIP program and showed that surgical complications significantly increased hospital costs. Major complications increased costs by almost \$12,000 per admission. Their conclusion was that to successfully manage health care costs, private sector hospitals should model their outcomes analysis and surgical improvement programs after the VA NSQIP system. This initial feasibility analysis of using the VA NSQIP system in the private sector has already been performed and demonstrated that use of the NSQIP system can generate reasonable predictive models in non-VA hospital.

Further integration of the NSQIP program into mainstream private health care is continuing and is a major focus of the American College of Surgeons.

As health care costs have grown, so have health care management organizations. Learning how to interact with these organizations is crucial for the improvement of health care delivery and allocation of resources. Recent reports have demonstrated that surgeons feel deficient in the understanding of the public health and business aspect of surgery. These principles can be taught by individuals who have an expertise in health care delivery systems and overall health care management. If necessary, surgical departments could enlist these experts to concisely review the important components of the health care delivery system to surgical trainees. In the daily care of patients, costs and

appropriate utilization of resources should be discussed as another way to teach this important principle.

Assessment of the Core Competencies

The ACGME has not only mandated the teaching of these six core competencies, but also has stated that residents must be evaluated to ensure they have acquired these skills. In the future, there is little doubt that these, or similar, core competencies will be used to assess practicing surgeons as well. Hence, the need to document the acquisition and maintenance of these competencies is important to all surgeons, not just those in training. Historically written medical examinations, such as the American Board of Surgery in Service Training Exam, have previously been the only measure of the educational success of a training program. However, this exam evaluates only two of the core competencies (i.e., medical knowledge and patient care). To accurately assess the other core competencies, different assessment tools need to be developed, and will vary from program to program. Small group and problem-based learning sessions are effective environments for faculty to assess the success of residents in learning the core competencies such as professionalism and communication. Sidhu and associates suggested that regular meetings with residents should be scheduled to allow frequent feedback of resident performance. Furthermore, clinical evaluations should incorporate rating systems for professionalism and interpersonal skills. If a resident is consistently rated as deficient in these categories, further counseling and training can be used to address the deficiencies.

CONCLUSION

The goal of the ACGME core competency mandate has been to ensure that patient care continues to improve into the 21st century. The goal of the modern surgical educator is to develop better means to ensure that the material is properly taught and, even more importantly, truly learned. This provides an exciting venue for introduction of new educational initiatives and development of innovative educational programs. These innovations should serve to move surgical education forward, allowing better training of the surgeons of the future.

- Gastroesophageal reflux disease (*contd.*)
 pathophysiology of, 583–586
 preoperative evaluation in, 591
 procedure selection in, 592–593
 secondary to paraesophageal hiatal
 hernia, 629
 suggested therapeutic approach to,
 590–591
 surgical principles in, 591–592
 symptomatic assessment in, 589–590
 in Zollinger-Ellison syndrome, 669
- Gastrointestinal bleeding
 in gastric cancer, 672
 obscure, 726–727
 portal hypertension and, 806–807
 postoperative, 260
- Gastrointestinal endoscopy, small-bowel
 perforation in, 250, 727
- Gastrointestinal sarcoma, 914–915
- Gastrointestinal stromal tumor, 676–677,
 717–720, 915–916
- Gastrointestinal system
 intraluminal surgery and, 305
 pediatric, 1002–1017
 appendicitis and, 1012–1014
 duodenal obstruction and, 1003–1004
 Hirschsprung disease and, 1015–1017
 hypertrophic pyloric stenosis and,
 1002–1003
 intestinal duplication and, 1014
 intestinal obstruction and, 1003
 intussusception and, 1011–1012
 malrotation and midgut volvulus and,
 1005
 Meckel diverticulum and, 1014–1015
 necrotizing enterocolitis and,
 1008–1011
 postoperative complications and,
 259–261, 261*t*, 1196–1197
- Gastrojejunostomy, 665
- Gastroparesis, 678, 679*t*
 in burn patient, 157
- Gastroschisis, 898
 in child, 1021–1022
 intrauterine rupture of umbilical cord
 and, 1020
- Gastrostomy, 680
 in esophageal atresia and
 tracheoesophageal fistula, 998–999
 jejunostomy and, 27
 percutaneous endoscopic, 26*t*, 27
- Gated blood pool scan, 461
- Gatifloxacin (Tequin), 87*t*
- Gaucher's disease, 890
- Gelatins, 40
- Gene chip, 323
- Gene expression
 cellular response to injury and, 14
 tumorigenesis and, 186
- Gene regulation, 310–313, 312*t*
- Gene therapy, 211, 318–320
- General anesthesia, 1207–1211, 1210*t*
 induction of, 1218–1219
 in minimally invasive surgery, 296
 postoperative complications of,
 247
 postoperative nausea and vomiting
 and, 1220–1221
 postoperative pain and, 1221
 potency, efficacy, lethal dose, and
 therapeutic index of, 1202–1203
 preoperative evaluation and preparation
 for, 1211–1212
 reversal of, 1220
- Genetic code, 312*t*
- Genetic factors
 in cancer, 192–197, 193–194*t*
 colorectal, 751
 gastric, 670, 671*t*
 soft tissue sarcoma, 906–907
 thyroid, 952
 in obesity, 685
 in primary hyperparathyroidism,
 964–965
 in thoracic aortic aneurysm, 497–498
- Genetic manipulations, 324–326
- Genital trauma, 1063
- Genitofemoral nerve, 925, 927
- Genitourinary reconstruction, 1183
- Genome, 313–314
- Gentamicin, 86*t*
- Germ cell tumor
 mediastinal, 428–429
 ovarian, 1026, 1078–1079
- Ghrelin, 656
- Giant cell arteritis, 549–550
 aneurysm formation in, 498
- Giant cell tumor of bone, 1138–1139
- Giant condyloma acuminata, 767
- Giant hairy nevus, 333
- Giant prosthetic reinforcement of visceral
 sac, 935–936
- Gianturco coils, 444
- Gigantomastia, 1181
- Gingival tumor, 380–381
- Gittes needle suspension, 1071
- Glasgow Coma Scale, 102, 102*t*, 1105,
 1106*t*
- Gleason score, 1047
- Gleevec, 210, 319
- Glenohumeral joint
 arthritis of, 1159

- dislocation of, 1152–1153
- instability of, 1158–1159
- Glial tumor, 1116
- Glomerular filtration rate, 1040–1041
- Glomus body, 330
- Glottic tumor, 383–385
- Glucagon, 848
- Glucagon-like peptide 2, 706*t*
- Glucagonoma, 868
- Glucocorticoids, response to injury, 5–6
- Glucose metabolism
 - after surgery, 21
 - in burn patient, 147, 156
- Glucose-6-phosphate, 21
- Glutamine, 30–31
- Gluteal flap, 1181
- Gluteus medius limp, 1140
- Glycemic control, postoperative
 - complications in, 271
- Glycopeptides, 87–88*t*
- Glycosaminoglycans, 166–167
- Goblet cell, 703
- Goiter, 949–950, 961
- Goldie Coldman hypothesis, 208
- Gonadal artery, 1037
- Gonadotropin-releasing hormone, 345
- Gorlin formula, 462
- Gout, 1141–1142
- G-protein receptor, 14, 316
- G-protein(s), 316
- Gracilis myocutaneous flap, 1183
- Graded compression sonography in acute
 - appendicitis, 787–788
- Graft
 - aortic, 109–110
 - aortobifemoral bypass, 533
 - popliteal-to-tibial, 535
 - skin, 181
 - in burn patient, 153, 154
 - for head and neck defects, 392
 - in lower-extremity reconstruction, 1184–1185
 - in soft tissue reconstruction, 1170–1171, 1171*t*
 - splenorenal, 541–542
 - xenograft, 471
- Graft rejection, 216–217
- Gram-negative bacteria, 82*t*, 83
- Gram-positive bacteria, 81–83, 82*t*
- Granulocyte-macrophage colony
 - stimulating factor, 10*t*, 13
- Granuloma
 - in Crohn disease, 712
 - laryngeal, 374
- Granulosa-theca cell tumor, 1073–1074
- Graves disease, 946–949
- Gray, 212
- Great toe
 - bunion of, 1164
 - fracture of, 1151
- Great vessels, thoracic outlet trauma and, 118–119
- Greater omentum, 901
- Greater saphenous vein, 556
 - stripping of, 566
- Greenfield filter, 258
- Groin hernia, 920–942
 - abdominal wall substitutes in, 929
 - anatomy of, 925–927
 - anesthesia for, 929–930
 - Bassini herniorrhaphy for, 931–932
 - complications of repairs for, 939–940, 940*t*
 - conventional preperitoneal prosthetic
 - repair for, 934
 - diagnosis of, 927–928, 928*t*
 - epidemiology of, 920–921
 - etiology of, 923*t*, 923–925
 - giant prosthetic reinforcement of
 - visceral sac for, 935–936
 - iliopubic tract repair for, 936–937
 - incarceration or strangulation of, 921–922
 - Kugel-Ugahary repair for, 937
 - laparoscopic inguinal herniorrhaphy for, 937–938
 - laparoscopic repair of, 295
 - Lichtenstein tension-free hernioplasty
 - for, 932–934
 - mesh plug and patch for, 934
 - natural history of, 921
 - pediatric, 940–941
 - preoperative care in, 929
 - Read-Rives repair for, 935
 - repair principles in, 930–931
 - Shouldice herniorrhaphy for, 932
 - symptoms of, 927
 - totally extraperitoneal herniorrhaphy
 - for, 939
 - transabdominal preperitoneal
 - herniorrhaphy for, 938–939
- Ground substance, 166, 330
- Growth factor receptor, 316
- Growth factor therapy, 182
- Growth hormone
 - response to burn, 147
 - response to injury, 6–7
- Guanine, 310
- Gunshot wound, 101–102
 - abdominal, 104
 - rectal, 132
 - urethral, 1053–1054

- Gustillo classification, 1184
- Gut-associated lymphoid tissue, 704
- Gynecology, 1061–1101
- benign tumors and, 1073–1074
 - diagnostic procedures in, 1061–1064, 1062*t*
 - ectopic pregnancy and, 1067–1068
 - endometriosis and, 1067
 - gynecologic operations and, 1089–1100
 - abdominal, 1096–1099
 - dilatation and curettage in, 1089–1090
 - endoscopic, 1090
 - hysteroscopic, 1092–1096
 - laparoscopic, 1090–1092
 - vaginal, 1100
 - malignant tumors and, 1074–1089
 - cervical carcinoma in, 1079–1084, 1080*t*
 - endometrial cancer in, 1084–1086, 1085*t*
 - germ cell tumors in, 1078–1079
 - ovarian tumors in, 1074–1078, 1075*t*
 - vulvar cancer in, 1078*t*, 1086–1089
 - pelvic floor dysfunction and, 1068–1070
 - pelvic organ prolapse and, 1070–1071
 - stress urinary incontinence and, 1071–1073
 - vulvar and vaginal infections and, 1064–1067
- Gynecomastia, 345–346, 1182
- H**
- Hairy cell leukemia, 887
- Hallux valgus, 1164
- Halothane hepatitis, 1215
- Halo-vest combination, 115
- Halstead radical mastectomy, 361
- Hamartoma, bile duct, 812
- Hamartomatous polyp, 753
- Hamstring injury, 1160–1161
- Hand instruments for minimally invasive surgery, 300–301
- Hand-assisted laparoscopic access, 298
- Hangman's fracture, 1110
- Hard palate tumor, 381
- Harris-Benedict equation, 23, 155, 156*t*
- Hartmann's procedure and mucus fistula, 740
- Hasson technique, 297, 302
- Haversian system, 1130
- Head and neck cancer, 377–391
 - alveolus and gingiva, 380–381
 - buccal mucosa, 381
 - etiology and epidemiology of, 377
 - floor of mouth, 380
 - hypopharynx and cervical esophagus, 382–383
 - laryngeal, 383–385
 - lip, 379
 - nasopharynx and median skull base, 386
 - neck mass and, 386–387
 - nose and paranasal sinuses, 385–386
 - oral tongue, 379–380
 - oropharyngeal, 381–382
 - palatine, 381
 - reconstructive surgery in, 1180
 - retromolar trigone, 381
 - salivary gland, 390–391
 - thyroid, 952–960
 - AMES classification of, 1191–1192, 1192*t*
 - anaplastic carcinoma in, 959
 - follicular carcinoma in, 956
 - Hürthle cell carcinoma in, 956–957
 - lymphoma in, 959–960
 - medullary carcinoma in, 958–959
 - metastatic, 960, 961–962
 - molecular genetics of, 952
 - older adult and, 1191–1192, 1192*t*
