About the Editor

Lyle J. Micheli, M.D., is one of the world's leading experts in sports medicine. He is a clinical professor of orthopaedic surgery at Harvard Medical School and the O'Donnell Family Professor of Orthopaedic Sports Medicine at Children's Hospital Boston. Dr. Micheli cofounded the world's first pediatric sports medicine clinic, the Division of Sports Medicine, at the Children's Hospital Boston in 1974, and he remains its director to this day. Dr. Micheli oversees the clinic's mission to treat child and adolescent patients with injuries of an orthopaedic nature and to sponsor research into the mechanisms of sports injuries, the techniques of rehabilitation and treatment, and the physiology of exercise and conditioning. In addition to directing the Division (which also specializes in dance medicine), Dr. Micheli has been the attending physician for the Boston Ballet since 1977.

Associations such as the American Academy of Orthopaedic Surgeons, the Chinese Association of Sports Medicine, the National Center for Sports Safety, and the International Olympic Committee have invited Dr. Micheli to speak and teach courses. In 2010, he became the Secretary General of the International Federation of Sports Medicine, having long been associated with that venerable organization, which predates even the International Olympic Committee Medical Association. Thanks to this association, Dr. Micheli has become even better known as a lecturer around the world.

Closer to home, Dr. Micheli is also a former president of the American College of Sports Medicine, former chairman of Massachusetts Governor's Council on Fitness and Sports, and a founder of the National Youth Sports Safety Foundation. He maintains a very active clinical practice at Boston Children's Hospital. Dr. Micheli personally sees between 170 and 200 patients every week. In addition, he performs an average of 1,100 surgical operations annually.

An able athlete himself, in the 1960s, Dr. Micheli represented Harvard College as an undergraduate in football, rugby, lacrosse, and boxing, while still finding the time to graduate *cum laude*. Dr. Micheli remains active in the rugby community and has served as medical director of the United States's national governing body for the sport.

Dr. Micheli is the author of an extensive number of scholarly articles. He has written five books for a general audience including *The Sports Medicine Bible* (1995) and *The Sports Medicine Bible for Young Athletes* (2001). He has also written or edited numerous academic texts. He is married to Anne and has two daughters who maintain an active interest in sports and dance. He resides in Brookline, Massachusetts, close enough to Children's Hospital Boston to bicycle to work when the New England weather is clear—and often when it isn't.

Among Dr. Micheli's many professional activities, awards, and achievements to date are the following:

- Medical Team, Boston Marathon, Finish Line Director
- Attending Physician, Boston Ballet
- Team Physician, U.S. Figure Skating Association
- Chair, Medical and Risk Management Committee, U.S.A. Rugby
- Honorary Member, National Athletic Trainers Association
- Fitness Practitioner Advisory Board, Aerobics and Fitness Association of America
- Advisory Council, Massachusetts Special Olympics

- Serves on the Editorial/Advisory Boards for more than 20 journals
- Leader, Citizen Ambassador Program Sports Medicine Delegation to East Germany and the Soviet Union
- Citation Award, American College of Sports Medicine
- Medal of Honor, Boston Ballet
- President's Award, Massachusetts Association of Health, Physical Education, Recreation and Dance
- William G. Anderson Award, American Alliance for Health, Physical Education, Recreation and Dance
- Gold Star State Council Member of the Year, National Association of Governor's Councils on Physical Fitness and Sports
- Inaugural Inductee to Athletic Trainers Massachusetts Hall of Fame
- St. Bede Academy, Peru, Illinois, Athletic Hall of Fame Inductee
- American Academy of Pediatrics Thomas E. Schaffer Award recipient (for lifetime contributions to the field of Sports Medicine)
- Given more than 100 lectures or speaking engagements since 2000
- Published nearly 150 refereed journal articles
- Published more than 100 non-refereed articles

About the Advisory Board

James R. Andrews is a founding member of Andrews Sports Medicine and Orthopaedic Center in Birmingham, Alabama, and a founder and Medical Director of the American Sports Medicine Institute (ASMI), a nonprofit institute dedicated to injury prevention, education, and research in orthopaedics and sports medicine. Through ASMI he has mentored more than 250 orthopaedic/sports medicine Fellows and more than 45 primary care sports medicine Fellows. Dr. Andrews is also a founding partner and Medical Director of the Andrews Institute and Andrews-Paulos Research and Education Institute in Gulf Breeze, Florida. A native of Homer, Louisiana, he graduated from Louisiana State University (LSU) in 1963, where he was Southeastern Conference pole vault champion. He completed LSU School of Medicine in 1967 and his orthopaedic residency at Tulane Medical School in 1972. He is a member of the American Board of Orthopaedic Surgery and the American Academy of Orthopaedic Surgeons and served as the 2009–2010 President of the American Orthopaedic Society for Sports Medicine. He is Clinical Professor of Orthopaedic Surgery at the University of Alabama Birmingham Medical School, the University of Virginia School of Medicine, the University of Kentucky Medical Center, and the University of South Carolina Medical School. Dr. Andrews provides coverage to several collegiate and professional teams including Auburn University, the University of Alabama, the Washington Redskins, the Tampa Bay Rays, and the LPGA. He also serves on the Board of Little League Baseball. Dr. Andrews has been inducted into both Alabama and Louisiana's state Sports Halls of Fame.

John Bergfeld is the former Head of Sports Medicine and now is Senior Surgeon, Department of Orthopaedics and Director of the Operating Rooms at the Cleveland Clinic, Cleveland, Ohio. Dr. Bergfeld served in the U.S. Navy as Chief of Orthopaedics of the United States Naval Academy, U.S. Naval Hospital, Annapolis, Maryland and aboard the U.S.S. Dubuque (1970–1973) with rank—Commander MC USNR. He served as a President of the American College of Sports Medicine (1984–1985) and as President of the American Orthopaedic Society for Sports Medicine (1992–1993). He served as Team Physician for the Cleveland Browns (NFL; 1976–2002), as Team Physician for the Cleveland Cavaliers (NBA; 1986–2001), as Physician to Cleveland Ballet (1976–1990), at Baldwin Wallace College (1996–present) and at the Cleveland Metropolitan Schools (1976–present). He has received numerous awards and honors and presently serves as consultant to the Cleveland Browns and Cavaliers. Dr. Bergfeld founded the Cleveland Rugby Football Club in 1964.

Arthur L. Boland received his M.D. from Cornell University Medical College in1961. After an internship and assistant residency in general surgery at New York Hospital-Cornell Medical Center, he served in the U.S. Army in Germany for two years. He completed the Harvard Combined Orthopaedic Residency Program in 1969. Dr. Boland is an assistant clinical professor of Orthopaedic Surgery at Harvard Medical School, Chief of Orthopaedic Surgery at the Harvard University Health Services, and Emeritus Head Surgeon for the Harvard Athletic Department. Dr. Boland has been an assistant team physician for the New England Patriots and Boston Bruins and was a member of the medical staff of the 1984 Olympic Games. He has also served as team physician for the U.S. Hockey Team at the World Championships in 1993 and has been an orthopedic consultant for the U.S. Rowing Team. Dr. Boland has served on numerous committees for several professional organizations, including the American Academy of Orthopedic Surgeons Committee on Sports Medicine and its Committee on Outcomes Research. He has been President and a member of the Board of Directors of the American Orthopaedic Society for Sports Medicine, President of the Herodicus Society, and a member of the program committee of the International Cartilage Repair Society, and he has served on the Strategic Planning and Membership Committees of the International Society of Arthroscopy, Knee Surgery and Orthopaedic Sports Medicine. In 2000 Dr. Boland was the recipient of the American Orthopaedic Society for Sports Medicine's "Mr. Sports Medicine Award: In Recognition and Appreciation for his Outstanding and Meritorious Service to Sports Medicine Throughout the World." In 2005 he was inducted into the American Orthopaedic Society for Sports Medicine's Hall of Fame, the Society's highest honor.

Robert C. Cantu holds many professional responsibilities, including those of Clinical Professor, Department of Neurosurgery and Co-Director Center for the Study of Traumatic Encephalopathy, Boston University School of Medicine; Senior Advisor to the NFL Head, Neck and Spine Committee; Founding member and Chairman of the Medical Advisory Board Sports Legacy Institute; Adjunct Professor of Exercise and Sport Science and Medical Director of the National Center for Catastrophic Sports Injury Research, University of North Carolina; Co-Director, Neurologic Sports Injury Center, Brigham and Women's Hospital; Chief of Neurosurgery Service, Chairman of the Department of Surgery, and Director of Sports Medicine at Emerson Hospital; Neurosurgical Consultant for the Boston Eagles football team; and Neurosurgical Consultant for the Boston Cannons professional soccer team. He has authored over 340 scientific publications, including 22 books on neurology and sports medicine, in addition to numerous book chapters, peer-reviewed papers, abstracts and free communications, and educational videos. Dr. Cantu's 2009 media appearances include providing testimony to Congress on the "NFL and Concussions," *CNN with Lou Dobbs* on the NFL Congressional Hearings, *CNN Saturday Morning,* and *60 Minutes,* as well as numerous radio programs for NPR and other networks.

Joseph M. Cummiskey attended medical school at University College Dublin from 1964 to 1970. He did his post-graduate training for 10 years in Northern California at Stanford University and the University of California, Davis, where he played and coached the Stanford University team for 3 years. His position then evolved into selection of the Northern Californian team and refereeing on the West coast. He returned to Ireland in 1985 to the then-new Blackrock Clinic. Dr. Cummiskey served as the Honorary Secretary of the Irish Sports Medicine Society from 1985–1988. He was Chief Medical Officer of the Olympic Council of Ireland from 1989–2000. A three year spell as secretary general of the Irish Sports Medicine association was followed by a 10 year spell as the chief medical officer of the Olympic Council of Ireland. He became a member of the International Olympic Committee Medical Commission in 2000. This was followed by joining the executive committee of the European Olympic Committee Medical Commission, the International Federation of Sports Medicine, and by being a member of the Medical and Scientific Commission of the European Federation of Sports Medicine Associations (EFSMA). In 2006 he entered the field of International Federations. He was soon on the Union of Cycling Medical Commission, the International Federation of Bobsleigh and Skeleton, and the International Cricket Council Medical Commussion. The most recent election saw him become the President of the European Federation of Sports Medicine Associations, the central body of the 41 countries of Europe.

Eduardo Henrique De Rose was born in Porto Alegre, Brazil, on August 8, 1942—the third son of parents emigrated from Italy. He married Regina Celi Fonticielha in 1967. They have two sons and one daughter. He holds dual citizenship with Brazil and Italy. He graduated with a degree in medicine from the State University of Sciences of Health in Porto Alegre, Brazil. Next he specialized in Sports Medicine at the University of Tours, in Tours, France. He earned a Masters degree in Sports Medicine in the University La Sapienza, in Rome, Italy. He earned an M.D. at the University of Cologne in the School of Physical Education in Cologne, Germany. He has been awarded the degree of Doctor "Honoris Causa" of the Pontifical Catholic University in Porto Alegre, Brazil. De Rose has been a strong member and elected board member of many boards and societies. He has been a member of the Medical Commission of the International Olympic Committee since 1984. He has been a member of the foundation board of the World Anti-Doping Agency since 1999. He has been President of the Medical Commission of the Association of National Olympic Committees since since 2003. He has been Honorary President of the International Federation of Sports Medicine since 2002. He has been President of the Medical Commission of the Pan American Sports Association since 1979. He has been Honorary President of the Pan American Confederation of Sports Medicine since 1991. He has been President of the Medical Commission of the South American Sports Organization since 1995. He has been a member of the Medical Commission of the Brazilian Olympic Committee (COB) since 1973. He has been President of the Anti-Doping Commission of the Ministry of Sports of the Brazilian Government since 2002. He has been Secretary General of the National Anti-Doping Organization of Brazil since 2008.

Avery Faigenbaum, Ed.D., is a full professor in the Department of Health and Exercise Science at The College of New Jersey. He serves on the editorial boards of several professional journals and is frequently quoted by national media. He was elected Vice President of the National Strength and Conditioning Association (NSCA) in 2005 and served on the Massachusetts Governor's Council on Fitness and Sports from 1998 to 2004. He was honored by the NSCA with the 1999 Junior Investigator of the Year Award, the 2000 State Director of the Year Award, and the 2003 *Strength and Conditioning Journal* Editorial Excellence Award. He is also a Fellow of the NSCA and American College of Sports Medicine. He is the author of numerous scholarly articles, as well as eight books for a general audience, including *Youth Strength Training* (2010) *Youth Fitness* (2001), and *Progressive Plyometrics for Kids* (2006). As an active researcher and practitioner in the field of pediatric exercise science, he continues to develop successful youth strength and conditioning and lecture at professional conferences worldwide

Walter R. Frontera is Dean of the Faculty of Medicine and Professor of Physical Medicine and Rehabilitation (PM&R) and Physiology at the University of Puerto Rico (UPR). Dr. Frontera completed his medical studies and a residency in PM&R at the University of Puerto Rico and received a doctoral degree in applied anatomy and physiology at Boston University. After completing his training, Dr. Frontera returned to the UPR School of Medicine and in 1993 he became the Chief of the Department of PM&R. In 1995 he spent a sabbatical year at the Karolinska Hospital in Stockholm, Sweden, in the Department of Clinical Neurophysiology studying the effects of aging. In 1996 he was recruited to Harvard Medical School to establish the Department of PM&R and was appointed the Earle P. and Ida S. Charlton Professor and Chairman of the Department of PM&R at Harvard Medical School and Spaulding Rehabilitation Hospital. His primary research interest is the study of the mechanisms underlying muscle atrophy and weakness in the elderly. His research has also included the study of skeletal muscle dysfunction in patients with neuromuscular diseases and muscle function with exercise training in patients with HIV. Dr. Frontera's research has been funded mainly by the National Institutes of Health. He has more than 200 scientific publications, including 76 peer-reviewed articles and 11 edited books. Currently, Dr. Frontera serves as the Editor-in-Chief of *The American Journal of PM&R*. He is a Regional Vice President of the International Society for PM&R; a charter member of the Kottke Society (an honorary society in rehabilitation medicine); and a fellow of the Association of Academic Physiatrists (AAP), the American Academy of PM&R, the American College of Sports Medicine, and other societies and organizations. In 2008 he was elected member of the Institute of Medicine of the National Academies (Washington, D.C.), and in 2009, member-at-large of the National Board of Medical Examiners. Dr. Frontera has presented more than 214 invited lectures in 52 countries and served as a grant reviewer and graduate research examiner for universities in Canada, South Africa, and Hong Kong. Active in international sports medicine, he is Past-President of the International Federation of Sports Medicine (FIMS). He has received several prestigious awards, including the AAP's Distinguished Academician Award in 2005 and Outstanding Service Award in 2010, the Best Scientific Research Paper (3 times) presented by the American Academy of PM&R, and the Harvard Foundation Award for his contributions to the field of PM&R. He is an honorary member of the Aragonese-Spanish Society of Sports Medicine, the Spanish Federation of Sports Medicine, the Malaysian Society of Sports and Exercise Medicine, the Chilean Society of PM&R, the Dominican Society of PM&R, the Euskalerria Society of Rehabilitation, and the Italian Society of PM&R.

Mary Lloyd Ireland is an orthopaedic surgeon and Associate Professor at the University of Kentucky, in Lexington, Kentucky. Dr. Ireland received her medical degree from the University of Tennessee. Her residency was at the University of California, Irvine, and her fellowships in Sports Medicine were at Children's Hospital Boston, Harvard University, Boston, Massachusetts, and Hughston Orthopaedic Clinic, Columbus, Georgia. She is a fellow of the American Academy of Orthopaedic Surgeons (AAOS) and American College of Sports Medicine. She is a member of the American Orthopaedic Society for Sports Medicine, the Ruth Jackson Orthopaedic Society, the American Orthopaedic Association, and an honorary member of the National Athletic Trainers Association. She served as Head Physician at the Olympic Sports Festival in Minneapolis, Minnesota in 1990 and as a Medical Staff Member at the Olympics in Barcelona, Spain in 1992. She has published numerous articles and chapters. She is co-editor of *The Female Athlete* (Saunders 2002) and editor of the AAOS *Instructional Course Lectures–Sports Medicine,* published (2005). She continues to pursue research on gender differences, and treatment and prevention of knee and shoulder injuries.

Mark Jenkins, the managing editor of the *Encyclopedia of Sports Medicine,* is the author of several books on sports health, including the *Sports Medicine Bible* and *SportsWise,* both of which he co-authored with Lyle Micheli. His feature articles have appeared in publications as wide-ranging as *The Wall Street Journal* and *Rolling Stone.* Mark is a former competitive athlete in rugby and squash, and he continues to play tennis and also bodysurf where he lives on the Island of Martha's Vineyard, Massachusetts. Mark is well-known locally and nationwide for his humorous National Public Radio (NPR) commentaries about island life.

Mininder S. Kocher is the Associate Director of the Division of Sports Medicine at Children's Hospital Boston and is an Associate Professor of Orthopaedic Surgery at Harvard Medical School. Dr. Kocher graduated Phi Beta Kappa from Dartmouth College where he was a member of the basketball and track and field teams. He graduated with honors from the Duke University School of Medicine. Clinically, Dr. Kocher's practice specializes in pediatric, adolescent, and adult sports medicine. He performs 600–700 operations annually and sees over 100 patients weekly in clinic. He is referred patients nationally and internationally. He lectures locally, regionally, nationally, and internationally. He is the head team physician for Babson College, Lasell College, Northeastern University, and the Boston Public School Sports Medicine Initiative. He is a physician for the Boston Ballet, the U.S. Ski Team, USA Track and Field, the Boston Marathon, and US Figure Skating. He has been elected to the elite sports medicine societies: The Herodicus Society and The ACL Study Group. In terms of research, Dr. Kocher is a renown orthopaedic health services researcher. Dr. Kocher has published over 100 peer-reviewed scientific articles, over 30 book chapters, and 3 textbooks. Administratively, Dr. Kocher is the Associate Director of the Division of Sports Medicine at Children's Hospital Boston. He is very involved with numerous professional organizations. He is a consultant reviewer for numerous medical journals and is a grant reviewer for numerous organizations.

John C. Richmond was a cum laude graduate of University of Pennsylvania in 1972 with a degree in Marine Biology. For his four years at University of Pennsylvania, he competed as a lightweight oarsman. John attended Tufts University School of Medicine, and was elected to Alpha Omega Alpha, Medical Honor Society in his junior year, and was President of that Society in his senior year. His residency training included two years of General Surgery at the Hospital of University of Pennsylvania, and three and half years of Orthopaedic Surgery at Tufts University Combined Orthopaedic Residency. Dr. Richmond is currently a Professor of Orthopaedic Surgery at Tufts University School of Medicine and an Adjunct Professor of Biochemical Engineering at Tufts University. He is the Chairman of the Department of Orthopedic Surgery at the New England Baptist Hospital, and practices at the Boston Sports and Shoulder Center in Chestnut Hill, MA. He was the Team Physician at Tufts University for 26 years and now serves as a consultant to the Athletic Department. His major focus in practice and research has been in advancing the treatment of the injured athlete, with projects ranging from basic science to long-term clinical outcomes. With various research teams at Tufts University he has received many awards, including the O'Donahue Clinical Research Award and the Cabaud Basic Science Research Award from the American Orthopaedic Society for Sports Medicine.

Martin P. Schwellnus holds an MBBCh (cum laude) from the University of the Witwatersrand, an MSc (Med), and a Doctor of Medicine degree from the University of Cape Town. He has been awarded fellowships from the American College of Sports Medicine and the International Sports Medicine Federation. Currently he is a full professor in Sports and Exercise Medicine at the Faculty of Health Sciences of the University of Cape Town, a Consultant Sports Physician at the Sports and Exercise Medicine Clinic at the Sports Science Institute of South Africa in Cape Town. He is also the Director of the FIFA (Fédération Internationale de Football Association) Medical Center of Excellence in Cape Town, and Director of one of only four International Olympic Committee (IOC) Research Centers in the world. His committee activities are extensive and include the following: Member of the IOC Medical Commission–Medical and Science group, Past Vice President of the International Sports Medicine Federation (FIMS), Vice President of the African Union of Sports Medicine (UAMS), and member of the CAF Medical Committee. He has over 300 publications in international sports medicine and national peer reviewed and non-peer reviewed scientific journals and has authored numerous chapters in sports medicine books. His current main research interests are the aetiology, prevention, diagnosis, and treatment of exercise associated muscle cramps (EAMC); the epidemiology of illness in athletes (including football players); the epidemiology, aetiology, diagnosis, and treatment of medical conditions in athletes; the biomechanics of overuse injuries in sports; genetics and sports injuries; and the epidemiology of injuries in sports.

Angela D. Smith, pediatric orthopaedic surgeon at the Children's Hospital of Philadelphia and its Sports Medicine and Performance Center, served as president of the American College of Sports Medicine, and received its Citation Award in 2006. She recently completed 2 terms as chair of the Education Commission of the International Federation of Sports Medicine, coordinating and teaching courses for health professionals worldwide. She serves on the advisory boards of the American Fitness Index and the Exercise Is Medicine initiative and is frequently quoted by national and international media. Her interests focus on injury prevention and rehabilitation, particularly for young athletes and for women pursuing sport or fitness activity. Through her clinical practice, public education efforts, and teaching in the University of Pennsylvania School of Landscape Architecture, she aims to improve each person's physical fitness, to improve their health, performance and self-esteem. She pursues her own lifelong passion for fitness and skating as a masters competitor, continuing to win Masters Senior medals at the U.S. Adult National Championships, recently becoming the U.S. National Showcase Masters Champion.

William D. Stanish is a professor of Surgery at Dalhousie University, within the Division of Orthopaedic Surgery. He is also Director of the Orthopaedic and Sport Medicine Clinic of Nova Scotia and has been since its inception in 1976. He received his medical degree at Dalhousie University, Halifax, Nova Scotia, Canada. Dr. Stanish was awarded the prestigious COA French Traveling Fellowship in 1978. He has held past presidencies in the Canadian Academy of Sport Medicine, the Orthopaedic Society of Nova Scotia, the Herodicus Sports Medicine Society, and has held executive positions on a number of provincial, national, and international societies. Dr. Stanish was Chief Medical Officer for the 1984 Olympics in Los Angeles as well as the 1988 Olympics in Seoul. Dr. Stanish is a past Deputy Editor of *The Journal of Bone and Joint Surgery,* and has held positions on the Editorial Board of the *American Journal of Sports Medicine, Techniques in Knee Surgery,* among many others. As a clinical scientist, he has fostered research in the areas of physiology of biomechanics of ligaments and tendons. His peer reviewed publicatoins by 2009 numbered 198. He has co-authored the highly regarded textbooks *The Oxford Textbook of Sports Medicine* and *Tendinitis: Its Etiology and Treatment*. Dr. Stanish has lectured worldwide and has been the recipient of many medals, honors, and awards.

Willem van Mechelen, MD, PhD, FACSM, FECSS (1952) is employed by the Vrije Universiteit Medical Centre in Amsterdam as a full professor of Occupational and Sports Medicine. In this capacity he is the head of the Department of Public and Occupational Health (120 fte), codirector of the EMGO+ Institute (350 fte), director of Research Centre Body@Work TNO VUmc and director of the Vrije Universiteit Medical Centre spin-off company Evalua Nederland BV. Willem van Mechelen is a board certified occupational physician, epidemiologist and human movement scientist. He is a editorial-board member of 8 peer-reviewed sports and exercise medicine journals, and associate editor of the *Clinical Journal of Sports Medicine* and of the *Journal of Physical Activity and Health*. He has (co-)authored more than 350 papers. He is a fellow of the American College of Sports Medicine and of the European College of Sports Sciences. In 2010 he received the American College of Sports Medicine citation award.

Introduction

I have been a sports medicine doctor here at Harvard Medical School for almost 40 years, and I am convinced more than ever that this is one of the most exciting fields in the health care continuum.

The field of sports medicine is thriving in response to the demand for health care professionals to care for the growing number of men, women, and children who are participating in vigorous physical activity. Yes, it may be true that some of society's problems are due to inactivity among our citizenry, but paralleling this phenomenon has been an explosion in organized sports and recreational exercise.

At one time, there might have been a few privileged, upper-class ladies and gentlemen who could play golf, tennis, and polo, but now there are myriad sports and exercise opportunities open to all people, irrespective of age, class, race, or gender. And just as one kind of activity fades from the headlines (jogging and in-line skating), another one takes its place (extreme sports and Pilates).

With the growth in sports and exercise has come a concomitant increase in the number of related injuries. Often these are "acute" injuries, such as a sprained ankle while playing basketball or a skinned knee from falling off a mountain bike. There has also been a rise of so-called *overuse* injuries. Unlike acute injuries, which are the result of an accident, overuse injuries occur because athletes do too much of exactly what they're supposed to be doing, whether it's serving a tennis ball or jogging every evening. Trying to prevent overuse injuries has been one of the focal issues of sports medicine doctors like me.

Because there are so many segments of the population now engaging in sports and exercise, their sports medicine needs are also different. The young athlete, for instance, is not just a miniature adult and shouldn't be treated medically as such. Older athletes have their own special needs, as do active women.

Remember, too, that sports medicine is not just a specialty focusing on injuries. In addition to preventing, treating, and rehabilitating injuries, sports medicine deals with nutrition, conditioning, biomechanics, psychology, and more.

All this is to say that there are now many different people included in a sports medicine team compared with when I started in the field all those decades ago. Here, at the Division of Sports Medicine at Children's Hospital Boston at Harvard Medicine School, we have not just orthopedists but primary care physicians, athletic trainers, sports psychologists, nutritionists, podiatrists, and others.

With all the career opportunities available, it's no wonder that so many more people are developing an interest in sports medicine. For the same reason there are more athletes to be cared for, there are more people with an interest in sports and exercise who want to develop their interest into a career in health and medicine.

That is why I and so many of my peers got involved in sports medicine—we were athletes who became doctors, and we wanted to blend our occupation with our avocation. Now I see exponentially more people doing the same! Bravo to you, and I trust you will get the same enjoyment out of it as I and my contemporaries have.

The purpose of this encyclopedia is to provide an introduction to those very people who are developing an interest in sports medicine, as well as those who are presently working in the field. We have covered a marvelously broad spectrum of topics in what I trust is sufficient, but not overwhelming, detail.

As with any resource of this size and scope, a lot of planning went into its creation. How to decide which topics to cover? To a tree trunk called sports medicine, we attached branches of subspecialties such as nutrition and physical therapy and then twigs and leaves that represented topics and subtopics within those areas. At times, this seemed overwhelming given the scope of the field, but gradually and over time, we developed a headword list that was comprehensive but as short of redundancies as possible (though "better redundant than incomplete" was one of our mottos!).

Wherever it was feasible, we asked contributors to make their contributions as easy to understand for as many readers as possible. In many cases, this meant asking eminent scientists and academics to write at a level to which they are not necessarily accustomed, and I am grateful that so many were willing to make this necessary adjustment. I can speak from personal experience when I say that writing in this way after so many years of writing for scientific publications can be a challenge. Of course, sometimes our text will take a more scientific bent, but sometimes this is essential given the particular subject matter.

Above all, I am extremely pleased that we have contributions from so many preeminent experts in their fields. The list is long, and I run the risk of neglecting someone, so I will mention just a few names—Dr. Wilma Bergfeld (dermatology), Dr. Art Boland (history of sports medicine), Dr. Bob Cantu (catastrophic injuries), Dr. Eduardo De Rose (doping), Dr. Avery Faigenbaum (children's fitness), Dr. Steven Pribut (athletic footwear), and Dr. Jim Whiteside (team physician). The fact these men and women were willing to contribute entries says much about their interest in bringing their respective specialties to as wide an audience as possible.

I hope this will be your "go-to" guide when you have a question about sports medicine. Regardless of whether you use a hard copy of the *Encyclopedia of Sports Medicine* or the online version, I trust that, like generations of encyclopedia buffs before you, you will take pleasure in perusing this resource and searching randomly through it for the sheer pleasure of absorbing the knowledge you will find inside.

It has been an enormous pleasure to work with the many hundreds of health care professionals who contributed to this resource, as well as our august body of advisers. I hope the readers will take as much pleasure in the fruits of our labors.

Please enjoy and make use of this terrific and comprehensive resource, that it may educate you on one of the most fascinating areas of medical specialty—one I am pleased, proud, and honored to have worked in all these years.

Lyle J. Micheli, M.D.
Boston, Massachusetts

A Note on the Parts of the Encyclopedia

The *Encyclopedia of Sports Medicine* contains a number of invaluable features that combine to create a resource for all levels of need. First, the List of Entries enumerates the topics covered in the four volumes, a simple list in the same A-to-Z order in which they will appear in the encyclopedia. Next, a Reader's Guide organizes the entries into subject groups, so that the reader can see at a glance the natural clusters of related entries. These subject headings are as follows:

- Conditioning and Training
- Diagnosis and Treatment of Sports Injuries
- Diet and Nutrition
- Doping and Performance Enhancement
- Exercise Physiology, Biomechanics, and Kinesiology
- Injuries and Disorders
- Injury Prevention
- Medical Conditions Affecting Sports Participation
- Rehabilitation and Physical Therapy
- Special Populations
- Specialties and Occupations in Sports Medicine
- Sports Psychology
- Sports and Society
- Sports and Sports Medicine
- Sports Specific Injuries
- Women and Sports

Entries also contain two significant elements to guide the reader to more information inside and outside this encyclopedia. The *See also* section comprises cross-references to related entries within this project. The Further Readings are not a bibliography or references for every fact provided in the entry but a select list of readings and websites that the author chose above hundreds of others for first-stop research on the subject.

The *Encyclopedia of Sports Medicine* contains three items in addition to the alphabetical entries that combine to make it a unique didactic and reference source. The Glossary is a list of significant terms with their definitions, a critical study tool for students of all medicine programs and a memory aid for researchers and practitioners. Appendix A is an astounding compilation of descriptions and photographs of taping techniques. It covers the materials, procedures, and postassessment protocols for the most common of these applications. A related group of entries are the six on musculoskeletal tests, with a collection of more than 150 photographs of important methods for diagnosing injuries (Musculoskeletal Tests, Ankle; Musculoskeletal Tests, Elbow; Musculoskeletal Tests, Foot; Musculoskeletal Tests, Hand and Wrist; Musculoskeletal Tests, Hip; Musculoskeletal Tests, Knee; Musculoskeletal Tests, Shoulder; and Musculoskeletal Tests, Spine). Appendix B is an extensive list of organizations related to sports medicine.

As a final note, a little more information about the Further Readings, as they may be some of the most valuable items in this encyclopedia: References can be written in any number of styles, most developed by and named for a specific organization representing a large field of study. In this encyclopedia, the items in the Further Readings have, for the most part, been formatted in accordance with the American Medical Association (AMA) guidelines. However, the AMA is not the only style used within the medical profession. We have respected the diversity of our contributors and retained the journal abbreviations following PubMed guidelines. (PubMed, or MEDLINE, is the style used for references in the U.S. National Library of Medicine.) Abbreviations for journals indexed in MEDLINE can be viewed online at http://www.nlm.nih.gov/tsd/serials/lji.html. The following link is especially useful and provides a concise explanation of the U.S. National Library of Medicine's PubMed style. There are two standard formats in use—summary format, with article title first, and author-first summary format (as in the American Medical Association [AMA] style: see http://www.nlm.nih.gov/bsd/policy/cit_format.html).

A

Abdominal Injuries

Injuries to the abdomen as a result of participation in sports are uncommon. However, when such injuries do occur, they can be potentially life threatening. Therefore, to be sure that these injuries do not get overlooked, it is especially important to be aware of the types of abdominal injuries that may occur and how they may present.

Ten percent of all abdominal injuries result from sports-related trauma. Abdominal injuries occur most often in contact sports such as rugby, soccer, football, and wrestling. Noncontact sports, including horseback riding, downhill skiing, and waterskiing, can also result in abdominal injuries from high-speed deceleration mechanisms. Recreational activities such as bicycling can cause abdominal injuries from falls and from the impact of handlebars.

Anatomy

The abdominal cavity is separated from the chest cavity by the diaphragm. The position of the diaphragm varies with respiration. During expiration, the diaphragm may be as high as the fourth anterior rib. This is important because the abdominal contents may be raised well into the chest and, therefore, may be exposed to chest wall trauma.

The peritoneal cavity contains solid organs including the spleen, liver, and pancreas and hollow, viscous organs such as the stomach and the small and large intestines. Other structures that may be injured include the lower ribs, the bladder, retroperitoneal organs (e.g., the kidneys) and spaces, the abdominal wall muscles, and blood vessels.

Evaluation of Injury

Abdominal injuries may result in serious bleeding and shock. If an athlete on the field appears to be in shock, assessment of airway, breathing, and circulation should be quickly performed by qualified personnel. Paramedics should be called to transport the athlete to hospital. Intravenous access should be obtained by trained health care personnel (doctor, nurse, or paramedic) in two separate sites with large-bore cannulas, and the patient should receive rapid infusion of normal saline solution en route to a trauma center.

Details of Injury

Abdominal injuries in sports are usually caused by a rapid deceleration or high-energy impact. Pain may occur immediately or develop more insidiously. The location, quality, and severity of pain can help determine what injury has occurred. Pain may be aggravated by activities such as walking or coughing. Athletes with abdominal injuries may also have other symptoms, such as back pain or blood in the urine.

Physical Findings

It is important to monitor the heart rate and blood pressure of any athlete who has sustained an abdominal injury. If the blood pressure is low and the heart rate is high, the athlete may be in shock. There may be bruising of the abdomen, as well as bloating, abrasions, or lacerations at the site of impact. Palpating the abdomen can determine the area of greatest tenderness. Contusions or bruising of the abdominal wall muscles can be difficult to distinguish from an underlying abdominal injury. Tenderness with contusions is usually well localized, and pain may be elicited through contraction of the affected muscle. With abdominal injuries, however, tenderness with palpation may be more diffuse. Up to 50% of athletes with significant abdominal injury do not initially have any tenderness to palpation of their abdomen. If a serious abdominal injury is suspected because of the type of trauma, the injured athlete should be reexamined by a doctor over several hours.

Injuries to solid abdominal organs, such as the liver or spleen, cause bleeding, resulting in irritation and pain in the abdomen. Pain can initially be mild, with no palpable tenderness. Injuries to hollow organs, such as the bowel, result in peritonitis, or infection of the abdomen, which can cause severe pain. The pain is initially localized to the site of injury, but as the injury progresses, peritoneal signs, such as referred tenderness and loss of bowel sounds, develop. Injuries to organs behind the peritoneal cavity, such as the kidneys, may not cause peritoneal signs, particularly if trauma is minor. Blood in the urine may be the only sign of an injury to the kidneys.

Traumatic injuries to the abdomen may result in other injuries that may not be immediately obvious. For instance, injuries to the abdomen may also cause a chest injury, such as a pneumothorax (air in the chest outside the lungs). Conversely, trauma to the lower chest wall, such as the ribs, may result in injury to abdominal organs, such as the liver or spleen.

Investigations

An athlete who has sustained an abdominal injury may be bleeding internally. Blood loss can be determined by measuring the hemoglobin in the athlete's blood. A drop in the hemoglobin suggests significant blood loss. If a serious abdominal injury is suspected, a CT scan may show the exact nature of the injury. The combination of repeated abdominal examinations and CT scan usually detects any significant abdominal injury. CT scan alone can potentially miss clinically significant abdominal injuries.

Types of abdominal injury:

- Splenic lacerations, contusions
- Splenomegaly, splenic rupture (caused by the Epstein-Barr virus)
- Liver lacerations, contusions
- Kidney injury
- Pancreas injuries
- Bowel injuries
- Sportsman's hernia
- Muscle contusions, sprains

Prevention of Injury

Although abdominal injuries are uncommon, certain injuries may be preventable. Appropriate safety equipment should be worn for any particular sport or recreational activity. Attention to proper sports technique can minimize the incidence of overuse injuries, such as muscle strains. Conditioning is also very important. Appropriate core strength will help maximize protection in contact sports, as well as minimize overuse injuries in noncontact sports.

Return to Sports

Sideline decisions regarding allowing an athlete to return to play following an abdominal injury should be based on pain severity and resolution. Heart rate and blood pressure should be normal, and there should be no peritoneal signs or significant tenderness to palpation on abdominal exam. In addition, athletes should be able to exercise without increasing pain.

Specific guidelines vary with the severity of injury. Solid-organ contusions require a normal CT scan 2 to 3 weeks before an athlete can return to practice. A prolonged period of healing is necessary for lacerations or hematomas to solid organs. If the injury is severe enough to require organ removal, full healing should take about 6 to 24 weeks. Strenuous activity following organ removal should be delayed for 6 to 8 weeks, and participation in contact sports should be delayed for 12 to

24 weeks, depending on the specific advice of the surgeon performing the surgery.

Abrasions and Lacerations

Abrasions and lacerations are among the most common skin injuries seen in athletes.

Abrasions

An *abrasion* is the result of damage to the epidermis (superficial layers) of the skin resulting in superficial erosions or ulcerations. Abrasions are caused by friction or pressure forces directed against the skin. They commonly occur while skateboarding, cycling, or inline skating. Prevention includes wearing protective clothing and gear.

Cleaning of a superficial wound can be done with the use of a sterile saline solution and application of petrolatum or topical antibiotic ointment. If the abrasion is deeper than the epidermis, the wound should be evaluated for foreign body material. Cleaning of the wound should be more extensive to prevent infection and permanent discoloration of the skin from the foreign debris. Wound debridement is important to reduce the risk of infection. Cleaning of wounds with high-pressure irrigation is more effective than cleansing with low-pressure irrigation. Irrigation with an 18- or 19-gauge needle attached to a 20- or 30-milliliter (ml) syringe provides adequate pressure of 5 to 8 pounds per square inch (psi), or 35 to 55 kilopascals (kPa), for debridement. Pain can be alleviated with topical or local anesthesia. Management of erosions or ulcerations may include a hydrocolloid dressing to aid in wound healing. Hydrocolloid dressings aid in wound healing by maintaining a moist environment. They do not require a secondary dressing, are fibrinolytic, are absorbent, increase angiogenesis, and act as bacterial and physical barriers. Infected wounds should be treated with antibiotics such as cephalexin 500 milligrams (mg) twice daily for 10 to 14 days or dicloxacillin 500 mg three times a day for 10 to 14 days.

An athlete may typically return to competition after proper repair and bandaging of the abrasion (see Figure 1, p. 4).

Lacerations

A *laceration* is the tearing of the skin resulting in an irregular wound. Lacerations are often caused by impact injury from a blunt object or force. They commonly occur in contact sports and are the most common type of sports-related facial injury. Lacerations may occur after a fall, commonly occurring on the elbow, knee, or eyebrows. Tissue injury is typically minimal, and infections are usually low. However, the laceration may extend through the full thickness of the skin into the subcutaneous tissue. When the injury occurs over a bony prominence, such as the brow, cheek, chin, or teeth, a jagged tear in the skin occurs, with variable skin ischemia and necrosis.

Wound repair is an important process in restoring the skin to its pre-injury state. For acute wounds, the repair process progresses from coagulation to inflammation, proliferation, cell migration, and tissue modeling. After an acute injury, coagulation and inflammation begin immediately. Clot formation begins with the release of blood cells and blood-born elements, such as platelets, from the disrupted blood vessels. Through the intrinsic and extrinsic pathways, platelets direct the clotting of the wound and release chemotactic factors that attract other platelets, leukocytes, and fibroblasts to the wound. Inflammatory white cells aid in the debridement of necrotic material and bacteria. Growth factors are activated because of the injured environment secondary to hypoxia, proteases, and low pH. A fibrin plug, consisting of platelets, is embedded within a meshwork of fibrin,

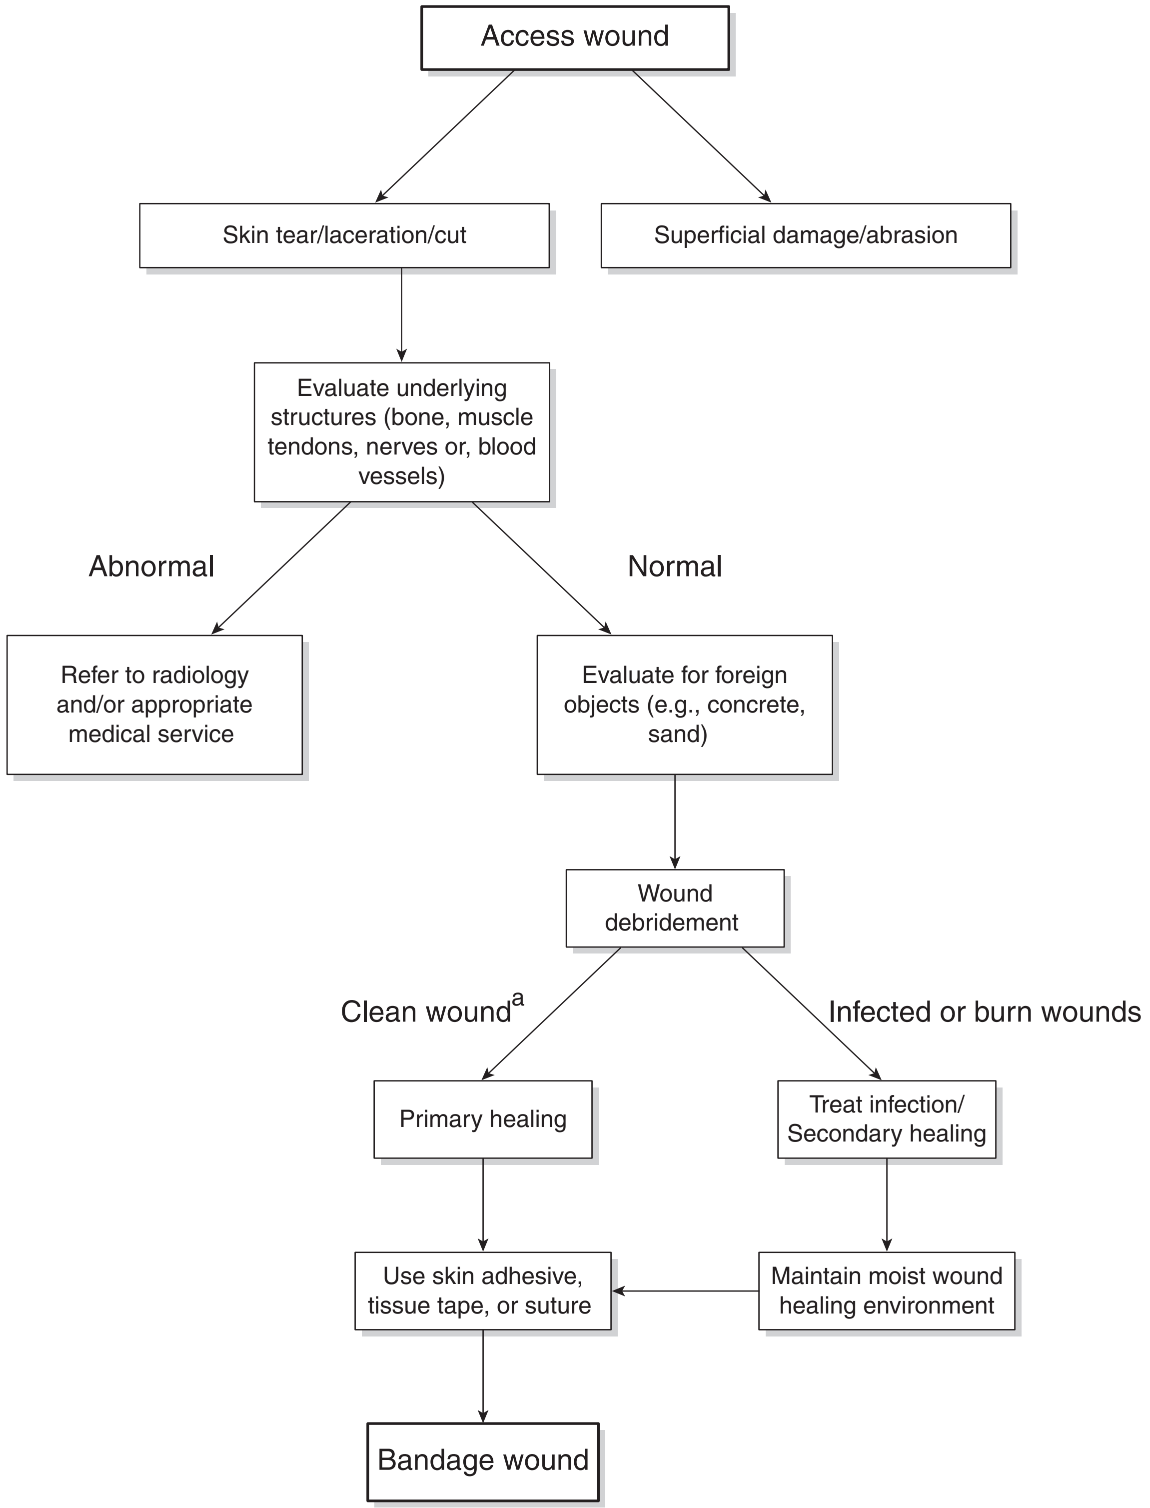

Figure 1 Treatment of Abrasions and Lacerations

Note: [a]Superficial wounds/abrasions can be treated with skin adhesive or tissue tape, or maintained with a moist wound-healing environment after wound debridement.

fibronectin, vitronectin, and thrombospondin. This provides a temporary cover for protecting the wound. When cross-linking of fibrin does not occur, the function, and likely migration, of keratinocytes is impaired. Keratinocytes proliferate within the first hours after the injury is sustained. Within 24 to 48 hours, monocytes are present in the wound and become macrophages. These are important for killing bacteria, scavenging tissue debris, and phagocytosis. The macrophages attract fibroblasts, which create a collagen network of fibers. During this stage of proliferation, granulation occurs. Fibroblasts become myofibroblasts, which help contract the wound and assist with remodeling. Epitheliazation results in epithelial cells migrating to the epidermis around the wound and growing over the granulation tissue.

An individual's state of health can also impede the wound-healing process. Deficiency of vitamin C or zinc can impair wound healing. Vitamin A is important in epithelialization as well as collagen production and degradation. However, too much vitamin A is considered toxic. The estimated toxic dose is 25,000 international units/kilogram (IU/kg). Iron deficiency may delay wound healing as iron is a cofactor in collagen synthesis. Underlying endocrine disorders, such as diabetes or corticosteroid use, can also slow the healing process. Knowing the athlete's medical history can be critical to ensuring a rapid healing process.

Appropriate treatment of lacerations is important to decrease the risk of excessive scar formation and displeasing cosmetic results. Due to the rich blood supply of the face, lacerations in this location may bleed significantly. Control of hemostasis is the first step in the management of lacerations. Direct continuous manual pressure to the area of injury with sterile gauze is helpful for achieving hemostasis. After hemostasis is achieved, exploration of the wound should be completed to determine the severity and extent of involvement of bone, muscle, tendons, nerves, or blood vessels. Fractures of any underlying bony prominences should be excluded through initial palpation, with referral to radiology as needed. Residue, such as concrete or sand, from the foreign object that caused the injury may be left within the wound. Wound debridement is important to reduce the risk of infection and later reaction to the foreign body(ies). The wound should be irrigated with sterile saline solution. Cleansing of wounds with high-pressure irrigation is more effective than cleansing with low-pressure irrigation. Irrigation with an 18- or 19-gauge needle attached to a 20- or 30-ml syringe provides adequate pressure of 5 to 8 psi (35 to 55 kPa) for debridement.

The type of wound closure used depends on the wound. Primary healing occurs when the laceration is clean and is closed with skin adhesives, tissue tapes (Steri-Strips), or sutures. Secondary healing occurs when the wound is left open to heal by the formation of granulation tissue, contraction, and epithelialization. Typically infected and burn wounds heal through secondary healing. Delayed primary closure is often used for lacerations that are not considered to be clean enough for primary closure. The wound is left open to heal for 5 to 10 days in a moist wound-healing environment, and then it is sutured closed. A moist wound-healing environment includes the use of dressings that retain moisture to improve pain control, effect painless autolytic debridement, provide physical and bacterial barriers, and promote the formation of granulation tissue. Examples of such wound dressings are hydrogels, alginates, hydrocolloids, foams, and films. Hydrocolloids are favorable as they do not require a secondary dressing, are fibrinolytic, are absorbent, increase angiogenesis, and are bacterial and physical barriers. Delayed primary closure decreases the risk of infection through achieving bacterial balance, and granulation tissue formation creates an optimal environment for the wound's oxygen requirements.

Temporary closure of superficial and small lacerations can be done with tissue tapes (Steri-Strips) or butterfly bandages, which aids the wound in achieving hemostasis and allows the athlete to resume playing. These are appropriate if the wound does not exhibit great tension. To ensure that the strips or bandages are secure, a liquid adhesive, such as compound benzoin tincture or 2-octylcyanoacrylate, can be applied. The depth and location of the laceration may also determine the type of treatment rendered. Full-thickness lacerations may require closure with sutures. Deep, absorbable sutures may be needed for better approximation of the edges. Nonabsorbable sutures should be used for skin closure, which should optimally be completed in 8 to 12 hours. Burst or jagged laceration edges should be trimmed with a sterile scalpel to create a more linear and smooth edge, which is better for approximation of the wound for closure with sutures. The sutures are typically removed in 5 to 7 days if they are located on the face and ears, 3 to 5 days for eyelid sutures, 7 days for neck sutures, and 7 to 14 days for scalp sutures. Sutures on the trunk and extremities should be left in place for 10 to 14 days and occasionally longer to reduce the risk of wound dehiscence if the closure is under extreme tension. If the wound is easily approximated with subcutaneous sutures, then they can be removed in 7 to 14 days. After removal, the addition of tissue tapes may be needed to add strength to the healing wound.

With ear lacerations, it is important to completely cover the exposed cartilage and evacuate any blood to prevent a hematoma. Hematoma formation can result in pressure necrosis of the cartilage, loss of stability and shape of the ear, and infection. Hematomas should be drained within 72 hours with the use of an 18-gauge needle and syringe or through incision and drainage. Simple lacerations can be repaired with nonabsorbable, monofilament sutures. When cartilage is exposed, suturing the skin over the cartilage should be sufficient as the cartilage itself does not need sutures. If the cartilage must be debrided, only up to 5 millimeters can be removed to prevent ear deformity.

Antibiotics are often not needed for the treatment of simple lacerations. A wound that has remained open for several hours or is heavily contaminated may require a 7- to 10-day course of antibiotics. Lacerations from human bites may also require antibiotics, and tetanus prophylaxis guidelines should be followed.

The athlete may typically return to competition after proper repair and bandaging of the laceration. Bandaging can be completed with a sterile, nonadherent dressing. The location of the laceration, its severity, and the potential for recurrence of the injury should be taken into consideration. The wound will gain in strength 2 to 3 weeks after the repair, with a peak tensile strength at 2 months. The final tensile strength is about 70% to 80% of the pre-injured skin 1 to 2 years later. Full-thickness wounds are associated with delayed healing and more scarring. If wound dehiscence or infection is of concern, the patient should follow up within 48 hours for a wound check.

Accessory Navicular

The *accessory navicular* is an extra bone in the foot that can become painful. Not every person with an accessory navicular will have pain. However, when it is causing pain, it can be difficult to treat and may necessitate surgical removal.

Anatomy

The navicular is one of the tarsal bones in the foot. It is located on the inside, or medial aspect, of the foot, at the arch. The accessory navicular is an ossicle, or extra bone. Some people are born with this ossicle.

The posterior tibialis muscle tendon attaches to the navicular bone. This muscle *inverts* (turns in) and *plantarflexes* (points toward the toes) the ankle. This muscle also helps stabilize the medial arch of the foot. The tendon will insert on the accessory navicular, which may cause pain and muscular dysfunction, including loss of the medial arch (flat foot).

The accessory navicular is present at birth, but it is then a soft cartilage. It will begin to ossify (from into a bone) around 9 to 11 years of age. It is usually connected to the navicular with a fibrous union. Some physicians believe that approximately 50% will fuse to the navicular in late adolescence, but this has not been definitively established.

Causes

About 10% of people have an accessory navicular. However, not that many people have symptoms related to it. If the ossicle is large, it can cause a large bump on the medial aspect of the foot. This bump will rub against shoes and can become very painful.

Also, injuries of the fibrous union between the accessory navicular and navicular bone can cause pain. These injuries may destabilize the ossicle, resulting in abnormal motion. This is analogous to a fracture. However, the fibrous tissue connecting the two pieces tends to heal poorly, resulting in continued pain. The attachment of the posterior tibialis muscle causes a constant pull and stress on the ossicle.

If a large portion of the posterior tibialis tendon attaches to the accessory navicular, it can disturb the supportive function of the muscle. This leads to flat foot and an even more prominent accessory navicular bone.

Clinical Evaluation

Many patients will present in childhood with a symptomatic accessory navicular. As the accessory navicular begins to ossify, it may become more symptomatic. An accessory navicular that has no symptoms is not problematic, and treatment should not be initiated unless it becomes symptomatic.

History

Many patients will present in early adolescence with a painful bump on the inside of their foot. If they are very athletic, the pain will worsen during and after activity. Even walking can be painful, and the pain can eventually become a constant discomfort. It will generally improve with rest. If the bump is larger, the patients frequently complain of pain when it rubs against their shoes or if something hits the bump.

The patient and family often have concerns about flat foot, which is commonly associated with the accessory navicular.

Physical Exam

Patients will usually have a flexible (nonrigid) flat foot. They will have a bony prominence over the medial aspect of the foot at the arch. This prominence is painful to palpation. Resistance testing of the posterior tibialis muscle is often painful as well.

Diagnostic Imaging

X-ray films should be obtained. Comparison views of the other foot may be helpful. If the patient is young, the ossicle may not have ossified yet, so it may not be seen on X-ray. The accessory navicular will appear as a distinct ossicle proximal and medial to the navicular bone.

In a patient with an accessory navicular that is not clearly the cause of pain, a bone scan or magnetic resonance imaging (MRI) may help pinpoint the diagnosis.

Classification

Type I: A small ossicle located entirely within the posterior tibialis tendon and separate from the navicular bone

Type II: The classic accessory navicular, which has a fibrous connection to the navicular and also has a portion of the posterior tibialis tendon attached

Type III: A cornuate navicular, which represents a bony fusion of the accessory navicular to the navicular, resulting in a bony prominence on the medial foot.

Treatment

Nonoperative

Accessory navicular treatment is initially nonoperative. If the pain is significant, the patient may

Accessory navicular

benefit from 4 to 6 weeks with the foot in a fracture boot or a cast. This should be followed by ankle strengthening and range-of-motion exercises designed to return the athlete to full speed of movement without pain. Crutches may be helpful early, but the patient can bear weight as tolerated.

When the pain is less severe, activity modification is the primary treatment. The pain can be decreased by keeping the athlete from performing activities that cause pain (usually weight-bearing activity). During this time, the athlete can try ice and over-the-counter medications to help control the pain. The athlete should wear good, supportive shoes and consider an arch support or orthotic to help stabilize the arch, which may reduce the pull of the posterior tibialis muscle. Donut padding around the painful prominence may be helpful. Again, exercises designed to improve overall ankle function through increasing strength, flexibility, and balance should be instituted when it is possible to do them without significant pain. It may take the athlete 4 to 6 weeks to return to full activity without symptoms.

If the pain subsides and the athlete can return to full activity, there is no need for any further treatment. The patient should return if symptoms return at a later date. Athletes who do not get full relief from activity modification may then need casting. If the symptoms are not responsive to the full spectrum of nonoperative care, the patient should be seen by an orthopedic surgeon.

Operative

The most common operation is the Kidner procedure. This involves removal of the accessory navicular and repositioning of the posterior tibialis tendon onto the navicular bone. This requires significant postoperative immobilization because the tendon has been manipulated. This procedure may restore the arch of the foot because of the improvement in the position of the posterior tibialis tendon.

Some surgeons will remove the ossicle, but there are concerns that this may disrupt the stability of the foot and result in poor function of the posterior tibialis muscle, causing it to tire easily.

However, there is a recently developed technique that allows surgeons to remove the ossicle and strengthen the attachment of the posterior tibialis tendon without complete detachment and reattachment. This allows for a quicker return to activity without prolonged immobilization.

After surgery and the required immobilization, the athlete will frequently need physical therapy to help strengthen the ankle to return it to normal function. Orthotic use may be helpful in the postoperative patient who still has flat feet.

Achilles Bursitis

Posterior heel pain in the athlete may be due to any of a number of causes. Possible diagnoses include tendinitis, retrocalcaneal bursitis, or Achilles bursitis, to name a few. In this entry, *Achilles bursitis*—specifically, bursitis of the retro-Achilles or superficial bursa—is examined in detail, including its causes, symptoms, and treatments.

Anatomy

The Achilles tendon is composed of fibers originating in the muscles of the calf (the gastrocnemius and soleus). The tendon is palpable from the lower one third of the calf down to the calcaneus or heel bone. In the region where the Achilles tendon attaches to the calcaneus, there are two bursae—the retro-Achilles bursa and the retrocalcaneal bursa—that work together to reduce friction by the Achilles tendon. The *retro-Achilles*, *calcaneal*, or *superficial bursa* lies between the insertion of the Achilles tendon and the overlying skin. In contrast, the retrocalcaneal bursa—which is addressed elsewhere—lies between the anterior surfaces of the Achilles and the calcaneal bone itself.

Epidemiology/Etiology

The retro-Achilles bursa can become inflamed as a result of damage to the Achilles tendon or excessive external (shoe) pressure on the area. This bursa is the one that is most commonly enlarged. This enlargement is attributable to overly tight running shoes and, historically, high heels—leading to its common name, "pump bump." Achilles bursitis is most common in runners but can occur in any athlete who wears ill-fitting shoes.

Signs and Symptoms

Patients complain of pain over the posterior heel. Redness, swelling, and significant pain can be localized to the bursa just under the skin overlying the Achilles. Usually, this is just below the position of the shoe's heel counter. This may be thickened or enlarged.

Physical Exam

The area, if thickened, may be palpable. To localize the retro-Achilles bursa, the examiner should lift the skin posterior to the Achilles—the bursa lies just under the fingers. In contrast, the retrocalcaneal bursa is localized by pinching the soft tissue anterior to the tendon. In addition to pain, the patient will also have decreased passive dorsiflexion, or flexion at the ankle.

Diagnostics

Physical exam is usually sufficient for diagnosis. If pain is recalcitrant to treatment, X-ray should be considered to rule out a Haglund deformity. Another disorder in the differential diagnosis can be calcaneal stress fracture, which will require further imaging to diagnose.

Treatment

Because ill-fitting shoes commonly contribute to this problem, careful attention to footwear is the first place to start. Alterations can be made by changing shoes outright or adding padding to the shoe being worn. Ice massage is also helpful at times. As with any superficial bursitis, the physician can aspirate the bursa and give a small steroid injection—though this should be done with caution considering the proximity to the Achilles tendon and the attendant concern for Achilles rupture.

If this is a chronic problem, consideration should be given that over time, small bony flakes or avulsions can become hardened and thickened, creating a bony prominence in longtime runners. Treatment for this also includes adding padding or changing shoes. Heel lifts or orthotics may also be helpful in this situation. Surgery is rarely indicated due to proximity to the Achilles tendon.

Prevention

Catching this problem early facilitates successful treatment. Athletes should always be aware when changing shoes that different pressure patterns on the posterior foot can cause inflammation. If this is noticed, increasing padding or changing shoes is the best thing to do.

Achilles Tendinitis

Since humans began walking on two legs, the Achilles tendon likely has been a common site of injury. Achilles injury is most common among professional and recreational athletes of all ages, and the Achilles is the most frequently injured tendon in the ankle. *Achilles tendinitis* is, basically, pain in and around the Achilles (triceps surae) tendon. Terminology varies widely, and terms such as *tendinopathy, tendinitis, partial rupture, paratenonitis, tenosynovitis,* and *achillodynia* have all been used to describe this entity. For the purpose of this review, this terminology will be consolidated under the term *tendinitis*. Achilles tendinitis is a multifactorial problem. Everything from anatomy to footwear can play a role in its development. In this entry, these causes will be investigated, and general treatment options will be addressed.

Anatomy

The Achilles tendon is composed of the conjoined tendon of the calf muscles—the gastrocnemius and the soleus—and is the largest tendon in the body. These muscles contribute to the ability to plantarflex (point the toes) and give strength to this motion, as well as absorbing the weight of the body in ambulation; in short, they give the primary force needed to walk, run, and jump. The most distal portion of the tendon has poor blood supply; this is especially true in the area 2 to 6 centimeters (cm) above the calcaneus, or heel bone.

Epidemiology

Incidence of Achilles tendinitis is highest among those who participate in middle- to long-distance running, track-and-field events, tennis, volleyball, and soccer. Men seem to be more prone to developing Achilles tendinitis than women, and it affects the older athlete more often than the younger athlete. The athlete who is reentering training after a period of inactivity is also at risk.

Etiology

Achilles tendinitis is largely multifactorial in causation. In competitive athletes, most of these injuries are attributable to a chronic, repetitive overload of the tendon unit. In recreational—including "weekend warrior"—athletes, it is usually due to acute overloading. In this particular problem, the most common training error is increasing activity too quickly. This usually includes increasing mileage rapidly, increased interval training, or increased hill running. Previous in\juries also play a role, both to the Achilles itself as well as to the surrounding tissues (as in plantar fasciitis). In the professional athlete, chronic overuse that eventually results in tendon pain and poor remodeling is usually blamed.

Anatomic malalignments can also play a role. *Pes planus* (flat foot) and *pes cavus* (high-arched foot) have both been suggested as contributing factors to Achilles injuries. These anatomic factors place increased stress on the Achilles tendon as a stabilizer of the ankle. Another factor is decreased flexibility. Tightened muscles in the calf (particularly the gastrocnemius-soleus complex) have been suggested to increase the likelihood of tendinitis.

Improper footwear has also been implicated. Each individual foot is unique, and with a proper shoe the impact to the foot as well as the amount of pronation allowed can be controlled. Shoes with soft, unstable casing are not firm enough to resist compression during foot pronation. Soft heel counters also do not hold the foot in the right position, though a too rigid shoe is equally detrimental.

Signs and Symptoms

Individuals will likely present with decreased gastrocnemius flexibility, pain, tenderness, and swelling at the site. Crepitus may also be present. Pain is worse with active plantarflexion (pointing of toes)—especially when weight bearing. This pain is generally worse on arising from sleep. The activities sufferers dread the most include walking up hills or down stairs. In addition, running and jumping may become impossible.

Physical Exam

Tenderness is noted along the Achilles. Most commonly, a thickened, tender nodule is found on the proximal one third of the tendon. Pain will occur with single-legged heel raise of the affected extremity. Rupture of the Achilles should be ruled out, though this complaint is usually of a more acute nature—in contrast to the more insidious onset of tendinitis. This can be tested by doing the Thompson Squeeze Test. The patient should lie prone on the exam table. The calf of the leg is squeezed; if there is plantarflexion of the foot, the tendon is intact; however, if it is markedly decreased or absent, it indicates rupture.

Diagnostics

Though the diagnosis of Achilles tendinitis is mostly clinical, imaging modalities may be used. If thickening of the Achilles is observed, some physicians may include X-ray evaluation in the workup. Musculoskeletal diagnostic ultrasound is also an option. This can be especially helpful as it can be performed in the physician's office, and the patient's pain can be a guide. Generally, a heterogeneous configuration of tendon fibers suggests tendinitis, and a homogeneous configuration suggests a normal tendon. Increased blood flow to an area is also an indicator of injury. If the course is prolonged or the patient fails to respond to conservative therapy (usually after 6 months), further imaging may be necessary. This imaging would include magnetic resonance imaging (MRI).

Treatment

As with most musculoskeletal injuries, the earlier the treatment, the better the outcome. Initial treatment should include rest, ice, and the use of acetaminophen or nonsteroidal anti-inflammatory agents such as ibuprofen or naproxyn. Stretching before exercise is encouraged, in addition to decreasing mileage, avoiding banked roads and hills, and changing footwear.

The amount and duration of rest are not well defined. If the pain occurs only after activity, one guideline states that training should be decreased by 25%. If the pain occurs with activity but does not restrict performance, training should be decreased by 50%. If the pain restricts performance, then the athlete should discontinue specific sports training, but substitute exercise (e.g., swimming) would be encouraged. Rest should continue 7 to 10 days after the symptoms have subsided. Subsequently, a gradual return to activity is encouraged.

Appropriate shoes should have a flexible sole and molded heel pad. If the athlete is a pronator (has a flat foot), orthotic correction is recommended. Heel lifts have also been shown to relieve the stress to the Achilles tendon; if used, this should be about 0.5 inch (1.3 cm) high. If this approach is used, aggressive Achilles stretching should also be performed since the lift shortens the Achilles tendon. These lifts are typically used for several weeks.

In more severe cases, a walking boot may be considered for temporary unloading. *Under no circumstances should steroid injections be used.* They have been shown to compromise the vascular system as well as contribute to weakening and possible necrosis of the tendon.

Physical therapy should include primarily stretching and eccentric strengthening exercises to mobilize the tissue. These eccentric exercises can significantly improve symptoms in 3 to 6 months. Ultrasound has also been reported to have some success.

Surgery has been shown to have a limited role in the correction of Achilles tendinitis. This is primarily because the area most commonly affected has poor blood supply, so surgical healing is difficult. If complete tendon rupture occurs or the injury is particularly recalcitrant to conservative measures, a surgeon should be consulted. However, most experts recommend that a full course of conservative rehabilitation and therapy be completed before surgical intervention is considered.

Prevention

Perhaps the best treatment of Achilles tendinitis is prevention. This can be achieved by knowing and avoiding the predisposing factors. Resistance training should be done to increase the strength of the calf and other lower extremity muscles. A stretching program can also help maintain or achieve greater flexibility. Correcting structural defects of the foot with orthotics can also decrease the chance of future Achilles injury. Also, understanding the proper footwear, training surfaces, and training programs to use helps decrease the extrinsic risks of developing Achilles tendinitis. As part of these precautions, warm-ups should be included in any training program, and if one is starting to train for a running event or starting exercise after a sedentary period, the first week is the most likely to result in injury. Having "easy days" interspersed with hard training also allows the body time to recover. Overall, one can see that this multifactorial problem can only be treated and prevented in an equally multifactorial way.

Achilles Tendon Rupture

The Achilles tendon is extremely important in any activity in sports that involves foot flexion. The tendon has its origin at the muscle-tendon junction of the gastrocnemius muscle and inserts on the posterior calcaneus bone of the ankle. The function of the tendon is to flex the foot. It is continually under tension to be able to carry out this function.

Pathophysiology and History\

Achilles tendon rupture or tear generally occurs in the third to fifth decade of life. This is a time when the tendon is aging and not as pliable as in earlier life, thus making it more prone to injury or damage due to continued microtrauma. Rupture usually happens to an athlete who is not properly warmed up or stretched or in someone who has a naturally tight tendon in sports involving jumping, such as volleyball, basketball, or dance. When the tendon is torn, the patient often reports hearing a "pop" and describes a tearing sensation in the lower leg. If looking at the patient from behind, there is often a gap seen between where the Achilles tendon should be and the edge of the calcaneus bone. The area then frequently becomes swollen and bruised. Often, patients report that they cannot walk correctly as they cannot adequately push off with the affected foot.

Physical Examination

A patient with Achilles tendon rupture cannot walk on his or her own. Crutches are often required. Movement is affected, as the patient cannot properly plantarflex or flex the affected foot. Strength is also diminished on the affected side. The doctor is often able to feel a missing section of tendon as he or she follows it from the calcaneus to the gastrocnemius. The examiner also can feel swelling and sometimes, if enough time has elapsed, see bruising. The most important physical examination test to be performed is the *Thompson Test*. The patient's calf is squeezed. If the foot does not flex at all after squeezing, then the tendon has completely ruptured. Plain X-rays can often show the missing tendon, but the best test to see a complete

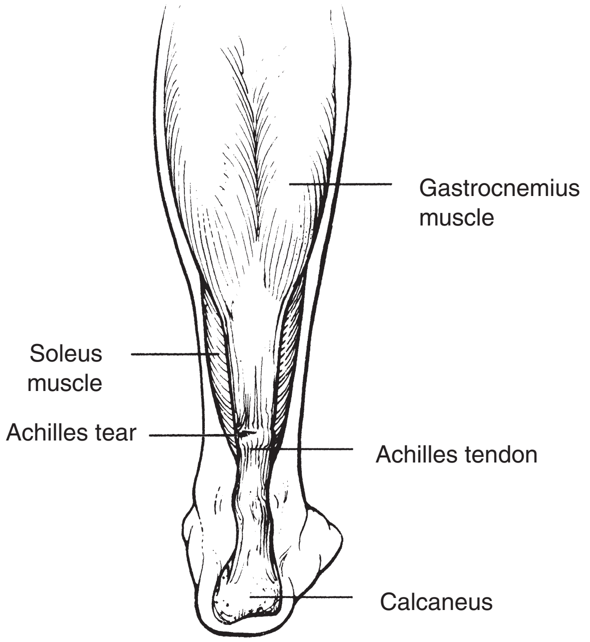

Figure 1 The Calf Muscles and Achilles Tendon Showing Achilles Tear

tendon rupture is magnetic resonance imaging (MRI; see Figure I).

Nonoperative Treatment

Treatment can be handled in nonoperative or operative fashion. Nonoperative treatment is recommended for those who cannot tolerate surgery, such as those with associated medical conditions that could render surgery dangerous. These people have their leg placed in a cast, with the foot in flexion for several weeks while using crutches. This option is generally approached with caution, as a complication from this treatment may be permanent calf weakness. After casting, the patient uses a heel lift for up to 3 months to assist in healing. The patient should undergo physical therapy to restore function. Return to sports is allowed after the athlete is able to pass provocative testing that involves simulation of the chosen sport.

Operative Treatment

Operative treatment is recommended for athletes and the athletic population, including those with physical occupations. Surgical options have less risk of permanent calf weakness, provide better ability to push off, and reduce the chance of reinjury from another rupture.

Surgery should be attempted as soon as possible since the tendon is normally under tension. When unattached, therefore, the tendon may migrate up the leg toward the back of the knee. Surgery includes reattachment of the tendon followed by immobilization, with the foot in partial flexion for several weeks to allow healing. During the initial healing process, patients are kept on crutches and then progressed through partial weight bearing to full weight bearing. A heel lift is generally used after immobilization for 4 to 6 weeks to assist with recovery. Physical therapy is then begun to restore motion and function. Total recovery generally takes several months. Return to sports is generally permitted after healing is complete, physical therapy is completed, and the athlete can pass provocative testing in the chosen sport.

Acromioclavicular (AC) Joint, Separation of

Injury to the acromioclavicular (AC) joint is relatively common during sports participation. Men in their 20s are the most prone to sustaining an AC joint injury. Sports in which athletes are most at risk for an injury to the AC joint include hockey, football, rugby, and soccer, although any contact sport has an increased risk for such an injury.

Anatomy

The AC joint is a diarthrodial joint connecting the distal end of the clavicle to the medial acromion. The ends of these bones are covered with hyaline articular cartilage and are separated from each other by a fibrocartilagenous meniscus–type structure of varying shape and size. The AC joint is surrounded by a thin capsule that is stabilized by four strong AC ligaments (anterior, posterior, superior, and inferior).

The AC ligaments are the primary restraints for anterior-posterior (AP) translation of the clavicle. Of the four ligaments connecting the acromion to the clavicle, the posterior and superior ligaments provide the most support against displacement. It is, therefore, important to maintain their integrity when performing surgical procedures involving the AC joint.

The coracoclavicular (CC) ligament is the primary restraint against superior and inferior translation of the distal clavicle. It connects the inferior surface of the clavicle to the base of the coracoid. The CC ligament is made up of two ligaments—the conoid and trapezoid ligaments. The trapezoid ligament is the more lateral of the two ligaments and also acts as a primary restraint to compression of the AC joint. The normal radiographic distance between the coracoid and the clavicle is 1.3 centimeters. This is clinically important when differentiating incomplete versus complete AC joint separations.

Etiology

Most injuries to the AC joint occur by direct trauma. The classic mechanism of injury to the AC joint is an impact to the lateral aspect of the shoulder with the arm held in adduction. Because of the stronger ligamentous stability of the sternoclavicular joint, the majority of the force sustained during a traumatic event is directed to the AC joint. Falling on an outstretched hand can also injure the AC joint. With this mechanism of injury, the humeral head is forced upward, driving it into the undersurface of the acromion.

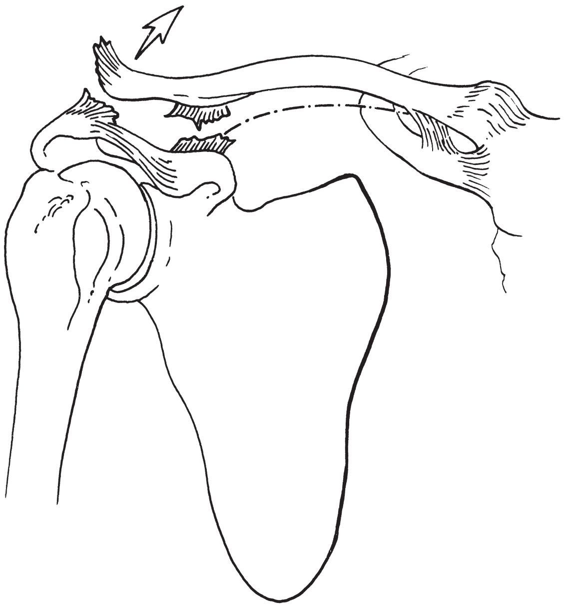

Figure 1 Acromioclavicular Joint Showing Separation

Note: Acromioclavicular joint separation is a sprain (stretch or tear) of the ligaments that connect the scapula (shoulder blade) to the clavicle (collarbone).

Classification

The Rockwood classification of AC joint injuries separates them into six different types. Type I injuries are characterized by a sprain of the AC ligament with no injury to the CC ligaments. Because both ligaments remain intact, no radiographic abnormality is present. In a Type II injury, the AC ligament is completely disrupted, and the CC ligaments are sprained. On radiographs, there is less than 25% superior displacement of the distal clavicle with respect to the acromion. In AC joint injuries of Types III to VI, both AC and CC ligaments are completely disrupted. The clavicle displaces superiorly between 25% and 100% in a Type III injury and greater than 100% in a Type V injury. In a Type IV AC joint injury, the clavicle is displaced posteriorly into or through the trapezius muscle. The clavicle is displaced inferiorly in relation to the acromion and can even be found inferior to the coracoid in a Type VI injury (Figure 1).

Clinical Presentation

Patients who sustain an AC joint dislocation localize pain to the AC joint itself. They may complain of pain radiating to their neck and deltoid. The AC joint may also be swollen. The upper extremity is often held in adduction with the acromion depressed. The clavicle may appear elevated due to the depressed acromion.

The classical presentation is a triad of point tenderness, pain over the AC joint with cross-arm adduction, and relief of symptoms with an injection of a local anesthetic at the AC joint.

Physical Exam

The physical examination of the patient with an injured AC joint should include a neurovascular examination of the upper extremity. The contours of the patient's bilateral shoulders should be compared. In a severe AC joint injury, the shoulder may appear depressed, with a prominent distal clavicle. The AC joint is often swollen and may be tender to palpation. Tenderness along the CC ligaments and at their insertion on the coracoid is helpful in determining the extent of the injury. After an acute injury, range of motion is often restricted, and the patient may not be able to perform specialized tests.

The *cross-arm adduction test* is a specialized test that examines the patient for pain at the AC joint by placing compression across the joint. It is most useful for minor or chronic AC joint injuries. It is performed with the arm elevated to 90° and then adducted across the chest with the elbow bent to approximately 90°. Pain at the AC joint with this maneuver is a positive test.

The *O'Brien test* with pain referred to the AC joint can also be indicative of injury to the AC joint. The test is performed by flexing the shoulder to 90°, pronating the arm so that the thumb is pointing toward the ground, and adducting the arm approximately 15° from the sagittal plane. The patient then resists a downward force placed on the distal forearm by the examiner.

The sternoclavicular joint should also be examined to rule out multiple ligament injuries.

Imaging

The AC joint is best visualized when one third to one half of the X-ray penetration required for glenohumeral joint exposure is used. Standard views of the injured shoulder should include AP, lateral, and axial views (the axial view helps differentiate a Type III from a Type IV injury). A *Zanca view* is a specialized view for imaging the AC joint. It is performed by tilting the X-ray beam 10° to 15° cephalad and using only 50% of the standard shoulder AP penetration strength. The Zanca view is the most accurate view for determining the position of the distal clavicle in relation to the acromion.

A comparison view of the uninjured shoulder can be taken to determine the normal AC and CC joint spaces. Stress or weighted radiographs have not been found to be useful and are no longer a routine part of the work-up of an AC joint injury.

Treatment

Conservative treatment is recommended for Types I and II and most Type III AC joint injuries. Treatment should include ice, analgesics, and sling immobilization for 3 to 7 days. Return to sports is allowed 1 to 2 weeks after Types I and II injuries and 4 to 6 weeks after a Type III injury. Football players may benefit from cutout pads to reduce contact with the AC joint when returning to play.

Treatment for Type III injuries is controversial. Most physicians recommend an initial trial of nonoperative treatment in most cases, including those injuries in professional athletes. An operative approach is, however, considered by some physicians for throwing athletes (particularly baseball pitchers) and people who do heavy labor, whose activities place substantial demands on the upper extremity.

Methods of operative fixation for AC joint injuries include direct ligament repair or ligament reconstruction. Repairs can be augmented with sutures or metallic screws. Ligament reconstruction can be performed by transferring the coracoacromial ligament into the end of the resected distal clavicle or anatomically with an allograft.

After Surgery

Following ligament reconstruction, the arm is supported with a sling and swathe for 4 to 6 weeks. At the 2-week follow-up, gentle range-of-motion exercises with the patient in the supine position are begun. Strengthening and range-of-motion exercises with the arm unsupported in the upright position should be delayed for 4 to 6 weeks to allow the repair sufficient time to heal. Heavy-weight training and return to sports is allowed at 3 months postoperatively.

Acupuncture

Throughout the United States and around the world, people practice what has come to be known as *complementary* and *alternative medicine*. This is medicine that is used as a complement or alternative to conventional Western medicine. One of the most widely recognized practices within complementary medicine is the ancient art of acupuncture. Acupuncture is an age-old practice of working with the body's natural energy flow to achieve balance. Practiced by trained and licensed practitioners, its current uses are many and varied, and its practice is safe and effective.

This entry reviews the philosophy of acupuncture, its methods and uses in and out of the athletic arena, current research on acupuncture, and its future directions.

Philosophy of Acupuncture

Part of traditional Chinese medicine, acupuncture is used to promote health and to maintain the balance of *yin* (cold, slow, passive principle) and *yang* (hot, excited principle). Acupuncture is practiced using a variety of techniques to stimulate specific points on the body and unblock the flow of energy (*qi*) along the body's meridians and, thus, achieve balance.

Practitioners and Practice of Acupuncture

Although the stimulation of specific body points can be practiced in several different ways, the most common acupuncture technique involves the use of thin, solid, stainless steel needles of varying length and gauge, placed at specific body points along the meridians. These needles may be stimulated by movement or by electrical current. The needles themselves are regulated by the Food and Drug Administration (FDA) and are required to be sterile, nontoxic, single use, and used by a licensed practitioner. Another commonly used method of stimulating the body is acupressure, in which the specific body points receive manual manipulation with the therapist's hands and fingers instead of needles.

Although acupuncture practitioners can come from several different professional bases, most states require a license of some kind, although the requirements for attainment of that license (i.e., the specific training) may vary. Although it may seem harmless, potentially dangerous side effects of acupuncture, if performed by an untrained practitioner, include infection and punctured organs. Licensed acupuncturists are those who have studied for 3 or more years in an Oriental college of medicine. Chiropractors can practice acupuncture, provided they have received additional training in acupuncture. Physicians and dentists can also add acupuncture to their practice if they obtain additional training in acupuncture, although the length of required training varies by state, to a maximum of 300 hours. Physicians may also become board certified in acupuncture by the American Board of Medical Acupuncture.

Like other health care visits, acupuncture visits follow a certain format. Typical acupuncture sessions include a discussion of the individual's medical history (e.g., medical conditions, menstrual cycle, eating and sleeping habits), as well as an examination of the patient's posture and mental state (e.g., tone of voice, emotional stress). Sessions can vary in length, although once the needles are in, they usually last from 20 to 30 minutes. Though acupuncture can be used alone, sessions are often accompanied by the use of Chinese herbs, often in the form of an infusion (tea). Many sessions may conclude with recommendations for some lifestyle changes (e.g., change in diet, physical activity).

Uses of Acupuncture

Acupuncture has been employed in treatment of a variety of conditions, ranging from mental conditions and headaches to immune disorders, musculoskeletal problems, and asthma. Acupuncture is extensively used in the sporting arena. Many athletes have found acupuncture an effective method of pain control. Acupuncture has also been used to treat musculoskeletal injuries, as well as to improve performance and prevent injuries. As an adjunct to appropriate training, acupuncture promotes muscle building and glycogen storage, stimulates substrate usage at the time of performance, and treats injuries or other chronic conditions that might affect performance.

Acupuncture has also found its way into the operating room. Acupuncture analgesia is one of the main methods of providing operative analgesia in Beijing and has been found to be beneficial in neurosurgery, thyroid surgery, tonsillectomies, and some open-chest surgeries. Acupuncture research has also demonstrated reduced dependence on conventional pain medications and a decrease of brain activities associated with pain on magnetic resonance imaging (MRI). Although further research is needed, some studies have demonstrated improvement in asthma symptoms with acupuncture, resulting in a decrease of symptoms from exercise-induced asthma when acupuncture was provided before the activity. Acupuncture research has also shown better control of allergic symptoms in patients using acupuncture in conjunction with herbs. Studies of acupuncture and acupressure have demonstrated a decrease in nausea and vomiting in patients after surgery and in those undergoing chemotherapy. The relief and prevention of headaches is another of the studied benefits of acupuncture. Acupuncture has also been noted to promote fertility by improving fertility-related functions, such as improvement in sperm count as well as improved follicular health and ovulation and increased vaginal lubrication.

Acupuncture has been found to be successful in treating addiction to illicit substances. As it is believed that addiction is a self-directed attempt to balance *qi,* acupuncture is said to balance *qi* and has been shown to stimulate the release of endorphins by the peripheral nerves, resulting in increased feelings of well-being, and to provide relief from withdrawal symptoms. Studies have also demonstrated greater relapse prevention with auricular acupuncture. With other mental health conditions, acupuncture helps decrease the duration of hospitalization, as well as improving social interactions, mood, and sleep.

Research and Future Directions

As with many practices of complementary medicine, acupuncture research designs of the past have been difficult to interpret. Currently, the National Institutes of Health (NIH) are conducting several studies on acupuncture, relating to the treatment of low back pain, how acupuncture works, and meridians and *qi* flow. With growing research in acupuncture, practitioners believe that it will increasingly complement and integrate with conventional medicine. Currently, one third of conventional medical schools have curricula that include acupuncture.

Aerobic Dance, Injuries in

Among the many current approaches to improving cardiovascular fitness is aerobic dance. As with any aerobically oriented conditioning program, the goal is to increase the participant's cardiovascular strength, muscular endurance, and overall wellness. This entry explores the common forms of aerobic dance and how it became popular, as well as common injuries and the ways to prevent them.

Aerobic dance, more commonly called aerobics, is practiced in a class format, often located in community centers, gyms, and fitness centers, but can it also be performed at home using videos or video game consoles. A group fitness instructor leads the class to music with an upbeat tempo so that the participants' heart rates are between 65% and 85% of their maximal heart rate during exercise. Sessions range in length from 30 minutes to 2 hours.

In 1968, Kenneth Cooper published his highly successful book *Aerobics;* aerobic dance entered the fitness industry in the early 1970s, popularized by entertainment and media figures including Judi Sheppard Missett, Richard Simmons, Jane Fonda, and Billy Blanks.

Aerobic dance can be performed as step aerobics, Jazzercise, Zumba, and lightweight resistance training in the form of circuit training. What each of these has in common with the others is the repetitive dynamic nature of moving one's body through different planes of motion with other fitness participants who have similar fitness goals.

Step aerobics, more commonly called aerobics, became popular in the 1980s. It is high impact and has participants stepping up and down in all planes of motion at variable speeds and rhythms. The height of the plastic platform (step) can be adjusted to increase or decrease the intensity of the exercise. The popularity of the original form of step aerobics has diminished somewhat in the past decade with the introduction of modified versions in an effort to counter the increased tendency to injury and with the advent of low-impact aerobic dance classes. The low-impact versions of step aerobics reduce the risk of injury by having exercisers keep one foot always in contact with the surface of the step or floor. With either type of step aerobics, the beat or tempo of the class is kept at either 32 or 64 beats steps^{-1} minute^{-1}. Common injuries associated with step aerobics are patellar tendinitis, Achilles tendinitis, and low back pain. Participants can significantly reduce the chance of these common overuse injuries by being more thorough with their stretching regimen and by cross-training with resistance training and other forms of aerobic exercise.

Low-impact aerobics can come in other forms, such as Nia and Zumba. Nia began in the 1980s and is a blend of several well-known forms of exercise, such as yoga, tai chi, jazz dance, and modern dance. This holistic alternative to step aerobics is popular worldwide and is taught by more than 2,100 instructors.

Zumba originated in the early 2000s and is based on Latin rhythmic dance and creative multiplanar movements; it is currently taught in fitness centers in more than 70 countries around the world. Participants are engaged by a dynamic blend of music and the excitement of an enthusiastic instructor.

Jazzercise was established in 1969, just a year after the publication of *Aerobics*. Currently, according to Jazzercise.com, this form of aerobic dance has 7,800 instructors teaching more than 32,000 classes weekly in more than 30 countries. Jazzercise combines movements seen in yoga, Pilates, kickboxing, and resistance training.

There are a multitude of aerobic dance modalities, each with its own unique style of exercise selection, movement, beat/tempo, and interaction between the instructor and the participants. As with step aerobics, all styles of aerobic dance have an inherent risk of injury. The sheer volume of repetitive motions during aerobics that are not typically sustained in activities of daily living render participants susceptible to the following common overuse injuries:

- Plantar fasciitis
- Heel spurs
- Shin splints
- Sesamoiditis
- Turf toe
- Achilles tendinitis
- Patellar tendinitis
- Knee bursitis

Often these overuse injuries are just a symptom of kinetic chain dysfunction and muscular asymmetries. Symptoms of injury may appear in one area of the body when the "real" or original injury causing these symptoms is in a completely different body part. For example, low back pain can actually be a symptom of tightness in the hip flexor, but the hip will go untreated because of the mistaken belief that it is the back that needs to be "fixed."

It is prudent for participants to consult their physician prior to engaging in an aerobic dance program. People who are just starting exercise should meet with a certified fitness professional or personal trainer for an initial exercise assessment. The fitness professional/personal trainer will be able to provide a novice exerciser with a subjective and objective assessment of needs in order to help prescribe the right blend of exercises to prevent the risk of overuse injury due to preexisting muscular asymmetries. Most fitness centers that host aerobic dance classes also have certified personal trainers who will provide a brief initial assessment of needs and exercise for first-time users. With a clean bill of health from their doctor, participants can enjoy the physical fitness benefits of aerobic dance.

Aerobic Endurance

Endurance training is regular participation in an exercise program designed to enhance endurance and increase muscle resistance to fatigue. Aerobic energy metabolism is the process by which the body produces energy in the presence of oxygen. Aerobic metabolism is the primary form of energy production during endurance activities such as long-distance running, cycling, swimming, and rowing. Endurance training aims to maximize aerobic energy metabolism through adaptations in the heart, lung, and muscle systems. This type of training can result in improvements in general health, physical fitness, and sports performance while also speeding recovery and rehabilitation from injury or illness.

Background: Energy Metabolism

The body breaks down food in the form of carbohydrates, fats, and proteins to produce energy in the form of adenosine triphosphate (ATP). ATP is the substrate that most cells in the body use as an energy source. ATP can be produced by cells either with or without oxygen. *Aerobic metabolism* is the process by which the body breaks down food to produce ATP in the presence of oxygen. This type of energy metabolism is used during longer-duration, moderate-intensity activities such as jogging. *Anaerobic metabolism* is the process by which body cells quickly produce ATP on demand without relying on oxygen. Muscle cells use anaerobic metabolism for short-duration, high-intensity activities such as sprinting. This type of energy production is short-lived, however, because in addition to producing ATP, anaerobic metabolism also produces lactic acid. Lactic acid accumulation in muscles produces early fatigue. The *lactate threshold* is the point at which lactic acid buildup in the muscles begins to impair performance.

Endurance Training

Power and speed exercises rely primarily on anaerobic metabolism, while endurance activities mostly use aerobic metabolism to produce ATP. Because lactate is not produced during aerobic metabolism, the muscles are able to continue to function without developing early fatigue. Thus, the body is able to continue endurance activities for longer periods of time.

All exercise activities depend on the complex interaction between the *cardiovascular* (heart and blood vessels), *pulmonary* (lungs), and *neuromuscular* (nerves and muscles) *systems*. Oxygen enters the bloodstream through the lungs, the heart pumps the oxygen in the blood through the blood vessels to the muscles, and the muscles use the oxygen in the blood to produce energy through aerobic metabolism. Endurance training is the process by which the body increases the capacity of the heart, lungs, and muscles to produce energy so that the duration and intensity of exercise can be maximized and the onset of muscle fatigue is delayed.

During exercise, both the heart rate (the number of heartbeats per minute) and the stroke volume (the amount of blood pumped out with each heartbeat) increase. This produces a significant increase in the cardiac output (the amount of blood the heart pumps per minute). During exercise, both the respiratory rate (the number of breaths per minute) and the diffusion capacity (the ability of the lungs to absorb oxygen into the blood) increase. This causes an equally increased amount of oxygen to be absorbed into the bloodstream through the lungs. Endurance training produces measurable increases in both the stroke volume of the heart and the diffusion capacity of the lungs. This allows more oxygenated blood to get to the muscles during exercise. Thus, more energy can be produced through aerobic metabolism. This prevents lactic acid from building up in the muscles and causing early muscle fatigue.

Endurance training also produces measurable differences in the muscles. Muscles become both stronger and more efficient at extracting oxygen from the blood. This occurs through an increase in muscle size, an increase in the number of tiny blood vessels inside the muscles, and an increase in the ability of muscle cells to produce energy through aerobic metabolism.

Measuring Aerobic Fitness

Aerobic fitness can be directly measured with special equipment that is used to determine the amount of oxygen the athlete consumes per minute. This figure, called the "$\dot{V}O_2$," can be quantified and steadily increases as the athlete's fitness improves. Another way to measure aerobic fitness is to measure how much lactic acid is accumulating in the blood during exercise. This is done with a blood test following a defined activity. Lower lactic acid levels in the blood following exercise indicate a higher level of aerobic fitness. This shows that the muscle cells are relying on aerobic metabolism and avoiding anaerobic metabolism for energy production. Studies have shown that untrained athletes reach their lactate threshold at lower levels of $\dot{V}O_2$ than trained athletes, indicating that lactic acid buildup occurs slower as fitness or endurance level increases.

Children and Adults

Growing children are still developing their heart, lung, and muscular systems. Compared with adults, children use more oxygen and have higher heart rates, lower stroke volumes, and higher respiratory rates during exercise. Because their muscular system is still developing, children exercise less efficiently than adults and require more energy for any given task. Children also produce more heat and have less efficient cooling systems (i.e., they sweat less) than adults. This makes children more susceptible to changes in climate than adults. On a positive note, children do recover more quickly and experience less pain with intense workouts.

Aerobic endurance has been studied in children and is noted to steadily improve throughout childhood. The greatest increases in aerobic fitness are seen during puberty, which may be related to hormone production and muscular development. Endurance training can produce measurable increases in fitness in children, just like it can in adults. However, for unknown reasons, endurance training in children produces only about one third of the increase in aerobic fitness as compared with what would be expected for adults following a similar training program.

The Ideal Endurance Training Program

An endurance training program consists of activity duration, frequency, and intensity. Typical frequency and duration for aerobic endurance training programs are three to five sessions per week at 30 to 60 minutes per session. Activity intensity may be the most important factor in producing measurable increases in aerobic endurance. Studies have shown that aerobic fitness increases significantly following high-intensity exercise. Activity intensity is usually quantified as a percentage of the maximum heart rate. The maximum heart rate of an athlete can be estimated by subtracting the age of the athlete from 220. High-intensity exercise occurs when the athlete's heart rate reaches 80% of its maximum.

Training Errors

The most common training error is "too much too soon." Sudden increases in training duration, frequency, or intensity are likely to lead to pain and injury. A prudent way to increase training activities is to follow the "10% rule": Do not increase the duration, frequency, or intensity of an activity more than 10% per week. Children are especially susceptible to overuse injuries from overtraining. Before starting any training program, a preparticipation exam and adequate rehabilitation from all injuries is vital. Ignoring persistent pain, especially in children, can lead to significant injuries, including stress fractures and osteochondritis dissecans lesions.

Air Pollution, Effects on Exercise and Sports

Air pollution is a problem for all, but it can be a particular problem for athletes. During exercise, both the tidal volume (the volume of one breath) and the respiratory rate increase, resulting in a minute ventilation (the amount of air inhaled in 1 minute) of up to 20 times the resting values. Because of increased ventilation, there is greater delivery of air pollutants to the athlete's airway, which magnifies the deleterious impact of airborne toxins. Also, breathing during exercise is largely through the mouth and not the nose; thus, inhalation bypasses one of the usual means of air filtration, which further increases toxin exposure. Finally, exercise may increase the ease with which compounds cross from the air into the bloodstream. The increased exposure of the athlete is in direct proportion to the level of aerobic work in a given sport and the duration of the exercise; it also depends on the location of the activity, with greater exposure to air pollutants outdoors. Thus, the a marathoner or a cyclist, who may exercise aerobically for hours out of doors, would be expected to suffer more than a swimmer or a weight lifter.

Air Pollution: An Ongoing Concern

Airborne toxin inhalation by athletes has been highlighted in the media during the preparations for many Olympic Games, including the 1984 games in Los Angeles, the 1996 Olympics in Atlanta, the 2004 Athens Olympics, and the recent 2008 games in Beijing. Since vehicle exhaust is a major source of air pollutants, Olympic cities have often initiated strict traffic control policies in the months leading up to the games. For example, prior to the 1996 Olympic games in Atlanta, an integrated 24-hour public transportation system was established, park-and-ride services were instituted, telecommuting and alternate work hours were encouraged by businesses, delivery schedules were altered, and the downtown was closed to private automobile traffic. During this time, all measured pollutants, including ozone, particulate matter <10 micrometer (μm), carbon monoxide (CO), nitrogen dioxide (NO_2), and sulfur dioxide (SO_2), decreased significantly. Interestingly, also during this time, pediatric emergency room visits and hospital admissions for asthma were also reduced by over 40%, suggesting that the reduction in air pollution also benefited other vulnerable populations. Beijing, home of the 2008 summer games, is one of the most polluted cities in the world, and it faced similar challenges in improving air quality in anticipation of the Olympics. While their efforts produced the best air quality the city has experienced in 10 years, the levels on most days did not reach the World Health Organization safety limit of an Air Pollution Index (API) of 50. In the weeks and months leading up to the games, some athletes announced that they would not be participating due to pollution-related health concerns.

Relationship Between Air Pollution and Athletic Performance

But how exactly do pollutants affect athletic performance? This depends not only on the sport but also on the specific pollutant in question. The U.S. Environmental Protection Agency (EPA) and similar agencies around the world track the levels of six principal air pollutants, including ground-level ozone, particles, nitrogen dioxide, carbon monoxide, sulfur dioxide, and lead (Table 1).

In addition, volatile organic compounds, a group of airborne hazardous toxins produced by both industrial and natural sources, also have adverse health effects that can be amplified by exposure during exercise.

Ground-Level Ozone

Ground-level (trophospheric) *ozone* (trioxygen, O_3) is the product of reactions between nitrogen oxides and volatile organic compounds containing hydrocarbons. Both of these substrates are produced by combustion from cars, industrial and power plant emissions, gasoline vapors, and chemical solvents, as well as by some sources in nature. Because ozone depends on light for its production, ozone levels tend to be higher on bright sunny summer days. Also, since its removal from the air depends largely on it being deposited on the ground, lack of rain to "wash away" pollutants will result in the accumulation of ozone. These two environmental factors, coupled with air current patterns, have a significant impact on the amount of trophospheric ozone. While stratospheric ozone helps protect us by diffusing harmful ultraviolet radiation from the sun, trophospheric ozone has potentially deleterious health effects. Ozone is known to trigger exacerbations of asthma, increase reactivity to histamine and methacholine, and aggravate bronchitis in animal models and clinical trials. Heavy exposure results in cough, chest pain, throat irritation, dyspnea, nausea, headache, and congestion. It can reduce lung function, cause pulmonary inflammation, and with repeated exposure can result in scarring of the lung and declining lung function.

At rest, an ozone level of 0.4 parts per million (ppm) has been demonstrated to alter airway hyperreactivity in normal subjects; however, during moderate exercise, the level of ozone associated with the development of bronchospasm (airway constriction) may be closer to 0.1 to 0.2 ppm. Independent of exercise, exposure to a high level of ozone (>1 ppm) is associated with increasingly severe respiratory symptoms, and an exposure to 50 ppm for 30 minutes is considered potentially lethal. Ozone may also potentiate the impact of other inhaled pollutants and allergens. For example, ozone pretreatment has been demonstrated to potentiate bronchoconstriction

Table I Air Pollutant Standards Based on World Health Organization (WHO) and National Ambient Air Quality Standards (NAAQS) Guidelines

Pollutant	*WHO Standard*	*NAAQS*	*Impact on Health*	*Notes*
Particulate matter 2.5 µm	10 µg/m^3 (annual mean) 25 µg/m^3 (24-hour mean)	15 µg/m^3 (annual mean) 65 µg/m^3 (98% of 24-hour mean)	Cough, shortness of breath, reduced lung function, cardiac events including ischemia and myocardial infarction, reduced heart rate variability, cancer	Lowest level at which cardiopulmonary and lung cancer mortality rates have been shown to increase with more than 95% confidence interval
Particulate matter 10 µm	20 µg/m^3 (annual mean) 50 µg/m^3 (24-hour mean)	50 µg/m^3 (annual mean) 150 µg/m^3 (24-hour average, not to be exceeded more than once every 3 years)	Same as above	Lowest level at which cardiopulmonary and lung cancer mortality rates have been shown to increase with more than 95% confidence interval
Ozone	100 µg/m^3 (8-hour mean)	0.12 ppm (maximum daily 1-hour average, to be exceeded no more than once per year over 3 consecutive years) 0.08 ppm (3-year average of fourth highest daily 8-hour average)	Cough, wheezing, bronchospasm, chest pain, sore throat, lung inflammation, change in lung function, nausea, headache	
Nitrogen dioxide	40 µg/m^3 (annual mean) 200 µg/m^3 (1-hour mean)	0.053 ppm (annual mean)	Wheezing, cough, bronchospasm, increased susceptibility to respiratory illness	Contributes to acid rain
Sulfur dioxide	20 µg/m^3 (24-hour mean) 500 µg/m^3 (10-minute mean)	0.03 ppm (annual mean) 0.14 ppm (24-hour mean)	Wheezing, cough, bronchospasm, exacerbation of existing heart disease	Contributes to acid rain
Carbon monoxide		9 ppm (10 mg/m^3) (8-hour average, not to be exceeded more than once per year) 35 ppm (40 mg/m^3) (1 hour, not to be exceeded more than once per year)	Low blood oxygen	

Sources: Compiled from WHO and NAAQS data.

Note: ppm = parts per million; µm = micrometer; µg/m^3 = micrograms/cubic meter of air; mg/m^3 = milligrams/cubic meter of air.

in response to sulfur dioxide, another of the six commonly tracked air pollutants. Thus, the deleterious impact of air pollutants appears to be synergistic, and because vehicular exhaust is a common source of many pollutants, environmental exposures are also usually concomitant. Interestingly, although chronic respiratory decline may persist, there appears to be a reduction in the severity of acute respiratory responses to ozone following chronic ozone exposure.

Particle Pollution

Particle pollution is likewise an important factor in air quality. There are two EPA-recognized categories of particle air pollutants: (1) particles less than or equal to 2.5 μm in diameter ($PM_{2.5}$), or fine particles, and (2) those 2.5 to 10 μm in diameter (PM_{10}). Particles 10 μm or larger are typically deposited on the nasal septum; however, this filtering is bypassed during exercise, when most athletes breathe through their mouths. Particles between 2 and 10 μm are typically deposited in the branching airways of the lung, while particles in the 0.2- to 2-μm range are usually deposited in the alveoli, where they are cleared by intra-alveolar cells or absorbed and cleared by the lymphatic circulation. Particles less than 0.2 μm were previously believed to be exhaled; however, growing evidence suggests that these can also be deposited in the alveoli and absorbed into the bloodstream.

$PM_{2.5}$ particles are of particular importance regarding health consequences. Although their chemical composition varies, these particles include sulfate, nitrate, organic carbon, elemental carbon, and organic crust materials. Sources include power generation, car and truck emissions, fertilizers and animal feed, wildfires, and metallurgical mining operations. Exposure has been associated with cough, shortness of breath, impaired lung function, chronic bronchitis, and reduction in normal heart rate variability. Recent evidence supports an association between exposure and myocardial ischemia, heart attack, and premature death. These risks appear to be magnified by exercise.

Carbon Monoxide

Carbon monoxide levels are also closely monitored. Carbon monoxide displaces oxygen from hemoglobin; thus, inhalation of high levels impairs oxygen delivery, which not only limits athletic performance but also may impair other oxygen-dependent body functions. The primary source of carbon monoxide is vehicle exhaust, and in cities an estimated 95% of carbon monoxide is produced by motor vehicles. A study of runners in New York City found that carbon monoxide levels increased from 1.7% to 5.1% following a ½ hour of running near a busy roadway. The elevated level is equal to the typical carbon monoxide level of a chronic cigarette smoker. Carbon monoxide is also identified as exacerbating adverse respiratory and cardiovascular responses to other inhalants, including particulate matter and sulfur dioxide.

Sulfur Dioxide and Nitrogen Dioxide

Like many other pollutants, *sulfur dioxide* and *nitrogen dioxide* are produced by burning fuels. Sulfur dioxide is also a common by-product of oil refining and manufacturing and of metal ore extraction. Both cause acute bronchoconstriction, which can be magnified during exercise. Sulfur dioxide and nitrogen dioxide also both combine with other chemicals in water to produce acid rain.

Volatile Organic Compounds

A final class of chemicals that can be discussed in this context are *volatile organic compounds*. These too are contained in car exhaust, and levels are increased near busy roadways. Common examples include benzene, chloroform, toluene, ethylbenzene, and xylene. Many of these are known carcinogens. Benzene, for example, has been linked with both leukemia and lung cancer. In one study, after only 20 minutes of running along a busy roadway, levels of toluene, ethylbenzene, and xylene were significantly increased compared with the pre-exercise levels; thus, as with other airborne pollutants, exercise in polluted environments increases the exposure of the athlete to these toxins.

Pollution is a worldwide concern. The Kyoto Protocol is an international agreement signed in December 2007 to address global warming through the reduction of environmental pollutants. The agreement expires in 2012, and negotiations are under way for a new international agreement to take its place. Recent efforts exploring alternative energy resources, such as electric and hybrid cars, which are designed to reduce dependence on fossil fuels, are also likely to result in improved environmental conditions. As these efforts move forward, it is likely that the world will become a healthier place for athletes and nonathletes alike.

Alcohol and Exercise

The consumption of alcohol has always been thought to help in relaxation, mood alteration, and increasing sensory pleasure. Reducing stress and inducing relaxation have often been cited by athletes and habitual exercisers as the main reason for their alcohol consumption.

Research for many years has focused on the consumption of alcohol and its implications for sports and exercise. Two results are clear: (1) the rate of injury in sports increases with alcohol intake and (2) performance gradually decreases. Whether the use of alcohol is sporadic or over a longer period of time, studies show that when alcohol is present in the body, muscles become inefficient in using glucose and amino acids, which decreases energy. Alcohol also impairs the required metabolic processes during exercise. The cross-sectional area of muscle fibers has been shown to decrease with chronic alcohol use. Consumption after exercise negatively affects blood viscosity. On the other hand, exercise decreases the rate at which the number of mitochondria in the liver declines when one imbibes alcohol. In fact, exercise may increase the rate at which the liver metabolizes alcohol. And exercise perhaps reduces the damaging oxidative effects of alcohol.

Alcohol and Athletes

Alcohol abuse is intertwined with social practices, and sports participants and athletes are not exempt from the tendency to abuse alcohol. In collegiate sports in particular, alcohol misuse is probably underreported, as many studies have confirmed that the problem exists but is often regarded as "normal behavior" by college students.

Studies show varying patterns of alcohol use among the different sports. For example, athletes who play rugby, cricket, hurling, soccer, and Gaelic football have the highest percentage of alcohol consumption. In contrast, the percentage of alcohol consumption among athletes in horse racing, cycling, and tennis is low.

Acute alcohol consumption adversely affects psychomotor skills, and therefore, performance suffers. Acute consumption also reduces the body's ability to adapt to cold environments.

Alcohol and Musculature

Chronic alcohol consumption decreases the vascularity of muscles, and this has been hypothesized to be the cause of its detrimental effects on muscle tissue. Skeletal muscle weight, along with DNA and RNA content, decreases with continuous alcohol use. Alcohol-induced alterations to the normal metabolic processes in muscle tissue, as well as damage to nerves, result in muscle atrophy.

Some studies show that athletes have a higher rate of alcohol consumption immediately prior to their sporting events, and that a significant number of them are chronic alcohol consumers. This situation may be a reflection of the athletes being uninformed about alcohol's detrimental effects, and perhaps the lack of monitoring and education by exercise specialists, training specialists, fitness trainers, coaches, physical therapists, and sports physicians.

In the recovery period after exercise, blood homeostasis, or the ability of blood to maintain normal function, is affected adversely by alcohol consumption, particularly due to alcohol's effects on some clotting factors and hormones. Specifically, blood clotting becomes exaggerated in the recovery phase. There are implications that these alcohol-induced effects on blood homeostasis, along with conventional risk factors such as age, smoking, and abnormal lipid profiles, lead to higher atherosclerosis rates.

Alcohol consumption after a competition or after training appears to be common among athletes. Of particular concern in relation to this practice is the onset of brain infarction, or the development of a blood clot in the brain, leading to decreased blood flow. This was seen in some studies to occur with drinking to the point of intoxication. Although the available evidence does not show a higher incidence of cardiovascular disease with moderate alcohol consumption, some studies suggest that the increase in heart rate, blood flow, and platelet aggregation caused by alcohol may predispose athletes to thrombotic events, or events that lead to blood clots.

In a study examining the effect of alcohol on lipid levels after exercise, no differences were observed in total cholesterol and high-density lipoprotein levels during recovery. Triglycerides, however, increased substantially 5 hours into the recovery period.

Other problems arise from excessive alcohol use. Cardiac muscle is adversely affected by acetaldehyde, an alcohol metabolite. Cardiac dysfunction may result from excessive alcohol use. Arrhythmia may also result from the temporary weakening of left ventricular contraction and the increased myocardial irritability associated with alcohol consumption. These effects appear to be related to acute, heavy use, not to chronic use.

Alcohol and Liver Functions

The toxicity of acetaldehyde (a breakdown product of alcohol) to the liver is well-known, and the fact that alcohol is broken down mainly in the liver leads to a concentration of detrimental effects in this organ. Among heavy drinkers, 10% to 35% develop alcohol hepatitis, and 10% to 20% suffer from liver cirrhosis. In patients with cirrhosis, exercise capacity and oxygen consumption decrease markedly. In alcoholic patients, cardiac dysfunction is very evident, with no increase in left ventricular function during exercise. Impairment of cardiac function has been seen in cirrhotic patients, possibly due to thickening and stiffening of the walls of the heart, ultimately leading to decreased ability to exercise.

Alcohol intake decreases resting glycogen (the storage form of sugar) as well as glucose output. The liver's preoccupation with alcohol metabolism also contributes to decreased production of new sugars for energy. The end result is hypoglycemia, a decrease in blood glucose and, consequently, stored muscle glycogen. Exercise needs glucose as a fuel and taps stored glycogen as well.

Alcohol and Kidney Functions

An increased tendency to urinate is another effect of alcohol. The release of an antidiuretic hormone (a substance that inhibits urination) normally produced by the body so that the kidneys conserve water is reduced by the intake of alcohol. Urine becomes diluted as a result. Dehydration can result if the kidneys do not reabsorb water back into the body. Muscular functions are diminished when electrolytes and essential minerals are excreted in higher concentrations than normal. Total body water drops, specifically affecting muscle functions and nerve conduction because of the loss of the electrolytes potassium, chloride, and magnesium. Moreover, almost all physiological functions become impaired by dehydration.

Athletic performance is greatly affected by body water. A decrease of 1 liter (L)/minute in cardiac output has been observed with each liter of water lost in dehydrated conditions. An elevated heart rate of up to 8 beats $minute^{-1}$ L^{-1} of water lost has been observed as well. Perceived exertion becomes higher because the muscles during exercise are performing harder, but less nutrients and oxygen are available to them. Blood pressure may decrease during dehydration, and central blood volume also decreases, causing the athlete to experience fainting or a "light-headed" feeling.

The ability of the body to transfer heat from contracting muscles to the skin's surface is impaired by consuming alcohol during exercise, and corresponding impairments in blood flow, sweat rate, and blood volume may occur. Heat-related injuries may increase with the faster rise in core body temperature.

Rehydration after alcohol consumption has been shown to be very important in maintaining bodily functions. Because the volume of fluids in the stomach has the greatest influence on gastric emptying, it has been suggested that the sooner the athlete imbibes water, the faster the resolution of the fluid deficit occurs.

Conclusion

Motor skills—reaction time, hand-eye coordination, accuracy, balance, and complex muscle coordination—are adversely affected by alcohol consumption. Mistakes committed on simple musculoskeletal tasks increase with alcohol intoxication. Performance suffers and injuries rise with alcohol abuse, particularly due to the resultant impaired balance, increased reaction time, and decreased accuracy with tasks.

The overwhelming evidence supports the notion that alcohol use hinders exercise and participation in sports. Athletes, in particular, should be counseled against alcohol consumption and constantly educated regarding the body's response to alcohol in terms that they can relate to: performance, maintenance of skills, endurance, strength, and ability.

Allergic Contact Dermatitis

Allergic contact dermatitis (ACD) is a skin disorder caused by a variety of agents that an athlete may be exposed to during practice or competition. Items such as equipment, local factors on the playing field, and even topical medications in the training room have all been described as potential triggers of this condition. ACD affects all calibers of athletes in all types of sports. Identifying this uncomfortable and debilitating rash, treating it appropriately, and helping to prevent its recurrence is the duty of the sports physician.

Pathophysiology

ACD is an immunologic reaction classified as a Type IV reaction, or *delayed-type hypersensitivity.* The degree of sensitization is variable from person to person, as some individuals may exhibit reaction to some agents, while others do not. For example, the allergen in poison ivy will sensitize nearly 70% of exposed persons, while the chemical allergen found in wetsuits will sensitize a relatively small percentage of individuals.

ACD presents in two stages. The first is called the *induction phase,* which occurs when a person is first exposed to a new allergen. Sensitization by the immune system to this new agent requires a minimum of 4 days to develop. However, many athletes may come in contact with an allergen repeatedly for months or even years before developing clinical sensitivity. The second phase, the *elicitation phase,* occurs after allergic sensitization has occurred. After the athlete is again exposed to the offending allergen, the dermatitis will manifest within 24 to 48 hours.

Prevalence Within Sports

Athletes of nearly every sport played are at risk of developing ACD. From the chemical composition of their gear to the type of tape used in the athletic training room, many different sources of allergens have been reported in a variety of sports.

The incidence of ACD from water sports such as swimming, diving, fishing, and snorkeling has been well documented. The chemicals in the rubber of wetsuits have been described as triggers of this skin condition. In addition, swimmers who are sensitive to the chemicals used to disinfect pools may exhibit the characteristic symptoms of ACD.

Among the myriad skin disorders that plague runners, joggers, and walkers, ACD is especially debilitating. As in other sports, the materials used in manufacturing of training equipment may be responsible for the development of ACD. The inside of the running shoe tends to be moist, and this moisture will leach out the specific chemicals responsible for causing ACD. It has been shown that the neoprene inserts of certain brands of running shoe cause ACD of the soles of the feet.

Soccer players and other field sport athletes are also at risk for ACD. In this population, the skin condition is usually caused by equipment or chemicals used in maintaining the field. Reactions to the lime used in field markings, known as "cement burns," have been found in several athletes. This rash was noted to occur either during or after completion of a match and became worse after a hot shower.

Items commonly found in the athletic training room may also predispose individuals to ACD. There have been many reports of skin reactions to the chemical resins used in athletic tape. It has been reported that analgesic sprays, topical medications, and anti-inflammatory creams/gels have caused ACD in athletes. Other training room products that cause ACD include eucalyptus oil and lanolin preparations.

Diagnosis

To diagnose ACD, the team physician must first recognize the dermatologic manifestation associated with the condition. On sensitization and then reexposure to the allergen, the dermatitis starts to manifest within 24 to 48 hours. An intensely itchy, very red rash develops rapidly, followed by vesicle and/or blister formation. Lesions are usually very well demarcated and will often originate at the site of contact with the allergen; however, new lesions may appear at distant, seemingly unrelated sites as a result of transfer of the allergen by the hands. In time, a chronic stage may occur, characterized by thickened, fissured skin.

There is considerable variation in the intensity of the reaction, depending on the body area affected. The mucous membranes are usually spared, as well as the hair-bearing scalp. Palms and soles tend to be much less affected than the dorsal and interdigital areas. The eyelids and skin around the eyes are especially sensitive, while involvement of the armpits is rare.

Although clinical diagnosis of ACD is the usual practice, the gold standard for formal diagnosis is patch testing. This procedure attempts to re-create the skin manifestation using a minute concentration of the offending allergen. The TRUE Test, manufactured in Denmark, is a commercially available patch testing kit that contains patches with 24 commonly encountered allergens. The upper back is the favored site for testing, and it is imperative that hair be removed using an electric rather than a straight razor to minimize damage to the skin being tested. Patches should remain on the skin for 48 hours and are then removed, with the reading done in 72 to 96 hours. A classically positive patch test reaction consists of reddened skin, mild edema, and small, closely set vesicles.

Treatment

Treatment of ACD depends on the severity of the condition. Acute manifestations are best treated with wet dressings for the first 24 to 36 hours using Burow's solution. Topical steroid creams are useful against mild to moderate ACD. Although rarely needed, oral corticosteroids are effective against severe ACD. Itchy skin and hives are generally well managed with oral or topical diphenhydramine. If secondary infection is suspected, the use of antibiotics may be warranted.

Prevention of future outbreaks should also be a goal for the team physician. Although avoidance of the offending agent is the ideal management, it may not always be feasible. Substitution of alternative equipment, such as nonrubber shoe insoles or eye goggles, may be helpful in this process. In any event, one must be sure that substitution of a certain item with another does not also trigger the allergic reaction.

Return to Sports

The decision surrounding return to play is determined by the athletes' level of discomfort and their willingness to return. Complicating bacterial secondary infection may preclude immediate return and should be addressed on a case-by-case basis. The likelihood of reexposure to the initial trigger should also be taken into account. Prophylaxis with nonsedating antihistamines may be necessary, especially if repeated contact with the offending agent is likely.

Allergies

Allergic reactions are caused when the immune system is triggered into action by an *allergen*, which is a protein, or antigen, producing a clinical allergic reaction. These allergens elicit a response by immunoglobulin-E (IgE), causing various symptoms depending on the body system affected. This entry will explore different issues related to allergies, including allergic rhinitis and venom allergies, and how to diagnose and treat different types of allergies. Allergies can significantly affect an athlete's performance; for example, failure to adequately control allergic rhinitis can lead to an increase in upper respiratory symptoms, which can impede an athlete's breathing, resulting in suboptimal performance.

Allergic Rhinitis

Allergic rhinitis is the term used to describe inflammation of the nasal mucosa that causes symptoms ranging from nasal discharge to sneezing to nasal itch. Allergic rhinitis is caused by specific allergens in the environment.

Epidemiology

Allergic rhinitis can occur at any age but most commonly affects children and adolescents, with the mean age of onset around 8 to 11 years. Recent studies and surveys indicate that allergic rhinitis may affect around 40 million people in the United States alone, and the annual health care costs may be around $15 billion. In childhood, it is more common in boys but occurs equally in both sexes in adulthood. Allergic rhinitis can affect persons of all races, and prevalence varies depending on geographic location (i.e., warm vs. cold, rural vs. urban).

Etiology

Pollens and mold spores are the allergens that are generally responsible for seasonal allergies. These pollens usually come from trees, grasses, and weeds that depend on the wind for pollination, which produce large quantities of lightweight pollen that can be breathed in, triggering symptoms. Flowering plants and those plants that depend on insect pollination typically produce a heavier pollen that rarely causes symptoms. The seasons and the location determine the type of allergies a patient may develop. For example, the highly allergenic ragweed is found in the Midwest and the eastern United States and typically produces pollen from August through September. See Table 1 for further details.

Table 1 Common Environmental Allergens

Indoor	*Outdoor*
Dust mites	Weeds (especially ragweed)
Pet dander (most common in cats and dogs)	Trees
Cockroaches (especially important in large cities)	Grasses
Indoor molds	Molds

Pathophysiology

In patients who are susceptible to allergies, exposure to an allergen leads to a cascade of events that result in characteristic symptoms. When a patient is exposed to an allergen, he or she can develop allergic sensitization, which is characterized by the production of specific IgE directed against these antigens. Mast cells, which are present in the nasal mucosa, bind IgE, which leads to immediate and delayed release of a number of chemical mediators. These include histamine, kinins, leukotrienes, prostaglandin D2, and others. Through a series of chemical reactions, these mediators eventually cause the common symptoms associated with allergies, such as nasal congestion, itching, and sneezing. This is the immediate response, and over the next 4 to 8 hours, the late-phase response occurs. This occurs through recruitment of other inflammatory cells such as neutrophils, eosinophils, macrophages, and lymphocytes. All these cause continued inflammation. The symptoms are similar but with more congestion and mucous production and less sneezing and itching.

Diagnosis and Testing

Clinical Features

Patients can present with a wide array of symptoms and complaints, so a detailed history is extremely important in helping to determine not only if a patient has allergic rhinitis but also what allergen in the environment is triggering the symptoms and how best to treat the patient. Things to consider when taking the history include determining if the symptoms are seasonal or perennial (year round), which organ systems are affected, and what triggers the symptoms, such as specific outdoor or animal exposures. Other history to elicit includes response to past medications, exposures at the workplace, and whether there is a family history of allergies. A personal history of asthma or atopic dermatitis correlates with allergic rhinitis.

Physical Examination

The most common physical findings are usually confined to the nose, mouth, ears, and eyes. Patients may have any or all symptoms in any combination. Patients can have “allergic shiners,” which are dark circles under the eyes related to nasal congestion. White, pale, blue-gray turbinates in the nasal exam are consistent with allergic rhinitis. The nose also usually has a thin, clear secretion. A “nasal crease” is a horizontal crease across the lower half of the bridge of the nose caused by repeated upward rubbing of the tip of the nose. This is also known as the “allergic salute” and is seen commonly in children. The ear exam may reveal fluid in the middle ear as a result of Eustachian tube dysfunction. Examination of the eyes may reveal reddened conjunctivae and excessive lacrimation. The throat exam can show “cobblestoning,” which describes streaks of lymphoid tissue in the posterior pharynx.

Testing

Allergic rhinitis can often be diagnosed by the clinical history and the exam findings, but skin testing is helpful to confirm the diagnosis and to determine specific allergen sensitivity. Identifying specific allergens can help direct prevention and treatment. The most common test is the scratch or prick test, in which a drop of extract is scratched or pricked through the skin using a needle or other testing device. The antigen in the extract binds to IgE on skin mast cells, and histamine and other mediators are released, creating a wheal if the patient is allergic to that antigen.

Intradermal testing can also be done, in which the extract is injected into the dermal layer of the skin. Intradermal testing is more sensitive than skin testing, but it also has a higher amount of false-positive results. Radioallergoabsorbant testing (RAST) involves measuring the proportion of specific IgE to allergens in the blood. RAST testing is generally less sensitive than skin testing.

Treatment

Prevention

Treatment can be divided into two categories: (1) prevention/avoidance and (2) pharmacological therapy. Avoidance can consist of using dust mite covers on pillows and on the bed, extermination of cockroaches, or, if the allergen is pet dander, keeping the pet out of the bedroom to minimize the dander in the area where the patient sleeps. Frequent washing of bedsheets, vacuuming, and minimizing the amount of carpet in the house are all strategies that may help. For outdoor allergies, keeping windows and doors closed, minimizing outdoor time during high pollen counts, or wearing a mask when mowing the lawn or gardening are a few strategies that may help prevent allergies.

Pharmacological Therapy

Treatment is determined based on the frequency and severity of the symptoms. Patients with intermittent symptoms may benefit from oral decongestants, oral antihistamines, or both. Patients with more severe or chronic symptoms often benefit from an intranasal steroid spray. Patients with eye symptoms may benefit from ocular antihistamine drops. It is not uncommon for patients to be on a combination of or on all these medications at a time. A leukotriene receptor antagonist can also be added to help relieve symptoms.

Allergen immunotherapy can also be used, with the intention of increasing the threshold level for symptoms to occur after exposure to an allergen. Immunotherapy consists of injections that contain small amounts of the allergens the patient is allergic to, with the expectation that this will help "desensitize" the patient to the offending allergen. Given the expense and the fact this is long-term therapy, it is usually reserved for patients with chronic symptoms that are refractory to the aforementioned medications.

Venom Allergies

Allergic reactions to insect stings constitute a real medical problem, with about 50 deaths per year in the United States. The most common stinging insects are of the order Hymenoptera, which includes yellow jackets, wasps, and bees. The most serious reaction that happens is anaphylaxis, usually occurring within 15 minutes of the sting. Symptoms include generalized urticaria, flushing, angioedema, and edema of the upper airway. Patients may also develop shock and hypotension, resulting in death.

Testing can be done to diagnose venom allergies, and once a diagnosis has been made, venom immunotherapy can be initiated. Patients who are at risk should always carry an epinephrine self-injection device to be used in case they are stung. This is important for athletes who train in warm-weather environments, where they at risk of being stung. They should either carry an epinephrine pen with them, if they are participating in a solo sport or are training by themselves, or have their trainers or medical staff have an epinephrine pen readily available. The epinephrine pen should be renewed every year.

Altitude Sickness

High altitude is generally defined as an elevation above sea level greater than 6,500 feet (ft), or 2,000 meters (m). Above this elevation, unacclimatized athletes may develop *altitude sickness*, or acute mountain sickness (AMS), shortly after their ascent. AMS reflects cerebral abnormalities and is one end of a spectrum of severity that includes high-altitude cerebral edema as a more severe potential consequence of ascent. High-altitude pulmonary edema and high-altitude cerebral edema occur at similar altitudes and, though uncommon, are potentially fatal.

Given that most persons traveling to high altitudes are doing so to perform physical activity of some kind, be it skiing, climbing and mountaineering, or competing in an endurance race or soccer match, it is wise to be aware of the deleterious effects of elevation above sea level.

Epidemiology

Epidemiological data from Colorado suggest an incidence of AMS of 22% at altitudes of 1,850 to 2,750 m (7,000 to 9,000 ft) and 42% at altitudes of 3,000 m (10,000 ft). The summit of Mt. Everest is 8,848 m (29,028 ft), which is considered extreme altitude.

Pathophysiology

The reason why altitude can result in AMS appears to be related to the reduced supply of oxygen (***hypoxia***), particularly to the brain and lungs. This deficiency of oxygen stimulates increased blood flow, leading to increased pressure and eventual leakage of fluid out of the smallest blood vessels in these areas. This leakage results in swelling in the brain (*cerebral edema*) or lungs (*pulmonary edema*).

Causes

Risk factors for altitude sickness include residence below 900 m, previous episodes of altitude sickness, physical exertion, and some cardiopulmonary conditions (though not hypertension, coronary artery disease, diabetes, or mild chronic obstructive pulmonary disease). Children appear as susceptible as do adults, while older adults (>50 years old) have decreased susceptibility. Women have an equal risk for altitude sickness, though a lower risk for high-altitude pulmonary edema. Physical fitness has no protective effect.

Persons with previous experience of high-altitude pulmonary edema may have a recurrence rate of 60% should they ascend rapidly to higher than 4,600 m. Such individuals seem to have a reduced ventilatory response to hypoxia and an exaggerated pulmonary pressor response to hypoxia and exercise, though they are otherwise quite healthy. Endothelial function might be responsible for this impairment. Those susceptible to high-altitude pulmonary edema appear to have a genetic difference in their sodium channels.

Definition

Altitude sickness is a relatively subjective syndrome with nonspecific symptoms. The Lake Louise Consensus Group defines altitude sickness as the presence of headache in an unacclimatized individual who has recently arrived at an altitude above 2,500 m, who in addition is experiencing one or more of the following symptoms: anorexia, nausea or vomiting, insomnia, dizziness, and lassitude or fatigue (Figure 1).

Clinical Presentation

Altitude sickness often presents with nonspecific symptoms such as decreased appetite, nausea or vomiting, difficulty sleeping, dizziness, and fatigue. The presence of one or more of these symptoms in an unacclimatized athlete who has recently (typically 6–10 hours earlier) ascended >2,500 m is necessary for a diagnosis. There are no physical signs unless someone progresses to cerebral edema. In this case, changes in consciousness and difficulty with balance and coordination (ataxia) may be present. Eye findings such as papilledema and retinal hemorrhage or even a palsy of one of the cranial nerves may also be present, indicative of the increased intracranial pressure. Drowsiness can progress to stupor and even to brain herniation and death over a period of hours or days.

High-altitude pulmonary edema commonly occurs the second night at a new altitude and rarely after more than 4 days at a given altitude, owing to changes in blood vessels in the lungs. Acute pulmonary edema is suggested by deteriorating performance during activity and breathing difficulty at rest, a "moist" cough, severe weakness, drowsiness, skin color change (cyanosis), increased heart rate and breathing rate, and crackles on auscultation of the lungs with a stethoscope. Orthopnea is rare, but fever up to 38.5 °C is common. Pink or bloody sputum is a late finding.

Diagnosis

Diagnosis of altitude sickness is clinical, and laboratory tests or imaging are not very helpful, unless

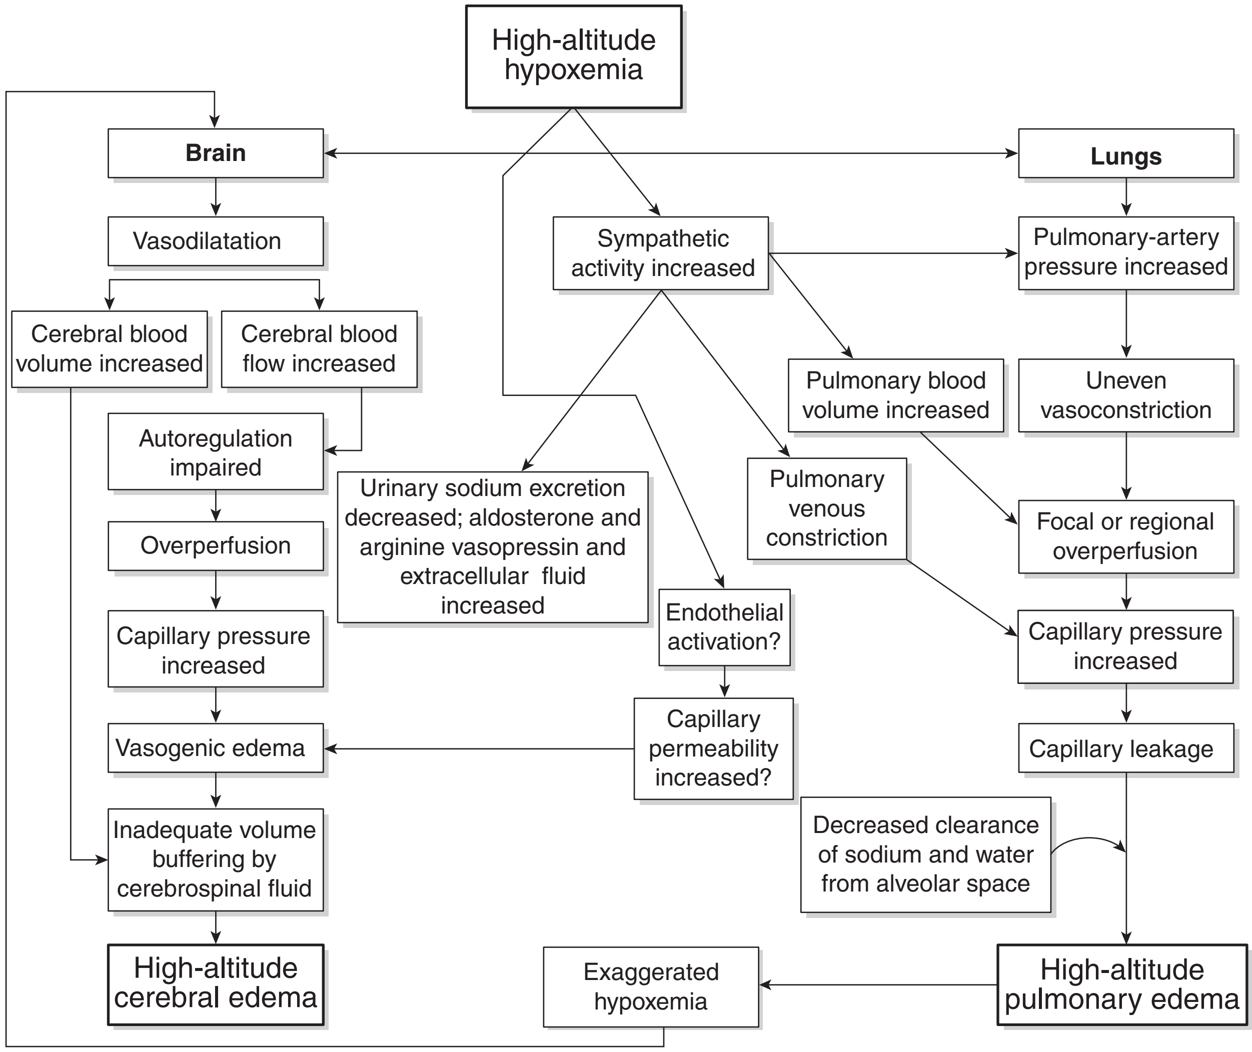

Figure 1 Altitude Sickness Pathophysiology

Source: Hackett PH, Roach RC. High-altitude illness. *New Engl J Med.* 2001;345(2):107–114. Reproduced with permission.

perhaps to exclude another diagnosis. In a patient with pulmonary edema, electrocardiography often demonstrates subtle abnormalities reflecting right heart strain. Chest radiography generally reveals patchy infiltrates, found in both lungs in more severe cases.

Treatment of Altitude Sickness

Treatment of altitude sickness begins with preventing further ascent until the symptoms have resolved. If no response to medical management is seen, descent is also indicated. If cerebral edema is suspected, descent should be immediate. Descent and supplemental oxygen are the treatment of choice; descent can be accomplished in a portable hyperbaric chamber. Acetazolamide appears to reduce symptom severity within 24 hours and is useful when descent or oxygen is not an option. Dexamethasone has been shown to be equally effective, if not superior, and can have a more rapid effect within 12 hours. After altitude sickness has resolved, any further ascent should be made with caution, perhaps with acetazolamide prophylaxis. Other agents have been studied, but results are mixed.

Prevention of Altitude Sickness

The best strategy for the prevention of altitude sickness is a gradual ascent to promote acclimatization. Acclimatization is the physiologic method of progressively increasing sleeping altitude. Published guidelines state that once above 2,500 m, the altitude at which one sleeps should not be increased by more than 600 m in 24 hours and an extra day should be added for every increase of 600 to 1,200 m. Expert opinion recommends prophylaxis for those who plan an ascent from sea level >3,000 m (sleeping altitude) in 1 day and for those with a history of altitude sickness. The old climbers' dictum is "climb high, but sleep low." Maximal acclimatization occurs at 3 to 6 weeks.

Acetazolamide is usually the preferred pharmacotherapy; it should be started 12 to 24 hours before ascent and continued for 3 or 4 days. Dexamethasone is an alternative, and *Ginkgo biloba* also has been shown to be effective.

Treatment of High-Altitude Pulmonary Edema

Treatment of high-altitude pulmonary edema is focused on increasing oxygenation by having the patient breathe supplemental oxygen, which reduces pulmonary artery pressure, reverses the effects of the illness rapidly, and also benefits the brain. Descent, supplemental oxygen, or both are nearly always successful. Patients with severe pulmonary edema, which arterial oxygen saturations have failed to improve, and those with concomitant high-altitude cerebral edema must be moved to a lower altitude and possibly hospitalized. Nifedipine can be used as an adjunct or for prophylaxis; however, it is not as effective as supplemental oxygen.

Altitude and Performance

Maximal oxygen consumption ($\dot{V}O_2max$) will decrease with altitude (~1% per 100 m above 1,500 m) and can significantly affect competitive athletic events. Acclimatizing at altitude for 3 to 6 weeks prior to competition has been recommended, though significant improvements in performance are seen over a shorter window of time, and there is little further improvement after 21 days. Athletes should consider scheduling travel to coincide with a tapering plan that allows for some high-intensity efforts to be performed at the competition altitude before the event. The relative training load should be maintained while considering that maximal exercise capacity will be reduced. This is probably of little benefit for short (<1 minute) anaerobic events and is often impractical. The acclimatization process causes an increase in red blood cell mass and a resultant increase in the oxygen-carrying capacity of blood. An alternative to acclimatization is the use of commercially available hypoxic generator tents, which seem to be as effective over a 3-week period. This effect has been shown to increase aerobic power and exercise performance at sea level, hence the use of "altitude training."

Further Research at Altitude

The brain ultimately regulates exercise effort, but only a few studies have tested this directly. These studies have shown that exercise involving large amounts of muscle (e.g., cycling) at altitude is limited *before* signs of muscle fatigue develop. When subjects are given supplemental oxygen at the point of exhaustion, they are able to continue cycling at higher work rates, suggesting that exercise at altitude may be highly influenced by central factors such as cerebral hypoxia. Athletes who take the time and energy to properly adjust to altitude prior to competition can maximize their potential at altitude. There unfortunately is no "magic bullet," and there is a great deal of individual variation. Coaches and endurance athletes are perhaps best served by avoiding the described medical complications at altitude and allowing their bodies to adjust.

Amenorrhea in Athletes

Amenorrhea is the absence or cessation of the menstrual cycle in a woman of reproductive age. The disorder is further subdivided into primary and secondary types. Primary amenorrhea is the absence of a menstrual cycle by the age of 15. If the menstrual cycle appears at puberty but subsequently ceases for more than 3 months, the diagnosis is called secondary amenorrhea.

Amenorrhea has several different etiologies. A hormonal interaction between the hypothalamus, pituitary, and ovaries controls the onset of menstruation and the monthly cycle. An abnormality in the function of any one of these organs can lead to amenorrhea. The reproductive tract must also be free from anatomic abnormalities. Last, hormones from outside the hypothalamus-pituitary-ovarian axis can influence the menstrual cycle. These outside influences include thyroid hormone and cortisol.

Exercise and Amenorrhea

Amenorrhea in an athlete represents a unique situation. Excessive exercise can lead to either primary or secondary amenorrhea. Many theories have been explored in an attempt to explain this relationship. As stressful situations such as death in the family or divorce can cause amenorrhea, the stress associated with strenuous exercise may be the cause of amenorrhea in these athletes. Some studies have shown that stress can inhibit certain hormones, which would lead to suppression of menses. Definitive evidence is lacking, and interestingly, adolescents with stressful music careers do not experience a similar disruption in their menstrual cycle.

A second explanation for amenorrhea in a high-level athlete is a disorder of energy balance. If energy expenditure exceeds caloric intake, the athlete's body may allot available energy to necessary functions at the expense of other, nonnecessary functions such as reproduction. This adjustment can occur within one to two menstrual cycles. As a result, athletes with a normal body fat composition can experience menstrual disturbances after relatively short intervals (months) of intensive activity if their dietary intake does not correspondingly increase as well. The energy imbalance may be intentional on the part of the athlete, or it may be accidental. Many adolescent athletes underestimate the additional energy demands of high-intensity exercise.

Anorexia nervosa lies at the end of the spectrum of poor energy balance. This disorder is characterized by refusal to maintain a healthy body weight due to intense fear of gaining weight. Irregular menstrual cycles can occur early in the disease before significant weight loss. Amenorrhea is almost always present in severe weight loss when a female is less than 20% of ideal body weight. Epidemiologic evidence does not show that anorexia is more prevalent in athletes relative to their age-matched counterparts. However, individuals involved in aesthetic sports such as diving, gymnastics, and ballet are at high risk for disordered eating habits.

The Female Athlete Triad

Young female athletes may develop a combination of conditions including irregular menstrual cycles, low bone mineral density, and disordered eating. This cluster of findings is called the *female athlete triad.* Low calorie intake relative to energy expenditure can lead to menstrual disorders as discussed above and also compromised bone strength. The most severe pathology is manifest as anorexia nervosa, amenorrhea, and osteoporosis. These individuals are at risk for stress fractures and are likely at risk for more severe fractures late in life. Few athletes exhibit all three elements of the triad. The signs and symptoms should be viewed on a continuum, and athletes showing suggestions of one sign should be considered at risk for the others.

Clinical Evaluation

A comprehensive history and thorough physical examination should begin the clinical evaluation. Attention should be paid to diet, exercise, menstrual history, and signs of secondary sexual characteristics such as breast development and pubic hair growth. Body mass index (weight in kilograms divided by square of the height in meters) should be calculated and compared with normative values if disordered eating is a consideration. Signs of hormonal abnormalities should be assessed.

Diagnostic Tests

History and physical exam findings can determine appropriate diagnostic testing. Every patient needs a pregnancy test, as one of the most common causes of amenorrhea is pregnancy. Anatomic reproductive abnormalities can be evaluated by pelvic ultrasound in primary amenorrhea. Serum hormone level measurements may be necessary to assess proper endocrine function.

Specific testing for an athlete with elements of the female athlete triad evaluates for signs of energy imbalance. Daily dietary intake needs to be evaluated. Initial labs include evaluation of serum electrolytes, screening for anemia, and assessment of thyroid function. A bone density test can be considered if risk factors are present.

Prevention

Many causes of primary and secondary amenorrhea are associated with genetic predispositions and are not preventable. However, amenorrhea secondary to low energy availability and the female athlete triad are avoidable with awareness. Leading national medical associations emphasize education of athletes, coaches, athletic trainers, and the health care team to help recognize and prevent disordered eating. Athletes should be counseled on proper caloric intake and nutritional requirements, including intake of calcium and vitamin D. Many school departments include screening questions on athletic preparticipation physical exam forms pertaining to elements of the female athlete triad. Screened individuals should be educated and counseled appropriately.

Treatment

Treatment of primary and secondary amenorrhea is aimed at the specific cause. This is focused on treatment of amenorrhea associated with excessive exercise and decreased energy intake. Patients' counseling should involve the physician, athletic trainer, nutritionist, coach, and parents. If a severe eating disorder is suspected, treatment should include a psychiatrist and/or psychologist. Often an increase of 300 to 400 kilocalories (kcal)/day (1 kcal = 4186.8 joules) in the form of an energy bar is sufficient to correct the energy imbalance. Athletes should also be encouraged to take calcium and vitamin D supplements to meet recommended daily requirements. Oral contraceptive pills restore normal menstrual flow but do not address the underlying energy deficit and do not restore bone mineral density.

American College of Sports Medicine

The American College of Sports Medicine (ACSM) is the world's largest professional organization of sports medicine physicians, practitioners, and scientists. ACSM, based in Indianapolis, Indiana, was founded in 1954, and currently, there are more than 20,000 national and international members. This organization fosters sports medicine education, clinical practice, and scientific research through multiple media including professional meetings, continuing education, newsletters, publications, leadership organizations, certification, and research funding.

Mission Statement

According to the organization's website, ACSM's mission is as follows:

> The American College of Sports Medicine promotes and integrates scientific research, education, and practical applications of sports medicine and exercise science to maintain and enhance physical performance, fitness, health, and quality of life.

Education

Continuing educational opportunities are made available through ACSM in the form of medical journals, newsletters, conferences (national and international), online courses, certification workshops, and regional chapter meetings. Popular ACSM-hosted conferences attended by thousands of individuals yearly include the Annual Meeting, the Team Physician Course, the Advanced Team Physician Course, and the Health & Fitness Summit & Exposition. Popular publications include *Medicine & Science in Sports Medicine, Exercise and Sport Science Reviews, ACSM's Health & Fitness Journal,* and *Current Sports Medicine Reports*. Through these media, health professionals and exercise scientists network and cooperate by sharing knowledge as well as disseminating research.

Certification

ACSM was the first professional organization to certify individuals as health fitness professionals, and to date, they have certified more than 25,000 individuals. Certifications include two health fitness certifications (Certified Personal Trainer and Certified Health Fitness Specialist) and two clinical certifications (Certified Clinical Exercise Specialist and Registered Clinical Exercise Physiologist). These individuals gain varying levels of training, from personal fitness assessments and rehabilitation to exercise testing, prescription, counseling, and supervision. By choosing a credentialed health fitness professional, the consumer can be assured of being provided expert services by a person who has met the standard requirements and has demonstrated competency in knowledge, skill, and ability.

Research: ACSM Foundation

ACSM has committed considerable time and effort to developing the scientific knowledge that drives clinical practice. Research ideas and data are presented and discussed at its conferences and meetings and at roundtable discussions by worldwide experts. Research papers are consistently disseminated in its scientific journals. In 1984, the ACSM Foundation was founded. Its roles include fundraising, managing endowments, and distributing funds both to the college and to individuals as research awards. Yearly, the ACSM Foundation awards approximately $100,000 in research funding. This funding is often awarded to promising young investigators starting their careers.

American Medical Society for Sports Medicine

The American Medical Society for Sports Medicine (AMSSM) was founded in 1991 by five family physicians. The organization was formed specifically to meet the needs of primary care, nonsurgical sports medicine physicians. Its stated mission is to "offer a forum that fosters a collegial relationship among dedicated, competent primary care sports medicine physicians as they seek to improve their individual expertise and raise, with integrity, the general level of sports medicine practice."

AMSSM's membership includes 1,124 members with physicians from all facets of primary care and musculoskeletal medicine. This includes family medicine, pediatrics, internal medicine, emergency medicine, preventive medicine, and physical medicine and rehabilitation.

The AMSSM strives to link the rapidly expanding scientific literature to the practice of clinical medicine. Additional functions of the AMSSM include the following:

- To foster research in sports medicine through provision of grants and awards
- To promote state-of-the-art sports medicine practice via collaboration and publication of clinical monographs and position statements
- To provide cutting-edge educational and networking opportunities via the AMSSM annual meeting and involvement with the American College of Sports Medicine (ACSM) Advanced Team Physician course
- To provide a means for publication of original articles and case studies through its official association with the *Clinical Journal of Sports Medicine*
- To provide online research tools to its members via journal links and a subscription to *Sports Discus*

The goals of the AMSSM are as follows:

- To develop and maintain a national society of primary care sports medicine physicians who share a common philosophy, body of knowledge, and expertise related to sports medicine and its practice
- To provide multidisciplinary educational opportunities for primary care medicine physicians using meetings, video and printed materials, and educational tools
- To encourage and support research in the area of sports medicine
- To work with the AMSSM Foundation
- To encourage and support the development and regular review of the knowledge base in sports medicine
- To develop, and lead in formulating, position statements, guidelines, and educational materials on sports medicine topics for both professional and lay use
- To provide a venue for ideas and information sharing among colleagues on the practical aspects of sports medicine practice and delivery of care
- To represent primary care sports medicine physicians and advertise their ability to give high-quality care to the public
- To promote the health and safety of athletes and physically active individuals through education of all involved in their care

The AMSSM supports research in the area of primary care sports medicine and sponsors the following publications:

Clinical Journal of Sports Medicine

British Journal of Sports Medicine

Sports Discus

Beginner Triathlete Articles

In addition to the above, the AMSSM offers a number of services through its website. These include "Sports Medicine Self Care" and "When to Call a Doctor." These services give information about various topics in sports medicine and advice about sports injuries from a primary care physician's perspective. Information on sports medicine fellowships and how to contact a sports medicine physician is also available on the AMSSM website.

American Orthopaedic Society for Sports Medicine

Established in 1972 by a group of renowned orthopedic surgeons, the American Orthopaedic Society for Sports Medicine (AOSSM) is recognized as a world leader in sports medicine education, research, communication, and fellowship. The society works closely with many other sports medicine specialists, including trainers, physical therapists, family physicians, and others, to improve the identification, prevention, treatment, and rehabilitation of sports injuries. Formed originally as a forum for education and research with 100 members, AOSSM today has more than 2,500 members.

AOSSM's members are physicians and allied health professionals who demonstrate scientific leadership, involvement, and dedication in the daily practice of sports medicine. Such activities may include service as a team physician at any level of competition; educating persons involved with the health of athletes; service in local, regional, national, and international competitions; and the presentation of scientific research papers at sports medicine meetings.

The unifying interest of the membership is their concern with the effects of exercise and the monitoring of its impact on active individuals of all ages, abilities, and levels of fitness. While many members treat high-profile athletes who play on professional teams, many others devote their practices to helping out their community by treating players on the local high school or junior college team.

Through research and advances in surgical and rehabilitation techniques, orthopedic sports medicine specialists have been able to treat and rehabilitate athletes whose injuries were once career ending and put them back in the game.

AOSSM Activities

Patient Education Materials

The society develops an array of patient literature to help clinicians meet the information and education needs of their patients.

Clinical Practice Materials

AOSSM develops and disseminates monographs, pocket cards, and other materials that have direct application for orthopedists and others with an active interest in sports medicine. Examples of topic areas developed include concussion management, helmet removal, female anterior cruciate ligament injuries, and the role and responsibilities of team physicians.

Traveling Fellowship Program

This annual international exchange with European and Pacific Rim nations allows selected fellows to travel internationally to lecture on and observe orthopedic sports medicine care.

Sports Medicine Research

AOSSM maintains an active research program, including the First Time Investigators Grant program, the Herklotz/AOSSM Sports Medicine Endowment, and other award programs for outstanding research.

Education

In addition to the educational programs and the society's annual meeting, AOSSM partners with a variety of other medical and/or sports-related organizations to provide quality educational courses, including the NFL (National Football League) Physicians Society, NBA (National Basketball Association) Physicians Society, American College of Sports Medicine, American Medical Society for Sports Medicine, American Academy of Orthopaedic Surgeons, and National Athletic Trainers' Association. To guide these endeavors, as well as to provide members with a framework for their own educational endeavors, the society has developed a CME (continuing medical education) Curriculum.

American Osteopathic Academy of Sports Medicine

The American Osteopathic Academy of Sports Medicine (AOASM) is a multispecialty, national sports medicine organization. It was chartered by the American Osteopathic Association in 1976 and incorporated in 1987. AOASM physicians are involved in clinical practice, medical education, and research. They provide medical and sports medicine care to athletes at recreational, collegiate, professional, and Olympic levels. Physicians completing osteopathic medical school, residency training, and a sports medicine fellowship are eligible to sit for an exam, which if successfully passed earns them a Certificate of Added Qualifications in Sports Medicine. This certification validates that the physician is trained to provide comprehensive medical management to athletes as well as the general patient population.

The AOASM works collaboratively with other sports medicine groups to develop guidelines for the medical care of athletes, to promote exercise as part of a healthy lifestyle, and to represent its members on relevant political issues. The application of specialized manual medicine skills in the diagnosis, treatment, and prevention of neuromusculoskeletal injuries, disorders, dysfunctions, and diseases is an educational focus for the organization. Members of the AOASM are active as faculty in osteopathic as well as allopathic academic medical institutions. Membership categories provide opportunities for physicians, fellows, residents, medical students, and allied health professionals to participate in the organization.

The AOASM is the oldest primary care–based sports medicine specialty. Osteopathic medicine uses a holistic, comprehensive approach to the prevention, diagnosis, and management of sport- and exercise-related injuries, disorders, dysfunctions, and disease processes. The founders, pioneers and expert sports medicine specialists, realized that while there were several physician organizations that support sports medicine, there was no forum specifically for osteopathic sports medicine physicians.

The purpose of the AOASM is to advance a mutually respectful relationship among dedicated, competent sports medicine specialists and to provide a quality educational resource for AOASM members, allied health sports medicine professionals, and the general public.

The vision of the AOASM is to champion the health, well-being, and safety of athletes and physically active people.

The stated mission of the AOASM is to provide

- an educational forum for physicians and health care professionals to address the quality of health care for individuals in competitive, recreational, occupational, and industrial settings;
- leadership to establish and promote fitness and exercise guidelines and to guide health care policy relating to wellness, physical activities, and sporting events; and
- a collegial environment in which physicians and other health care professionals can expand their content knowledge and enhance their clinical skills in primary care sports medicine.

Anabolic Steroids

Steroids in sports have been in the news for decades, and they continue to be a significant problem in sports. The term *anabolic* means that the chemical induces tissue production, or muscle building. Not all steroids are anabolic (muscle building), and steroids of all kinds have significant therapeutic benefits when used properly.

The term *steroid* includes dozens of different chemical compounds, natural and synthetic, that differ from one another in just a few carbon or hydrogen atoms. The most commonly discussed steroids can be separated into two general groups—corticosteroids and gonadal steroids. *Corticosteroids* are produced naturally in the adrenal glands (just above the kidneys) and include glucocorticoids and mineralocorticoids. Glucocorticoids are widely used as anti-inflammatories and immune system modulators. The glucocorticoid cortisone, in pill form or the injectable form, is used to treat conditions ranging from lupus to asthma to poison ivy. Corticosteroids such as depomedrol are used as injectable treatment for tendinitis or bursitis. Mineralocorticoids help regulate water and electrolyte levels and are not typically used in sports treatment or as performance enhancers.

Gonadal steroids are naturally produced in the ovaries in females and in the testes in males. They help produce secondary sex characteristics such as hair distribution and breast development, as well as prepare the body for reproduction. Estrogen is the predominant feminizing hormone in females, and testosterone is the masculinizing, or virilizing, hormone in males. Testosterone has an anabolic effect, which means that it promotes protein synthesis and cellular production, especially in muscles. It is this anabolic effect that has been used by athletes since the 1930s to aid in tissue healing and to build muscle mass. Anabolic steroids also have a medical role in the controlled treatment of severe burns, short stature, and recently human immunodeficiency virus (HIV)-related wasting.

Anabolic steroid use is banned by all major sports governing bodies, including the National Collegiate Athletic Association (NCAA), International Olympic Committee (IOC), National Football League (NFL), Major League Baseball (MLB), National Hockey League (NHL), and Fédération Internationale de Football Association (FIFA). They are banned both because they give an athlete an unfair competitive advantage and because they can be dangerous to the athlete's health. Even the delivery system of steroids can be dangerous. Injectable steroids require needles, which can pass viruses such as hepatitis and HIV. Oral steroids (pills) can cause liver failure, and anabolic steroids may contribute to liver or brain cancers.

Transdermal steroids are now available in odorless and colorless adhesive patches and creams that are simply placed on the skin and absorbed. This makes their use easier for proper medical treatment but also harder to detect if they are being abused without a prescription. Possession of anabolic steroids without a prescription is a federal crime punishable by fines and prison.

Athletes who use these steroids for performance enhancement often use 10 to 20 times the typical therapeutic dose. They often use them in cycles of 4 to 6 weeks, with a 4- to 6-week steroid-free period. Other chemicals also may be used in conjunction with steroids. For instance, diuretics are used to mask steroid use in urine tests. Other chemicals, such as tamoxifen (an estrogen blocker), are used to combat unwanted side effects such as gynecomastia (breast development in males). These masking agents are considered banned substances and are included in the panel of drugs tested in sports.

Serious side effects from anabolic steroid abuse also include avascular necrosis, which is the breakdown and collapse of joints, especially in the hips. Tendon ruptures may be more common. Blood pressure and cholesterol profiles can be adversely affected, leading to cardiovascular problems, including heart attack and stroke. Other side effects include acne (especially on the back), testicular atrophy, and premature balding. Women who use anabolic steroids may develop masculine features such as an enlarged, squared jaw; male-pattern balding; and coarse body or facial hair. Personality disorders, including outbursts of aggression, may also be exacerbated by anabolic steroids.

Anaphylaxis, Exercise-Induced

Exercise-induced anaphylaxis is a distinct form of physical allergy with a spectrum of symptoms including itching (pruritus), hives (urticaria), angioedema, wheezing, hypotension, fainting (syncope), and in rare instances even death. Urticaria is an early sign of true anaphylaxis. This entry discusses exercise-induced anaphylaxis, its triggers, how to diagnose the condition, and treatment strategies.

General Considerations

Epidemiology

The age of onset ranges from childhood through adulthood. This condition affects males and females equally, and about half the patients have a history of atopy. Attacks can range from a few times per month to once a year. Most cases have been reported in athletes who exercise regularly. There are some studies that suggest that the severity of the anaphylactic events may decrease over time.

Pathogenesis

The exact mechanism is not known, but mast cells are known to be a factor because studies have shown elevated levels of serum histamine and tryptase during attacks. Studies have also shown mast cell degeneration on skin biopsies done after an attack. There may be a priming phenomenon at work, where one stimulus acts as a cofactor for the reaction to occur. Food, medication, or other factors (see below) may act as the primer, and then the exercise triggers the event. Exercise alone does not cause anaphylaxis, and eating the food without exercise also does not cause an anaphylactic event. An individual must first be "primed" by eating the food, and when this is followed up by exercising (the "trigger"), it has the potential to cause an anaphylactic event.

Triggers/Associated Factors

Exercise-induced anaphylaxis can be triggered by any physical activity, but it is more common in aerobic sports and running. Factors that have been associated with this condition include menstruation, use of aspirin and NSAIDs (nonsteroidal anti-inflammatory drugs), and exposure to cold weather or hot, humid weather. Some patients have a food-dependent variant, where they need to ingest a certain food, then exercise, which provokes an anaphylactic response. Common foods associated with these reactions are celery, wheat, shellfish, cheese, eggs, chicken, hazelnuts, oranges, apples, peaches, grapes, and cabbage.

Diagnosis and Testing

Clinical Signs and Symptoms

Within several minutes of exercising, patients experience a prodromal phase that consists of fatigue, warmth, pruritus, and redness of the skin (erythema). These symptoms then progress to large hives that become confluent and eventually appear as angioedema. If the patient continues to exercise, the attack progresses to systemic anaphylaxis with cardiovascular (hypotension, tachycardia, syncope), respiratory (wheezing, stridor), and gastrointestinal (nausea, vomiting, abdominal pain) symptoms. Once the attack occurs, it can last from 30 minutes to 4 hours. There can also be a later-phase reaction that causes headache, fatigue, and warmth, lasting from 24 to 72 hours.

Testing

The diagnosis can often be made based on history. Exercise testing can be performed, but it is cumbersome. Testing needs to be done in a controlled environment with medical personnel, epinephrine, and resuscitative equipment present. Vital signs and spirometry should be monitored. It is also recommended that an intravenous (IV) line be in place both to draw serum markers and to administer medications if necessary. False-negative challenges are common, so testing may need to be repeated on multiple occasions.

Treatment

Nonpharmacologic

The first step in effective management is to identify and avoid specific foods, medicines, or other triggers. Patients may need to limit the intensity and/or frequency of exercise. The athlete should avoid exercise for 4 to 6 hours after eating and during extremely hot, humid, or cold weather. At the first sign of itching, the patient should stop exercising immediately. The athlete should also *never exercise alone*. It is important to have a partner to exercise with in case of an anaphylactic attack. In extreme cases, the athlete may have to switch sports or even stop exercising altogether. Athletes should also wear a medical bracelet that lets people know they are prone to exercise-induced anaphylaxis and may need to receive epinephrine.

Pharmacologic

In the case of an acute attack, antihistamines can be used as the choice for managing early symptoms such as *pruritus*, but if the antihistamines do not help/stop the attack, epinephrine should be administered. Epinephrine should be the first choice for any severe or rapidly developing symptoms. Administration of IV fluids may also help the patient.

Patients who are identified as prone to exercise-induced anaphylaxis should carry self-injectible epinephrine (EpiPen or TwinJet) at all times, especially while exercising. They should also train/exercise with a partner, who can inject them if necessary. Antihistamine therapy has demonstrated only partial benefits in the prevention of anaphylaxis.

Anatomy and Sports Medicine

This entry is designed to provide the reader with a basic framework for the understanding of gross muscular anatomy as it applies to sports medicine. It is intended as a quick reference to the large muscle groups and their actions rather than a comprehensive anatomical review. The entry's systematic approach to major mechanical motions and the muscles that control them will help the reader become familiar with the various muscle groups that work in a coordinated fashion to control the movements of the human body. To complement the text, it is recommended that the reader consult a standard anatomical atlas to allow visualization and thus a better understanding of musculoskeletal anatomy.

Neck

The motion of the neck is described in terms of rotation, flexion, extension, and side bending (i.e., the motion you would use to touch your ear to your shoulder). The direction of the action can be ipsilateral, which refers to movement in the direction of the contracting muscle, or contralateral, or movement away from the side of the contracting muscle.

Rotation is one of the most important actions of the cervical spine, and it decreases as you move your neck toward the thoracic and lumbar spines. Rotation is accomplished primarily by the sternocleidomastoid, which side bends the neck to the ipsilateral side and rotates contralaterally. Together, both sternocleidomastoid muscles act to flex the neck and raise the sternum to assist in forced inhalation. The anterior and middle scalenes both act to ipsilaterally rotate the neck, as well as to elevate the first rib ipsilaterally. The splenius capitis and splenius cervicis act to rotate the head ipsilaterally.

Side bending is also an important action of the cervical spine. The sternocleidomastoid is involved in cervical side bending. The posterior scalene ipsilaterally side bends the neck and also elevates the second rib. The splenius capitis and splenius cervicis also assist in neck side bending. The erector spinae muscles (iliocostalis, longissimus, and spinalis) are the large deep paraspinal muscles of the back. All three act to ipsilaterally side bend the neck.

Neck flexion refers to the motion used to touch the chin to the chest and is accomplished primarily by the sternocleidomastoid as mentioned above. It is assisted by the longus colli and the longus capitis, which also flex the head and the neck.

Neck extension is the opposite of flexion and is accomplished by many of the muscles listed above, including the splenius cervices, splenius capitis, iliocostalis, longissimus, and spinalis.

Back

The back contains the origins of many of the muscles identified in the previous section. The axial skeleton provides the literal backbone of the human body and protects the spinal cord, which innervates almost all the muscles in the body. The erector spinae muscles extend and side bend the back. The semispinalis also extends the back. The small muscles of the vertebrae (multifidi and rotators) provide rotation, extension, and side bending of the back. The quadratus lumborum side bends the lumbar spine and also depresses the thoracic rib cage.

The scapula is elevated by the trapezius and rhomboid major and rhomboid minor and levator scapula.

Shoulder

The shoulder is a complex ball-and-socket joint comprising the head of the humerus, clavicle, and scapula. The shoulder's central motions are flexion, extension, abduction, adduction, internal rotation, and external rotation, all of which will be described below.

Shoulder Flexion

Shoulder flexion is movement of the shoulder in a forward motion. An example of shoulder flexion can be seen when reaching forward as you would to grasp a door knob. This action is accomplished primarily by the deltoid, pectoralis major, coracobrachialis, and biceps brachii (which is composed of a long head and a short head).

Shoulder Extension

Extension of the shoulder is opposite to flexion. Pure shoulder extension is the movement of the arm directly behind the body, as in receiving a baton in a relay race. This movement is accomplished by the latissimus dorsi, deltoid, teres major, and triceps muscles. The triceps, as the name suggests, consists of three heads that originate from different surfaces but share the same insertion at the olecranon process of the ulna and act to extend the elbow.

Shoulder Adduction and Abduction

Shoulder adduction and abduction serve to move the arm toward and away from the body, respectively, in a lateral motion. They can be visualized by picturing someone doing jumping jacks. When the arm is moved away from the body, the motion is called abduction; the arm moving toward the body is adduction. Adduction is accomplished primarily by the pectoralis major, latissimus dorsi, teres major, triceps, and coracobrachialis. The supraspinatus and deltoid are the two main abductors of the shoulder.

Shoulder External Rotation

An example of external rotation is seen in a tennis backhand stroke. External rotation of the shoulder is primarily attributed to the deltoid, teres minor, and infraspinatus.

Shoulder Internal Rotation

Internal rotation of the shoulder is the opposite of external rotation. When reaching into your back pocket, the primary movement of the shoulder is internal rotation. This movement is achieved through the coordinated movement of the pectoralis major, latissimus dorsi, deltoid, teres major, and subscapularis.

The rotator cuff, which acts primarily to stabilize the humeral head, or the ball of the ball-and-socket shoulder joint, is commonly injured in the older population and overhead-throwing athletes. The four rotator cuff muscles are the teres minor, subscapularis, supraspinatus, and infraspinatus. Several of these muscles have tendons that run under the acromion, a bony prominence off the end of the scapula. These tendons, as well as the subacromial bursae, are commonly compressed and pinched, again in older populations and in overhead-throwing athletes. This compression is commonly referred to as *shoulder impingement*.

Arm, Wrist, and Hand

Forearm Flexion

Flexion of the forearm refers to the shortening of the angle formed at the elbow, bringing the hand closer to the shoulder. The primary muscles involved in forearm flexion are the biceps brachii, brachialis, and brachioradialis. Minor contributions to forearm flexion are provided by the coracobrachialis, pronator teres, palmaris longus, flexor carpi radialis, flexor carpi ulnaris, and flexor digitorum superficialis.

Forearm Extension

Extension of the forearm is, as you would expect, the opposite of flexion. It is the action that serves to increase the angle at the elbow, moving the hand away from the shoulder. This action is primarily accomplished by the triceps brachii. The other muscles that make minor contributions to forearm extension include the extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum, extensor carpi ulnaris, and anconeus.

Wrist Flexion

Wrist flexion refers to the movement of the wrist toward the palm. This action is carried out by the flexor carpi radialis, flexor carpi ulnaris, flexor digitorum superficialis and profundus and flexor pollicis longus.

Wrist Extension

Wrist extension is the opposite of flexion and serves to shorten the angle at the back or dorsum of the wrist. The muscles responsible for this action are the extensor carpi radialis longus and brevis, which also abduct the hand at the wrist; the extensor digitorum, which also extends the second to fifth fingers; the extensor digiti minimi, which also extends the fifth digit and adducts the hand; and the extensor carpi ulnaris, which also adducts the hand. Other small muscles that cross the wrist joint may also add to wrist extension but to only a small degree, so they will not be covered here.

Wrist Supination and Pronation

Wrist supination refers to the rotation of the wrist that brings the palm facing up. This is visualized by imagining the hand rotating as if it is holding a bowl of soup. The supinator acts to supinate the forearm. The biceps brachii also adds to the supination. Pronation is the opposing action and acts to rotate the wrist so that the palm is facing down. The pronator quadrates pronates the forearm with the pronator teres.

Hand

The hand is a complex structure as it is involved in fine motor coordination and complex task performance. The muscles of the hand are generally much smaller and have more extensive nerve innervation. Most of the actions of the hand are coordinated movements and use coordinated muscle activity to carry out specific movements. The simple action of typing on a keyboard requires the utilization of a multitude of muscles and must be performed precisely. Because of this, the muscles of the hand will not be covered in detail; rather, the primary action of each muscle will simply be listed for general reference. For understanding of the movements of the hand, some knowledge of joint and bone anatomy is necessary. The main bones of the hand are the carpal bones, the metacarpal bones, and the phalanges. The carpal bones refer to the bones of the wrist and are attached distally and proximally as well as to each other through a complex arrangement of ligaments. Distal to the carpal bones are the metacarpals, which refers to the bony part of each finger within the hand itself. These bones lie within the part of the hand that you would call the palm. Extending out from each metacarpal are the phalanges, the bones of the fingers. Each joint of the finger is referred to as an *interphalangeal joint.* The last knuckle or joint is the distal interphalangeal (DIP) joint; the middle knuckle, the proximal interphalangeal (PIP) joint; and the largest and closest knuckle, the metacarpalphalangeal (MCP) joint, as it lies between the metacarpals and the phalanges of each finger. These are referenced below in relation to the muscles of the hand.

The following muscles originate at the posterior surface of the radius or the ulna, but all have their actions in the hand. These include the abductor pollicis longus, which abducts and extends the thumb; the extensor pollicis brevis, which extends the MCP joint of the thumb; the extensor pollicis, which extends the distal phalanx of the thumb; and the extensor indicis, which acts to extend the second MCP joint.

Hand Intrinsics

Although several of the muscles of the hand have their origins in the forearm, there are many small muscles of the hand that have both their origin and their insertion within the hand. These are referred to as *hand intrinsics*. These include the palmaris brevis, which assists with grip; the umbricals, which flex the MCP joints and extend the interphalangeal joints of the fingers; the palmar interossei, which adduct the fingers toward the third or middle finger; and the dorsal interossei, which abduct the fingers away from the third finger. All the interossei flex the MCP joints and extend the IP joints.

The thenar eminence is the lateral volar (palmar) muscle complex of the hand, composed of three muscles that are all innervated by the median nerve. The abductor pollicis brevis abducts the thumb. The flexor pollicis brevis flexes the MCP joint of the thumb. The opponens pollicis acts to oppose the thumb to the other fingers. The adductor pollicis is not part of the thenar eminence, but it acts to adduct the thumb.

The hypothenar enimence is the medial volar muscle complex of the fifth finger. It contains three muscles that are innervated by the deep branch of the ulnar nerve. The abductor digiti minimi abducts the fifth finger. The flexor digiti minimi flexes the fifth finger. The opponens digiti minimi opposes the fifth finger with the thumb.

Abdomen

There are essentially four muscular layers of the abdominal wall. The innermost layer is the rectus abdominis, which has longitudinal muscle fibers that flex the trunk and stabilize the pelvis. The transversus abdominis has fibers that run perpendicular to the rectus and act to compress and support the abdomen as well as provide static core stabilization. The internal oblique layers run perpendicular to the external oblique and act in conjunction with the external oblique on the opposite side of the body to flex and rotate the trunk toward the side of the contracting internal oblique ("same-side rotator"). The outermost layer is the external oblique, which works as above in conjunction with internal oblique to flex and rotate the trunk and provide core stabilization.

Hip

Hip Flexors

The hip joint is another complex ball-and-socket joint similar to the shoulder; however, as a weight-bearing joint, it can sustain considerable load. The socket of the joint, therefore, is much deeper than that of the shoulder, which allows for greater stability but sacrifices some of the range of motion seen in the shoulder. Hip flexion refers to the hip motion that brings the knee toward the chest.

The major muscles of hip flexion include the iliopsoas, which is made up of the psoas major, psoas minor, and iliacus. Together, these muscles act mainly to flex the hip, but they also contribute to abdominal flexion and hip stabilization. Other hip flexors include the sartorius, which in addition to hip flexion contributes to external hip rotation and knee extension and abduction; the rectus femoris, which also acts in knee extension; the pectineus, whose action includes adduction and internal rotation; and the gracilis.

Hip Extensors

Hip extension is accomplished using primarily the muscles of the posterior thigh and buttocks, which when contracted serve to move the thigh into a midline from a flexed position or the trunk into erection when bent forward. Hip extension is mostly accomplished by the gluteus maximus, the biceps femoris (which is divided into two heads, the long head and the short head), the semitendinosus, and the semimembranosus. A minor contribution is also provided by the adductor magnus and other small pelvic muscles.

Hip Adductors

The movement of adduction is used to describe a direction of limb motion that serves to bring the limb from a lateral position to its more axial alignment. Again, picturing the legs during a jumping jack exercise, one can see abduction when moving away from the midline, and adduction when moving toward. The main hip adductors are the adductor magnus, the adductor brevis, and the adductor longus. A minor contribution to hip adduction is performed by the pectineus and the gracilis.

Hip Abduction

Abduction is similar to adduction but in the opposite direction. This action moves the limb away from midline in a lateral direction to the plane of the body. The main abductors of the hip are the gluteus medius, gluteus minimus, and tensor fascia lata. These three muscles also serve to internally rotate the thigh in an extended position and externally rotate the thigh in the flexed position. Another minor contributor is the piriformis.

Hip internal rotation and external rotation are complex movements. As these motions include many muscle groups and depend entirely on the position of the hip, they fall outside the scope of this entry.

Knee

Knee Extension

Extension of the knee is accomplished by a group of muscles collectively referred to as the *quadriceps femoris* (or "Quads"), which increases the angle of the knee, bringing the lower leg into a straight position. Knee extension is used in the forward, swing phase of the gait and is integral in movements such as kicking. This group includes the vastus medius, vastus lateralis, and vastus intermedius and the rectus femoris, which overlies the above three muscles. A minor contribution is provided by the sartorius.

Knee Flexion

Knee flexion refers to bending of the knee from the straight position and is again an essential motion in a normal gait. The muscles that perform this action oppose those of knee extension and are generally referred to as the *hamstring muscles*. Weakness of this muscle group is believed to contribute to anterior cruciate ligament (ACL) instability, resulting in ACL rupture, a common sports injury. Knee flexion is a coordinated effort that includes the biceps femoris and the semimembranosus and semitendinosus muscles. Small contributions are made by the gastrocnemius and several other smaller and less significant muscles that cross the knee joint posteriorly.

Ankle and Foot

Ankle Dorsiflexion

The muscles of the lower leg and foot are very complex and work in many planes. Their actions depend not only on whether the person is weight bearing but also on the position of the foot. Following is a brief overview of these actions.

Dorsiflexion refers to ankle flexion in the direction of the dorsum, or anterior surface of the foot (the surface of the foot viewed from above). Dorsiflexion is accomplished by several muscles that typically have multiple functions. The tibialis anterior, which in addition to dorsiflexion also inverts the foot, stabilizes the foot when striking and locks the ankle when kicking. The extensor digitorum longus (EDL) acts simultaneously with foot extension to extend the last four toes. In addition to the EDL, approximately 20% of individuals have a muscle called the *peroneus tertius*. The extensor hallucis longus primarily acts in big toe dorsiflexion, but it also acts to dorsiflex, as well as weakly invert, the ankle.

Ankle Plantarflexion

Plantarflexion refers to flexion of the ankle in the direction of the sole of the foot. This is most easily demonstrated by having a person stand on his or her toes. The majority of ankle plantarflexion is performed by the large calf musculature that includes the gastrocnemius and the soleus (which lies just behind the gastrocnemius). It is generally accepted that these are two distinct muscles; however, there is some debate as to whether the gastrocnemius and the soleus are two parts of the same muscle.

Other smaller muscles include the plantaris, which runs obliquely between the gastrocnemius and the soleus; the flexor hallucis longus, which contributes to ankle flexion but primarily big toe flexion; the flexor digitorum longus, which also flexes the second to fifth toes; the peroneus longus, which flexes the ankle and everts the foot; and the peroneus brevis, which, in addition to plantarflexion, everts the foot.

Foot Intrinsics

Foot intrinsics, similar to hand intrinsics, are muscles that arise from the foot and do not cross the ankle joint and whose action is confined to the foot. The bones of the foot are similar in nature to those of the hand, but the bones of the foot are referred to as *tarsal* (instead of carpal) *bones*.

The intrinsic muscles of the foot include the abductor hallucis, which adducts the big toe; the flexor digitorum brevis, which flexes the second to fifth toes; the abductor digiti minimi, which abducts and flexes the fifth toe; the quadratus plantae, which assists in toe flexion; the lumbricals, which flex the metatarsalphalangeal (MTP) joints and extend the DIP and PIP joints; the flexor hallucis brevis, which flexes the big toe; and the adductor hallucis, which has two heads that share an insertion on the lateral side of the base of the proximal phalanx of the big toe—the oblique head arises from the base of the second to fourth metatarsal bones, and the transverse head arises from the ligaments of the MTP joints of the third to fifth toes, the action of which is to adduct the big toe. The flexor digiti minimi brevis extends and adducts the fifth toe. The dorsal interossei abduct the toes, and the plantar interossei adduct the toes.

Anemia

Anemia is a condition resulting in reduced numbers of red blood cells. It limits the ability of the blood to carry oxygen and other nutrients around the body and the excretion of waste products (carbon dioxide). The reduction in the red blood cells results in the starvation of tissues of oxygen and nutrients. Anemia may occur in a variety of people, especially athletes.

Persons with anemia feel tired and become fatigued easily. Symptoms of anemia may include the following:

- Paleness
- Weakness
- Chest pains (severe cases)
- Shortness of breath (severe cases)
- Heart palpitations (severe cases)
- An increased heart rate
- Weight loss
- Fatigue
- Numbness and tingling in the hands and feet
- Depression

Women are more likely than men to have anemia due to menstruation. Of the various causes of anemia, only some are mentioned here to present a brief idea of the condition:

- External bleeding/trauma
- Chronic disease
- Iron deficiency anemia
  - Loss of iron at a greater rate than normal (blood loss)
  - Poor absorption of iron
  - Low-iron diet

- Vitamin B_{12} anemia
  - Failure of the stomach lining to produce intrinsic factor
  - Removal of the small intestine
  - Crohn disease
- Folic acid deficiency
- Pregnancy
- Alcoholism
- Bleeding disorders
- Infection
- Hereditary conditions

Although there are more than 400 different forms of anemia, this entry addresses only those anemias related to or caused by sports.

Sports Anemia

Sports anemia refers to a period in early training when athletes develop low blood hemoglobin for a while, likely reflecting normal adaptation to physical training. Aerobic training increases blood volume, fluid volume, and red blood cell count. While true anemia requires treatment, temporary reduced red blood cell count seen early in training goes away by itself after a while.

Physically active young women, especially those engaging in endurance activities such as distance running, are prone to iron deficiency. Iron status may be affected by exercise in a number of ways. One possibility is that iron is lost in sweat, and although the sweat of trained athletes contains less iron than that of others, it is simply an adaptation to conditioning. Still, athletes sweat more profusely than sedentary people.

In addition, in some athletes at least, physical activity may cause small blood losses through the digestive tract when they take aspirin for sores or to relieve pain.

Low intake of iron-rich foods, combined with iron losses aggravated by physical activity, leads to iron deficiency in physically active individuals. It impairs physical performance because iron is crucial to the body's handling of oxygen. Since one consequence of iron deficiency anemia is impaired oxygen transport, aerobic work capacity is reduced because the person tires very easily.

Sports Hematology

The most common finding in athletes is a dilutional *pseudoanemia* that is caused by a plasma volume expansion rather than an actual blood loss. Pseudoanemia is not a pathological state and normalizes with training cessation in 3 to 5 days. Pseudoanemia should be distinguished from conditions associated with lowered blood counts. To determine the true anemia state in an athlete, one must take into account not only blood losses secondary to exercise, such as foot strike hemolysis or iron losses through sweat, but losses due to nonathletic causes as well. Depending on the age and sex of the athlete, consideration must be given to evaluation of the gastrointestinal or genitourinary systems for blood loss. Finally, a comprehensive nutritional history must be taken, as athletes, especially women, frequently do not consume adequate dietary iron.

Although experiments with blood doping revealed improvements in running time to exhaustion and maximal oxygen uptake, the introduction of recombinant erythropoietin has rendered blood doping little more than a historical footnote. However, improvements in performance are not without risk, and use of exogenous erythropoietin has the potential for increased viscosity of the blood and thrombosis with potentially fatal results.

Pseudoanemia

Regular physical training leads to an increase of plasma volume by 10% to 20%. Therefore, a hemoglobin concentration slightly below normal values in the presence of low-normal serum ferritin levels in athletes is usually due to a dilutional pseudoanemia. Since regular physical activity increases iron loss, mild iron deficiency and sometimes true iron deficiency anemia can occur, especially when nutritional iron intake is insufficient and iron demand is increased because of growth or additional iron loss (menstruation).

Iron Deficiency in Female Athletes

Low levels of iron in the body are caused by several mechanisms and become symptomatic with the onset of iron deficiency anemia. Female athletes have an additional source of blood loss, menstruation. However, the most common cause of low hemoglobin levels in an athlete is dilutional pseudoanemia. Athletes are more sensitive to the effects of anemia and iron deficiency as exercise performance depends on maximal oxygen-carrying capacity to the active muscle and efficient oxygen utilization. Iron deficiency without anemia can also reduce athletic performance. Diagnosis is made by a blood count and red blood cell parameters, with ferritin serving as an index of body iron stores.

Iron Status in Athletes

Iron replacement would clearly be indicated if iron deficiency was present but would not be necessary if the observed changes were simply a physiological response. It is acknowledged that serum ferritin and hemoglobin decrease with some exercise conditions. Expansion of plasma volume and the shift of iron storage from the bone marrow to the liver show that the apparent reduced-iron status occurring with exercise is misleading. Iron deficiency is common in the general population, particularly women. Therefore, continued monitoring of iron status in athletes is necessary.

Football Players

It is important to monitor levels of serum iron and other factors of iron metabolism and oxygen transport as they play an important role in the functional ability of football players. A decrease in serum iron level can be the very first sign of development of iron deficiency anemia.

A significant decrease in serum iron level among footballers during both half-seasons is most probably due to increased loss and/or diminished absorption resulting from a high-intensity training process. Because the decline in serum iron may be an early sign of iron store depletion and iron deficiency anemia, it is important to evaluate it regularly, along with other factors of iron metabolism and oxygen transport.

Cyclists and Runners

Another cause of iron loss is red blood cell destruction; blood cells are crushed when body tissues (soles of the feet) make high-impact contact with an unyielding surface (the ground). This usually occurs in long-distance runners and cyclists. This occurs alongside pseudoanemia.

Supplements and Blood Doping

Athletes tend to have lower hemoglobin concentrations than their sedentary counterparts; this is called *sports anemia*. It is a false anemia and a beneficial adaptation to aerobic exercise, caused by an expanded plasma volume that dilutes red blood cells. Athletes, however, can also develop true anemia, most commonly caused by iron deficiency. True anemia inhibits athletic performance, but nonanemic iron deficiency does not. Iron supplements are useful for women endurance athletes who repeatedly develop iron deficiency anemia despite dietary advice. Supplementation improves performance only when hemoglobin concentration increases. Some endurance athletes today are blood doping by abusing recombinant human erythropoietin (rEPO).

Prophylaxis and Correction

Antioxidants, detoxicants, and membrane protectors are used. These treatments have a beneficial effect on the content of hemoglobin in erythrocytes. They appear beneficial to mechanisms of development of anemia during oxidative stress and are used for correction of the functional state of sportsmen.

Other therapies for anemia may include oxygen, fluids, fresh frozen plasma, platelet replacement, and vasopressors (medication to elevate blood pressure).

Anger and Violence in Sports

Violence and sports have been linked together, misleadingly, for the past several decades due to incidents where athletes have engaged in either unsportsmanlike or, in the extreme, criminally aggressive behavior inside or outside their sporting arena. Consistent with this theme, anger has been implicated as a “bad emotion” that always leads to violence. The evidence that athletes are more angry or violent than nonathletes is spurious at best and gathers the bulk of its support from isolated incidents where athletes have transgressed, sometimes with very public and very extreme displays.

Theories Associated With Sports and Violence

Five theories are outlined below to illustrate the relationship between anger and aggression in sports. This provides a historical perspective of the thinking in the field and will lay the foundation for how interventions have been developed.

Frustration-Aggression Hypothesis

The earliest theory explaining the origins of aggression was the frustration-aggression hypothesis, advanced by John Dollard and his colleagues at Yale in 1939, which stated that aggression was always a consequence of frustration. *Frustration* was defined as occurring at times when the subject was unable to reach his or her goal. And though there have been several theories that have added to and refined this, it is easy to see this theory's application to the world of athletics. In fact, considering how frequently athletes try and do not succeed, it is perhaps surprising that athletes are not more aggressive.

Completion Hypothesis

Thirty years after the frustration-aggression hypothesis was introduced, Leonard Berkowitz put forward the completion hypothesis, which proposed that it was not just frustration that would lead to aggression, but when one experiences an aversive stimulus—which could be heat, noise, or fatigue—one is more likely to experience negative emotions, and these stressors, modulated by one's associated thoughts, lead to the instigation of aggressive behavior. For athletes, this could be exhaustion from training camp, the pain of nagging injuries that will not go away, the boos of the crowd, or the criticism of coaches or the media. The ability to prevent these stressors from affecting one's emotional, and in turn physical, volatility is one component of mental toughness.

Catharsis

Originating in the writings of Sigmund Freud, *catharsis* is the concept that emotions that are not released can build up, like steam in a pressure cooker, and the releasing of that energy is necessary for the individual's well-being. In sport, there are many opportunities for cathartic release, and the visceral satisfaction of dominance, especially amplified by the praise of the coaches and the roar of the crowd, can easily goad an athlete to be violent. The difficult task is to teach athletes when and how to release their pent-up energy in a focused, goal-directed manner that assists, rather than detracts from, their success in sports.

Behavioral Conditioning

Violence, like any other behavior, will increase or decrease in frequency based on the reinforcement or punishment that follows it. In sports, this is especially the case, but it can also be very confusing for an athlete. If a football player is lauded for sacking the quarterback and ending a drive, he is going to be more driven to repeat this behavior. Add to the equation that the player is to attempt to tackle the quarterback but must do so before he passes the ball. If he hits the quarterback after he throws the ball, not only is it a penalty, which hurts his team, but he may be suspended from play and/or fined at the professional level. This creates a differential reinforcement paradigm that can lead athletes to engage in aggressive behavior that falls within the rules of the game in one venue but is illegal in another.

The belief is that in contact and collision sports, the positive reinforcement so outweighs the punishment for aggressiveness that those participants are bound to be more violent. The logic makes sense, and athletes could benefit from learning skills to control their emotions and behavior, but the research is insufficient to conclude that athletes who play contact and collision sports are more likely than others to be violent.

Inverted-U Hypothesis (Yerkes-Dodson Law)

The inverted-U hypothesis, an updated version of the Yerkes Dodson law originally postulated in 1908, describes a curvilinear relationship between performance and arousal. Simply stated, as arousal increases, performance increases as well, but only up to a point. After that point is reached, performance decreases.

Studies of emotion in sports have supported this theory to a degree but with caveats. Individual differences have been noted, because different people experience emotion differently and it affects their performance differently. Also, there are task differences, meaning that some tasks have higher or lower levels of arousal before performance starts to decline. An example of this is related to anger arousal and different sports. A skill that requires fine motor coordination and concentration, such as putting in golf, will be negatively affected by comparatively lower levels of anger than the game of a football player when a defensive lineman is bull-rushing an opposing blocker, where higher levels of anger arousal may augment performance. Overall, anger at low and moderate levels can improve sports performance as it can contribute to increased stamina, energy, and strength with a lower perception of pain, but like other emotions, at higher levels, it can have a negative impact on performance.

Definitions

Anger

Anger is a normal emotion that everyone experiences from time to time in varying intensities. The body responds to anger with physiological arousal of the sympathetic nervous system. Often, anger is experienced in response to a real or perceived threat, insult, or provocation, but it can also stem from generalized irritability. Anger as an emotion should not be confused with the behavior that follows an emotion. Anger is an emotion that can be acted on outwardly, as in arguments or fights, or inwardly in the form of depression or anxiety. People sometimes believe that they get into trouble when they get angry. People do not necessarily get into trouble whenever they are angry, but they may get into trouble for what they do when they are angry. At very high levels, as explained in the previous section, anger can interfere with performance. Extreme anger can lead to poor decision making, decrease in fine motor coordination, slowing of cognitive processing speed, and impulsivity. At low and moderate levels, however, anger can improve sports performance by increasing strength and stamina while decreasing the experience of pain and exhaustion.

Aggression

Aggression has often been used to describe behavior with the intent to harm someone. This is but one aspect of aggression. Being aggressive is a positive quality that leads to success in sports and in life because it refers to the tenacity with which a person pursues his or her goals, thus the delineation of instrumental versus reactive aggression. *Instrumental aggression* in sports is aggression whereby the main intention is to achieve a sports-related goal. It may happen that an opponent, a teammate, or even the athlete himself may get injured in the process, but this is a side effect of the action, not the goal. An example may be a basketball player driving hard toward the basket for a layup and accidentally striking an approaching opponent in the chest with an elbow. The goal was to score the basket, not to injure the opponent. Instrumental aggression is the type of aggressiveness that needs to be harnessed and encouraged to lead to success in sports.

Reactive aggression, however, is behavior that has harming another as the primary goal. It is related to extreme anger and is usually a response to a perceived injustice by another player. An example would be a pitcher who throws the baseball at the head of the batter who hit a home run off him when previously at bat. It is reactive aggression that is of concern for athletes on and off the field.

Violence

Reactive aggression in its most extreme form is *violence*. Sports violence has been defined by sport psychologists as harm-inducing behavior outside the rules of sport, bearing no direct relationship to the competitive goals of sport.

Not all violence is related to anger, and there are times when violence may actually look like instrumental aggression. The coach who instructs players to injure another athlete so as to give their own team a better chance to win is not acting out of anger but with the goal of winning, although by doing so he is exhibiting and fostering exceedingly poor sportsmanship. Thus, reactive aggression may be spontaneous, in response to a set of circumstances, and needs to be curtailed because of the likelihood of player injury; it is far more distressing when there is a systematic plan to injure someone. This behavior is premeditated and criminal and has no place in sports.

Assertiveness

The term *assertiveness* has at times been used interchangeably with *instrumental aggression*. They are, however, very different. Assertiveness refers to one's willingness to stand up for one's rights. It is an important quality for athletes to have when communicating with their coach, their teammates, or other people in their life. Assertiveness is a style of communication; it is not aggressiveness.

Hostility

Hostility is a description of personal temperament; a hostile person is one whose predominant trait is anger. Often having a hostility bias, those with chronic anger tend to perceive neutral stimuli as provocative and have difficulty finding nonprovocative explanations for events (i.e., a hostile person may imagine that the person who bumped into her walking down the hall *must* have done so out of malice rather than by accident); such a person will have trouble generating nonviolent responses to such situations.

Violence in Sports

The public perception of athletes' tendency toward violence has been perpetuated by the heightened attention that athletes receive. Furthermore, the attention that an athlete receives may be compounded by the popularity of that athlete, the level of competition (professionals get more attention than amateurs), and the concentration of media attention given to sports in a particular region.

Using the broadest definition of *athlete,* athletes represent a population of millions worldwide, and there is no evidence that athlete identification is connected with violence. There have been studies that have associated athletes with elevated levels on anger scales, increased incidence of deviant behavior as compared with their nonathlete cohorts, and overrepresentation in sexual assault studies. These studies have many limitations, and the conclusions have limited generalizability.

The main reason why there is a perception that athletes are more violent than nonathletes is that so much attention is paid to sports and their participants. When an athlete is involved in a transgression, it is swept up by the media very quickly, as if to imply that being an athlete is somehow contributory to such behavior, whereas a nonathlete may engage in the same behavior without it being publicized.

Prisons in the United States are not overrun with athletes, and those who were athletes are in jail for their criminal behavior, not their athletic behavior. Similarly, there is no way to identify how many youths were diverted by their involvement in sports activities who otherwise would have gone down the path of violence.

There are athletes who engage in violent behavior. Considering the ubiquity of violence in our society, it would be unrealistic to believe that sports involvement could provide sufficient insulation to make athletes exempt from this trend. However, there is insufficient evidence to conclude that athletes are more violent than their nonathlete peers.

Problems With Research

One of the central reasons why studying anger and violence in sports is so difficult is that measuring those constructs has limited generalizability. This is true in the clinical literature as well. It is a mistake to assume that people who score high on anger scales always become violent. Questionnaires have limitations as how people report their emotions, attitudes, and behavior. Because questionnaires are often the best tool researchers have, despite their shortcomings, it is important to identify what has been used both to springboard further research with them as well as to stimulate the development of other methods of assessing anger and violence in athletes for future use. The instruments that have been used the most in the sport psychology literature are the Profile of Mood States (POMS) and the State Trait Anger Expression Inventory—second edition (STAXI-2). Other instruments that have been used less frequently but show promise are Bredemeier's Athletic Aggression Inventory (BAAGI) and the Competitive Aggressiveness and Anger Scale (CAAS), developed by Jon Maxwell and his colleagues.

Observation of behavior is challenging unless an individual is acting out with high regularity. This is unlikely as this type of behavior tends to select the athlete out of competition; the behavior hurts the team's performance, and the athlete then sees less playing time.

Arrest records are also misleading because an arrest does not necessarily indicate guilt. Furthermore, many factors go into whether or not someone is convicted, with innocence being only one of them; so the number of convictions cannot be used as an indicator either. Often, the quality of representation is a strong predictor of trial outcome and length of sentence.

For this reason, athletes who are involved in high-revenue sports and make more money should not be compared with other athletes with regard to brushes with the law, but rather, they should be considered along with other celebrities, such as music and film entertainers. If this is done, the impression that athletes are not held accountable for their deviant behavior might be understood in a more appropriate context.

Admittedly, the field of sport psychology needs to study the relationship between anger, sports, and violence in greater detail.

Athletes at Risk

Because athletes are under greater scrutiny than most people, they are often held to a higher standard. Therefore, anger management skills, which are life skills that all people need to learn, become even more important for athletes who may be measured with a lower threshold of acceptability.

Additionally, behavior that is considered a normal part of the game may be illegal when preformed outside the sports arena. For example, tackling someone is an expectation on the football field but is considered as assault outside that domain. This presents a potential stimulus differentiation problem for athletes as the same behavior will be differentially reinforced or punished in different contexts. It therefore becomes incumbent on coaches, administrators, and parents to teach young athletes how to recognize and regulate their emotional states so as to be in the best position to control their behavior on and off the field.

Drugs and Violence

Though outside the sports arena drugs and violence tend to go hand in hand, drugs are rarely the explanation offered for an athlete's propensity for hostile aggression. The most popular exception to this are *anabolic androgenic steroids* (AAS), drugs that increase testosterone levels, strength, muscle mass, and speed and, as a whole, present an opportunity for unfair advantage as athletes can outperform their "normal" biological limits. The term *roid rage* was coined to define a psychotic, violent reaction to AAS abuse. Many experts over time have stated that the incidence of roid rage is greatly exaggerated, concluding that it occurs very rarely. One of the difficulties, however, is that even if the base rate is extremely low, when there is an incident, it is often quite severe and gets a great deal of attention. The consequences are so significant that the low incidence rate is ignored, and the perception is that it is a more common occurrence than in fact it is. Research has associated elevated testosterone levels with increased aggressiveness. However, the research that shows that increase in violence is *caused* by steroids is equivocal. Scrutinizing the information, it is more accurate to say that AAS abuse is contributory toward violence rather than causative. The conclusions are based on the following:

- There are many AAS abusers who never become violent.
- Studies have not been able to control for the fact that people who endorse violence as a means to solve problems did not feel that way prior to AAS abuse.
- It is known that physical irritability is a precursor to aggressiveness. Steroid use often makes the user physically irritable, but not everyone becomes violent when they are irritable. Therefore, it is easier to conclude that AAS cause irritability, which in turn can lead to violence, than that AAS directly cause violence.
- Many medications and drugs have psychiatric side effects, but they appear very rarely. It is difficult to conclude, given the difficulties in conducting research on steroids, the likelihood of other factors contributing to a psychiatric reaction, the possible use of other illicit drugs, the personality variability of the abuser, and the accuracy of AAS dosages taken, that AAS alone are the causative agent in a roid rage reaction.

That is not to say that other drugs, legal or illegal, when abused by athletes cannot lead to violence. Most commonly, abuse of heroin and cocaine is self-selecting with athletes, meaning that athletes are less likely to develop severe addictions with either drug because if they do, it would interfere fairly quickly with their ability to perform as athletes. Therefore, even if these drugs were implicated with a heightened propensity for violence, athletes do not commonly abuse these drugs, so they are less likely to be the cause of violence by athletes.

Alcohol, on the other hand, owing to its disinhibitory properties, can make athletes who are prone to violent acting out more likely to indulge in violent behavior when under its influence. Athletes are not more vulnerable to alcohol's effects than nonathletes, but because of greater media attention, and perhaps because they may be more capable of doing damage, athletes who become violent when intoxicated are likely to find their names in the newspaper. Athletes who abuse prescription pills with similar disinhibitory properties, such as benzodiazepines (Ativan, Xanax, and Klonopin), may be at similar risk.

Alcohol may be the greatest contributor to violence at sports events, but this is more true of fans' unruly behavior while under its influence than of the behavior of athletes.

All the same, AAS abuse has been linked to athlete violence more often than any other illicit drug; however, the conclusion that AAS causes violence has not been supported.

Anger Management

As noted above, it is not anger per se that is the problem. Extreme levels of anger interfere with peak performance, and episodes of reactive aggression can lead to violence on and off the field. The goal, then, is not to ensure that athletes refrain from becoming angry but rather that they learn how to manage their anger and keep it at workable levels so that it can contribute to rather than sabotage performance.

Emotion Labeling

For athletes to become proficient at modulating their emotions, they need to become accustomed to identifying how they feel. Rarely does one verbalize an emotion when asked how one feels; usually, the question is responded to with "Okay" or "Fine." Emotion-labeling problems are commonplace in American society. Expanding athletes' vocabulary in describing how they feel is an important place to start, and this naturally expands to how their body reacts to emotion, specifically anger.

Education on Physiological Response to Anger

Because kinesthetic awareness is crucial to athletic success, athletes tend to be quite sensitive to changes in how their body feels. Thus, educating athletes about the bodily changes associated with anger (sympathetic nervous system arousal) enables them to relate easily to what is being described.

Expected physiological changes include increases in

- heart rate,
- breathing rate,
- blood pressure,
- muscle tension,
- sweating/perspiration, and
- the urge to urinate.

Helping the athlete understand that these signs are nearly identical to how their body reacts when they are anxious or nervous can sometimes normalize the experience as this is associated with the "butterflies in the stomach" seen in precompetitive anxiety. Remind the athlete that this is completely normal and is just a sign that his body is getting ready to do the things it has been trained for. Depending on the level of understanding of the athlete, one can either explain the physiology in detail or explain the "fight or flight" response as a programmed survival response and that these changes would help the athlete survive in the face of a threat.

The body does not realize that the athlete is getting ready to participate in a sport any more than it understands that you will not fight whenever you get angry. The spike in emotion coincides with your body getting ready to go.

This can be confusing for the athlete as the signs said to be produced by anger are also those that they normally see when participating in sports without an increase in anger. This discussion is important because it explains why it is so much harder to identify, let alone modulate, one's emotion during competition. To do this, one must become proficient in doing so in less stressful circumstances, outside the sports arena, first.

The physiological changes described above are said to be "all or none," meaning that when one is triggered by excitation, they all increase. Similarly, when one decreases, they all decrease. Identifying the bodily changes that one can directly control, namely, breathing rate and muscle tension, throws light on how to slow down the whole body and relax.

Last, by becoming more familiar with how their body feels when they are becoming increasingly angry, athletes can use the bodily cues as triggers to begin de-escalation techniques.

Arousal Management/De-Escalation

The skills most commonly prescribed to help athletes calm themselves are diaphragmatic breathing and imagery and visualization, but these are only two of several methods athletes can use.

Diaphragmatic breathing is a skill whereby an athlete can maximize oxygen intake by focusing on breathing deeply, flexing the diaphragm down and out, which results in the abdomen expanding outward as the lungs fill. The slow inhalation is followed by a significantly longer (some advise twice as long) exhalation through pursed lips. Repeating this process can help the athlete relax when tense or become more proficient at relaxing on demand.

Progressive muscle relaxation is another set of skills whereby the athlete is trained to control the tension of the muscles by alternatively, consciously flexing them, holding the tension and then slowly releasing it. This is done muscle group by muscle group and takes a good deal of time to gain proficiency in. Because the muscle tension, like the other sympathetic nervous system responses, is primarily all or none, the athlete can learn to relax the whole body by relaxing a single muscle group.

Another method of relaxation that is useful for athletes is *imagery and visualization*. Especially powerful is using imagery and visualization in conjunction with other relaxation techniques—for example, timing the athlete's diaphragmatic breathing with the ebb and flow of the ocean's waves, as they may be synergistic. First, the athletes can be guided through a relaxing scene, such as a quiet beachscape or any place athletes feel is particularly tranquil, where they can provide details of the sensory experience. There, the athletes are in charge of their visualization and are reminded of their ability to control their minds, their bodily response, and, ultimately, their ability to relax.

This can progress toward using imagery as a means to visualize the perfect sports performance and then, ultimately, a training ground where they can react to unforeseen obstacles and become prepared to "read and react." This works particularly well when anger is elicited early on, demonstrating its negative impact on cognitive processing and later, when the athlete becomes more proficient, remaining calm and able to solve problems despite potentially frustrating circumstances.

Music has also been found to have a profound impact on athletes' moods and arousal levels. Just as many athletes use music as part of their invigorating, precompetition routine, music can also be used to calm and center oneself, assisting with focus prior to competition.

All these tools, and others, can be used individually or in combination to assist athletes with increasing their emotional self-control, allowing them to adjust the "volume" of their emotions.

Trigger Recognition

By identifying the circumstances that are likely to lead to an athlete becoming angry, athletes can learn to recognize their triggers early and use their newly acquired arousal management tools to de-escalate rather than spontaneously react to a provocation. While these are often individualized, there are some triggers, called *direct triggers,* that are fairly universal and would lead most people to anger and to react forcefully. Direct triggers can be physical, such as being struck by another person, or they could be verbal. Verbal triggers could be insults, rudeness, cursing, accusations, unwelcome comments, or prejudicial comments.

Indirect triggers are more individualized and often are referred to as that athlete's "buttons" that can be pushed. They may be related to the athlete's insecurities, such as being called slow or weak, or may be denigrating comments about teammates or family members. It is a sign of greater personal strength to not react to these provocations as, often, the person's natural response is to react to the insult with a counterattack. By knowing themselves well, athletes are in a better position to recognize their triggers and compose themselves rather than respond in a way that is often as self-destructive as it may be dangerous to the provocateur.

Problem Solving

As mentioned earlier, frustration is a common precursor to anger and/or aggression. When athletes have difficulty solving problems, they are usually going to have more difficulty controlling their temper as well. Because problem solving becomes more difficult when the individual is very angry, there is the potential for an escalating cycle that ends badly. The whole situation gets further compounded when the athlete also has a hostility bias and has difficulty cognitively processing situations when angry. For this reason, teaching athletes basic problem-solving skills can go a long way toward keeping their emotions from interfering with their performance.

On a very basic level, the athlete must first be able to understand the factors that are involved in the problem that they face. This starts with a review of the 5 Ws and H—Who, What, Where, When, Why and How:

- Who is involved in the problem?
- What is the problem, and what details are important?
- Where is this occurring?
- When does it occur, and when do I need to solve this?
- Why is this a problem for me, and why is it difficult to solve?
- How did this become a problem, and how am I going to solve it?

Once the athlete is able to answer the associated questions, he or she can then generate a list of possible solutions. The athlete is encouraged to brainstorm solutions, and even if the problem is not sports related, using sports-based metaphors and hypothetical challenges can help the athlete feel increasingly confident of finding solutions to difficult problems. Often the athlete gets stuck because of difficulty generating multiple possible solutions, but with practice, the athlete will become more proficient in identifying several options that might help in solving the problem. This increasing self-efficacy in solving problems can help stave off frustration at not being able to find a solution easily.

Communication and Assertiveness Training

Once athletes get angry, their behavioral options, not to mention their word selection, become increasingly limited. Athletes can increase their personal strength by improving their communication skills, without which they will be more likely to become frustrated and less likely to reach their goals. For example, an athlete who is annoyed that he is not getting the amount of playing time he thinks he deserves is unlikely to persuade the coach to increase his playing time by yelling at the coach and demanding that she do as he says. Though it would be completely understandable for the athlete to be upset with the coach not meeting his requests, he would have a much better chance of meeting his objectives by calmly, in an even tone, asking to speak with the coach. He should then explain his frustration, why he would like more playing time, what he is willing to do to earn more playing time, and why it is in the team's best interest to give him more playing time; be receptive to the coach's feedback and respectful of the coach's authority; and leave the conversation poised and accepting of the outcome.

Good communication skills can improve with practice, and understanding how control of intense emotions can contribute to the process is crucial. Assertiveness training is a way to help athletes learn how to present themselves appropriately and stand up for their rights. It is important, however, to understand that although athletes have a right to be heard, their wishes do not have to be obeyed complied with by the coach or by anyone else. With their emotions in check, athletes are less likely to be frustrated when they are able to meet their goals through effective communication.

Cognitive Restructuring

People often become angry because of *cognitive distortions:* errors in the way they think, which lead them to see normal situations as provocative and have irrational ideas on how things *should* be. Athletes are no different in this regard, and teaching them to recognize that they may be perceiving things inaccurately and generating other views that may explain what they are seeing or experiencing can lead to improved emotional control and increased interpersonal relatedness. This skill is particularly useful with athletes who have the aforementioned "hostility bias," because it provides them an opportunity to challenge their previously existing cognitive tendencies that to them justified violence.

Prediction of Consequences

Even though there are plenty of things that happen that cannot be predicted (e.g., the outcome of a game or a match), there are also a great many that can. Many people do what they do in the heat of the moment and do not consider the consequences of their actions ahead of time. Athletes are often seen engaging in this type of behavior when they argue with a referee or umpire or get into a fight with another player. In the moment, they may think that they are justified in what they are doing, but would they still behave that way if they were fully aware of how important participating was to them and that they were risking being suspended and unavailable to help their team? Many people who engage in violent behavior claim that they could not control their impulses, but as you review their circumstances, if you change some details, you will find that most people control their impulses selectively, based on what they believe the outcome will be. Thus, teaching people to predict the consequences of their behavior can have a great impact on the decisions that they make in the moment.

It is important to remember that younger athletes will have more difficulty than those who are more mature in considering the longer-term consequences of their actions. That is why it is so important to teach these skills to youthful athletes as early as possible.

Angioedema and Anaphylaxis

Exercise-induced anaphylaxis and angioedema (EIA) is defined as a systemic allergic reaction specifically triggered by exercise. It is different from exercise-induced urticaria, or "hives," in that there does not have to be an elevation in core body temperature for it to occur. Urticaria is often associated with EIA, though it is most often different in character from exercise-induced urticaria. While it is seen in people of all ages, it is more often seen in late adolescence and early adulthood. Up to half of the patients have a personal history of atopy and two thirds have a family history of atopy. Although there are thousands of cases documented, only one death has been reported; however, some cases may go undocumented.

EIA is triggered only by physical activity, unlike *cholinergic* (exercise-associated) *urticaria*, which is triggered by an increase in core body temperature. EIA can be triggered by any physical activities, but aerobic activities have a stronger association. Brisk walking, running, aerobic sports, and dancing are the most commonly cited triggers.

The natural history of EIA involves four phases, and it can vary in severity from person to person. Within several minutes of exercise initiation, patients undergoing an EIA attack experience warmth, fatigue, erythema (redness), and pruritus (itching). This is the prodromal phase. The attack may be abated if these symptoms are recognized by the patient. Then in the early phase, large hives develop, which coalesce to become angioedema, particularly around the face and extremities. If exercise is continued, anaphylaxis, with cardiac (hypotension, syncope), respiratory (wheezing, stridor), and gastrointestinal (colic, nausea, vomiting) symptoms, develops. This is the fully established phase, and it is in this phase that EIA is most life threatening and most differs from cholinergic urticaria. The attack can last from 30 minutes to 4 hours. A late phase may occur, which includes headache, fatigue, and warmth. This can last for 24 to 72 hours.

Certain conditions may increase the likelihood of EIA. Symptoms are more likely to occur in women during menstruation. Aspirin as well as nonsteriodal anti-inflammatory drugs (NSAIDs) can increase the likelihood of attacks, and they are the medications most often linked to EIA. Increased ambient temperature or exposure to known allergens may also increase the likelihood of attack.

There are several subtypes of EIA. Urticaria that typically develops with EIA is 10 to 15 millimeters (mm) in diameter, though 10% of patients have urticaria similar to that with exercise-induced urticaria, with small wheals 1 to 4 mm in diameter. This is known as *variant-type EIA*. In addition, other subtypes include *familial* and *food-dependent EIA*. Food-dependent EIA requires both food ingestion and exercise. Either one alone will not produce the symptoms. This is a Type 1 immune response, with positive skin-prick allergy tests for the food. Exercise occurs within 3 hours of food ingestion. Shellfish, celery, chicken, hazelnuts, apples, peaches, grapes, wheat, grain flour, and cabbage have been implicated as foods that are more likely to predispose to an episode of EIA.

The mechanism of EIA is still not fully understood. From skin biopsies and blood samples, however, it is known that there is mast cell degranulation and elevated histamine levels. It is postulated that EIA occurs when an antigen is bound by immunoglobulin-E (IgE) to release histamine from mast cells or basophils. Skin mast cells degranulate and release histamine, which is the most likely mediator of symptoms. Other vasoactive factors released include prostaglandin D2, leukotrienes C and D, platelet-activating factor, and bradykinin. Elevated tryptase levels have also been documented. Proteins, polysaccharides, and haptens can initiate an IgE response. Haptens are not immunologically active alone but become so after binding with a host protein. The complement pathway may also contribute. It is possible that exercise stimulates release of a particular antigen to stimulate IgE activation and mast cell degranulation. In food-dependent EIA, it is possible that food or exercise provides a necessary cofactor for the reaction to occur. NSAID-associated EIA may have a mechanism that involves alterations in arachadonic acid metabolism.

Diagnosis of EIA is best done with exercise testing. Diagnostic testing includes exercise testing under controlled conditions, with epinephrine, resuscitative equipment, and medical personnel at hand and an intravenous (IV) line in place. Exercise testing consists of running on a treadmill or using a stationary bicycle with progressive increases in intensity. Testing may need to be repeated on multiple occasions, as false negatives are likely to occur. For diagnosis, it may be necessary to attempt passive warming to rule out cholinergic urticaria.

The primary modality of treatment is education. The patient must know to stop exercise as soon as symptoms occur. It is also important to have subcutaneous epinephrine on hand (EpiPen) and to use it with any symptoms of EIA. Patients susceptible to EIA should always exercise or train with someone who knows their condition and can administer epinephrine if needed. It also may be wise to avoid exercise up to 24 hours after eating a potential food trigger or during menses and avoid NSAIDs as well as aspirin prior to exercise. It may be necessary to decrease the intensity of exercise and avoid intense exercise during very cold, hot, or humid weather or during high pollen counts. It is also important to identify any foods that may act as triggers if eaten several hours prior to the attack and eliminate them from the diet if possible. There has been very limited success with treatment with antihistamines.

Although EIA is a life-threatening condition, and somewhat unpredictable with regard to attacks, EIA patients can continue to exercise with strict adherence to the above principles. Fortunately, the majority of patients experience either stabilization or decrease of their symptoms with time, likely due to activity modification and avoidance of known triggers.

Ankle, Osteochondritis Dissecans of the

Osteochondritis dissecans (OCD) of the ankle is an acquired injury to the talus or ankle bone. Ankle OCD occurs in all kinds of athletes but especially in those who are involved in running or high-impact sports. Many athletes who develop OCD of the ankle are involved in multiple sports and participate in athletic activity for many hours every day. The OCD lesion occurs in the bone directly underneath the cartilage of the talus. It can be thought of as a stress fracture to a small area of the talus bone. After the injury, this area of bone is not strong enough to support the cartilage over top of it, and if the injury progresses, eventually the cartilage over top of the bone can crack. In most cases, OCD of the ankle occurs in athletically active children without a definite injury. In these cases, it is thought to be an overuse injury occurring from repetitive microtrauma to the bone. In some cases, a single major ankle sprain can cause an OCD of the talus.

Anatomy

The ankle joint is the space between the tibia (shinbone) and the talus (ankle bone). The ends of the tibia and talus are covered with cartilage that resembles the shiny smooth white end of a chicken bone. The cartilage provides a smooth low-friction surface for the ankle to allow the patient to flex and extend the ankle joint freely. The bone directly underneath the cartilage of the tibia and talus is called the subchondral bone. The purpose of the subchondral bone is to support the cartilage during walking and running. It is the subchondral bone that gets injured in OCD of the ankle.

Causes

OCD lesions occur in two common locations: (1) in the front (anterior), outer (lateral) aspect of the talus and (2) in the back (posterior), inside (medial) part of the talus. Anterolateral lesions tend to be shallow and can occur with one or more ankle sprains. Posteromedial lesions are more common and usually are deeper lesions that occur from repetitive trauma, causing a small stress fracture. Soccer, football, and basketball players often sustain multiple traumatic ankle sprains and may develop an OCD lesion. If the patient continues to be active, the injured bone will eventually lose its blood supply. At this point, it will no longer be able to support the cartilage over the top, and if the activity continues, the cartilage can crack and break loose.

Symptoms

OCD of the talus can occur in athletes of all ages, although it most commonly occurs in highly active athletes aged 13 to 14 involved in soccer, basketball, football, or other high-impact sports. Patients complain of aching ankle pain, which becomes worse when running or sprinting. In some patients, but not all, there may be a history of multiple major ankle sprains. The pain is often located at the inner or outer aspects of the ankle, depending on the location of the OCD lesion. Pain may be severe enough to cause a limp. If the overlying cartilage is cracked and injured, the ankle will often swell, and mechanical symptoms such as catching or locking may be noted. In 10% to 25% of the cases, both the ankles will have an OCD lesion.

Diagnosis

An active athlete playing multiple high-impact running sports for many hours every day who presents with ankle sprains, swelling, and pain may have an OCD of the talus. On physical exam, the ankle joint is carefully inspected for signs of swelling. The front and back of the ankle are palpated for tenderness. The ankle is flexed and extended to see if either of these maneuvers causes pain. If OCD of the ankle is suspected, both ankles must be examined and X-rays must be obtained.

Depending on the size and location of the OCD lesion, it may or may not be visible on the X-ray. When visible, it appears as a small round crack in the subchondral bone (see white arrow in X-ray). The X-rays help determine the size and location of the lesion. If the growth plate of the tibia bone is visible on the X-ray, it indicates that the child is still growing.

The cartilage of the ankle cannot be captured by an X-ray. Therefore, when an OCD lesion is suspected, a magnetic resonance imaging (MRI) scan of the ankle may be obtained. The MRI scan is used to determine if the cartilage over the lesion is intact or cracked. If the cartilage is cracked, there will often be joint fluid underneath the lesion, which can be seen well on the MRI scan.

OCD of the ankle is generally classified as "stable" or "unstable." Stable lesions involve only the subchondral bone; the overlying cartilage is not broken. In unstable lesions, the overlying cartilage is cracked. Making this determination is important because stable lesions tend to heal well with rest and activity restriction. Unstable lesions do not heal as well and if left untreated can completely break off, forming a "loose body."

Treatment

The two most important factors involved in planning treatment for an OCD of the ankle are the age of the athlete and the stability of the lesion. In general, most stable lesions in children who are still growing heal without surgery. For partially unstable lesions in children with open growth plates or for stable lesions in patients who are already grown, a short period of nonsurgical management is often attempted. However, if the OCD lesion does not heal after 3 to 6 months, surgery is recommended. Unstable lesions and most lesions in patients with closed growth plates are treated with surgery.

Nonsurgical Treatment

The most important principle for nonsurgical treatment of OCD of the ankle is to stop the repetitive activities that cause the pain. This means that the patient must be removed from most sports that involve running and jumping. Nonimpact activities such as swimming and low-resistance cycling are encouraged. Compliance with these measures is often difficult in this highly active patient population. In addition, some physicians recommend using crutches and/or an air cast boot or short leg cast to immobilize the ankle.

The initial treatment phase of rest, possibly combined with crutches and immobilization, usually lasts for about 6 weeks. At this time, the patient's pain should be improved, and the crutches and boot or cast can be discontinued. Physical therapy is initiated, focusing on ankle range of motion and strengthening. At periodic follow-ups, the physician ensures that the patient's symptoms are improving and may follow the appearance of the lesion with serial X-rays. Full healing of the lesion can often take anywhere from 3 to 12 months. Some physicians will obtain a repeat MRI scan after 3 to 6 months to assess the healing of the lesion. Return to sports can take anywhere between 3 and 12 months and occurs when the athlete is painfree and the lesion has shown signs of healing.

Surgery

Surgery is recommended for unstable OCD lesions and for lesions that do not heal after an appropriate time period of nonsurgical management. Surgical intervention commonly involves ankle arthroscopy, although a larger incision may be necessary. During arthroscopy, the surgeon will directly look at and feel the cartilage over the top of the lesion. Depending on the appearance and feel of the cartilage over the lesion, the surgeon will decide how to proceed.

In some cases, the cartilage over the lesion will appear normal, with no cracks, but will feel like a softened mass. In these cases, the surgeon may drill tiny holes through the cartilage and across the OCD lesion. This technique is called *transarticular drilling*. The idea is to stimulate the underlying subchondral bone to bleed, which will allow it to heal. If the lesion is very large or if the cartilage is partially cracked, the surgeon may also perform internal fixation. In these cases, metal or bioabsorbable screws or bone pegs are placed across the lesion to provide stability and compression.

In some cases, the cartilage over the lesion will be completely destroyed or will have broken off to form a loose body. In these cases, the surgeon will often just remove the cartilage over the lesion or remove the loose body. The underlying subchondral bone will then be exposed. The surgeon may then elect to perform a *microfracture procedure,* in which a tiny pick is used to create small holes in the subchondral bone. These holes will bleed, and a blood clot will eventually form over the OCD lesion. Over time, the blood clot can repair the lesion with a fibrous form of cartilage. Newer cartilage transplantation techniques are often reserved for patients who have already had the microfracture procedure done but still have pain.

After Surgery

After surgery, the patient is placed in a short leg cast or air cast boot and is required to use crutches. Depending on the surgeon's preference and the procedure employed, crutches and boot or cast may be used for 6 weeks or more after surgery. Ankle motion is slowly increased over time. Physical therapy is often initiated to help the patient regain ankle motion and strength. The patient is not allowed to resume sports activities until the lesion is felt to have healed, which may take between 3 and 12 months. Athletes involved in high-impact cutting sports may benefit from wearing an ankle brace after surgery.

Ankle Fracture

Ankle injuries are among the most common injuries in sports. Approximately 15% of all ankle injuries involve fractures of the ankle. Sports that may put an athlete at risk include basketball, soccer, football, softball, and baseball, among others. Any sport that involves cutting or abrupt changes in direction may put undue stress on the supportive structures around the ankle, resulting in failure and, at times fracture.

Anatomy

The ankle joint is an articulation composed of three bones—the tibia, the fibula, and the talus. The bones are covered in cartilage at their ends, allowing for painless gliding movement of this *ginglimus* (hinge)-*type joint*. To enhance the stability of the ankle joint, the body has a number of ligaments that form attachments between the bones. They are the deltoid ligament complex, anterior talofibular ligament, calcaneofibular ligament, posterior talofibular ligament, and anterior and posterior tibiofibular ligaments.

The joint is somewhat like a saddle over the talus. Furthermore, the talus is wider anteriorly (in the front) than posteriorly (in the back), and as the ankle dorsiflexes (moves away from the ground), there is more bony contact in the joint, rendering it more stable.

Causes

As the ankle encounters a significant enough force, the structures that it consists of will fail in a predictable pattern based on the position of the ankle and the forces applied at the time of injury. The ankle may roll in or out or may be twisted from side to side. Last, direct impact from jumping from a height may cause the ankle to break (see Figure 1).

Symptoms

The symptoms of an ankle fracture are variable depending on the mechanism, the location of the fracture, and the severity of the injury. Pain may be directly over the break or may be referred to another area of the foot or lower leg. Swelling will be present over the area of soft tissues that have been stretched or torn. There may be a collection of blood in the area or in the joint itself, which is called *hemarthrosis*. As time passes, the blood that pools in the ankle may settle in the skin, causing color changes. If swelling is significant enough, there may be enough pressure on the nerves to cause numbness or tingling. Bearing weight through the ankle will generate extreme pain.

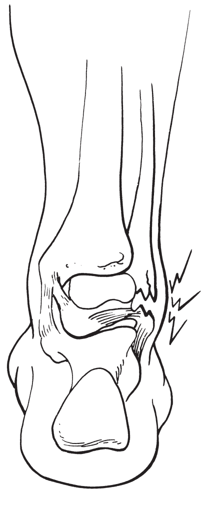

Figure 1 Example of an Ankle Fracture

Note: Ankle fractures usually affect the bottom end of the fibula on the outer side of the lower leg and usually occur in the same way many inversion sprains do; the athlete rolls over on the ankle, and the body's momentum breaks the bone.

Diagnosis

Diagnosis always begins with the history and a physical examination. The history commonly includes a fall with twisting of the ankle followed by immediate pain and swelling. The ankle is palpated for tender areas. Neurovascular status is assessed. This includes palpation of the dorsalis pedis and posterior tibial pulse, as well as assessing the sensation over the top and bottom of the foot and the first web space. Movement of the ankle and toes may be attempted but is often very painful. Breaks in the skin or frank bleeding raises the possibility of an open ankle injury, previously referred to as a *compound fracture*. These injuries are more serious because they pose an increased risk of infection and generally involve more energy.

Next, an X-ray examination is usually performed, which generally also includes a joint above and below the zone of injury. This would include the knee, tibia/fibula, and foot. Ankle X-rays should include three separate views, the anterior-posterior, lateral, and mortise. The *mortise view* is a 15° to 20° internal rotation view that shows the joint surface without the overlap of the tibia and fibula. The clear space between the tibia, talus, and fibula should be equal on the top as well as on both sides. Incongruency denotes not only fracture but also displacement of the talus and possible syndesmosis injury.

A number of classification schemes exist for ankle fractures. These are somewhat academic, but familiarization with them helps when physicians/ trainers are describing injuries via phone. The *Weber classification* describes the level of a fibula fracture. The *Lauge-Hanson classification* describes the position of the foot and the forces applied at the time of injury, which produce predictable patterns of injury. More important, a classification that truly directs treatment is the *Gustilo-Anderson,* which is applied to all fractures, describing the nature of open fractures and the amount of soft tissue involvement.

Treatment

Initial treatment generally takes place in the emergency department. For most closed low-energy ankle fractures that occur in sports, management begins with closed reduction and splinting. *Closed reduction* refers to "setting" the ankle when the fracture has displaced or moved from the normal bony alignment. Often this is preceded by adequate sedation and analgesia. Splints are usually made of plaster and do not entirely encompass the circumference of the leg to allow for swelling, which usually ensues over the first 48 to 72 hours. With *r*est, *i*ce, *c*ompression, and *e*levation (RICE treatment) over the first 10 to 14 days, swelling resolves, and further treatment plans are made. The patient should adhere to strict non–weight bearing until a reassessment is made. Prescription-strength pain medications are generally given after the initial evaluation.

Nonsurgical Treatment

At this point, patients usually follow up in the physician's office, and minimally displaced fractures, or those that have not moved far, can be placed in a short leg cast for another 4 to 6 weeks. Serial X-rays will be required to monitor both the healing status of the bone as well as the alignment. Casts are made of fiberglass and are of lighter weight than fiberglass splints. They are circumferential and should be molded to the patient's leg with certain forces applied to hold the alignment of the ankle appropriately. The ankle should be at 90° once the cast is complete to prevent stiffness following cast removal. The amount of time a patient is kept non–weight bearing depends on the stability and the injury pattern. The ankle may be transitioned to a CAM (controlled ankle motion) walker for progression to full weight bearing. Once the fracture is healed and weight bearing has begun, physical therapy focuses on regaining strength and range of motion of the ankle and lower extremity. The lack of use of the leg will result in atrophy of the muscles and stiffness of the joint; this must be overcome before the athlete returns to play, so as to minimize the risk of reinjury.

Surgery

Surgical indications, simply put, include significant angulation or displacement of the fracture, an incongruent joint, or a fracture that involves the joint surface. Other indications include open fractures, where the bone has been exposed to the outside environment, increasing the risk of infection. Surgery should be delayed until the swelling of the soft tissues around the ankle has resolved. Plates and screws are commonly used to stabilize the fracture fragments. Surgical planning includes determining the type of fixation, the size and number of plates and screws that will be needed, and the anatomic approach that will be used. Soft tissues are dissected in internervous and intermuscular planes to expose the bony fragments. The fracture site is reduced, or realigned, under direct vision and with the assistance of X-ray fluoroscopy. Hardware is then placed to stabilize the fracture and hold it in place until it heals. In many individuals, there is a paucity of soft tissue coverage over the ankle region, and plates and screws may become bothersome over time, requiring removal. For the most part, however, the plates and screws are left in place even after the fracture has completely healed. Following surgery, the ankle is placed again in a splint until swelling has resolved. A cast is then placed at about 10 to 14 days postoperatively, when the soft tissue swelling has resolved.

Return to Sports

Bony healing takes place over the 6 weeks following surgery or casting. Ligamentous healing may take several more weeks. Most daily activities and normal ambulation without a limp may be possible within 3 to 4 months. Return to sports at the same level is often a 9- to 12-month process, and overall recovery may take up to 2 years. As the athlete returns to his or her respective sport, AFOs (ankle-foot orthotics) are often used for additional support and can be weaned as strength, mobility, and confidence return.

Ankle Impingement

Ankle impingement, generally speaking, is a painful limitation to full range of motion of the ankle joint. Most often the inciting factor is trauma, usually an ankle sprain. However, infectious, rheumatologic, degenerative, and even congenital causes are also possibilities. The injury is one that is chronic in nature and is often seen in young athletes with repetitive injures, or repetitive motions in their respective sports.

Anatomy

The ankle joint is hinged, or a *ginglimus joint*. It is an articulation composed of three bones—the tibia, the fibula, and the talus. The cartilage that covers the surface of the joint allows for painless movement of dorsiflexion and plantarflexion. Dorsiflexion is movement of the foot toward the head, and plantarflexion is movement of the foot toward the floor. The ankle has many ligaments that help enhance the stability of the joint. These include the deltoid ligament complex, anterior talofibular ligament, calcaneofibular ligament, posterior talofibular ligament, and anterior and posterior tibiofibular ligaments. The names indicate the bone from which the ligaments originate and insert. The joint is shaped like a saddle over the talus. The talus is a trapezoid and is wider in the front than in the back. It is because of this shape, that the ankle is more stable when dorsiflexed (moves away from the ground).

Causes

Anterior impingement is often caused by forced dorsiflexion and activities that incorporate that movement such as soccer or ballet. Bone spurs may develop on the anterior tibia and talus, causing subsequent pain.

Anterolateral impingement is caused by repetitive inversion-type ankle sprains. This causes synovitis or a scar that limits ankle motion in that plane. The repetitive sprains cause overgrowth of tissue in the area, which then impinges on the cartilage surfaces, inducing pain.

Posterior impingement results from the posterior tissues becoming impinged following repeated plantarflexion (downward motion of the ankle). This causes repetitive microtrauma, resulting in inflammation and overgrowth of certain tissues. Activities such as dancing, kicking, gymnastics, or downhill running may predispose an athlete to this condition.

Symptoms

The patient will complain of pain as the primary symptom. The pain will be exacerbated by the movement that corresponds with the type of impingement. Anterior impingement will be worsened by forcing the ankle toward the head or lunging forward with the foot flat on the floor. These patients will also complain of stiffness in their ankle. Anterolateral impingement will cause pain along the anterior talofibular ligament and lateral gutter. They will often have a poor sense of where their ankle is in space, and their symptoms will seem worse with cutting activities. Posterior impingement is a more difficult diagnosis to make, but again the complaint will be pain or catching with push-off or forced plantarflexion.

Diagnosis

The diagnosis always begins with a thorough history and physical examination. Important questions to ask are as follows: When did the pain begin? Is it constant, or does it come and go? Is there a specific injury or trauma that occurred? Where specifically is the pain, and is there a movement that exacerbates it? (The athlete should try and localize the pain with a single finger.) Are there any associated catching, clicking, or mechanical-type symptoms? Has any treatment been tried that makes the pain better or resolves it? The physical exam begins with visual inspection for any obvious swelling or deformity. The ankle is palpated for tender areas. Neurovascular status is assessed. This includes palpation of the dorsalis pedis and posterior tibial pulse as well as assessing the sensation over the top and bottom of the foot and the first web space. Movement of the ankle and subtalar joint is assessed. This includes dorsiflexion, plantarflexion, inversion, and eversion. The patient with impingement may complain of pain at the extreme of one of these motions.

X-rays should include images of the joints above and below the injury. In the case of ankle impingement, this will generally include the knee, tibia/fibula, and foot. Ankle X-ray series should always include the anteroposterior, lateral, and mortise views. Most often these will result in normal findings. Subtle abnormalities that may be appreciated include an *os trigonum*, a small bone in the posterior ankle, present in about 7% of the population, which may contribute to posterior impingement. Spurs may be present on the talus or tibia anteriorly in those with anterior impingement. Lateral X-ray of the ankle in a forward lunging position may demonstrate bone-on-bone impingement. Magnetic resonance imaging (MRI) is helpful in identifying soft tissue involvement and is overall the more useful imaging technique.

Treatment

The goal of treatment is to relieve pain and resolve inflammation so that the athlete may return to sports at full strength. Generally, treatment begins with standard rest, ice, anti-inflammatories, bracing, orthotics, and physical therapy. Nonsteroidal anti-inflammatories are very useful in relieving inflammatory pain such as in the case of impingement. Ibuprofen and naproxen are two of the most commonly used over-the-counter medications. Other prescribed anti-inflammatories include sulindac and ketoprofen.

Nonsurgical Treatment

In addition to the nonsurgical measures listed above, other modalities that may be useful include electrotherapy, injections, and reevaluation of techniques in areas such as dance or ballet. Injections may be helpful as a diagnostic tool as well, helping to determine whether the pain is located in the ankle joint or the subtalar joint.

Surgical Treatment

Arthroscopic excision of the inciting tissue or ossicle is the surgical treatment of choice. Occasionally, open treatment may be required to achieve a thorough debridement. Generally, athletes are advised *r*est, *i*ce, *c*ompression, and *e*levation (RICE treatment) over the first week or two until the sutures are removed. They are allowed to bear weight as tolerated through the postoperative course. Rehabilitation focuses on strength, range of motion, and sport-specific goals. Operative intervention is successful in 80% or more patients.

Return to Sports

Generally, the athlete may be able to return to sports when he or she has regained full strength and painless range of motion. Most often these goals can be met at about the 5- or 6-week mark. Sport-specific training is especially important in dance and ballet, where technique may have been the root cause of the problem. Another important goal is proprioception, or the sense of where the joint is in space. This is often lost with impingement syndrome and can be improved on with aggressive physical therapy.

Ankle Injuries

Among athletes participating in sports, injuries to the ankle are very common. Ankle sprains alone account for about 25% of all sports-related injuries. Ankle injuries are particularly common in running and jumping sports such as volleyball, basketball, and soccer. In basketball, 20% to 50% of injuries involve the ankle; 17% to 29% of all soccer injuries are ankle injuries. Inversion (foot turned in) injuries are much more common than eversion (foot turned out) injuries because of the weakness of the lateral ligaments and the relative instability of the lateral ankle. Eversion injuries are uncommon. Most ankle injuries can be successfully treated conservatively with *p*rotection, *r*est, *i*ce, *c*ompression, and *e*levation (PRICE) and appropriate rehabilitation.

Anatomy

The ankle is a simple hinge joint consisting of the tibia, fibula, and talus. These three bones articulate at the ankle (talocrual) joint and are stabilized by ligaments and an interosseous syndesmosis. The tibia is the main weight-bearing bone in the lower leg. The tibia extends into the medial malleolus, which provides medial bony support for the ankle mortise. The distal tibia and fibula form the inferior tibiofibular joint, which allows for rotational movement essential for barefoot walking and running. The tibia and fibula create a boxlike mortise, in which the talus rests. The talus is wider anteriorly and narrower posteriorly, providing bony stability when the joint is in neutral position as the wider part of the talus is locked securely in the joint. Movement at the ankle joint is predominantly dorsiflexion (toes up) and plantarflexion (toes pointed down).

The third joint of the ankle, the subtalar joint, comprises the talus and the calcaneus and is separated into an anterior and posterior articulation divided by the sinus tarsi. The subtalar joint provides shock absorption, allows the foot to adjust to uneven ground, and allows the foot to remain flat on the ground when the leg is at an angle to the ground. Inversion (foot turned inward) and eversion (foot turned outward) of the ankle occur at the subtalar joint (Figure 1).

There are three muscle compartments of the ankle: anterior, lateral, and posterior. The boundaries between these compartments are formed by the interosseous membrane and the anterior aspect of the tibia. The anterior compartment consists of the extensor hallucis longus, extensor digitorum longus, and anterior tibialis muscles, which act primarily to dorsiflex the ankle. The anterior tibialis

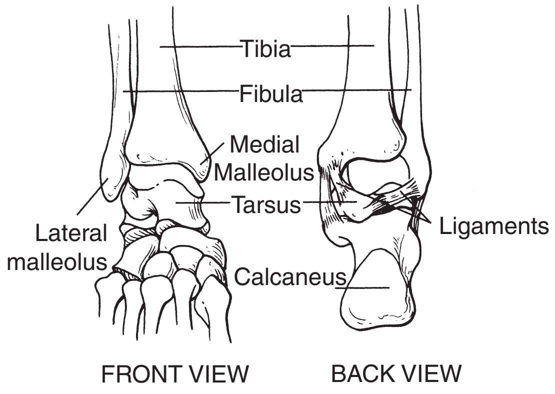

Figure 1 Ankle Anatomy

Notes: The ankle is stabilized by the lateral ligament complex: the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the posterior talofibular (PTFL) ligament. The ATFL is the primary ligamentous support protecting the ankle from inversion stress and is the most commonly injured ligament in the body. It originates at the anterior aspect of the lateral malleolus, runs almost parallel to the axis of the foot, and attaches to the talus anteriorly. The CFL is stronger than the ATFL; it runs from the tip of the lateral malleolus to the lateral surface of the calcaneus. The PFTL runs from the posterior aspect of the lateral malleolus to the posterior talus. Medial support is provided by the deltoid ligament, a fan-shaped structure emanating from the distal tibia. The deltoid ligament consists of a superficial layer, running from the medial malleolus to the medial aspect of the calcaneus, and a deep layer, originating from the medial malleolus and attaching to the talus. Anterior fibers of the deltoid ligament attach to the talus and navicular; posterior fibers attach to the talus. The high ligaments are the anterior inferior tibiofibular ligament, posterior inferior tibiofibular ligament, and interosseous syndesmosis.

attaches to the first metatarsal and cuneiform and inverts the foot. The lateral compartment consists of the peroneus longus and brevis muscles, which evert the foot. The peroneus brevis attaches to the base of the fifth metatarsal; the peroneus longus crosses the sole of the foot and attaches to the first cuneiform and the base of the first metatarsal. The posterior compartment has superficial and deep groups. The superficial group is the triceps surae and comprises the gastrocnemius, soleus, and plantaris. The deep group consists of the flexor hallucis longus, flexor digitorum longus, and tibialis posterior muscles. These muscles plantarflex the ankle, flex the toes, and invert the foot.

Innervation of the ankle is supplied primarily by the sciatic nerve. The dorsiflexors are innervated by the common peroneal nerve. The muscles of the posterior compartment are innervated by the tibial nerve. The peroneal muscles are innervated by the superficial peroneal nerve. The muscles of the anterior compartment are innervated by the deep peroneal nerve.

In pediatric athletes, open growth plates in the distal tibia and fibula predispose both children and adolescents to growth plate fractures not seen in adults. Children are also more likely to have avulsion fractures because the attachment areas of ligaments are relatively weaker than the ligaments themselves.

Evaluation of Injuries

Details of Injury

Ankle pain in an athlete can be from an acute or a chronic injury. The mechanism of injury, specifically whether it was an inversion or eversion injury, can suggest which structures have been damaged. The onset of pain and the ability to weight bear immediately after an injury can also help determine the severity of the injury. Pain that increases with continued activity suggests a ligamentous injury rather than a fracture. The location of pain, swelling, and bruising can also help suggest the particular injury. The degree of swelling, bruising, and disability may indicate the seriousness of the injury.

For chronic injuries, it is important to determine what treatment has already been instituted: medication history, PRICE (*p*rotection, *r*est, *i*ce, *c*ompression, and *e*levation), duration of restricted weight bearing, taping/braces, or physiotherapy. It is also important to ascertain if there is a previous history of injury.

It is important to assess the athlete's sport, position, and level of competition and what stage the athlete is in his or her season or training.

Physical Findings

Injuries of the ankle may result in swelling, bruising, or deformity of the ankle. The athlete may walk with a limp or be unable to weight bear.

Range of motion of the ankle may be decreased in all directions. Pushing the foot outward against resistance may cause pain behind the lateral malleolus if there has been an injury to the peroneal tendon. The point of maximal tenderness to palpation can help localize the structures injured.

There are some special tests that can help diagnose ankle injuries, such as the anterior drawer test, lateral talar tilt, proprioception or balance, and hopping and lunge test. The anterior drawer test assesses for stability of the lateral ankle. One hand is used to stabilize the lower leg. The ankle is slightly plantarflexed and grasped by the heel. Pressure is exerted upward, and the degree of excursion is compared with that of the uninjured ankle. The talar tilt test assesses the integrity of the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the deltoid ligament. One hand is used to stabilize the lower leg; then the ankle is grasped by the heel, and medial and lateral movements of the talus and calcaneus in relation to the tibia and fibula are noted. Proprioception is assessed by having the athlete stand on the injured leg with eyes closed and comparing the balance with that on the uninjured side. Functional assessment is made by having the patient hop on the injured side and perform a lunge to determine the degree of dorsiflexion.

"High" ankle sprains involve injuries to the anterior tibiofibular ligament or the syndesmosis. Tests that help diagnose high ankle sprains include the squeeze test and the external rotation test. The squeeze test is performed by compressing the proximal tibia and fibula between the examiner's hands. Pain elicited in the syndesmosis is considered a positive test. The external rotation test is performed by stabilizing the lower leg with one hand while abducting the foot with the other hand. A positive test reproduces pain in the syndesmosis.

Investigations

Palpation to determine the maximal point of tenderness can help determine whether investigations are necessary in ankle injuries. If the maximal point of tenderness is bony, X-rays should be obtained. The Ottawa Ankle Rules can help determine the need for X-rays (Figure 2).

Osteochondral (bony) injuries may not be apparent on X-rays. If an athlete with an ankle injury is not progressing as expected, or if there is persistent significant pain and disability, other investigations should be done, such as bone scan, ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). CT provides superior bony detail, whereas MRI provides better definition of soft tissues, such as ligaments and tendons.

The Ottawa Ankle Rules

An ankle X-ray series is necessary only if there is pain in the malleolar zone and any one of the following:

1. Bone tenderness at the posterior edge or tip of the lateral malleolus
2. Bone tenderness at the posterior edge or tip of the medial malleolus
3. Inability to weight bear both immediately and in the Emergency Department

A foot X-ray series is necessary only if there is pain in the midfoot zone and any of the following:

1. Bone tenderness at the base of the fifth metatarsal
2. Bone tenderness at the navicular bone
3. Inability to weight bear both immediately and in the ED

Figure 2 The Ottawa Ankle Rules

Types of Injury

Table 1 lists the types of ankle injuries.

Table 1 Ankle Injuries

Common	*Uncommon*
Lateral ankle sprain	Medial ankle sprain
Fractures	Osteochondritis dissecans of talus
Peroneal tendinitis	Peroneal subluxation
Accessory navicular	Chronic instability of the ankle
Apophysitis	Posterior tibial tendinitis
	Anterior-posterior impingement
	Reflex sympathetic dystrophy
	Syndesmosis injuries (high ankle sprain)

Prevention of Injury

Ankle injuries can be prevented by ensuring good overall fitness and conditioning. Athletes should endeavor to maintain an appropriate weight with proper nutrition and healthy lifestyle behaviors.

A preparticipation assessment at the start of an athlete's season can elicit any injuries or muscle imbalances that may predispose to injury during the season and allow for appropriate rehabilitation in the preseason. The proper protective equipment for the sport should be worn, properly maintained, and replaced as necessary. Ankle taping or supportive bracing should be used as necessary. Prior to practices and games, athletes, coaches, and trainers should "walk the field" to identify any potential hazards, such as uneven playing surfaces or debris on the playing surface. Practices should emphasize appropriate warm-ups and specific skill drills, such as balance training, cutting, jumping, and landing, to improve strength, flexibility, and neuromuscular control.

Education is vital to help prevent injuries. Athletes, parents, trainers, and coaches should know basic injury care and when to seek medical attention. It is important that injuries are promptly identified and rehabilitated to prevent their worsening.

Return to Sports

Return to sports following an injury can be tricky, but basically, the athlete should be able to weight bear, run, jump, and do everything necessary for his or her sport without pain. Depending on the injury, it may be necessary for the athlete to be non–weight bearing for a period of time to allow healing to occur. During this time, the athlete can participate in non–sport-specific aerobic activity, such as swimming and stationary biking, to help maintain cardiovascular conditioning and increase blood flow to the extremities. Physical therapy may be necessary to improve range of motion, strength, and balance, as well as reduce swelling.

Once the athlete is able to fully weight bear and is comfortable with the activities of daily living, he or she can proceed through a functional return-to-sport protocol (Table 2), under the direct supervision of a certified athletic trainer, physiotherapist, or physician. The athlete should not experience any sharp pain when progressing to more advanced tasks; mild discomfort is acceptable. If pain increases, the athlete should go back to the previous step for 2 to 3 days before

Table 2 Some Examples of a Functional Return-to-Sport Protocol

1. Toe raises, both legs together: 1–3 sets, 15 repetitions
2. Toe raises, injured leg alone: 1–3 sets, 15 repetitions
3. Balancing on the injured leg: 1–3 sets, 30 seconds in duration
4. Walking at fast pace: 1–3 times, 50 yards (yd; 50 yd = 45.7 meters) each
5. Jumping on both legs: 1–3 sets, 10 times each
6. Jumping on the injured leg: 1–3 sets, 10 times each
7. Easy-paced, straight-line jogging: 1–3 times, 50 yd each
8. Sprinting (half speed, quarter speed, and full speed): 1–3 times each, 50 yd each
9. Jogging, straight and gradual curves: 2–3 laps around the field, court, or track

trying to advance again. Athletic taping or a foot orthosis may be necessary for the remainder of the sport season to prevent reinjury. The athlete may be able to return to a less demanding player position sooner than his or her typical position.

In sports such as cross-country, track, and running, the athlete can gradually advance to the desired distance at this point. For more demanding sports (football, soccer, basketball, baseball, tennis), the athlete needs to advance to more sport-specific drills, such as the following:

1. Running figure eights (half speed, quarter speed, full speed): 1–3 times each
2. Crossovers, 40 yards (yd; 40 yd = 36.58 meters): 1–3 times to the right and left
3. Backward running (back peddling): 1–3 times, 40 yd each
4. Cutting (half speed, quarter speed, full speed): 1–3 times
5. Sport-specific drills
6. Return to sport

Ankle Instability

Ankle instability is a term that describes patients' perception that their ankle is "giving way." Laxity of the ankle ligaments is found on examination, caused by acute ankle sprain or recurrent injury (chronic ankle instability). Ankle instability can involve the lateral or medial ankle ligaments. Ankle sprains are a common sports-related injury, accounting for up to 40% of all athletic injuries. Sprains are particularly prevalent among basketball, soccer, and football players and account for 10% of emergency department visits.

Anatomy

The lateral ankle ligament complex is composed of the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the posterior talofibular ligament (PTFL). The ATFL runs from the distal fibula to the talar neck and is the primary restraint to anterior displacement on the tibia. It functions to restrict ankle inversion, particularly in plantarflexion. It is the weakest lateral ankle ligament and is most commonly involved in lateral ankle sprains. The CTFL is the primary ligamentous restraint to ankle inversion in dorsiflexion and is injured in at least half of all lateral ankle sprains. It runs from the distal fibula to the lateral calcaneus. The PTFL extends from the posterior fibula to the lateral talus. This ligament is injured in 10% of lateral ankle sprains.

The medial ankle ligament (deltoid ligament) is the strongest ankle ligament. It arises from the medial malleolus of the tibia and inserts at multiple sites, including the calcaneus, the talus, and the spring ligament of the foot.

Dynamic stability is provided by the peroneal muscles on the lateral side of the ankle. These muscles function as evertors. Medially, the tibialis posterior muscle aids in hindfoot inversion and medial ankle stability.

Etiology

The position of the ankle at the time of the sprain determines the pattern of ligament injury. Lateral ankle sprains result from inversion and internal rotation of the foot on an externally rotated leg. In plantarflexion, the ATFL is usually injured in isolation. In dorsiflexion, both the ATFL and the CFL may be injured.

Medial ankle ligament injuries are much less common than lateral ankle injuries. Isolated medial injuries typically occur as a result of excessive hindfoot eversion, as in dancing, landing on an uneven surface, or running down stairs. Often patients are predisposed to injury by valgus alignment of the hindfoot and/or tibialis posterior tendon dysfunction.

In some chronic ankle injuries, patients can present with both medial and lateral ankle instability.

Chronic ankle instability is characterized by persistent pain, recurrent sprains, and repeated instances of the ankle giving way. While the etiology of chronic instability is multifactorial, a history of primary ankle sprains is a major contributor. Chronic ankle instability can arise as a result of pathologic laxity, degenerative changes, strength deficits, impaired proprioception, and/or poor neuromuscular controls. (See the entry Ankle Instability, Chronic.)

History

Acute ankle sprains typically present with an inversion-type injury associated with sports participation, a slip and fall, or other traumatic event. Patients complain of pain, stiffness, and swelling at the ankle, worsened by weight bearing. Depending on the severity of the injury, the patient may be unwilling to weight bear on the limb.

Chronic ankle instability can present as a series of multiple ankle sprains, "giving way" episodes, deformity, and/or pain.

Physical Examination

On examination of the acutely sprained ankle, one notes ecchymosis and edema about the injured soft tissues, tenderness about the bony and ligamentous landmarks, and limited ankle range of motion due to pain. In lateral ankle injuries, the ATFL and CFL are most often tender, whereas tenderness over the deltoid ligament is characteristically present in medial instability.

Dynamic stability is assessed by a strength test of the peroneal muscles (resisted eversion of the foot) and the tibialis posterior (ability to complete a single limb heel rise).

Ligament laxity is assessed by means of two special tests: (1) the *anterior drawer test* and (2) the *inversion stress test*. The anterior drawer test assesses the ATFL for laxity as the examiner passively translates the talus anteriorly on the tibia. The examiner uses the inversion stress test to look for laxity of the CFL by passively inverting the hindfoot on the tibia. Both tests use the contralateral uninjured limb as a baseline for comparison. Excessive motion is considered a positive result. In the acutely injured ligament, these tests can be painful, helping to confirm the diagnosis.

The examination of an ankle with chronic instability further requires an assessment for contributing deformity about the lower extremity. These include excessive heel valgus and a planovalgus "flat" foot (for medial injuries) or cavus-type deformities with hindfoot varus and/or plantarflexion of the first ray (for lateral injuries). Examination for the presence of generalized ligamentous laxity should be carried out, as well as ruling out other pathology that may mimic chronic instability (ankle or hindfoot fractures, arthritis, tarsal coalition, osteochondral injuries, peroneal tendon injuries, etc.). In chronic injuries, laxity of the ankle ligaments may be more easily demonstrated due to the lack of an acute injury, while other clinical signs may be subtler, with little or no ecchymosis and edema limited to a joint effusion.

Imaging

The indications for X-ray evaluation in the case of an ankle sprain are well-defined by the Ottawa Ankle Rules. Patients require ankle X-rays when they present acutely with pain about either malleolus and at least one of the following:

- Bony tenderness about the distal 6 centimeters of either malleous
- Inability to weight bear on the extremity following injury and later on exam

X-rays should include standing anterior-posterior, lateral, and mortise views. Radiographs in an isolated ankle sprain will be normal or may note a small bony avulsion of the distal tip of the lateral malleolus where the ATFL has been torn. A lateral shift of the talus in the ankle mortise or tilting of the talar body suggests an occult ankle fracture (usually proximal fibula) and warrants further imaging.

The Ottawa Foot Rules are also important in the evaluation of patients with ankle injuries and indicate that X-rays are required when patients present acutely with midfoot pain and at least one of the following:

- Tenderness about the base of either the fifth metatarsal or the navicular
- Inability to weight bear on the extremity following injury and later on exam

X-rays should include standing AP, lateral, and oblique views of the foot. Radiographic evaluation of chronic ankle instability should begin with the above-described foot-and-ankle X-rays to rule out pathology that may mimic or contribute to ankle instability. This may include malalignment, arthritis, osteochondral injury, or tarsal coalition. Undiagnosed fractures of the lateral process of the talus are a common source of ankle-instability-like symptoms. A computed tomography (CT) scan is helpful for more detailed imaging where bony pathology is suspected, such as tarsal coalition or bony/articular injury. Magnetic resonance imaging (MRI) is a useful diagnostic adjunct that can reveal swelling, ligament injury, tendon tears, bone bruising, or occult fracture. Synovitis, osteochondral lesions of the talus, loose bodies, and peroneal tendon tears are often seen on MRI in association with chronic ankle instability.

Management

Acute ankle sprains are graded from I to III. Grade I describes a mild ligament stretch with no instability, minimal swelling and tenderness, and no significant functional impairment. Grade II describes partial tears with mild to moderate instability, increased tenderness, and increased swelling. Grade III injuries are characterized as complete rupture of the ligament, significant instability, severe pain and swelling, and significant functional impairment.

Acute ankle sprains are treated with functional management. This consists of *r*est, *i*ce, *c*ompression, and *e*levation (RICE). This is followed by a short period of immobilization (taping, bandaging, or bracing), then physiotherapy (active range of motion, weight bearing, proprioception training, peroneal strengthening). Primary surgical management of acute ankle instability is being debated, but current evidence is lacking to support such management.

Chronic ankle sprains are best managed early in the disease process. Lack of improvement with conservative management warrants referral to an orthopedic surgeon and is an indication for surgery, provided other conditions in the differential diagnosis have been ruled out or addressed. The goal of instability surgery is to restore the deficient soft tissue stabilizers of the ankle. Most procedures address the lateral ankle ligament complex and fall into two major groups: (1) anatomic repair of the ligaments and (2) tenodesis stabilization. Anatomic repair involves re-approximation of the ATFL and possibly CFL to the lateral malleolus or an in-substance repair. Plication of the ligament is often done concurrently to account for lengthening of the ligaments. Modifications of this technique have been described to facilitate repair where the ligament remnants are of poor quality. The most commonly used method of anatomic repair is the Bröstrom procedure.

Tenodesis stabilization procedures are indicated for patients with lateral ankle instability with failed anatomic repair. Some seek to replace the deficient lateral ligaments by rerouting all or a portion of the peroneus brevis to provide the static function of the ATFL or CFL. Other surgeries use hamstring graft to re-create these structures. Overall, outcomes favor anatomic repair over reconstruction due to nerve injury, wound complications, and deteriorating outcomes over time.

With respect to medial ankle instability, most cases can be managed with functional rehabilitation. Surgery to reconstruct the chronically failed deltoid ligament is an ongoing area of interest, but there are no standard reconstructions with predictably good outcomes at present.

Surgical management for instability associated with foot-and-ankle deformity is pathology dependent and may include tendon transfers, osteotomies, or fusions.

Some authors advocate ankle arthroscopy at the time of surgery before proceeding with ligament repair or reconstruction to identify and treat concomitant foot-and-ankle pathology, such as osteochondral lesions of the talus, ankle impingement, or osteophytes.

Ankle Instability, Chronic

Chronic instability of the ankle is a condition that may arise after one or more acute ankle sprains. Ankle sprains, which most often involve tearing or stretching of the lateral (outside) ligaments of the ankle during excessive inversion (in which the foot rolls inward), are among the most common injuries in all of orthopedics. Following such acute injuries, the majority of people will have a full functional recovery without surgery. However, around 10% to 20% of people will suffer from chronic lateral instability, in which there is persistent "giving way" of the ankle and recurrent sprains.

Anatomy

Ligaments are strong bands of connective tissue made of collagen fibers. Ligaments surround joints and provide the connection from one bone to another. The lateral ligamentous structures are most commonly affected in both acute ankle sprains and chronic ankle instability. Of the lateral ankle ligaments, the weakest and most frequently injured in inversion injuries is the anterior talofibular ligament (ATFL), which runs from the anterior (front) aspect of the distal fibula distally to the anterolateral aspect of the talus. The ATFL is normally the primary restraint to internal rotation of the foot when the ankle is in plantarflexion (in which the foot is pointing downward relative to the leg).

In more severe ankle sprains, the calcaneofibular ligament (CFL), which runs from the distal tip of the fibula distally (toward the sole of the foot) and slightly posteriorly to the lateral aspect of the calcaneus, may additionally be torn or stretched. Normally, the CFL restrains the internal rotation of the foot during ankle dorsiflexion (in which the foot points upward relative to the leg). Although it is the second weakest lateral ligament of the ankle, injury to the CFL requires more than double the force required to tear the ATFL.

Causes

Severe or recurrent inversion injuries, when forced internal rotation of the foot occurs with the ankle in plantarflexion, are the most common precipitating events that lead to ankle instability. While such injuries frequently occur during athletic activity, accidents during everyday activities or a forceful step on uneven ground may also cause such a sprain.

Chronic instability has been linked to a wide range of etiological factors, which are typically divided into (a) those contributing to mechanical instability, in which the ligaments themselves remain looser than normal after injury, and (b) those contributing to functional instability, in which a person's control or use of the joint is abnormal and predisposes him or her to recurrent injury.

Mechanical instability of the ankle can result from physiologic ligamentous laxity or joint hypermobility, in which a person's ligaments are physiologically looser than normal. Alternatively, a suboptimal healing response in the lateral ankle ligaments may lead to scar tissue that is weaker or elongated following a sprain.

Functional instability stems from loss of proprioception or muscle weakness. Proprioception, the nervous system's ability to detect and control the position of a body part in space, is inherently compromised when the structures around a joint are injured. If there is no adequate retraining of ankle proprioception in the recovery period, this can leave a person prone to recurrent sprains and chronic instability. These proprioceptive qualities also involve the peroneal muscles, which become weaker as a result of the trauma and the immobilization period that typically follows a sprain. Peroneal weakness has been reported in almost one quarter of patients with recurrent ankle sprains.

Symptoms

The primary complaint from patients with chronic ankle instability is a feeling of the ankle giving way or recurrent painful inversion sprain episodes of varying severity. Patients may present acutely with pain, swelling, and ecchymosis about the lateral aspect of the ankle or may present between episodes, when the ankle appears normal but continues to feels "unstable" or "loose."

Diagnosis

The diagnosis of chronic ankle instability is generally made from a history of subjective instability or recurrent ankle sprains for a period of 6 months or longer. Functional instability is evaluated through strength and proprioception testing. Manual strength testing, with specific attention to assessing for peroneal muscle weakness against resisted eversion, should be performed. Proprioception should be evaluated with a modified Romberg test (in which the patient stands on one foot at a time, with the eyes first open, then closed) or with more sophisticated stabilometry testing (available at many physical therapy facilities).

The two primary physical examination maneuvers used for assessment of mechanical instability are the anterior drawer test and the ankle inversion test. The *anterior drawer test* or *prone anterior drawer test* is performed with the patient in the prone (face down) position, with the feet extending over the end of the examining table. The examiner puts one hand on the distal leg for stabilization and pushes the heel steadily forward with the other hand. The test is considered positive when the talus advances anteriorly 3 to 5 millimeters or more. The *inversion stress test,* also called the *talar tilt test,* is designed to assess CFL integrity. The patient lies in the supine (face up) position or on the side, with the foot relaxed and the knee bent, to relax the gastrocnemius (calf) muscle. The talus is then tilted from side to side into adduction and abduction, with a positive test consisting of asymmetry compared with the unaffected side.

Standard radiographs of the ankle (three views—anterior-posterior, lateral, mortise) should be used to rule out fracture following ankle injuries. Rarely, magnetic resonance imaging (MRI) may be used when severe ligamentous injury is suspected and the patient is unable to tolerate physical examination maneuvers because of pain in the acute period.

Treatment

Nonsurgical Treatment

In patients with recurrent instability, if proper compliance with rigorous ankle strength and proprioception training has not occurred, an additional course of physical therapy should be prescribed before surgery is considered, regardless of the chronicity of the symptoms. Around 3 to 4 weeks following a sprain, strength training should be initiated and focused not only on the plantarflexors (calf muscles) and dorsiflexors (anterior shin muscles) of the ankle but also on the peroneal (lateral leg) muscles. Proprioceptive training for the ankle is most commonly performed with a simple tilt board. During athletic competition, ankle taping and use of lace-up braces and "high-top" footwear have been shown to decrease the rate of recurrent sprains.

Surgery

When symptoms of chronic ankle instability last for greater than 6 months and mechanical instability persists despite compliance with a focused functional rehabilitation program, operative treatment should be considered. A number of different procedures have been described to treat chronic ankle instability, which may be divided into (a) anatomic, in which the goal is to repair the normal lateral ligamentous structures, and (b) reconstructive, in which the adjacent tendons are transferred, weaved, or reconstructed so as to provide static stabilization in place of the ligaments. The most commonly used anatomic procedure is the Brostrom-Gould procedure, in which the two ends of the torn ATFL and CFL are each sutured together or imbricated (overlapped) to shorten and strengthen the attenuated ligament-capsule complex. Advancement of the proximal edge of the extensor retinaculum onto the distal fibula reinforces the repair.

Most of the reconstructive procedures, such as the Evans, Watson-Jones, Larsen, and Chrisman-Snook procedures, involve weaving a portion of the peroneus brevis tendon through the fibula to one or more areas on the hindfoot. The more bony sites that are incorporated into the reconstruction, the more stable the ankle is, but with the effect of restricting or altering normal ankle motion to some degree, so use of these techniques should be individualized based on the instability and the goals for functional recovery.

Rehabilitation

While traditional postoperative rehabilitation regimens include long periods of cast or brace immobilization, ranging from 6 weeks to as much as 10 to 12 weeks in nonathletes, more recent evidence suggests that short-term immobilization and initiation of range-of-motion therapy within 2 to 4 weeks may be associated with earlier returns to work and athletic competition. Active eversion/inversion and strength training are delayed until after 6 weeks, to allow for ligamentous healing.

ANKLE SPRAIN

Ankle sprains are one of the most common injuries sustained during recreational and competitive sports such as soccer, basketball, football, and running. Although a common injury, many individuals do not seek medical attention and are self-treated. Depending on the extent of the injury, inadequate treatment of an ankle sprain may lead to chronic pain, decreased range of motion, or instability. In addition, a self-diagnosed ankle sprain may actually be a more severe injury, such as a fracture at or distal to the ankle complex.

Every year, there are 1 to 2 million cases of ankle sprain, constituting 15% to 20% of all sports-related injuries. Of all types of ankle injuries, 75% to 85% are ankle sprains, with the majority of them caused by an ankle inversion injury. Approximately 40% of ankle sprains can lead to chronic injury.

There are a number of contributing factors that may predispose an individual to sustain an ankle sprain, which can include the following:

- Previous history of ankle sprain/injury
- Older individuals who are sedentary

- Overweight individuals/obesity
- "Weekend warriors," who do not train/engage in sports actively and consistently
- Type and frequency of sport that involves more stress on the ankle complex

Anatomy

The ankle is a type of hinge joint. This joint is formed by the articulation of three bones: the talus, tibia, and fibula. The talus acts as a hinge within this complex, allowing the foot to move up (dorsiflexion) and down (plantarflexion). There are two ligamentous complexes that help provide stability to the ankle. The lateral ligamentous complex is made up of three ligaments: (1) anterior talofibular ligament, (2) posterior talofibular ligament, and (3) calcaneofibular ligament. The medial ligamentous complex is also known as the deltoid ligament and is composed of four ligaments: (1) anterior tibiotalar ligament, (2) posterior tibiotalar ligament, (3) tibiocalcaneal ligament, and (4) tibionavicular ligament. Because of these four ligaments, the medial ligamentous complex is more stable than the lateral complex, which is why most ankle sprains are due to an inversion injury. Of all the ligaments, the most common injured ligament is the anterior talofibular ligament (Figure 1).

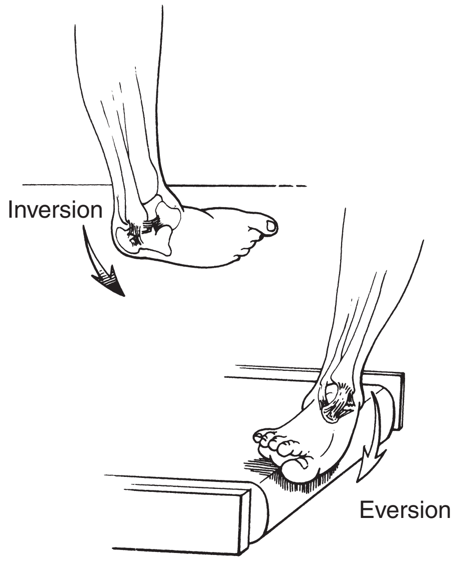

Figure 1 Inversion and Eversion Injuries to Ankle Ligaments

Note: An ankle sprain is a stretch, tear, or complete rupture of one or more of the ligaments that hold the bones of the ankle joint together.

Clinical Evaluation

History

A thorough history will help determine the severity of the ankle sprain as well as aid in determining if it is an injury other than an ankle sprain.

It is important to ask about the position of the ankle at the time of injury, the mechanism of the injury, and the time of the injury. This will help provide the location of the injury site and its associated pathology. A history of past or recurrent ankle sprains provides clues to the overall stability of the ligaments of the ankle and its predisposition to increased frequency of injury. Ascertaining whether the patient was immediately able to bear weight after the injury can provide information as to whether or not a fracture has occurred and the need for radiological evaluation. If the patient is a child, a growth plate fracture is likely, and radiographs of both ankles should be taken for comparison if indicated. A history of numbness in the foot could indicate a neurovascular injury, and proper medical attention should be given.

Physical Examination

When evaluating an ankle injury, the following key features should be addressed.

Inspection. Look for any bruising, discoloration, or swelling both around the ankle joint as well as in structures distal to it (foot and leg). Ask if the athlete can bear weight and also observe his or her gait. Additionally, an inspection of the foot to see if it is pes cavus (arched foot) or pes planus (flat foot) can alter the biomechanics of the ankle joint. Observing the position of the knees, whether they are in valgus (knock-kneed) or varus (bowlegged), can also provide clues to the stress placed on the ankle joint.

Range of Motion. Test the ankle joint both in plantarflexion and in dorsiflexion, as well as inversion (supination). Compare this range of motion with that of the uninjured ankle.

Palpation. Feel the structures around the ankle joint. Pain along the inferior-posterior portion of the lateral ankle joint (distal fibula) may indicate a fracture, whereas pain along the anterior lateral ankle may be a strain of the anterior talofibular ligament. Pain along the inferior-posterior portion of the medial ankle may also indicate a fracture of the distal tibia. It is important to also palpate the surrounding bones of the ankle, including the cuboid, the navicular, and the base of the fifth metatarsal, as these are other commonly missed foot fractures in ankle injuries. Additionally, primary care physicians often miss a fracture of the proximal fibula after a severe ankle injury (Maisoneuve fracture), so every ankle exam should involve palpating the proximal fibula. A connective tissue complex known as the *interosseus membrane* connects longitudinally in between the tibia and the fibula. It is also known as a syndesmosos. This distinct, often missed fracture occurs due to the tremendous force of a high-impact ankle injury, which travels along the syndesmosis and exits at the proximal fibula. Furthermore, palpating distal pulses in the foot and ankle as well as checking for paresthesias may indicate neurovascular compromise.

Additional Testing.

- *Ligament laxity:* Checking for ligament laxity with "drawer tests" can help identify partial or complete tears by physical exam alone. This is performed by stabilizing the area above the ankle joint with one hand and placing the other hand behind the heel (calcaneus) of the foot. With the foot in slight plantarflexion, the examiner applies an anterior force on the heel of the foot to see if the joint will gap. An excessive gap (>4 millimeters) with no end point indicates a complete tear of the anterior talofibular ligament. In addition, checking for gapping and an endpoint during inversion testing will also give clues to a calcaneofibular ligament tear.
- *High ankle sprain:* A "squeeze test" of the distal tibia and fibula resulting in pain can indicate a syndesmotic sprain injury. Additionally, a "crossed-leg" test can also be performed. In this exam, while sitting, the athlete places the lateral side of the ankle on the opposite knee. If there is pain directed to the medial side of the ankle, it can indicate a syndesmotic injury.

Ankle sprains are classified into three grades depending on the severity of the injury:

Grade I: No ligamentous tear, no or minimal loss of function, minimal pain, minimal swelling, no or minimal bruising, and no difficulty bearing weight

Grade II: Partial ligamentous tear, minimal to moderate loss of function, moderate pain, moderate swelling, minimal to mild bruising, some difficulty bearing weight

Grade III: Complete ligamentous tear, severe or complete loss of function, severe pain, severe swelling, mild to severe bruising, and difficulty bearing weight

Imaging Studies

X-Rays

Many believe that all ankle injuries should undergo X-ray evaluation, but this is often debated in medical circles. A cost-effective method to determine if X-rays are needed is to use the Ottawa Ankle Rules, according to which ankle X-ray series should be obtained in case of any one of the following:

- Bone tenderness in the distal 6 centimeters of the posterior-inferior portion of the tibia or fibula
- Inability to bear weight immediately after the injury and in the physician's office/emergency room

Foot X-ray series should be obtained in case of any one of the following:

- Bone tenderness at the base of the fifth metatarsal or navicular bone
- Inability to bear weight immediately after the injury and in the physician's office/emergency room

The use of clinical judgment is emphasized when applying the Ottawa Ankle Rules; their use is at the medical provider's discretion. If a finding on a physical exam is concerning (such as tenderness to palpation at the cuboid), then X-rays should be performed.

If the initial radiographs are negative for fracture but the physician still strongly suspects that there might be one, the patient can be immobilized and given crutches with instructions to return for repeat radiographs in 1 to 2 weeks.

Computed Tomography (CT) Scans

If the radiographs are negative and conservative treatment of a presumed ankle sprain does not improve the athlete's symptoms, a CT scan can be considered to test further for a possible fracture.

Magnetic Resonance Imaging (MRI)

If an athlete has recurring symptoms due to an ankle injury or sprain, an MRI can be considered to further evaluate the soft tissue structures as well as bone contusions or fractures. Depending on the MRI findings, either continued nonsurgical management or surgical intervention may be followed.

Treatment

The basic tenets of ankle sprain treatment include the PRICE (*p*rotection, *r*est, *i*ce, *c*ompression, and *e*levation) method:

For Grade I ankle sprains, protection may or may not be needed. Simple RICE therapy with activity as tolerated is initiated. Initially, range-of-motion exercises are instituted to prevent stiffness, and then gradually, strengthening and balance exercises are recommended.

For Grade II ankle sprains, PRICE treatment is used, and the ankle can be protected with the use of an air-cast splint. Once the pain and swelling have improved, return to activity and stretch/strength therapy are recommended.

For Grade III ankle sprains, the athlete may need to be immobilized in a short leg cast or cast-brace for 2 to 3 weeks. Rarely will an individual require surgery, unless there is another complicated issue. Afterward, treatment is similar to that for Grade I and II injuries.

Anti-inflammatories such as ibuprofen can be used, and analgesics such as acetaminophen may also be helpful for pain control.

Surgical intervention is reserved for those cases where conservative therapy with immobilization and physical therapy has failed.

Prevention of Injury

To help prevent ankle sprains, it is important to review what predisposing factors can be changed.

Those with a previous history of ankle sprains have a higher chance of reinjury, and the greater the number of past sprains the greater the likelihood of recurrence. Lace-up ankle braces have been found to be useful for those with this kind of injury history. Taping can temporarily help stabilize the injured ankle, but it has limited use after 20 to 30 minutes of activity.

Decreasing the amount of stress on the ankle joint will also be helpful. Weight loss in those who are overweight and orthotics for those with foot biomechanic issues can be considered.

Continuous training will help develop strength and proprioception of the ankle, and realizing your body's limits by recognizing the warning signs that you are susceptible to injury is important.

Ankle Support

Ankle support refers to any of several means by which external stabilization can be applied to the ankle joint. This typically includes both bracing devices and taping. Ankle support is relevant to the field of sports medicine because of the high incidence of ankle injuries among athletes participating in sports. Approximately 15% to 25% of all musculoskeletal injuries are ankle sprains. Athletes involved in basketball, football, and volleyball typically have the highest rates of ankle sprains. This entry reviews the types of ankle supports, the indications for their use, and the associated risks and benefits.

Types of Ankle Support

Ankle supports can be categorized as *bracing* or *taping*.

Bracing

Bracing can be divided into rigid and functional. *Rigid bracing* (i.e., a cast or removable boot) is typically reserved for acute injuries and is not adaptable for use during sports since it immobilizes the ankle in all planes of motion. *Functional bracing* allows for improved dorsiflexion and plantarflexion but still limits inversion and eversion motions. Functional bracing is therefore used most often in athletes during recovery from acute injuries and for return to play. The two most common types used for athletes are semirigid and soft braces. Semirigid braces incorporate thermoplastic molded medial and lateral supports that are typically either padded or have air-filled chambers. They are then secured around the lower leg with Velcro straps. Soft braces are canvas or neoprene based, and most lace up the front. Several soft braces have a lateral and/or medial plastic buttress and Velcro straps that secure them into position. They tend to be cheaper than semirigid braces and are easier for the athlete to obtain since they can typically be purchased in pharmacies and sporting good stores. Functional braces range in price from $25 to more than $100.

Taping

Taping is another form of ankle support. Certified athletic trainers (ATCs) are best qualified to tape athletes properly. The exact methods of taping differ, but the basic components of any ankle taping include Tuf Skin application, heel and lace pads with skin lube to prevent skin blisters, alternating anchor strips and horseshoe strips, heel locks, a figure eight, and closing strips to hold it all together. Prewrap is used between the skin and the tape by some athletic trainers. This may reduce skin irritation; however, some athletic trainers feel that it results in less support by the tape. After athletic participation, the tape is removed by cutting it off and is therefore not reusable. The average cost of a roll of tape is around $1.50. Usually, two ankles can be taped with this quantity. Therefore, long-term use of ankle taping can be costly.

An ankle brace makes it possible to compete in sports activities despite an injury.

Source: Can Stock Photo, Inc.

Risks and Benefits of Ankle Supports

Bracing, either semirigid or soft, has several advantages over taping. Although there is an upfront cost to the athlete, it is reusable. Athletes can put on their braces themselves and therefore do not need to have access to an athletic trainer, as for taping. They can also easily adjust the brace's fit for comfort and stability throughout the practice sessions and the competition. Adjustments can be made quickly and without the assistance of a trainer.

The main benefit of taping is that it is less bulky than most braces and therefore can fit easily into all footwear. The cost of taping also usually falls on the athletic department, and therefore, in most instances it is free for the athlete. It also creates a lot of waste since it is disposed of after use. The biggest problem associated with taping is that the tape loosens after approximately 20 minutes. Unfortunately, most athletic practices and competitions outlast the "life" of the tape. Therefore, the protective benefits of the tape are lost, and the athlete may be at an increased risk of injury during this time.

Indications for Ankle Support

Primary Prevention

Very little scientific data exist to support the use of ankle bracing in preventing ankle injuries in an athlete who has never sustained an ankle sprain before. However, primary prevention, or prophylactic use of a brace, is very common. Because basketball, volleyball, and football have the highest injury rates, these are also the sports where the greatest number of athletes choose to use a brace for primary prevention. Functional semirigid or soft braces are the most commonly used.

Acute Injuries

Traditionally, treatment for an acute lateral ankle sprain has been with rigid bracing. In recent years, research has shown that early motion improves recovery, so functional bracing has come into favor. Many athletes who visit an emergency room or require urgent care have their injured ankle placed into a semirigid brace. These athletes will typically need to be transitioned into a soft brace or a semirigid brace with a hinge at the ankle joint to allow more functional athletic movements. Taping can also be applied under the brace to provide a small degree of additional support.

Secondary Prevention/Chronic Injuries

Ankle bracing plays an important role in secondary prevention, the prevention of another ankle sprain after one has already occurred. Scientific evidence overwhelmingly supports the use of an ankle brace during sports after an athlete has sustained an initial ankle sprain. Regular use of a brace can help prevent reinjury as rhe athlete undergoes full rehabilitation with a focus on proprioceptive skills. An ankle brace should be used for 6 months after the initial ankle sprain.

With recurrent ankle inversion injuries, chronic ankle instability may result. Individuals with functional instability can also benefit from the use of ankle braces. Long-term use of bracing may be more beneficial for this athletic population.

Anorexia Nervosa

Disordered eating has been found to be more prevalent in athletes than the general population. Various studies have shown the prevalence to range from 15% to 62% among athletes, and female athletes are more often affected than male athletes. Disordered eating includes the spectrum of anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified. This entry focuses specifically on anorexia nervosa, which is seen in 1% to 3% of the general population, and highlights the importance of proper diagnosis and treatment to prevent its devastating health consequences.

Definition

Anorexia nervosa is defined in the *Diagnostic and Statistical Manual of Mental Disorders*—fourth edition, text revision (*DSM-IV-TR*). It is a type of disordered eating that is characterized by refusal to maintain a normal body weight (less than 85% of expected weight), intense fear of gaining weight (in spite of being underweight), a disturbed self-evaluation of body shape, and three consecutive cycles of amenorrhea.

There are also two specific subtypes of anorexia nervosa: (1) a restricting type and (2) a binge-eating/purging type. In restricting-type anorexia nervosa, the athlete does not regularly engage in self-induced vomiting or the use of laxatives or diuretics. In the binge-eating/purging type, people do engage in these types of behaviors.

Risk Factors

There are many contributing factors that can place an athlete at higher risk for anorexia nervosa. Athletes are most at risk during adolescence and young adulthood. They often face pressure to perform well in their sport from peers, parents, coaches, and others in the community. Athletes are also often placed in an environment where they have a strong personal desire for accomplishment; attaining a certain body type can often help them accomplish their goals.

Participation in certain sports can increase the risk of disordered eating as well. Sports with weight classifications, such as wrestling, boxing, and weight lifting, can lead to disordered eating patterns. In sports such as gymnastics and figure skating, athletes are under greater pressure to maintain a thin body. Also, there are sports where a lean body can contribute to performance, including long-distance running, swimming, and track events.

Additionally, athletes with poor self-esteem, poor body image, a history of sexual abuse, and a family history of substance abuse, mental illness, and disordered eating are at higher risk of developing anorexia nervosa.

Evaluation

Prompt identification of athletes at risk for anorexia nervosa is an important step in prevention of disordered eating. Early intervention can be successful in preventing its devastating health consequences. When there is concern that an athlete is engaged in disordered eating behaviors, a complete history and physical examination are necessary. All athletes should be asked about their training regimen and nutrition history, and female athletes should be asked about menstrual irregularities. Specifically, a nutrition history may include recent weight loss or gain, maintenance of a diet diary, and identifying restrictions on the types of food the athlete eats. They should also be asked about self-image, body satisfaction, performance in classes or work, and satisfaction with current athletic performance. Any coexisting medical disorders should be evaluated, as well as past history of eating disorders and current engagement in any binge-eating/purging type of behavior.

Physical examination should include a head-to-toe evaluation, including a pelvic exam for women. Signs that may be present on physical examination include low body weight, low blood pressure, bradycardia, lanugo (growth of fine, downy body hair), dry skin, thinning scalp hair, decreased body temperature, facial edema, abdominal tenderness, and cardiac arrhythmias. If there is sufficient concern, a complete blood count, a comprehensive metabolic panel, a lipid panel, urinalysis, and a ferritin and thyroid panel should be obtained to rule out specific medical conditions. Common laboratory abnormalities seen with anorexia nervosa include low white blood cell count, elevated liver function tests, increased total cholesterol, hypokalemia, hyponatremia, hypomagnesemia, hypophosphatemia, hypocalcemia, ketonuria, and low ferritin. Additionally, an electrocardiogram (EKG) should be obtained to rule out ventricular arrhythmias. If severe abnormalities are found, urgent inpatient admission may be warranted.

Medical Complications

The adverse health outcomes associated with anorexia nervosa can become chronic, lifelong concerns and may be fatal. There is a 12% to 18% mortality associated with untreated anorexia nervosa. Specific consequences of anorexia nervosa can include menstrual abnormalities, infertility, low bone density, malnutrition, delayed gastric emptying, cardiac arrhythmias, and death. The mental health impacts of disordered eating—poor performance in school, work, and athletics; loss of friendships; and poor self-esteem—are difficult to measure but may be profound.

Treatment

The best treatment for anorexia nervosa is prevention. This should be done by identifying those

Diagnostic Criteria for Anorexia Nervosa

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of the expected.)

B. Intense fear of gaining weight or becoming fat, even though underweight.

C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.

D. In postmenarcheal females, amenorrhea, that is, absence of at least three consecutive menstrual cycles (a woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen) administration.

Specify Type:

- Restricting Type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).
- Binge-Eating/Purging Type: During the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

athletes most at risk for developing disordered eating. This may include athletes with specific family histories, those with a past history of disordered eating behavior, athletes immediately after injury, or athletes in sports that place specific emphasis on thin body types or endurance. Ideally, effective screening for disordered eating should take place at preparticipation physicals each year. Early counseling may be effective in preventing disordered eating.

Treating an athlete with anorexia nervosa requires a well-coordinated team approach. Involvement of the athlete, parents, coaches, athletic trainers, nutritionists, psychologists, and physicians is critical for successful treatment. Any specific abnormalities found on physical exam or laboratory analysis may warrant inpatient hospitalization and should be addressed immediately given the high mortality rate associated with this disorder. Proper outpatient treatment is also critical to avoid any further progression of serious complications. This may include individual or group therapy, and SSRI (selective serotonin reuptake inhibitor) therapy should also be considered. Athletes should be closely monitored for recurrence of disordered eating behavior, as well as for low bone density or menstrual irregularities. Athletes with anorexia nervosa may also need modification of their level of involvement in competition and/or their training program.

Anterior Cruciate Ligament Tear

The *anterior cruciate ligament* (ACL) is one of the major ligaments of the knee. It connects the thighbone (femur) and the shinbone (tibia) and prevents the tibia from moving forward when a person turns and pivots. Although a torn ACL used to be an injury that occurred only in athletes, it is becoming more common in any age-group and at various activity levels as more and more people become physically active. Other tissues in the knee, including the meniscus (a fibrocartilaginous shock absorber) may be injured at the same time, as may other ligaments in the knee. The treatment plan will be influenced by what tissues are injured, the current activity level, and what activities the individual would like to do in the future. The final plan of care will be decided on together by the patient and the physician.

Anatomy

The ACL is probably the best known of the four major ligaments of the knee. It connects the tibia, a bone of the lower leg (shinbone), to the femur (or thighbone). It prevents the tibia from moving too far forward in relation to the femur. The ACL has to work the hardest, and is the most important, in sports, where it provides stability during cutting and pivoting motions (e.g., in soccer and football). An injury to the ACL may require surgery followed by a rehabilitation program to allow for return to high levels of activity. The athlete who suspects that he has suffered a knee injury should seek out a qualified physician for an evaluation (Figure 1).

Causes

Most injuries to the ACL occur when an individual makes a sudden cut or turn and the foot stays planted on the ground. Injuries can also take place when landing from a jump (volleyball and basketball) or during contact with another player. Downhill skiing is also an activity that can be a risk for ACL injuries, especially with boots that come relatively high up the calf, which stabilize the ankle but result in increased potential stresses across the knee.

Women are known to be at higher risk for ACL injury than men; however, much of this risk can be reduced by participation in conditioning and training programs that emphasize the importance of strength and flexibility as well as the proper warm-up and cooldown periods. Learning correct jumping and landing techniques is also a critical component of these programs. Programs that take as little as 15 minutes three times a week have been found to be effective. (See the Further Readings. Work on soccer players was spearheaded by Bert Mandelbaum, MD, and Holly Silvers, PT. The website www.aclprevent.com/pepprogram.htm provides a detailed ACL injury prevention program that can be accomplished in 15 minutes three times per week during the season, replacing the traditional warm-up period. Videos and instructions on the Sportsmetrics™ program for collegiate athletes are available through its website, www.sportsmetrics.net.)

Symptoms

Patients who have an ACL injury frequently feel or hear a "pop" in the knee at the time of injury and often will experience swelling within the first 2 hours of injury. This is due to bleeding within the joint from torn blood vessels in the injured ligament. The knee may be painful to walk on, especially if other structures within the knee are also damaged. The instability caused by the loss of the ligament function can result in a "giving way" or "loose" feeling in the knee. This may be particularly noticeable when trying to change directions during walking or running.

After several weeks, the swelling will typically subside, and walking becomes more comfortable. Symptoms of instability that persist often warrant surgical intervention, although some ACL injuries

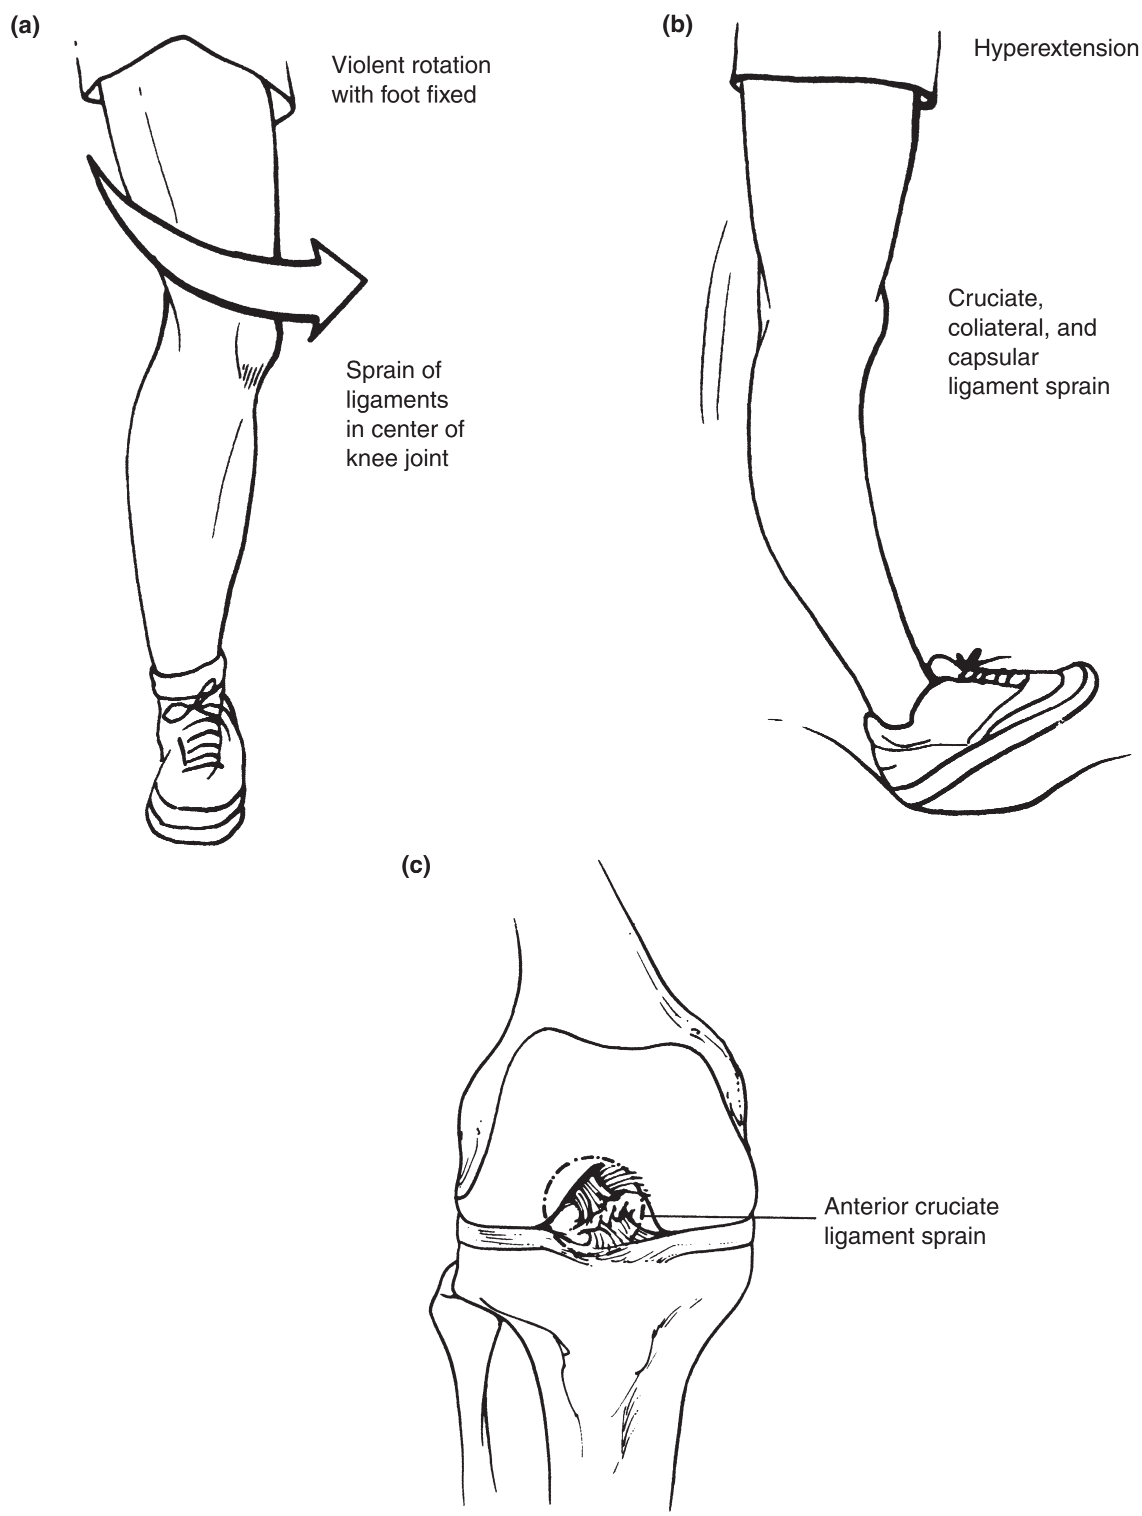

Figure 1 (a), (b) Mechanisms of an (c) Anterior Cruciate Ligament Tear

Notes: An anterior cruciate ligament (ACL) sprain is a stretch, tear, or complete rupture of one of the two ligaments that lie in the center of the joint, connecting the ends of the thigh- and shinbones. Unlike most ligament sprains, which are classified according to severity as first, second, or third degree, ACL sprains are almost always complete ruptures—the ligament is torn completely in two.

can be treated nonoperatively (see discussion below). Long-term instability, or looseness, of the knee, however, is believed to predispose patients to early osteoarthritis.

Diagnosis

The history and physical examination are important for diagnosis of an ACL tear. In an acute (sudden) injury, joint swelling is a good indicator. Swelling that occurs within the first few hours of the injury can be especially indicative of an injury causing bleeding in the joint, while swelling that occurs the next day may be due to the inflammatory response. In addition, examination of the knee with specific tests may be helpful in determining whether the injury is to the ACL or another structure within the knee, such as the menisci or the cartilage.

Imaging of the knee may also be recommended. X-rays can be used to rule out a fracture, but the ACL itself will not be visible on these studies. To assess the ACL, a magnetic resonance imaging (MRI) scan may be ordered. In some cases, arthroscopy (putting a small camera into the joint) may be required to determine if there is a tear in the ACL. This is rarely required; however, if this is needed, treatment of the tear can usually be accomplished at the same time.

Treatment Options: Nonoperative Approach

Some individuals who tear their ACL may elect not to have surgery but may choose to have rehabilitation to treat their knee. People who decide not to have surgery usually do not participate in sports that involve cutting or pivoting activities that would place stress on the knee. Most people with this type of lifestyle will be able to function normally without having surgery to reconstruct their ACL.

Patients are referred to physical therapy to work on walking normally, strengthening, range of motion, and controlling swelling and pain. Even if surgical reconstruction is elected, patients will still need rehabilitation prior to surgery. Most patients are required to achieve normal walking, nearly full motion and strength, and reduced swelling before surgery. This helps minimize problems with motion and strength postoperatively.

Treatment Options: Operative Approach

Surgical Techniques

Because a repair (or suturing together) of torn ACL fibers is not effective, the current surgical treatment of an ACL tear is to remove the torn ACL tissue and replace it with a graft of tendon. Commonly, this is an *autograft* (from the patient's own tissue). There are several choices for where the tendon tissue to replace the ACL can come from. These include two of the hamstring tendons or, less commonly, part of the patellar tendon (the tendon from the patient's kneecap to the bottom leg bone). Allograft tissues that come from a donor can also be used, although these are less frequently recommended as a first-line graft choice in patients under 20 years, owing to the higher failure rate in patients in this age-group. Allograft tissues include either a patellar tendon or other soft tissue, including most commonly the tibialis anterior and Achilles tendons. In a scientific review of autograft choice, the graft does not influence the outcome. Rather, accurate placement by the surgeon, stable initial fixation of the graft, patient compliance, and rehabilitation are believed to optimize the results. The surgeon performs the surgery with the help of a small camera called an arthroscope. The skin incisions are only for the surgeon to harvest the graft if the patient chooses autograft and to drill tunnels at the original site of the ACL. The graft is placed within the tunnels and fixed by any of several means to provide immediate stability prior to healing and to help stabilize the graft to the bone.

Risks of Surgery

Risks of surgery include bleeding, infection (around 1%), nerve or vessel injury (most commonly an area of numbness on the skin adjacent to the incision), failure of the graft (up to 10%), knee stiffness (5–25%), and the need for further procedures. Rare risks include bleeding from acute injury to the popliteal artery (overall incidence is 0.01%), weakness or paralysis of the leg or foot, and a blood clot in the veins of the calf (0.1%). The goal of ACL reconstruction surgery is to prevent instability of the knee. It does not make the knee completely normal or return it to its preinjury status. Patients will still have an increased risk of developing arthritis in the knee after an ACL injury, even if surgery is performed.

Risks Specific to Allograft Use

Allografts are grafts taken from cadavers and are becoming increasingly popular. The advantages of using allograft tissue include elimination of pain caused by obtaining the graft from the patient, decreased surgery time, and smaller incisions. Although there is some theoretical risk of disease transmission, including viral or bacterial infection, the use of allografts that have undergone rigorous donor screening, serological testing, and formal processing has significantly reduced this risk. The Food and Drug Administration (FDA) has regulated this field very closely since 1993 to ensure the safety of allograft transplant. Over the past decade, more than 5 million musculoskeletal allografts have been distributed to surgeons for transplant into patients with a remarkable record of safety.

Alternatives to Surgery

Surgical treatment is usually advised for patients who want to get back to activities that involve cutting and pivoting. However, deciding against surgery is reasonable for select patients. Nonoperative management of isolated ACL tears is likely to be successful or may be indicated in patients

- with partial tears and no instability symptoms;
- with complete tears and no symptoms of knee instability during low-demand sports, who are willing to give up high-demand sports; and
- who do light manual work or live sedentary lifestyles.

In addition, children and adolescents who still have open growth plates should discuss this with their surgeon, along with their parents or guardians. Some patients will be advised to use nonoperative treatment (including bracing, physical therapy, and activity modification) until additional growth is completed, at which time an ACL reconstruction can be performed. For children with open growth plates having instability symptoms even with these treatments, other procedures may be used to temporarily stabilize the knee until growth is near completion, when a standard ACL reconstruction can be performed more safely.

Preoperative Care

The patient who decides to have reconstructive surgery to treat an ACL tear may be asked to have a complete physical exam by the family physician before surgery to assess his health and to rule out any conditions that could interfere with the surgery.

Before surgery, patients should tell their doctor about any medications being taken and will be told which to stop taking before surgery. This typically includes aspirin and anti-inflammatory medications such as ibuprofen (e.g., Advil, Motrin) or naprosyn (e.g., Aleve), all of which should be stopped 10 days before surgery. Acetaminophen (e.g., Tylenol) may be taken in the week preceding surgery, but be sure not to exceed the recommended daily dose.

Tests such as blood samples or a cardiogram may be ordered by the doctor to help the patient prepare for the procedure.

Rehabilitation

Nonsurgical Rehabilitation

Nonsurgical rehabilitation for an ACL injury will typically last 12 weeks if no mechanical symptoms are present (symptoms such as locking, catching, or giving way). This will consist of exercises to strengthen the muscles around the knee, avoidance of high-impact activities, and possibly use of a brace to stabilize the knee during the healing process. The patient can return gradually to activities when there is no more swelling in the knee and no pain and the patient has regained complete strength and control of the knee.

After Surgery

A cast or brace immobilizes the knee after surgery. Patients typically complete a course of rehabilitation exercises before gradually resuming normal activity.

Most doctors will have their patients take part in formal physical therapy after ACL surgery. This is typically a program that emphasizes regaining range of motion and strength of the knee. Many programs consist of a graded set of activities, with the early postoperative exercises putting no stress on the ACL, gradually progressing to more difficult and challenging exercises by the fifth or sixth month.

Apophysitis

Apophysitis is an overuse injury to a growth plate, commonly seen in young athletes. Apophysitis can be seen in many different parts of the body, including the elbow, pelvis, knee, and foot. It is one of the most common injuries seen in elementary-age children and young adolescents.

Anatomy

An *apophysis* is a bony protuberance near a physis, or growth plate, and serves as the insertion site of major tendons and ligaments. A physis, consisting of cartilage and new bone, is where bones actively grow during development, and as a bone matures, the physis will fuse and become all bone. However, while the physis is still open, it is weaker than all the surrounding tissues, including the formed bone, ligaments, tendons, and muscles, so when stress is applied to an apophysis, it generally is the part that is injured, resulting in apophysitis. In most cases, the tension from a repetitively firing tendon is what causes the apophysitis.

Epidemiology

The increase in organized sports participation has resulted in a similar increase in injuries among pediatric athletes. Increased specialization at a young age, year-round training, and increased intensity of training at an early age also contribute to overuse injuries in general and to apophysitis in particular.

Causes

Most cases of apophysitis have a number of causes. These causes can be divided into two broad categories: intrinsic and extrinsic. Intrinsic factors are issues related to the patient's body. Examples include biomechanical abnormalities such as pes planus (flat foot), pes cavus (high arches), excessive pronation, limb length differences, or abnormal rotation of the thigh (femoral anteversion). Muscular imbalances can be another intrinsic factor. If one muscle is significantly stronger than its antagonist muscle (e.g., the quadriceps and hamstring muscles), then abnormal stresses can occur at a joint, resulting in injury. This often occurs when an athlete focuses too much on one muscle group. Another common cause is inflexibility. Children who are going through their adolescent growth spurt are at risk for this because bones tend to grow faster than muscles, resulting in inflexibility. The growth spurt also happens to be the time when many types of apophysitis are at highest risk. Muscular weakness, poor conditioning, or inadequate muscular endurance can also cause apophysitis.

Extrinsic factors are issues related to the patient's interaction with the environment. Shoes are a common extrinsic factor. It is important for athletes to use shoes that are designed for their sport, appropriate for the competition and practice surface, and correct for their foot type. It is also important to replace shoes regularly; it is generally recommended to replace running shoes every 300 to 500 miles (mi; 1 mi = 1.6 kilometers) and other shoes every season. Training errors are also another common extrinsic factor. Many athletes increase their training intensity too fast, resulting in an overuse injury. Other training errors include improper techniques, such as improper throwing or weight lifting, training on too hard or too soft a surface, or using equipment that is not suited to one's size, age, or ability.

Symptoms and Signs

Most cases of apophysitis have a gradual onset of pain. Pain initially tends to be worse after activity and improves with warming up, but as the pain worsens, it will be present during activity and, eventually, become constant. Specific activities tend to worsen the pain, depending on which type of apophysitis the patient has. There may be swelling, or bony protuberances may become more prominent. Examination will show point tenderness at the site of the apophysitis, and resisted strength testing of the affected tendon may be painful. The natural history of most of these entities is to resolve without sequelae once the physis fuses.

Diagnosis

Most cases of apophysitis can be diagnosed based on the history and physical exam. However, X-rays can sometimes be helpful. X-ray films may show enlargement or fragmentation of the apophysis or widening of the physis. Comparison views of the unaffected limb can be useful to see differences, as the appearance of growth plates can be extremely variable. Magnetic resonance imaging (MRI) and computed tomography (CT) scans are generally not needed unless the diagnosis is in doubt.

Treatment

Treatment will depend on the location of the apophysitis, but there are some general principles. Pain is generally controlled initially by ice and nonsteroidal anti-inflammatory drugs (NSAIDs). Relative rest is often the most important treatment, limiting the activities that cause pain. Rehabilitation to address muscular imbalances, muscular weakness, and lack of endurance is important to allow return to activities. Biomechanical abnormalities should be addressed, often with orthotics or heel lifts. Sports techniques should be analyzed, and if any errors are found, they should be corrected. Return to activities should be gradual, avoiding too rapid an increase in intensity. Since most of the apophysitis will eventually resolve when the physis closes, sometimes treatment involves trying to control the symptoms in order to allow participation until skeletal maturity is reached.

Examples of Apophysitis

Medial Apophysitis of the Elbow

Medial apophysitis of the elbow affects the medial epicondyle, the attachment of the flexor-pronator muscle group and the ulnar collateral ligament. It tends to present in children aged 9 to 14 in overhead sports and is often seen in pitchers who pitch too much or are attempting to break pitches at too early an age. If it is allowed to progress, it can result in an avulsion fracture of the apophysis. It presents with medial elbow pain with throwing, decreased velocity or distance of pitches, and decreased effectiveness while pitching. An exam will show tenderness on the medial epicondyle, a possible flexion contracture, and pain but no laxity with valgus stress testing. Treatment involves rest from all throwing for a minimum of 4 weeks, followed by a progressive throwing program over 6 to 8 weeks.

Iliac Crest Apophysitis

Iliac crest apophysitis is caused by tension on the iliac crest from the oblique muscles of the abdomen and the tensor fascia lata of the lateral thigh. It most commonly presents in runners during the adolescent growth spurt. Pain is worsened by running, walking, and twisting and bending of the torso. Examination will show tenderness over the iliac crest, and often patients will have tight hip flexors and abductors. Treatment involves rest, stretching, and strengthening of the affected muscles.

Osgood-Schlatter and Sinding-Larsen-Johansson Diseases

These two diseases affect the extensor mechanism of the knee. Osgood-Schlatter (OS) affects the tibial tubercle, the insertion of the patellar tendon, while Sinding-Larsen-Johansson (SLJ) affects the distal pole of the patella at the origin of the patellar tendon. They present in preteens (SLJ) or early teens (OS), with anterior knee pain that becomes worse with jumping and running. Patients with OS will often have prominent tibial tubercles. Examination will show tenderness over the distal pole of the patella in SLJ and over the tibial tubercle in OS. Patients will often have hamstring inflexibility. Treatment involves rest, strengthening of the extensor mechanism, and stretching of the hamstrings. Patellar tendon straps may give symptomatic relief.

Sever Disease

Sever disease is apophysitis of the calcaneus and occurs at the insertion of the Achilles tendon into the calcaneus. It presents in 9- to 12-year-old children, especially those who do a lot of running. Pain is worsened by running, kicking, and jumping. Examination will show tenderness over the posterior calcaneus, where the Achilles inserts, and the patient usually has very tight gastrocnemius and soleus muscles. They also often have biomechanical abnormalities with pes planus or excessive pronation. Treatment involves rest, stretching of the calf musculature, and strengthening. A heel lift can provide temporary relief of pain but should only be used for a short period of time as it can actually worsen the flexibility issues.

Arch Pain

The term *arch pain* describes an injury to the plantar fascia ligament of the foot. The *plantar fascia* is a strong fibrous band that runs along the bottom of the foot, starting from the heel bone, spanning the arch, and subsequently inserting into the ball of the foot. Excessive stress on the plantar fascia results in repetitive microtrauma, causing mild tears of the ligament. Arch pain is a common injury in runners and affects both the recreational and the professional runner. However, a nonathlete can also suffer from arch pain as a result of everyday walking or standing activity.

Although arch pain is not dangerous, it can range from mild to debilitating, resulting in limitation of activity. It is frequently seen in middle-aged women and men but can affect all age-groups, especially the very ambitious young athlete. Prompt identification of the causes and early treatment can often limit the course of the injury.

Anatomy

The plantar fascia is a strong band of connective tissue that originates at the heel bone, spans the arch of the foot, and subsequently connects to the toes. The fascia is part of a complex dynamic system of bones, tendons, and muscles of the foot that hold up the arch during weight bearing. The plantar fascia also assists in the transfer of weight from heel to toe during standing, walking, running, and jumping.

Symptoms

Typically, arch pain is described as occurring with the first steps in the morning or when getting up from a seated position. This is because the plantar fascia, foot muscles, and heel cord tighten overnight and while seated, with the foot in a plantarflexed position (toes pointed downward). On standing, the plantar fascia ligament is stretched, and pain results.

The pain symptoms are commonly described as a sharp stabbing or burning sensation. As the patient walks, the ligament loosens, resulting in diminishment of the pain symptoms. The pain will often decrease during activity; however, it typically returns after a period of resting. Frequently, an area of tenderness can be palpated at the medial insertion of the plantar fascia ligament into the heel bone.

Causes

The most common cause of pain of the arch is inflammation of the plantar fascia due to tiny tears of the plantar fascia through chronic repetitive stress. These *microtears* may lead to degenerative changes of the fascia. Excessive stress in a biomechanically imbalanced foot leads to repetitive microtrauma, causing small microruptures of the plantar fascia at its insertion at the heel. This subsequently leads to inflammation and pain. If left untreated, a so-called *heel spur* may develop as a sign of chronic overuse. It is important to note that the spur is only a symptom of the excessive stress and not the cause of the pain.

Certain foot types are predisposed to stress on the plantar fascia. These foot types include flat feet (pes planus) and high-arched feet (pes cavus). Flat feet tend to pronate, resulting in inward rolling of the arch during gait. This motion increases the stress along the plantar fascia ligament. Conversely, high-arched feet tend to have tight calf muscles with shortening of the Achilles tendon and plantar fascia, which also increases the biomechanical stress along the arch.

Injury to the plantar fascia can also result in arch pain. Injuries can be due to excessive training, a sudden increase in training volume, exercising on hard surfaces, and wearing poorly supportive footwear. For the more recreational athlete, body weight seems to be an important risk factor in damaging the fascia over time, consequently leading to pain. It is important to identify the cause of arch pain, whether it is biomechanical imbalance or overtraining. Proper identification will help direct treatment as well as prevent recurrence.

Diagnosis

Diagnosing arch pain is based primarily on patient history of symptoms and clinical examination of the foot. Pain symptoms are usually replicated with palpation of the plantar fascia. The most tender point is usually felt on the medial, plantar aspect of the heel, the major insertion of the plantar fascia ligament into the heel bone.

Imaging studies can be obtained to aid in making the diagnosis as well as ruling out other possible injuries. Plain X-rays of the foot can eliminate bone-related causes of heel pain such as bone tumors and cysts. However, X-rays cannot evaluate the plantar fascia itself. Studies that can examine the plantar fascia include ultrasound and magnetic resonance imaging (MRI). Ultrasound can measure the thickness of the plantar fascia, which is increased following injury. In cases where standard therapy has been ineffective, an MRI study may be appropriate to confirm injury to the plantar fascia and to eliminate causes of pain such as stress fractures of the heel or soft tissue tumors.

Other conditions that may mimic arch pain should be evaluated, especially in patients with ongoing pain and atypical symptoms. These conditions include rheumatoid arthritis, ankylosing spondylitis, Reiter syndrome, rupture of the plantar fascia, stress fracture of the heel bone, calcaneal apophysitis, necrosis of the plantar fat pad, sciatica, and fibromatosis of the plantar fascia.

Conservative Treatment

Treatment should always start conservatively and address the inflammatory as well biomechanical disorders. There is no single treatment that is accepted to be universally successful to treat plantar fasciitis. Instead, the pain symptoms respond to a variety of different conservative therapies.

Conservative care consists of nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroid injections, physical therapy, and home stretching exercises. There is some evidence that the use of NSAIDs may decrease pain and decrease the level of inflammation, but they do not address the biomechanics of the foot.

The biomechanics of the foot can be addressed with taping as well as orthotic devices. Antipronation taping can be done by a physical therapist to prevent the pronation motion that aggravates the arch pain. Over-the-counter orthotic devices can be purchased to prevent pronation and provide support to the plantar fascia ligament. In some cases, custom orthotic devices may be necessary to control the biomechanical factors involved in the arch pain.

Contracture of the plantar fascia and Achilles tendon has been implicated in the development and progression of arch pain. Thus, initiation of physical therapy to stretch these specific contractures is essential for resolution of the arch pain. Additionally, patients are educated on a home stretching regimen to continue treatment and prevent recurrence of the contractures. In addition to stretching, strengthening of specific muscle groups to prevent increased stress on the plantar fascia is effective in the treatment of arch pain.

Stretching of the plantar fascia and Achilles tendon can be achieved with night splints. Worn at night, these braces stretch the contractures while sleeping, reducing the early-morning pain commonly experienced with arch pain.

Physical therapy may also address the inflammation of the plantar fascia ligament with specific techniques such as ultrasound therapy iontophoresis. Iontophoresis uses a small electrical charge to deliver anti-inflammatory medications through the skin to the inflamed area. Use of this therapy can decrease the pain symptoms.

In severe cases that have been resistant to conservative therapy, an injection of corticosteroids in combination with a local anesthetic may be considered. This is typically given when other treatments have failed and pain has persisted for more than 6 months. The injection itself is painful, and there are associated risks, such as a steroid flare reaction, necrosis of the plantar fat pad, and recurrence of pain after a short period of time.

Although discussed controversially in the literature, extracorporeal shock wave therapy has been applied successfully in some cases. Extracorporeal shock wave therapy uses high-energy impulses to inflict microtrauma on the inflamed area. This microtrauma results in new blood vessel formation and promotes healing of the inflamed area.

Finally, modification of training is inevitable. Modification of training should focus on shifting from high-impact activities, such as running, to low-impact activities, such as swimming, treadmill training, or biking. In severe cases, cessation of activity and immobilization may be necessary to allow proper healing of all inflamed tissues.

A combination of conservative treatments has shown a success rate of approximately 90%. Thus, the initial treatment of arch pain should consist of the aforementioned therapies. In case of chronic pain symptoms, surgical intervention should be considered.

Surgery

In some cases, conservative therapy fails to adequately relieve the arch pain. When surgical treatment is required, the procedure of choice typically involves releasing the plantar fascia close to its insertion into the heel bone. If a very large heel spur is present, it may also be resected, but this is not recommended on a general basis. Postoperative healing may take several months, with protection of the heel necessary until the pain decreases. Typical operative complications include poor wound healing, infection, nerve injury, and heel stress fracture from the altered biomechanics of the foot following surgery.

Conclusion

Arch pain can be a significant problem affecting both the professional and the recreational athlete. Early diagnosis and treatment can help limit its course and prevent further interruption of athletic activities. Treatment of arch pain primarily consists of addressing the biomechanical issues and reducing the inflammation of the plantar fascia ligament. In most cases, the treatment of arch pain can be addressed conservatively, with only mild modification of sports activities. However, in severe cases, surgical intervention may be necessary.

Archery, Injuries in

Archery is seldom listed as a sport associated with injury. It is, however, far from injury-free. In 1989, D. L. Mann and N. Littke published the findings of a study of injury rates among 21 elite Canadian archers. Shoulder injuries predominated. They pointed out that elite male archers pull a 45-pound (lb; 1 lb = 0.45 kilogram) bow about 75 times a day in competition, approximating 3,400 lb (1,546 kg) pulled in a single day. This represents an enormous strain on the bony, ligamentous, and muscular structures of the shoulder girdle. In 1991, S. Fleck and G. Renfro reported that the rate of shoulder injury among archers approached that of elite swimmers. In 1984, Ann Stirland (senior consultant anthropologist with the Mary Rose Trust) postulated a possible correlation between the shoulder condition os acromiale and the protracted and continual use of heavy-poundage English longbows. The longbow used by the Medieval English archer was a 6-foot (ft; 1 ft = 0.30 meter) yew bow with a draw weight between 80 and 180 lb. Os acromiale is believed to be related to rotator cuff tear and was found in many of the skeletons from Henry VIII's flagship *Mary Rose*.

Based on these reports a web-based pilot study was done in 1996 in Britain on the incidence of injury in archers. The survey was posted on a popular Canadian archery website that was known to be visited by elite archers the world over. It was also published in a number of archery magazines in the United Kingdom and internationally. Archers were asked to report injuries that they believed were connected with their sport. Other data collected included country of residence, gender, the archery discipline, the length of time involved in archery, age at the time of injury, and answers to the following questions:

- Which part of the body was injured and which side?
- Are you right- or left-handed?
- How painful was the injury?
- What treatment was given, and how effective was it?
- How much time was spent away from archery as a result of the injury?
- Do you normally use the services of a physiotherapist?

Although this was a self-reporting study, the results obtained supported Mann and Littke's finding that shoulder injuries predominate in elite archery. In the first 12 months of the survey, over 100 reports were received. These reports represented archers from 20 countries, with the majority of reports received from archers in the United States and Canada. Reports were of persistent pain or loss of function in the upper limb, with shoulder pain predominating, but pain in the elbow, forearm, wrist, and hand was also reported. Less common was back pain and miscellaneous injuries to other areas of the body. Heavier draw weights and frequent archery practice seemed to produce the onset of pain. The majority of injuries involved joints in the upper limb and appeared to be related to the repetitive nature of the action of drawing a bow. These symptoms are related to repetitive strain injury to the rotator cuff in the shoulder and epicondyles of the elbow and if not recognized early can progress to muscular injury at the shoulder and elbow.

Working with the British Archery teams between 1990 and 2006, this author found that the findings of the pilot study were confirmed on a number of occasions, with elite archers suffering rotator cuff damage requiring surgical correction. Archers and their coaches need to be made aware of the risks involved in long hours of archery practice and competition. Early signs of repetitive strain injury often go unrecognized in the effort to achieve competitive success. The archer is often tempted to use too heavy a bow draw weight in striving to shoot longer distances as heavier draw weights produce a flatter trajectory of arrow and tighter groups at longer distances.

In archery, injuries to the shoulder occur due to overuse rather than isolated traumatic incidents. Muscular strains are caused by the extra arrows shot in training, changes in style, shooting an overweight bow, or a rapid return to shooting after layoff. The archer must learn that shoulder pain is a sign of early injury and must take corrective action rather than continue to shoot despite the pain. The best treatment for injury is to prevent it from getting worse when early signs appear. The coach should emphasize the use of a proper shooting technique. Careful matching of bow and arrows to the archer is imperative. The archer should realize the importance of warm-up and training programs to condition the muscles of the shoulder and upper back. Archery is an asymmetrical sport, and there is benefit in cross-training in a symmetrical sport such as swimming so that the balance of shoulder musculature is maintained. There is value in seeking the advice of a sports physiotherapist who understands the sport of archery when planning a training program or when rehabilitating from injury.

Between 1993 and 2001, the subject of sports injury in archery was of prime concern to the FITA (International Archery Federation) medical committee. The committee has since published findings of further surveys on archery sports injury in their book *Sports Medicine and Science in Archery*. The importance of shoulder-strengthening exercises for injury prevention is highlighted. They provide a full training program of exercises for strengthening and conditioning the shoulder.

Arousal and Athletic Performance

Understanding how *arousal* (*activation, excitement*) of varying intensity affects athletic performance is important for effective coping with stress-related emotional experiences in sports. What is emotional arousal? How is it manifested and measured? How is it related to the performance process and its outcomes? How can the optimal and dysfunctional effects of emotional arousal on athletic performance be explained? The sections below provide research-based answers to some of these questions.

Arousal as a Category of Bodily Experience

Traditionally, *arousal* describes the intensity of the physiological functions of an organism as a reaction to person–environment (P–E) relationships. However, the definition of arousal as a bodily *reaction* captures only one aspect of P–E relationships. According to Lev Vygotsky, to study something as *indivisible unity,* it is necessary to find a construct that would capture the characteristics of both interacting elements. In psychology, such a construct to study P–E interactions is *experience,* reflecting a person's attitude toward the environment and showing the meaning of environment for the person. Experience has a biosocial orientation because it is always someone's experience of something and as such is best represented as a unit of consciousness. Thus, the analysis of any difficult situation should focus not so much on the situation or on a person per se but on how *this* situation is *experienced* by *this* person.

From this perspective, arousal as *bodily experience* is a component of total human functioning reflecting the nature of past, ongoing, or anticipated P–E interactions. The P–E interactions representing the relationships between task demands and a person's resources include the predominance of an organism over the environment, the balance between a person and the environment, and the predominance of the environment over an organism. Three types of bodily experiences are (1) *statelike* situational experiences; (2) *traitlike,* relatively stable patterns of experience; and (3) *meta-experiences* as preferences and rejections of experiences based on awareness of their helpful or harmful effects. Meta-experiences determine an athlete's appraisal of performance situations and choice of coping strategies.

Multidimensionality of Situational Bodily Experience

Arousal as complex situational bodily experience is multidimensional, and its systems description as a component of performance-related *psychobiosocial states* includes at least five dimensions: *form, content, intensity, time,* and *context.*

Form Dimension

Arousal as situational bodily experience is a component of a performance-induced psychobiosocial state. The form dimension of this state involves several interrelated components with a sample of idiosyncratic descriptive labels (markers): *cognitive* (alert, focused, concentrated, confused, distracted), *affective/emotional* (worried, nervous, happy, angry, joyful, fearful), *motivational* (motivated, willing, desirous, interested), *volitional* (determined, brave, daring, persistent), *bodily (somatic)* (tired, jittery, sweaty, painless, breathless, choking), *motor-behavioral* (sluggish, relaxed, sharp), *operational* (smooth, effortless, easy, clumsy actions), and *communicative* (connected, related, in touch).

Arousal Content

Qualitatively, arousal as a situational *bodily state* of being *awake, activated, excited, energized, wired, psyched up,* or *exhausted* implies different levels of vigor and vitality. These experiences are located in different parts of the body (loose or cold legs, tense face, sweaty arms, and tense neck/shoulders) and accompany unpleasant, stress-related (anxiety, anger) and pleasant (joy, satisfaction, hopefulness) emotions. The physical energy related to these emotions acts to enhance the athlete's performance when properly channelled, whereas detrimental effects are likely when the energy is low or out of control.

The content of bodily experiences can be categorized within the framework of two closely related factors: (1) *hedonic tone* (pleasure/displeasure) and (2) *functionality* (optimal/dysfunctional effects). The four arousal categories derived from hedonic tone and functionality are (1) pleasant and functionally optimal arousal, (2) unpleasant and functionally optimal arousal, (3) pleasant and dysfunctional arousal, and (4) unpleasant and dysfunctional arousal. This framework helps identify the idiosyncratic labels of bodily experiences relevant for performance and reflecting the organism's readiness to perform from an athlete's perspective. Physiological changes (in heart rate, blood pressure, visceral functioning, and other autonomic nervous system reactions) represent another content characteristic of arousal-energizing (or de-energizing) approach and avoidance (or withdrawal) behaviors.

Arousal Intensity

The intensity of the bodily component of performance state characterizes the amount of strength, power, and effort invested in execution of a task and its energizing and organizing effects on performance. Traditionally, the impact of arousal on performance was estimated mainly at the group or interindividual level. This approach ignores the fact that different athletes require different arousal intensity levels (high, moderate, low) to give successful performances. Therefore, it is recommended to focus on estimation of the optimal level of arousal intensity at the individual level.

The "in/out-of-zone" principle (Hanin's individual zones of optimal functioning [IZOF] model) describes emotional arousal/performance relationships at the individual level. Specifically, athletes, depending on their available physical, technical, tactical, and psychological resources and readiness state, perform up to their potential if their actual arousal levels are within earlier established optimal zones of intensity and outside dysfunctional zones of intensity. In contrast, if an athlete's actual state is out of her optimal zone, she is likely to perform below her potential. The in/out-of-zone notion describes an idiosyncratic (high, moderate, or low) range of intensity producing optimal and dysfunctional effects on individual performance.

The concept of "item-intensity specificity," proposed by Charles Spielberger, suggests that the content of items captures the intensity of subjective experiences qualitatively. For instance, anger items vary in their ability to discriminate among different intensities; "upset," "annoyed," and "irritated" qualitatively imply less intensity than items such as "enraged," "furious," or "flared up."

Time and Context Dimensions

The temporal dimension includes the *topological* (phases, cycles, sequencing, periodicity) and *metric* (duration, frequency) characteristics of bodily experiences. Short-term dynamics involve bodily experiences prior to, during, and after a task execution. Current sport psychology research examines mainly precompetition emotions in the preparatory stage of the performance process. The resources-matching hypothesis suggests that optimal and dysfunctional emotions and bodily experiences reflect the availability (or unavailability) of resources and their effective or ineffective recruitment and utilization. Therefore, a change in resources and their recruitment and utilization will result in a change in the athlete's zones of optimal functioning.

The context dimension is an environmental characteristic of the impact of situational, interpersonal, intragroup, and organizational determinants of experience intensity and content in sports. Examples of situational impact are emotional experiences triggered in practice sessions versus competitions. Interpersonal and intragroup emotional responses reflect how an athlete experiences his contacts and interactions with a particular partner (or partners, the team, and management).

Assessment of Arousal

Arousal can be measured using objective and subjective measures. Objective measures are related to the fact that arousal affects several systems in the body. Subjective measures are based on the awareness of athletes and their ability to perceive and report their experiences.

Objective Measures of Arousal

Physiologically, arousal involves activation of the reticular activating system in the brainstem, the autonomic nervous system and the endocrine system, leading to increased heart rate and blood pressure and a condition of sensory alertness, mobility, and readiness to respond. *Physiological* measures of arousal include changes in brain wave patterns (electroencephalography—EEG), skin conductance or resistance (SCR), heart rate patterns (HR) or their variability, blood pressure (BP), and muscle activity (electromyography—EMG). Biochemical measures include epinephrine, norepinephrine, and the steroid hormone cortisol, obtained from urine and blood samples.

Low correlation among physiological measures suggests that different people in the same stressful situation may respond by changes in different measures. For example, one athlete may display an elevated HR or its variability, whereas another athlete may show an increase in BP or EMG. John Lacey's principle of "autonomic response stereotypy" suggests that it is important to identify an individual's predominant experience modality and the profile of the multiple physiological measures.

Subjective Measures of Arousal

Subjective measures of arousal include idiosyncratic bodily experiences that are described by self-generated labels (markers), including perceived heartbeat, a dry mouth, "butterflies in the stomach," cold and clammy hands, trembling muscles, sweating all over, and tension in the face, legs/feet, arms/hands, neck/shoulders, and stomach. The list of bodily markers also includes the characteristics of movements (smooth, easy, tight) and feeling thirst, hunger, cold, or pain (or painlessness).

Three standardized self-report measures to assess global arousal include the Activation-Deactivation Adjective Checklist (AD-ACL), the Somatic Perception Questionnaire (SPQ), and the Bodily Awareness Scale (BAS). (See the Further Readings.) As in the case of physiological measures, it is recommended to develop individualized bodily experience scales for each athlete with self-generated idiosyncratic labels.

Arthritis

Arthritis is defined as pain and inflammation of a joint. Osteoarthritis, rheumatoid arthritis, and gout are the most common. Approximately 40 million Americans have osteoarthritis. This entry discusses the causes, diagnosis, and treatment of these types of arthritis.

Osteoarthritis is believed to be caused by muscle imbalances, acute injury, cumulative injury, and genetic predisposition. *Rheumatoid arthritis* is the result of the immune system attacking the joints. *Gout* is caused by the deposition of uric acid crystals in the joints.

Diagnosis

Risk Factors

Osteoarthritis

Risk factors for osteoarthritis include advanced age, female sex, obesity, activity level, previous injury, and genetics. Osteoarthritis is more common in twins, suggesting a genetic component. Weight loss surgery showed that 89% of people had total resolution of their symptoms with an average weight loss of 98 pounds (lb; 1 lb = 0.45 kilogram). There is an increased risk of lower limb osteoarthritis in previously injured joints and in participants of repetitive, high-impact sports. Increased risk has not been found in recreational exercisers. Regular moderate exercise has been shown to decrease symptoms.

Rheumatoid Arthritis

Rheumatoid arthritis is more common in women and in smokers and their relatives. Seventy-five percent of women will have improvement or resolution of their symptoms during pregnancy. Exercise is not causative. Regular exercisers have been shown to have less fatigue and decreased disability.

Gout

Gout is more likely in those who consume alcohol, eat large quantities of meat or fish, or take water pills for high blood pressure and in men over age 30. There is no known link with exercise.

History

Osteoarthritis

Patients will present with complaints of pain in weight-bearing joints, such as the knees and hips. Onset peaks in the fifth decade but can present at almost any age. Patients describe pain and stiffness that slowly progresses over time to become severe and unremitting. Pain worsens with weight-bearing activities. Osteoarthritis can mimic rheumatoid arthritis, discogenic disease, joint infections, and ligamentous injuries.

Rheumatoid Arthritis

Patients will present with joint pain, swelling, and redness, most commonly in the hands and feet.

These symptoms are often symmetrical and in multiple joints. Pain is usually worse in the morning.

Gout

Gout presents with acute severe pain and swelling in one joint, most commonly the great toe. It can be confused with infection.

Physical Exam

Osteoarthritis

A detailed physical examination should be performed on the affected joints. Joint swelling, tenderness, and decreased range of motion is common. Joints may be slightly warm, but significant redness and warmth may indicate infection or other forms of arthritis.

Rheumatoid Arthritis

Patients will often have pain, swelling, and stiffness in symmetrical multiple joints. The finger and wrists are most commonly involved. Destruction of the finger joints may cause deviation of the fingers away from the thumb. The joints are usually boggy and painful, with decreased range of motion.

Gout

Joints affected by gout will be swollen, red, stiff, and extremely tender with movement. The great toe is most often affected, but gout can occur in almost any joint.

Laboratory Tests

Osteoarthritis

The gold standard for evaluating joint pain is joint fluid evaluation. The joint fluid analysis usually shows mild inflammation in osteoarthritis. There are no specific blood tests for osteoarthritis. Markers for inflammation such as erythrocyte sedimentation rate and C-reactive protein may be elevated, but they are often not necessary for the diagnosis.

Rheumatoid Arthritis

The diagnosis of rheumatoid arthritis can be aided by some blood tests. Rheumatoid factor will be elevated in approximately 70% of people with rheumatoid arthritis, but other rheumatic diseases may also show elevation of this factor. Anticyclic citrullinated peptide antibody (anti-CCP) is a more specific test for rheumatoid arthritis. Joint fluid analysis usually shows moderate inflammation.

Gout

Gout is normally diagnosed through a history and a physical exam. When the diagnosis is unclear, joint fluid can be evaluated for uric acid crystals, which are unique to gout. Checking the blood for uric acid levels is not an accurate test.

Radiologic Studies

Osteoarthritis

Weight-bearing X-rays should be taken of the weight-bearing joints to check for joint space narrowing, bone spurs, and sclerosis. Magnetic resonance imaging (MRI) should be performed if patients have locking or instability to evaluate for other causes of the symptoms.

Rheumatoid Arthritis

X-rays of patients with rheumatoid arthritis will show destruction and erosion of the joint space. Soft tissue swelling will also be seen. Fingers may demonstrate deviation away from the thumb.

Gout

Early gout will show no changes on X-rays. As gout becomes chronic, sclerosis and joint erosions may occur. Chronic gout may also demonstrate tophi, which are whitish nodules from deposition of urate crystals in the soft tissue, commonly just under the skin.

Treatment

Osteoarthritis

Treatment includes weight loss, activity modification, medications, supplements, physical therapy, joint injections, and joint replacement surgery.

Weight loss has been shown to be effective. Diet and exercise are the cornerstones of weight loss.

Activities such as swimming or stationary bicycle are recommended. These activities decrease the stress on the joints compared with activities such as running. Physical therapy can be used to strengthen the joints in order to prepare the patient for increased physical activity.

Acetaminophen is safe and effective when taken at recommended doses. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be added if pain control is not adequate. NSAIDs have been associated with increased risk of bleeding stomach ulcers, heart attack, and stroke.

Glucosamine is an over-the-counter supplement. Some studies indicate that it may be beneficial. A trial is reasonable since side effects are rare. Chondroitin is often found in the same preparation but is not as well studied.

Corticosteroid injections relieve pain by blocking the inflammation. These generally provide short-term relief (1–3 weeks) and sometimes provide long-term relief (6–12 months). There is concern that too many injections may cause damage to the joint.

Hyaluronic acid injections are designed to restore healthy joint fluid but are approved only for the knee. The patient may receive one to five injections depending on the medication chosen. The medical literature confirms that these are more effective than placebo and about as effective as NSAIDs and corticosteroid injections.

Joint replacement surgery is widely available for the knee, hip, and shoulder and in some areas for the thumb, fingers, ankle, and spinal disks. The arthritic cartilage is removed and replaced with special metals and/or plastics. Postoperative rehabilitation may take 6 to 12 months. Major risks include blood clots, infection, nerve injury, and reactions to anesthesia. Patients are recommended to confer with the surgeon to discuss surgical options, risks, and benefits.

Rheumatoid Arthritis

The most effective treatment for rheumatoid arthritis includes early diagnosis and disease-modifying antirheumatic drugs (DMARDs). Patient education regarding the nature of the disease, rest with flares, and appropriate physical and occupational therapy have been shown to improve symptoms. Patients are at increased risk of coronary atherosclerosis and should be monitored for osteoporosis if on corticosteroids and kept up to date with immunizations if on immunosuppressive medications.

Gout

The treatment of an acute gout focuses on pain relief. Prescription-strength NSAIDs are usually recommended first. NSAIDs have been associated with increased risk of bleeding stomach ulcers, heart attack, and stroke. If NSAIDs are ineffective or contraindicated, colchicine may be prescribed. It decreases uric acid levels by eliminating it through the stool. Side effects are diarrhea, cramping, and abdominal pain. Intraarticular corticosteroids may be indicated when oral medications fail.

For frequent and disabling attacks, patients may be started on probenecid. This prescription medication decreases uric acid by increasing its excretion through the kidneys. Eight glasses of water are recommended daily to prevent kidney stones. Probenecid should not be used with aspirin, which blocks its effects. Allopurinol acts to block production of uric acid but has risk for allergic reactions.

Arthroscopy

Arthroscopy is a technique in sports surgery that is becoming increasingly popular. It involves the insertion of a camera, or *arthroscope*, into a joint through small skin incisions termed *arthroscopic portals*. The image within the joint is then projected onto a video screen and can be used for both diagnostic and treatment purposes. Arthroscopy is a minimally invasive alternative to many open surgeries, with advantages including less pain, smaller incisions, and faster rehabilitation. Arthroscopy can be performed on many joints, but it is most commonly used in the knee, shoulder, elbow, hip, and ankle. The types of surgeries that can be performed arthroscopically and the list of joints in which they can be used is constantly expanding.

Anatomy

A *joint* is an articulation or connection between two bones that allows for movement. The type and structure of the joint will determine the level of movement allowed. For example, the knee is a hinge joint that allows bending (flexion) and straightening (extension) in the leg, whereas the shoulder is a ball-and-socket joint that allows arm motion in any direction. While each joint contains unique components related to its specific function, there are baseline similarities between joints that allow the concepts of arthroscopic surgery to be applied.

Joints are surrounded by a thick tissue called the *capsule*, which forms an enclosed space. The inner layer of the capsule is lined by synovium, which serves as a filter. The synovium secretes joint fluid, which lubricates the joint. There is cartilage attached to the ends of each bone in the joint. The cartilage is a form of connective tissue that resembles the shiny white portion of a chicken bone; it provides a smooth surface for joint movement. There are often ligaments (bundles of fibrous tissue) and tendons (ropelike muscle attachments to bone) that are around and inside joints and serve to stabilize them.

Indications

The indications for arthroscopic surgery include a wide range of conditions that involve the joints and the ligaments inside them. Arthroscopy is primarily performed for diagnostic purposes. In cases where the diagnosis is unclear after physical exam and imaging, some surgeons may opt to perform an arthroscopy to visualize the joint and locate the problem. Generally, the source of the pain can be found and addressed during the arthroscopy.

Debridement is a term used to describe the cleaning of a surface, and it can be applied to the joint. Often, a patient will have an arthroscopy due to pain or limitation of mobility. With arthroscopic debridement, the surgeon can smooth the roughened surfaces that may be causing the pain or excise any tissues that may be causing painful symptoms. Debridement can also be used to wash out a joint infection.

Many types of repairs of ligaments and tendons can be done through arthroscopy. Tears of ligaments or cartilage in the knee, such as anterior cruciate ligament or meniscus tears, can be repaired with the aid of arthroscopy. Shoulder injuries involving torn cartilage or tendons, such as rotator cuff tears and biceps tendon injuries, can also be repaired through arthroscopy. The requirement for arthroscopic repair is that the structure in question be within the joint space and in an area accessible by the arthroscopic tools.

Technique

The setup in the operating room for arthroscopy is very important. (See the entry Operating Room Equipment and Environment.) Like any other surgery, arthroscopy is done under sterile conditions in the operating room. Many surgeons use specific positioning devices to allow the limb or joint to be in the ideal position for the procedure. In some cases, traction with weights attached to the limb may be used to increase the joint space.

Small incisions (0.5 inch [1.3 centimeters]) are made in the skin, and an arthroscopic portal is made to access the joint. Fluid is inserted under pressure into the joint to make the joint space larger. A camera approximately the size of a pencil is inserted through these incisions to visualize the inside of the joint. The image from the camera is projected onto a monitor, which the surgeon will use to direct the movement and position of the camera. Many surgeons use the camera to photograph or videotape their intraoperative findings.

Every arthroscopic procedure begins with a *diagnostic arthroscopy*, which entails looking around the entire joint to either confirm or determine the causes of the patient's symptoms. The joint surface and the ligaments and cartilage in the joint are thoroughly inspected for tears or abnormalities. The recesses, or pockets, of the joint are checked for fragments of bone or cartilage that may indicate previous injury.

During the arthroscopy, the surgeon may use a variety of instruments. A probe, or a small metal hook, is used to feel and move the cartilage and ligaments seen on the camera. A small electric shaving device, also the size of a pencil, may be used to shave off injured or frayed areas of cartilage. Other small tools that fit through the small incisions and act as scissors, graspers, and cutters may be used to remove loose pieces of cartilage that are found in the joint.

In the event that a repair of a tendon or ligament is indicated, the surgeon may use anchors, screws, or sutures to hold the tendon or ligament in place. Many of these fit through the small incisions made for the camera and represent a favorable alternative to open surgery. Often, however, the more complicated cases may require a slightly larger incision in addition to the small incisions, to remove or insert larger tools or materials. Reconstruction, in which tissue is taken from elsewhere and used to re-create a missing or torn structure, is becoming an increasingly popular technique as well.

Benefits

Arthroscopic surgery has many benefits. When compared with open surgery, in which the joint is opened and the procedures are done under direct visualization by the surgeon, arthroscopy offers a minimally invasive approach to these procedures. The arthroscopic procedures require smaller incisions. Therefore, there is less scarring on the skin. There is less disruption of the tissues under the skin and in the joint and, consequently, less pain and faster healing. The smaller incisions also allow a smaller area to be exposed to the air, resulting in decreased risk of infection. Patients also tend to have less pain from the incisions from this procedure and are able to participate in rehabilitation sooner.

Limitations

Not all diseases or conditions involving a joint can be treated with arthroscopy. Some surgeries require large exposures of the joint, which arthroscopy cannot offer. Complicated arthroscopic cases may require the surgeon to repair the joint under direct visualization with an open procedure. This most often happens if a structure that needs to be repaired cannot be reached through the small incision without causing injury to other structures or if there is poor visualization within the joint due to bleeding or other factors. In the event of repeat surgeries, there are often complicating factors such as scar tissue or poor bone quality, which do not allow arthroscopic repair techniques to be used effectively.

After Surgery

Most arthroscopic surgeries are performed as outpatient cases, meaning that you may be able to go home on the day of your surgery. The incisions are small and can often be covered with Band-Aids. Depending on the type and location of the surgery, the surgeon will make recommendations regarding limitation of activity. Some procedures will require strict restrictions on activity and instructions on how to care for the operative site (such as using crutches or restrictions on lifting), while others may have no restrictions. Many people who undergo arthroscopic surgery will need physical therapy before they can resume their normal activities.

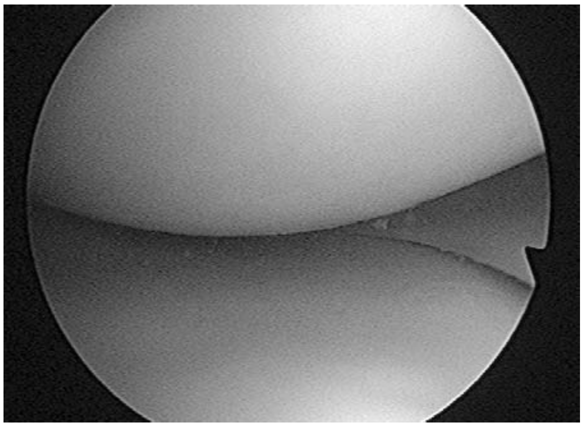
Articular and Meniscal Cartilage Regeneration and Repair

Normal function of the knee in both the athletic and the nonathletic population depends on the integrity of the many components that make up this complex joint. Structures made of cartilage in particular play a key role in maintaining normal function.

Within the knee, there are two different types of cartilage: (1) *articular* (hyaline) *cartilage*, which is the thin layer of smooth, white, shiny tissue covering the articulating bone surfaces, and (2) the *meniscal cartilages*, which are two crescent-shaped wedges of elastic cartilage that lie between these surfaces.

Structure and Function of Articular Cartilage

Articular cartilage has the lowest coefficient of friction of any known substance, which in conjunction with the additional lubrication provided by synovial joint fluid allows the articulating surfaces of the knee joint to slide freely against each other. In the healthy joint, articular cartilage is only a few millimeters thick, increasing in depth where the loads are greatest (see photo at top of column).



Arthroscopic view of femoral articular cartilage

Source: Photo courtesy of Angus Robertson, M.D.

Articular cartilage is made up of cellular and structural components. The cell population is composed of cells called *chondrocytes,* which are predominantly concentrated in the deeper cartilage layers adjacent to the bone surface. The supporting matrix is made up of long molecules called *glycosaminoglycans,* lying within a mesh of Type II collagen fibers. A large percentage of the weight of the tissue is made up of water, which gives the articular cartilage its elasticity and assists in lubrication.

Articular cartilage interfaces with bone at a layer called the *subchondral plate.* Unlike the underlying bone, the cartilage has no blood or nerve supply, which is in part why, when it is damaged, it is particularly poor at repairing itself.

Structure and Function of the Meniscal Cartilages

The meniscal cartilages function as load sharers and shock absorbers. They are crescent shaped when viewed from above and wedge shaped in cross section. There are two meniscal cartilages (menisci) in the knee, one medial and one lateral (see photo on next page). They are made of continuous circumferential bands of Type I collagen fibers attached firmly to bone at each end. Cells called *fibrochondrocytes* are embedded in the tissue. The menisci have a good blood supply around their periphery, extending approximately one third of the way radially into their structure. The remaining inner two thirds of the tissue is avascular. The cells in this part of the menisci are sparse and less metabolically active, taking their nutrition from the diffusion of nutrients and oxygen from the circulating synovial fluid.

Articular Cartilage Injury

Injury to articular cartilage in the knee can vary from small patches of softening or fraying to unstable or loose flaps or even patches of bare bone, where the cartilage has worn away altogether. This can occur through a variety of different mechanisms, including blunt direct or indirect trauma causing anything from minor "bruising" of the cartilage to major damage such as detachment of a fragment of bone and the overlying cartilage—an osteochondral injury. The cartilage may also be damaged by chronic conditions such as osteoarthritis. Disruption of articular cartilage structure and function can result in various symptoms including pain and joint swelling. The joint may click and feel unstable or "give way." Where there is more extensive damage, the knee may become increasingly stiff.

Meniscal Cartilage Injury

Meniscal injury commonly results from a twisting mechanism on a loaded bent knee. With increasing age, the meniscal cartilages become degenerate, less elastic, and are more liable to tear with minimal or no specific trauma. Classic symptoms include pain along the medial or lateral side of the knee, an effusion, a painful clicking, a sudden painful giving way, and locking (where the joint intermittently gets stuck and the patient is unable to straighten the knee). A variety of different clinical tests have been described for detecting tears. The most popularly used is the McMurray test, which involves putting the knee through a combination of flexion/extension, internal/external rotation, and varus/valgus movements in an attempt to elicit a click/clunk in the knee. The test itself has low sensitivity and only moderate specificity.

Investigations

X-rays have a limited role in investigating cartilage injury in the knee. They may be useful in demonstrating osteochondral injury, in identifying avulsion fractures implying an associated ligament or capsular injury, and in established osteoarthritis. Magnetic resonance imaging (MRI) is now the mainstay of investigation, providing relatively detailed imaging of both articular and meniscal cartilage. However, it is important to emphasize that MRI may still have a false-positive or -negative rate of up to 20% for meniscal tears.

The Treatment of Cartilage Injury

The first-line treatment of a cartilage injury not causing mechanical symptoms includes painkillers, anti-inflammatories, viscosupplementation (intra-articular injection of hyaluronate), and physical therapy. In cases where such measures have failed, a number of surgical options are available.

Most articular cartilage injuries are now treated predominantly using arthroscopic techniques (keyhole surgery). Rough surface cartilage can be smoothed using small motorized shavers or radiofrequency probes that superheat and melt the superficial layers of the cartilage, "welding" together cracks or fissures and "sticking down" unstable edges. When the injury has progressed to expose areas of bare bone, a variety of options are available depending on the size and depth of the defect. For small lesions, it is possible to roughen the bone surface and puncture the area with multiple little holes. This "microfracture" technique produces bleeding into the defect, thereby introducing stem cells from the adjacent bone marrow, allowing a reparative patch of cartilage to form. This cartilage is predominantly fibrocartilage rather than hyaline cartilage and has poorer mechanical properties. In association with the correct rehabilitation protocols, microfracture has reported success rates in the region of 80%. For larger lesions, techniques such as autolgous chondrocyte implantation can be employed. This procedure involves taking samples of cartilage from non-weight-bearing surfaces of the knee, culturing them in a laboratory for about 6 weeks, and injecting the multiplied cells back into the defect under a patch of collagen during a second operation. Alternatives include introducing these cells seeded into collagen membranes or gels, which are then used to fill the defect. Similar success rates to microfracture have been published, with the best results being for defects in the femoral condyles.

Where there is a deeper ostochondral injury, it is not enough simply to replace the cartilage layer. To restore the articular surface, osteochondral plugs must be taken from non-weight-bearing areas of the knee or from tissue donors and inserted into the defects. Synthetic engineered alternatives are also now available.

The meniscal cartilages have poor blood supply, and tears frequently fail to heal on their own, without surgical treatment. Most tears, particularly complex degenerate tears in older patients and those at the inner avascular edge of the meniscus, are irreparable, in which case the torn fragment can be removed using arthroscopic techniques. Loss of meniscal function decreases shock absorbancy and increases peak contact pressures, significantly increasing the risk of future arthritis. With this in mind, every attempt is made to preserve meniscal tissue when trimming a meniscal tear, which is termed a *partial meniscectomy*. Some tears in the outer third of the meniscus (where there is reasonably good blood supply) may heal if supported by sutures. Small, fresh tears in younger patients have the greatest chance of successful repair. Technological advances now allow meniscal repairs to be performed with arthroscopic techniques. If a meniscal tear is trimmed, postoperative rehabilitation can be rapid. If, however, a repair is performed, most surgeons will advise that the knee be protected for up to 6 weeks postoperatively, with limited weight bearing and bracing, and patients will be advised not to return to sports before 3 months postoperation.

In those younger patients where a large proportion of the meniscus has been lost, a number of techniques are being developed to try to restore meniscal function. These include the insertion of bioengineered meniscal scaffolds or meniscal allografts (meniscal transplants) into the knee to provide a framework into which the patient's cells grow and regenerate meniscal tissue. The results of these techniques, in terms of improvement in function, have been encouraging in the short term.

The Future

Improved MRI techniques are enhancing the structural imaging of articular and meniscal cartilage and are allowing mapping of metabolic activity within hyaline cartilage. Tissue engineering is increasingly being used to improve the quality of the regenerate articular cartilage produced by the techniques described above. This includes the production of better scaffolds to encourage cellular regrowth and work to improve the understanding of the cellular mechanisms involved in cartilage repair. New biological (absorbable) glues are being developed for meniscal repair, and the potential use of agents such as growth factors to enhance meniscal healing is being explored. In time, it is likely that a combination of gene therapy and tissue-engineering techniques will see patients being able to regrow organs, including the meniscal cartilages. However, at present the best advice remains to protect one's articular and meniscal cartilages through proper warm-up, safe training, good sporting technique, and regular exercise to keep supporting muscles strong and reflexes fast in an attempt to avoid damage to these important cartilage structures within the knee.

Asthma

Asthma is a disease that is characterized by airway hyperresponsiveness, reversible airway obstruction, and airway inflammation. The hyperresponsiveness is caused by an exaggerated bronchoconstrictor response to stimuli such as histamine. Airway edema can be caused by mucous hypersecretion, resulting in the formation of mucous plugs and swelling. This entry discusses various issues related to asthma, including diagnosis, classification, and treatment and management. (See the entry Asthma, Exercise-Induced.)

This is an important topic for sports medicine because undiagnosed or uncontrolled asthma can result in poor athletic performance and inability to achieve top physical fitness. It is important that athletes with asthma be diagnosed correctly and then treated optimally so that they can maximize their athletic potential.

Diagnosis

Clinical Manifestations

The presentation of asthma can vary, but some of the more common symptoms include wheezing (often recurrent), cough, recurrent chest tightness or shortness of breath, and increased sputum production. Symptoms of asthma are often sporadic and become worse at night. Symptoms typically occur or worsen with exercise, viral infections, exposure to allergens or irritants, weather changes (cold air increases symptoms), gastroesophageal reflux, laughing, and crying. The variations of presentation and triggers make an accurate history one of the most important tools in diagnosing asthma.

The physical exam may or may not demonstrate cough or wheezing. Wheezing typically occurs in the expiratory phase, but it can occur during inspiration as well. Other physical exam findings may be signs of allergic rhinitis (see the entry Allergies) and atopic rashes such as eczema.

Diagnostic Testing

Chest X-rays are helpful because they can exclude other causes of wheezing that mimic asthma, such as bronchitis, pneumonia, congestive heart failure, or foreign body aspiration. A typical chest X-ray finding in asthma is lung hyperinflation with a flattened diaphragm. A pulse oximetry reading can also be helpful.

Pulmonary function tests (PFTs) are the gold standard in helping diagnose and manage asthma. Spirometry can be done in the ambulatory or emergency setting and is an objective measure of lung function. Spirometry measures the expiratory flow rates, comparing baseline values based on the patient's age, race, and height. A decrease in forced expiratory volume in the first second after full inspiration (FEV_1) is characteristic in obstructive lung diseases, including asthma and chronic obstructive pulmonary disease. The hallmark of spirometry in asthma, though, is an increase in FEV_1 of >200 ml and of >12% from baseline after use of a bronchodilator. It is recommended to perform spirometry at the initial assessment in order to establish a baseline, after treatment has been initiated and symptoms have stabilized, during periods of prolonged loss of asthma control and at least every 1 to 2 years if the patient is stable.

If spirometry is normal and asthma is still suspected, a methacholine challenge can be done. This is done by having patients breathe increasing concentrations of methacholine and measuring FEV_1 and subjective symptoms after each dose. Testing stops if the methacholine concentration reaches 8 mg/ml without any significant change in lung function. This has a high specificity, meaning that a negative test essentially excludes asthma. A decrease in FEV_1 of greater than 20% from baseline is a positive test.

Peak flows are more variable and less reliable than in spirometry. They should not be used as the primary method of PFT. They are useful for daily outpatient monitoring, for identifying exacerbations, and for assessing the effects of treatment changes.

Classification

Asthma severity is determined by considering a number of different factors. Asthma categories are used to help direct the patient's treatment. If a patient has elements from more than one category, then the patient's asthma is categorized at the level of the most severe symptom. Asthma is categorized as intermittent or persistent, with persistent asthma divided into categories of mild, moderate, and severe. *Note:* The classifications below are for age 12 and older. There is a different set of criteria for children under 12.

Intermittent

Intermittent asthma is categorized by the following criteria:

1. Daytime symptoms occurring two or fewer days per week
2. Two or fewer nocturnal awakenings per month
3. Use of a short-acting beta agonist (SABA) for symptom control less than twice per week
4. No interference with normal activity
5. Normal FEV_1 between exacerbations
6. FEV_1 >80% of predicted value
7. FEV_1/FVC (forced vital capacity) ratio normal
8. One or no exacerbations per year requiring oral steroids

Mild Persistent

Mild persistent asthma is categorized by the following criteria:

1. Symptoms occurring more than twice per week but not daily
2. Three to four nocturnal awakenings per month
3. Use of a SABA for symptom control more than twice per week but not daily
4. Slight limitation in normal activities
5. FEV_1 >80% of predicted value
6. FEV_1/FVC ratio normal
7. Two or more exacerbations per year requiring oral steroids

Moderate Persistent

Moderate persistent asthma is categorized by the following criteria:

1. Daily symptoms of asthma
2. Nocturnal awakenings more than once per week
3. Daily use of a SABA for symptom relief
4. Some limitation in normal activities
5. FEV_1 between 60% and 80% of predicted value
6. FEV_1/FVC ratio reduced by 5% or less
7. Two or more exacerbations per year requiring oral steroids

Severe Persistent

Severe persistent asthma is categorized by the following criteria:

1. Symptoms of asthma throughout the day
2. Nocturnal awakenings daily
3. Use of a SABA multiple times per day
4. Daily activities severely limited
5. FEV_1 <60% of predicted value
6. FEV_1/FVC ratio reduced by >5%
7. Two or more exacerbations per year requiring oral steroids

Treatment

The goals of therapy are essentially to prevent the symptoms of asthma from occurring. Goals include limiting the patient's use of a SABA to less than twice per week, maintaining normal pulmonary function, and preventing loss of lung function. Treatment is also aimed at preventing recurrent exacerbations, keeping the patient as highly functional as possible, and minimizing the adverse effects of therapy. The approach to pharmacotherapy is based on increasing medications until the asthma is controlled and decreasing medications when possible to minimize side effects.

Inhaled corticosteroids are the most potent and consistently effective long-term control medication for asthma. The broad action of inhaled corticosteroids on the inflammatory process may account for their efficacy as preventative therapy, and their clinical effects are important. They reduce the severity of symptoms, improve asthma control and quality of life, improve spirometry, and help prevent exacerbations. Inhaled corticosteroids also diminish airway hyperreponsiveness and have been shown to reduce the use of systemic steroids, the frequency of emergency room visits and hospitalizations, and the incidence of death due to asthma attacks. Early use of low- or medium-dose inhaled corticosteroids has shown significantly improved asthma outcomes. Also, studies have shown that inhaled corticosteroids improve asthma control more effectively, in both children and adults, than leukotriene receptor antagonists or any other single long-term control medication.

For all patients, quick-relief medications may be needed. These include SABAs, which are used depending on the severity of symptoms. These can be used in up to three treatments at 20-minute intervals as needed. More than that amount should warrant a visit to the doctor or emergency room. For patients who have exacerbation of symptoms that cannot be controlled with a SABA alone, a short course of oral systemic corticosteroids may be needed. The use of a SABA is for symptom relief, not prevention. Also, use of a SABA more than twice per week generally indicates inadequate control and the need to step up treatment.

Current guidelines call for a stepwise approach to asthma control. In each step, care should be taken to evaluate the patient, educate the patient about asthma, try environmental control (such as removal of triggers), and manage other comorbidities. Prior to a step up, check adherence to medication, and try to modify other factors that may be triggering the asthma attacks. Last, if a patient's asthma has been well controlled for over 3 months, consider a step down to the previous level.

Step 1: This is usually for those patients with intermittent asthma, and a SABA is the only medicine needed.

Step 2: Steps 2 to 6 are generally for those patients with persistent asthma. In Step 2, the preferred choice of treatment is addition of a low-dose inhaled corticosteroid. Alternatives include cromolyn, leukotriene receptor antagonists (LTRAs), nedocromil, or theophylline (this medicine is rarely used because of the high number of side effects and interactions with other medications).

Step 3: The preferred treatment is a low-dose inhaled corticosteroid and a long-acting beta agonist (LABA) or a medium-dose inhaled corticosteroid. Alternatives are a low-dose inhaled corticosteroid and an LTRA or theophylline or zileuton. Also, consider consultation with an asthma specialist such as an allergist or pulmonologist at this step.

Step 4: The preferred treatment is a medium-dose inhaled corticosteroid and an LABA. Alternatives include a medium-dose inhaled corticosteroid and an LTRA or theophylline or zileuton. A specialist should be consulted at this step.

Step 5: The preferred treatment is a high-dose inhaled corticosteroid and an LABA; also consider omalizumab for patients who have underlying allergies.

Step 6: The preferred treatment is a high-dose inhaled corticosteroid, LABA, and oral corticosteroids, and again consider omalizumab.

Conclusion

Winter sports tend to increase the risk of an asthma attack because of the cold, dry air, but almost any sport can potentially induce an asthma attack. There have been many athletes at the professional and Olympic levels who have a diagnosis of asthma. With proper treatment and monitoring, they have performed well, and some have even won gold medals. As long as athletes with asthma have their symptoms under control, there are no limitations to participation. If the asthma is not well controlled or if it exhibits symptoms, the athlete should follow up with an allergist or a sports medicine physician experienced in treating asthma.

National Institutes of Health. *National Asthma Education and Prevention Program: Expert Panel Report III: Guidelines for the Diagnosis and Management of Asthma*. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007. NIH publication 08–4051.

Asthma, Exercise-Induced

Exercise-induced bronchospasm (EIB), also known as *exercise-induced asthma* (EIA), is a condition that obstructs the flow of air to the lungs during physical exertion. This condition can adversely affect the performance and fitness of athletes. EIB is defined as the presence of symptoms while exercising or, more formally, as a decline in FEV_1 (forced expiratory volume in the first second after full inspiration) or PEFR (peak expiratory flow rate) shortly after the onset or cessation of exercise. FEV_1 and PEFR are measured by pulmonary function testing. This entry discusses key issues related to EIB, including triggers, diagnosis and testing, treatment, and prevention.

Pulmonary Function Criteria

A 15% decline in FEV_1 with exercise is the generally accepted value for diagnosis of EIB. For people with a known history of asthma, a 20% decline in FEV_1 with exercise is sometimes used as the criterion. The maximal decrease in FEV_1 usually occurs after about 5 to 8 minutes of vigorous exercise, and pulmonary function tests (PFTs) usually return to baseline 60 minutes after exercise.

Epidemiology

Approximately 12% of the total population experiences symptoms of EIB. EIB can be detected in about 41% of those people with a history of allergic rhinitis, and 70% to 90% of asthmatics have EIB. There is equal distribution between the sexes, and it can occur at any age.

Risk Factors

A history of asthma is the biggest risk factor, followed by a family history of asthma, allergic rhinitis, recent infections (especially bronchitis), and chest symptoms such as cough and congestion.

Mechanism

The current understanding of EIB starts with the idea that hyperventilation during exercise causes drying of the airways and the epithelial cells, increasing intracellular osmolarity. This results in the release of mediators including histamine, leukotrienes, and others. These mediators then cause a transient bronchoconstriction or spasm. At the same time, another mechanism of EIB is taking place: The heat loss during exercise and the rapid rewarming of the airways after exercise cause reactive hyperemia of the microvasculature and edema of the airways, which sets up an osmotic gradient. This osmotic gradient results in the release of inflammatory mediators, causing bronchospasm.

Triggers

EIB can be triggered by cold air, dry air, or pollution or allergens in the air. Mouth breathing is more likely to cause symptoms because unlike nasal breathing, which warms the air, mouth breathing does not and is more likely to cause cooling of the airways and trigger EIB. Intense exercise is also more likely to trigger EIB, so sports such as cross-country skiing, basketball, long-distance running, soccer, and hockey are more likely to trigger EIB symptoms. Chemicals such as chlorine in pools, and insecticides, pesticides, herbicides, and fertilizers used in fields can also trigger symptoms.

Diagnosis and Testing

Clinical Signs and Symptoms

These can vary but typically may include wheezing, shortness of breath, cough, chest tightness, chest pain (usually reported more in children), feeling "out of shape," poor athletic performance, early fatigue, and a dry cough postexercise. Patients can have anywhere from one to a few symptoms. These symptoms are all similar to the symptoms found in asthma (see the entry Asthma), but they occur only while exercising and are of a shorter duration.

Physical Exam

Patients can present with some of the following exam findings: wheezing on lung exam, signs of atopic disease (e.g., eczema) on skin exam, cobblestoning or enlarged tonsils on throat exam, sinus tenderness or pressure, or enlarged and boggy turbinates on nasal exam. Patients often present with no clinical findings.

Testing

If the history points to the likelihood of EIB, a trial of albuterol (or another short-acting beta-2 agonist) is often sufficient. If the patient does not respond to the medication, has negligible reduction of symptoms, or has symptoms more consistent with asthma, then further testing is warranted.

Medication and Testing

During pulmonary function testing, certain medications need to be stopped/avoided so as not to confound the testing and produce false-negative results. For further information, see the entry Asthma.

Pulmonary Function Tests

These can range from hand-held spirometry, which can be done in the physician's office, to more formal testing done in a hospital setting, which can include a methacholine challenge or DLCO (diffusing capacity of the lung for carbon monoxide). The methacholine challenge is used to help diagnose asthma, whereas the DLCO test is used to diagnose pulmonary parenchymal disorders, such as chronic obstructive pulmonary disease. PFTs can be performed in many different ways to evaluate for EIB, but the most effective is to try and mimic the sport or activity that causes the athlete's symptoms.

Free Running

Baseline PFTs are performed prior to exercise. Next, the patient runs either outdoors or indoors until he or she has symptoms, and another set of PFTs are done and compared with the baseline PFTs. One of the advantages of this method is that it is the most likely to induce symptoms, is cheap, and requires minimal cardiovascular (CV) monitoring. Disadvantages include difficulty in controlling the environment, such as temperature and humidity, and that it may not trigger EIB in all patients.

Treadmill and Bicycle Ergometer

This testing is done by having the patient either run on a treadmill or ride a bicycle. Among the advantages are that CV and pulmonary monitoring can be done during the workout and the workload can be standardized. Disadvantages include expenses related to the equipment and that this testing is less likely to induce EIB because factors such as temperature, humidity, pollutants, and allergens are less likely to play a role indoors.

Special Testing

At present, the International Olympic Committee (IOC) requires prior notification for the use of a beta-2 agonist. This notification must be accompanied by objective evidence that justifies the need for the medication. At this time, the gold standard is a eucapnic voluntary hyperventilation (EVH) test. This test consists of hyperventilating dry air containing 5% carbon dioxide at room temperature, and a reduction in FEV_1 of greater than 10% is used to make the diagnosis.

Prevention and Treatment

Pharmacologic

Inhaled Beta-Adrenergic Agonists

This is the primary medicine used in prevention and treatment of EIB. Using this class of medicine (e.g., albuterol) about 15 to 30 minutes prior to exercise can often prevent or reduce the symptoms of EIB. A spacer should always be used with this medicine so that the patient receives the maximum amount of medication. Only the aerosolized form of albuterol has been shown to be effective in EIB and asthma. If the albuterol helps the patient, then no further medication is necessary.

Leukotriene Antagonists

This category of medicine can be added as second-line therapy and occasionally as first-line treatment. It is not as effective in athletes with isolated EIB but can help those with underlying asthma.

Inhaled Corticosteroids

These are not effective in isolated EIB but are the mainstay of treatment for athletes with asthma.

Antihistamines and Intranasal Steroids

These medicines can help athletes with underlying allergic rhinitis, which may trigger EIB and EIA.

Nonpharmacologic

There are various other ways to try to help treat and/or prevent the symptoms caused by EIB. Conditioning may help reduce the severity of the symptoms. Patients can be taught to "run through" their EIB, meaning that the athlete continues to exercise while having symptoms, and some athletes can push through these transitory symptoms and continue their exercise. Short bursts of vigorous exercise (e.g., wind sprints) may suppress EIB symptoms and induce short-term refractoriness. Warming up prior to activity induces bronchodilation and refractoriness to EIB, and cooling down after exercise can decrease postexercise EIB symptoms. Other tips include avoiding exercise in areas with a high pollen count or high pollution. Also, cold weather often exacerbates EIB, so exercising indoors during cold weather or wearing a scarf can help. Last, nasal breathing helps warm the air, so avoid mouth breathing.

Athlete's Foot

Athlete's foot, also called *tinea pedis* or *ringworm*, is a rash caused by a fungal skin infection. The skin areas most commonly affected are the plantar surface (sole) of the foot and the web spaces between the toes. It is estimated that at least 70% of all people will have a fungal foot infection at some point in their life. Athletes may be at slightly greater risk because the factors that predispose infection are warm, moist environments, such as those caused by shoe wear and walking barefoot in infected locker rooms and public showers. Other factors that predispose certain populations to infection are medical conditions such as hyperhidrosis (excessive sweating) and those that affect the immune system. It is seen in males more commonly than in females and is uncommon prior to puberty.

Anatomy

The skin has three layers. The deepest layer is called *subcutaneous tissue* and is composed of adipose (fat), nerves, hair follicles, arteries, veins, and sweat and oil glands. The middle layer is the *dermis*. It has two layers and varies in thickness depending on the location in the body. The deepest layer of the dermis is composed of thick collagen fibers, which have parallel alignment with the skin surface. This layer sits just on top of the subcutaneous tissue. The thin, more superficial (outer) layer of the dermis is also made of collagen fibers, which are randomly arranged. The most superficial layer of the skin is the *epidermis*. The epidermis constantly replenishes keratinocytes (skin cells), which flatten, die, and eventually slough. The overall thickness of the epidermis depends on the location in the body. It is thickest in the palms and soles. The epidermis is composed of five layers (from deep to superficial): (1) stratum basale, (2) stratum spinosum, (3) stratum granulosum, (4) stratum lucidum, and (5) stratum corneum. The stratum basale is named for the basal cells that form the base of the epidermis. They lie on top of the dermis, are shaped like columns, and are constantly dividing to replenish cells lost at the surface. Basal cells divide into keratin-producing cells called keratinocytes. These keratinocytes form microscopic spines that link them together; thus, this layer is called stratum spinosum. As the cells migrate toward the skin surface and become progressively flattened, they form a new layer, called stratum granulosum because the cellular cytoplasm appears granular under microscopy. The cells then die and become the outermost layer, the stratum corneum, which is composed of keratin. The keratin layer of the stratum corneum is the only layer infected by the fungi that cause athlete's foot. The stratum lucidum is a transition layer between the stratum granulosum and stratum corneum. It is only found in the thick skin of the palms of the hands and soles of the feet.

Causes

Athlete's foot is an infection caused by a type of fungi called *dermatophytes*. Able to infect only the top layer of dead keratin, dermatophytes affect the skin, hair shafts, and nails. Dermatophytes can be further classified into three genera: *Trichophyton, Microsporum,* and *Epidermophuton*. *Trichophyton rubrum* is the dermatophyte most commonly associated with athlete's foot, and although other dermatophytes can also cause athlete's foot, they are less common. Fungal spores from *T. rubrum* can live in human scales for up to 12 months and are therefore easily transmitted from person to person in locker rooms and public showers.

Symptoms

Fungal infections are frequently asymptomatic; however, some rashes are *pruritic* (itchy) and, if also infected with bacteria, can become painful. Athlete's foot can be categorized into four main types: interdigital (toe webs), moccasin, vesicular (blisters), and ulcerative.

Interdigital infections may be dry or macerated (soft from being wet). The dry type of infection is typically scaly, erythematous (red), and fissured (cracked). In the macerated type, the skin within the toe web is white, moist, peeling, and also sometimes fissured. The web between the fourth and fifth toes is the most common site of interdigital infection, although any of the web spaces can be involved.

In *moccasin*-type infections, the area involved is limited to the soles and lateral portions of the feet. The leading edge of infection is a well-defined line of erythema (redness). It is dry, with a fine scale and hyperkeratosis (thickening of the epidermis). Moccasin-type infections are commonly bilateral (right and left sides).

In *vesicular* infections, the raised, erythematous leading edge of the rash contains vesicles (small fluid-filled blisters) or bullae (large fluid-filled blisters), which are a sign of acute inflammation. The presence of pus indicates secondary bacterial infection.

Ulcerative-type infections are the spreading of interdigital infection to the dorsum (top) or plantar surface of the foot. They have characteristics similar to those of macerated infections and are usually secondarily infected with bacteria.

Diagnosis

Definitive diagnosis is made by obtaining a skin scraping from the leading edge of inflammation. The skin is collected using a No. 15 scalpel blade to scrape skin scales onto a glass microscope slide. The skin scraping is then evaluated for the presence of hyphae (fungus strands) under microscopy using potassium hydroxide (KOH) wet mount preparation.

Treatment

Athlete's foot can usually be treated with topical antifungal medications such as terbinafine (Lamisil), which can be purchased over the counter. Topical prescriptions such as ketoconazole or clotrimazole may also be used. The length of treatment ranges from 1 to 6 weeks depending on which medication is used. Oral prescription medications such as fluconazole or ketoconazole may be required for severe or resilient infections. If complicated with bacterial infection, antibiotics may also be necessary.

Prevention

Warm, moist environments are ideal conditions for athlete's foot. Tight, nonbreathable, or restrictive footwear causes excessive friction and sweating, which encourage fungal growth. Frequent changing of socks, application of powder to absorb moisture, and wearing sandals in locker rooms and public showers are key for preventing infection. Socks are not effective locker room wear for prevention.

Athlete's Heart Syndrome

The athlete's heart will adapt to the physiologic stress of strenuous physical conditioning. This "remodeling" of the electrophysiological, morphological, and functional status of the heart is normal in highly trained athletes but may be considered abnormal in other, less cardiovascularly fit individuals. These changes are termed *athlete's heart syndrome*. It is important for team physicians, as well as athletic trainers and coaches, to be aware of these adaptations and to avoid overinterpreting them and atttributing them to pathological states.

What Happens to the Heart With Exercise?

There are two basic types of exercise that place demands on the cardiovascular system: *dynamic* and *static exercise*. Both types challenge the heart to adjust to the variations in heart rate, contractility, myocardial oxygen consumption, and wall tension.

Dynamic demand (i.e., running) involves aerobic activity at lower resistance for long periods of time. Cardiac output is maintained by increases in stroke volume and heart rate. Mean blood pressure shows minimal change due to a decrease in peripheral vascular resistance and increase in systolic blood pressure, diastolic blood pressure remaining relatively constant. The heart also responds to aerobic conditioning by adaptations due to both volume and pressure overload. With increased stroke volume and the resulting increased cardiac output, left ventricular end-diastolic diameter increases, with proportional increases in septal- and free-wall thickness to help normalize wall stress. With this pressure overload, the heart increases both septal- and free-wall thickness to stabilize myocardial wall stress (LaPlace's law).

With static exercises such as weight lifting, which is primarily anaerobic, there are smaller increases in cardiac output, moderate rises in heart rate, and mild increases in stroke volume. Peripheral vascular resistance is increased. Free- and septal-wall thickness increases without increasing left ventricular end-diastolic diameter. As a consequence, the ventricular wall thickens to normal wall stress due to high afterload.

Physical Examination

Physical examination of the athletes shows characteristic changes in adaptation to physical activity. In endurance athletes, the pulse slows and increases in amplitude secondary to higher stroke volume and cardiovascular efficiency. Sinus rhythm is the norm, but sinus arrhythmia or premature beats are not uncommon. Additionally, the left ventricular impulse duration may be prolonged and displaced.

The first and second heart sounds may be highly pitched and sometimes split. Occasionally, this splitting of the second heart sound may last longer than 60 milliseconds and suggests a congenital heart lesion, such as an interatrial septal defect. Because of a greater diastolic filling rate, a third heart sound may be heard. Fourth heart sounds are less common but do occur and may be confused with hypertrophic cardiomyopathy or hypertension in older athletes.

Due to higher stroke volumes and the velocity of blood flow, Grades I to II systolic ejection murmurs may be heard in up to 30% to 50% of dynamic athletes. Last, a venous hum may be heard in the supraclavicular fossa due to the development of a thick muscular neck and the altered flow in the jugular vein. Venous hums are considered benign.

Electrocardiographic Changes

Sinus bradycardia is the most common electrocardiographic finding and is most common in endurance athletes. This is due to increased vagal tone. *Sinus arrhythmia* occurs at rest but disappears with exercise. It is also attributed to a "vagotonic" state. Sinus pause may also occur. First-degree *heart block* is seen in athletes and is felt to be due to changes in autonomic input. Second-degree heart block (Mobitz I or II) may also be due to cardiovascular conditioning. Complete heart block is rare in athletes and should be considered abnormal.

Incomplete right bundle branch blocks demonstrating intraventricular conduction prolongation is seen in athletes. Most commonly, this is attributed to right ventricular overload. Complete right bundle branch block or left bundle branch block is not common in the athletic population.

Ventricular hypertrophy is more commonly seen in endurance athletes than in static athletes. Using voltage criteria for left ventricular hypertrophy shows that this is a common condition in athletes. Voltage criteria add the deflections of SV_1 and RV_5, which is considered high if greater than 35 mm for left ventricular hypertrophy. Right ventricular hypertrophy is present if RV_1 plus SV_5 is greater than 10.5 mm.

ST and T wave changes are also reported in athletes due to alterization in repolarization. ST segment elevation and peaked, inverted, or tall T waves are examples of electrographic changes seen in athletes.

Echocardiographic Changes

Changes in the morphology of the heart include thickening of the myocardial walls and chamber enlargement. Often these correlate with the increase in heart size seen on chest radiographs.

Increase in left ventricular end-diastolic cavity diameter is the most common finding in dynamically trained athletes. The values in athletes, though increased in comparison with the control population, are usually lower than those found in patients with valvular or myocardial disease. The increase in left ventricular size is not believed to be solely due to the reduction in resting heart rate but is thought to correlate with the more highly dynamically trained the athlete is. The degree of dilation is usually within the accepted range of normal adult values. Changes may occur early in training, with some reported as early as the first week of training.

Left ventricular wall thickness in the posterior left ventricle and intraventricular septum are reported to be in conjunction with the change in left ventricular diameter. The degree of thickening is believed to correlate with training intensity. Wall thickness changes are generally modest and within the upper range of normal adult values. Thickening may be found in strength-trained and endurance athletes and decreases with deconditioning. Clinical correlation must be considered regarding the ratio of septal- to free-wall thickness, so as not to confuse athlete's heart syndrome with hypertrophic cardiomyopathy. A ratio greater than 1.3 is considered to be consistent with hypertrophic cardiomyopathy. Using this single value to diagnose hypertrophic cardiomyopathy is not recommended.

Increases in left ventricular mass, left atrial size, and right ventricular size have all been reported with athletic heart syndrome.

Exercise Treadmill Changes

Exercise treadmill testing is primarily used in athletes to evaluate aerobic and anaerobic metabolism. Determination of $\dot{V}O_2max$ (volume of maximal oxygen consumption) and anaerobic threshold has value for endurance-trained athletes and may assist in writing a valid exercise prescription.

The predictive value of exercise treadmill tests in evaluatinge coronary artery disease due to premature atherosclerosis or coronary artery anomalies is low because of the low prevalence of these diseases in the general athletic population. Its use in patients with cardiac disease is of unquestioned value in evaluation of coronary artery disease and myocardial perfusion.

Screening the Competitive Athlete

Knowledge of the changes due to athlete's heart syndrome helps the practitioner in the diagnosis of normal conditioning changes in the competitive athlete. Despite this knowledge, athletes are at risk for sudden cardiac death. In athletes younger than 35 years, hypertrophic cardiomyopathy is the most common killer. In those over age 35, atherosclerotic coronary artery disease is the most prevalent. In addition, heart-related cases of sudden death may be attributed to congenital abnormalities of the coronary arteries, Marfan syndrome with aortic dilation and dissection, idiopathic left ventricular hypertrophy, myocarditis, aortic stenosis, mitral valve prolapse, and prolonged QT syndrome, among others.

A cardiac screening questionnaire evaluating the cardiac history of the athlete is the most cost-effective and universally accepted first-line screening method. Parental involvement in filling out the questionnaire is recommended for acquiring complete information from younger athletes.

Physical examination with a careful cardiac examination should also be performed. Examination of the athlete should be done in a quiet setting free from distractions. Resting blood pressure should be evaluated. Using an appropriate-sized cuff is important, especially for bigger athletes. Palpation of radial and femoral pulses evaluates coarctation of the aorta. Ausculation of the heart should be performed by a knowledgeable physician. The first and second heart sounds, extra sounds in the systole and diastole, and systolic and diastolic murmurs should be evaluated and recorded.

Electrocardiograms, echocardiograms, exercise treadmill tests, and laboratory evaluations are usually not effective screening methods but should be reserved for individuals in whom the screening questionnaire and physical examination are suggestive of potential cardiac pathology.

Conclusion

Team physicians' knowledge of athlete's heart syndrome is important to avoid undue anxiety for the athlete due to misdiagnosis of cardiac pathology based on what are in fact normal physiologic changes in the athletic heart. Bradycardia and heart block due to enhanced vagal tone, ST and T wave changes due to early repolarization, eccentric or concentric cardiac enlargement due to chronic hemodynamic volume or pressure overload, and third and fourth heart sounds may all be normal in the athletic heart. Conversely, they may also indicate cardiac disease states. A detailed, accurate cardiac history and a careful physical examination, along with appropriate use of special tests, are indicated in cardiac evaluation of athletes.

Athlete's Nodules

Athlete's nodules is a term that refers to a broad category of nonnancerous skin conditions affecting athletes that occur in areas of high friction or repetitive trauma. The nodules represent overgrowth of a skin component called collagen and are often referred to as *collagenomas*. Diagnosis is typically uncomplicated. Treatment includes both medical and surgical options. Athlete's nodules are prevented by using properly fitted and padded athletic equipment at all times.

Anatomy

The skin is the largest organ of the body. It covers an area of approximately 2 square yards (1.67 square meters). The skin ranges in thickness from 0.5 millimeters (mm) on the eyelid to more than 4 mm on the palms of the hands and soles of the feet. Up to 15% of a person's body weight is made up by the skin.

The skin has two main layers: (1) an outer layer called the epidermis and (2) an inner layer called the dermis. The outer epidermal layer forms a protective barrier for the body. Skin cells in the deepest layer of the epidermis constantly divide and are pushed to the surface to replace dead skin cells that have been sloughed off. The inner dermal layer supports the function of the epidermis. Inside the dermis is a vast network of blood vessels, sensory nerves, and supporting protein fibers called collagen and elastin. These supporting fibers help maintain the shape and structure of the overlying skin.

Causes

Athlete's nodules are caused by repetitive friction or trauma against the skin. In most cases, the repetitive friction occurs between a piece of the athlete's sporting equipment and its interface with the skin. Over time, the skin responds to the trauma by increasing the amount of supporting collagen fibers in the dermal layer. The nodules form when there is an overabundance of these collagen fibers present at the site of repetitive friction.

An example of this process is seen with chronic rubbing of the feet from wearing tight-fitting athletic shoes. Used over the course of multiple seasons, tight and poorly fitting shoes can lead to athlete's nodules forming on the top of the foot. The top of the foot is where a tight shoe can exert the most pressure. Other examples of this process have been given unique names in the medical literature due to an association with specific sports: (a) surfer's nodules—lesions on the knees of surfers from friction against the surfboard, (b) knuckle pads—pads of skin over the knuckles of boxers from repetitive punching trauma, (c) cycler's nodules—growths on the buttocks of cyclists from friction against the bike seat, and (d) skate bite—nodules on the feet of ice hockey players from wearing tight ice skates. Despite these specific names, athlete's nodules can occur in any individual engaging in any sport.

Symptoms

Athlete's nodules can affect athletes of any age. The prevalence of these lesions is not well-known. The nodules may present without pain or other symptoms. The athlete may only be concerned about the appearance of the lesions.

Diagnosis

Evaluation of a skin lesion for diagnosing athlete's nodules begins with obtaining a careful clinical history. Special attention is paid to the equipment demands associated with the athlete's sport. If the lesion occurs at a site of repetitive friction with a piece of sporting equipment, it is highly indicative of athlete's nodules. Examination is performed with a visual inspection and palpation of the affected area. Athlete's nodules are well demarcated and skin colored. If the clinical history is suggestive, then the diagnosis is usually uncomplicated.

Depending on the site of the skin lesion, other diagnostic possibilities can exist. Other conditions such as skin callus, hypertrophic scar tissue, ganglion cysts, foreign body skin reaction, bursitis, and gout may mimic the features of athlete's nodules. These conditions may be considered before a diagnosis is made.

To confirm a diagnosis of athlete's nodules, a skin biopsy may be performed. A punch biopsy technique is often used to sample the different skin layers in the lesion. With the use of special cellular staining techniques, the biopsy specimen is examined under the microscope to determine the cellular contents and architecture of the lesion. The microscopic appearance of athlete's nodules will show increased density of collagen fibers in the dermis. In some cases, there is buildup of the outermost layer of the epidermis, which can be seen on the biopsy.

Treatment

Once the diagnosis is made, treatment options include medical and surgical therapies. If there is significant buildup of the outer portion of the epidermis, then several topical medical creams can be used to decrease the thickness. These medications include urea, lactic acid, and salicylic acid preparations. Potent steroid creams can be used and applied to the lesion to decrease the overabundance of collagen in the dermal layer. Alternatively, a steroid such as triamcinolone can be injected into the nodule.

Surgical excision of the lesion is another treatment option. However, with any surgical treatment of athlete's nodules, there is risk of scarring of the affected area, development of a hypertrophic scar, and/or recurrence of the nodule. The athlete should be fully aware of these risks before proceeding with an operation.

If the lesions are not bothersome to the athlete, then it may not be necessary to perform any medical or surgical treatment. In most cases, the nodules should improve with modifying and properly fitting the athlete's equipment.

Prevention

Preventing the occurrence of athlete's nodules requires that the athlete use properly fitted equipment. Properly fitted athletic shoes in particular are critical for the running athlete. If an athlete has been diagnosed with a nodule, it is important that his or her personal equipment be modified or refitted to prevent increased pressure or friction on potential sites. Customized protective pads can be worn over vulnerable anatomic sites for a given sport. As an example, in the case of the surfer, simply wearing a wetsuit can dramatically decrease the friction of the surfboard on the knees and can help prevent nodule formation.

Athletic Shoe Selection

For athletes, carefully chosen, well-fitted, comfortable athletic shoes are vital to success, while poorly selected, ill-fitting shoes can lead to performance problems. Athletic shoes serve diverse purposes, which include protection from the environment (from impact shock, abrasion, temperature, moisture), comfort, assisting in the prevention of injury, and, additionally in some sports, functioning to couple limbs and feet to the sporting device (e.g., skis, cycling pedals, snowboard, etc.), all of which contribute to optimal performance.

Athletic shoes are big business. The U.S. athletic shoe marketplace is a $19.4 billion per year business. Running shoes make up the largest number of shoes sold, followed by "low-performance" (fashion), basketball, and cross-training shoes. Marketing has always had a large impact on the selection of athletic equipment, particularly shoes. Because it is often hard to discern fact from fiction in advertising, marketing cannot be relied on to inform us about footgear. One must look farther than noticing which champion is wearing which kind of shoes or viewing the running and style magazines, in which one finds images of shoes hot off the waffle iron, shoes with the latest computer chip inside, shoes with springs, and shoes with air cells and gel. The hype surrounding a type of shoe must not be the major influence in selecting athletic shoes.

Advertising by manufacturers of athletic shoes does not stop at old-fashioned print and television advertising but now extends to the web, blogs, and social networks. The founders of Adidas and Puma, the Dassler brothers, were among the first to seek out famous athletes to wear their shoes. They aggressively competed against each other, convincing athletes to wear their products, often by paying them, despite restrictions on amateur athletes endorsing products. Athletes have been pursued to wear shoes to promote sales as far back as the Olympics of 1936. The holder of several world track records and soon to be a four-time Olympic gold medalist, Jesse Owens was persuaded to wear the shoe manufactured by the Dasslers' combined company, before their split. Abebe Bikila, the barefoot marathoner of 1960, was pursued by Tiger, Adidas, and Puma at the

Tokyo Olympics in 1964. He finally wore Pumas during the Olympic marathon event and set a world record. In 1972, Mark Spitz, Olympic swimmer and winner of six gold medals, walked to the podium carrying a pair of Adidas.

Principles of Athletic Shoe Selection

When selecting an athletic shoe, the athlete should make certain to obtain the proper sport-specific shoe. The motions and forces generated differ from one sport to the next. Weight lifting, tennis, and running each require different motions and place varied stresses on the feet and lower body. For example, tennis shoes require side-to-side, or lateral, stability. Lack of lateral stability could result in an ankle sprain. Running shoes, in most cases, are designed for straight-ahead motion and do not provide this type of stability. Sprinters require a shoe designed for forefoot contact, while the elite marathoner needs a shoe designed for midfoot contact.

Fit Comes First

Obtaining a correct fit is the first step in being prepared for athletic participation. With the majority of athletic shoes being sold in high-volume discount chain outlets, there is usually no knowledgeable and properly trained sales person available to assist with fitting. For this reason, a specialty store is important to success in choosing the proper shoe. Pay attention to both length and width. With the vast number of models available in a multitude of widths and sizes, the athlete is usually able to find the right fit. Shoes are now sized in a great range of lengths and in widths from AA to DDDD. Wearing the socks that will be used for participation in sports helps ensure correct foot measurement. However, each manufacturer uses their own models or lasts, over which the shoe is made, with no standardization for length and width. Consequently, precise fit must be checked inside the shoe. Length is usually measured using a Brannock device and then checked in both heel to toe (one finger's width longer than the longest toe is the correct length) and heel to ball. Width is also measured by the Brannock device and then visually examined for correctness. The foot should not press too hard against the upper at its outer borders, nor should it feel lost and float inside the shoe.

Foot Shape

The easiest method to determine one's foot shape is by doing the wet foot/paper bag test. Wet the bottom of the foot with water, step on a paper bag, and note the shape left behind. A significant curvature of the inner (medial) part of the foot indicates a high arch. A relatively bricklike shape with little curvature indicates a flat foot. A mild curve would indicate a normal or average foot type.

The *last* of a shoe refers to two things. One is the shape of the model used to make the shoe, and the second is the model of the foot itself. Here we are concerned with the shape. The average foot is considered to have a medium or normal arch with mild curvature in the horizontal plane. This foot type usually feels most comfortable in a shoe with a semicurved last. The high-arch, C-shaped foot is best fit in a shoe with a curved last. The flat foot, with its typical bricklike outline, feels best in a straight-lasted shoe.

Foot Type

Severe Overpronation

The foot undergoing severe overpronation usually has a low arch. After the heel or midfoot contacts the ground, the heel everts, resulting in a position that makes for inefficiency. This rotation also causes excessive torque and rotary forces in the Achilles tendon and continuing up the leg. The individual with this foot type does best in a motion control shoe. With somewhat less overpronation, one can wear a stability shoe. The additional supportive features included in the motion control shoe are helpful for those who suffer from severe overpronation. These include the long heel counter, external heel counter, multidensity midsole material, combination- or board-lasted shoes, and midsole support devices. The midsole materials are important in contributing to both cushioning and motion control. The major materials employed are based on ethylene vinyl acetate (EVA) and polyurethane (PU). EVA is foamlike and lightweight, providing cushioning and lowering the overall weight of the shoe. PU is denser and more durable, resisting compressive forces. In combination, they create a duo or multidensity midsole, allowing more resistance to the forces of overpronation on the medial (inner) side of the shoe.

Supinated Foot: Underpronator

Individuals with a C-shaped foot who underpronate can be susceptible to impact shock injuries and lateral overload injuries or ankle sprains. Lateral stability is important in a shoe, and one must avoid having too many pronation-resisting features. Neutral shoes are often good for this type of individual.

Cushioning Versus Support

Cushioning is an overhyped and overrated feature for many types of athletic shoes. Other features, including protection from overpronation, are much more important. Current shoes include many features to limit excessive pronation, including rigid heel counter, double heel counter, external heel counter, multiple-density midsole, and a variety of midfoot-stabilizing materials, which are often made of plastic or carbon graphite. The shoe's last shape will also assist in determining which shoe will fit a particular foot type.

Three-Phase Test of Stability

There are three basic tests to perform on a shoe to gauge its basic stability. Start by first grasping the heel of the shoe in one hand while squeezing the heel counter with the other. The heel counter should resist compression. The next test is perhaps the most important—evaluating for flexion stability. Solidly grip the heel of the shoe, and press the forefoot against a solid surface. The shoe should flex at the ball of the foot, where the toes and the foot meet. That is the natural flexion point of the foot, and the shoe should flex at that point. It should not flex in the middle or there may be inadequate resistance to excessive pronatory forces. The third test is for torsional stability. The heel is grasped in one hand and the forefoot in the other. Then try to twist or torque the shoe, and wring it like a towel. The shoe should resist these twisting forces.

Examine Worn and Old Shoes

Examine the sole of the shoe. Carefully observe where wear has occurred. Although many people are surprised that their shoes wear at the rear outer corner, most rear foot strikers wear at this part of the shoe. This is the point of first contact of the shoe with the ground, as most people walk and run with their feet slightly rotated from the center. Runners, however, also have what is called a *narrow base of gait*. A narrow base of gait means that the feet contact the ground close to the midline of the body. This creates additional varus (tilting in) of the limb. Forefoot wear may point to an individual who is a sprinter, runs fast, contacts the ground with the forefoot first, or all of the above. Uneven forefoot wear may show where one metatarsal is plantarflexed (sits lower) relative to the others or where one metatarsal may be longer than the others. With significant forefoot wear, the risk of stress fractures increases.

Next, place the running shoes on a flat surface and look from the back of the shoe to the toe. If the counter of the shoe is tilted in or bulges over the inner part of the shoe, it indicates excessive pronation. Look for a shoe with more stability, or replace the shoe sooner next time.

If the shoe tilts to the outside, it indicates a possible high-arched foot. In some cases, this can lead to ankle sprains. Possibly there may be an increased transmission of forces to the leg and back. Individuals with this type of foot may have lateral knee pain, low back pain, and outer leg pain and should avoid shoes with too much motion control.

Look at the top of the shoe, and note if the outline of the toes is visible. Check if the large or small toe presses against either side of the shoe. If this is so, if discomfort is present, or if there is a history of "black toe," the athlete should consider shoes that are wider or longer, or both.

The athlete with a flexible, pronated foot should consider a stiffer, board-lasted shoe. Look for a good counter and a sole that is rigid until the point where the toes attach. This offers resistance to torsion and inhibits overpronation. Slip-lasted shoes are frequently good for high-arched feet. Combination-lasted shoes are supposed to offer the best of both worlds: stability in the rearfoot and flexibility in the forefoot.

Soles

The sole of a shoe should not be worn down to the midsole. Often, more wear is seen on the outer corner of the heel than on the medial corner.

Carbon rubber is often used in areas of contact to resist wear and tear. Other sole materials with decreasing resistance to wear include tire rubber, solid rubber, EVA, and blown rubber.

Common Shoe Problems

One of the most common flaws in athletic shoes is an improper flex point. Many shoes bend too proximally rather than at the foot's natural bending point where the toes meet the foot. This creates increased tension in the plantar fascia in addition to interfering with the normal bending of the toes. Accordingly, the athlete must make certain there is adequate room at the toes. Finally, each foot needs to be individually measured and fitted. Humans are not bilaterally symmetrical, and often one foot measures a half-size or more larger than the other.

Injury History

Specific injuries should be taken into consideration when selecting an athletic shoe. Consider the thinking process in the following examples. Those with a history of plantar fasciitis will do best with a shoe demonstrating flexion stability. The athlete with a history of Achilles tendinopathy should wear a shoe with a firm midsole, a firm heel, and an adequate heel lift to take tension off the Achilles tendon. Individuals who have suffered from patellofemoral pain syndrome often benefit from a stability shoe with firm heel counters, in addition to physical therapy, quadriceps and gluteal muscle strengthening, and posterior muscle stretching.

Special-Needs Shoes

Athletic shoes can fill many needs. Snowboard shoes, ski boots, and cycling shoes each have a design specific to the sport. Running shoes may be specialized. Trail shoes are adapted specifically to the needs of the surface and environment of the trail. The enhancements that make these shoes better adapted to trail running include tread alterations for traction on wet surfaces, a protection plate (to prevent sharp-object penetration through soft EVA), additional toe protection, waterproofing, and additional lateral stability. Traction on the sole is obtained by mixing rubber derivatives with silica and carbon to provide longer wearing traction. Geometric lug patterns are seen, which provide lateral and forward-backward stability. The lugs have a "bite" that gives additional stability in soft soil. In 2008, as in all recent Olympics, the manufacturers were vying with each other to come up with something special. With temperatures expected to be extremely hot on the running surface, one manufacturer reintroduced soles with rice husks embedded in them to dissipate the heat. Perhaps rice husk soles would help those running the Badwater race in Death Valley, where ground temperatures of 150 °F are reached and the soles can actually melt.

Summary of Select Athletic Shoe Categories

The following are some select athletic shoe categories:

Running shoes: Offer good straight-ahead features; a variety of motion control devices are incorporated; slight heel lift

Court shoes: Tennis and basketball shoes are designed for side-to-side stability; usually a lower heel is present compared with a running shoe

Cross-training shoes: Possibly good for light weight lifting and exercise machines; an all-around shoe, not designed for any sport specifically; we recommend specific shoes for specific sports

Fitting Tips

Here are some tips for a proper shoe fit:

- Look for a sport specific shoe.
- Go to a specialty store.
- Take injury history into account.
- Measure feet each time shoes are fitted.
- When being fitted, wear the customary socks for the sport.
- Sock thickness affects the sizing and fit of shoes. Bring orthotics to fit shoes.
- Fit shoes later in the day since feet expand slightly by then.
- Leave a finger's width in front of the longest toe.
- Make sure both the heel-to-ball fit and the shoe length are matches for the foot.
- Make certain the shoe feels comfortable. It will not be feeling better in a week if it does not feel good right away.

- Check the shoe for manufacturing defects. It should line up perpendicular to the ground and not wobble.
- Replace athletic shoes regularly. Runners should replace shoes every 350 to 450 miles.
- Focus not on the stated size but on the actual fit.
- Do not wear a new shoe in a race or in a long-distance competitive event.

Athletic Trainers

Athletic trainers are health care professionals who collaborate with physicians to optimize activity and participation of patients and clients. Athletic training encompasses the prevention, diagnosis, and intervention of emergency, acute, and chronic medical conditions involving impairment, functional limitations, and disabilities.

Typical patients and clients served by athletic trainers include

- recreational, amateur and professional athletes;
- individuals who have suffered musculoskeletal injuries;
- clients seeking strength, conditioning, fitness, and performance enhancement; and
- patients referred by the physician.

Institutions where athletic training services are provided include

- athletic training facilities;
- schools (K–12, colleges, universities);
- amateur, professional, and Olympic sports venues;
- clinics;
- hospitals;
- physician offices; and
- community, recreational, and fitness facilities.

Athletic trainers also work in environments such as the performing arts (groups/companies); industrial, commercial, governmental, military, and law enforcement work settings; the movie industry (on the sets); rodeos; extreme sports; and auto racing.

Athletic trainers work under the direction of physicians and are clinically and academically qualified to medically treat patients and clients of all ages in any physical setting. The U.S. Department of Labor and the American Medical Association classify athletic trainers as allied health professionals. Their official title is certified athletic trainer (ATC) or athletic trainer (AT). All certified or licensed athletic trainers must have a bachelor's or master's degree from an accredited college or university to practice.

Athletic trainers receive a baccalaureate degree with an academic major in athletic training. The bachelor's degrees are in the premedical sciences, kinesiology, exercise physiology, biology, exercise science, or physical education. A similar graduate degree with a major in athletic training is also awarded for entry into the profession. Academic programs are accredited through an independent process by the Commission of Accreditation of Athletic Training Education (CAATE).

The following educational content standards are required for athletic training degree programs. As part of the Basic and Applied Sciences portion of the degree, students must receive formal instruction in the following specific subject matter areas: human anatomy, physics, human physiology, statistics and research design, chemistry, exercise physiology, biology, kinesiology/biomechanics, and rehabilitation.

The professional content of the degree must include formal instruction in the areas of risk management and injury prevention, pathology of injuries and illness, orthopedic clinical examination and diagnosis, medical conditions and disabilities, acute care of injuries and illnesses, therapeutic modalities, conditioning, rehabilitative exercise and referral, pharmacology, psychosocial intervention and referral, nutritional aspects of injuries and illnesses, and health care administration.

Nearly 70% of certified/licensed athletic trainer credential holders have a master's degree or higher advanced degree. Reflective of the broad base of skills valued by the athletic training profession, these master's degrees may be in athletic training (clinical), education, exercise physiology, counseling, health care administration, or health promotion. This majority of practitioners who hold advanced degrees are comparable with other allied health care professionals.

Athletic trainers are regulated and licensed health care workers. While practice oversight varies by state, athletic trainers practice under state statutes recognizing them as health care professionals similar to physical therapists, physiotherapists, occupational therapists, speech language professionals, and others. Athletic trainers are generally categorized as physical medicine and rehabilitation providers. Athletic training licensure/regulation exists in 46 states, with aggressive efforts under way to pursue licensure in the remaining states and to update outdated licensure practice acts.

The independent Board of Certification Inc. (BOC) nationally certifies athletic trainers. Athletic trainers must pass an examination covering topics within the six practice domains of athletic training: (1) prevention, (2) clinical evaluation and diagnosis, (3) immediate care, treatment, (4) rehabilitation and reconditioning, (5) organization and administration, (6) and professional responsibility. Athletic trainers must hold an entry-level bachelor's or a master's degree to become a certified athletic trainer. To retain certification, credential holders must obtain 75 hours of medically related continuing education credits every 3 years and adhere to Standards of Professional Practice. The BOC is accredited by the National Commission for Certifying Agencies (NCCA).

Other independent organizations that support and serve the athletic training profession are the National Athletic Trainers' Association (NATA) Research and Education Foundation (NATA Foundation) and the NATA Political Action Committee (NATAPAC).

The NATA Foundation is a 501(c)(3) nonprofit corporation separate from the NATA. Its mission is "supporting and advancing the athletic training profession through research and education." The NATA Foundation relies on voluntary support to sustain numerous programs to advance the profession. The goals and strategies of the foundation are to (a) advance the knowledge base of the athletic training profession; (b) encourage research among athletic trainers, who can contribute to the athletic training knowledge base; (c) provide forums for the exchange of ideas pertaining to the athletic training knowledge base; (d) facilitate the presentation of programs and the production of materials providing learning opportunities about athletic training topics; (e) provide scholarships for undergraduate and graduate students of athletic training; and (f) plan and implement an ongoing total development program that establishes endowment funds, as well as restricted and unrestricted funds, that will support the research and education goals of the foundation. To date, the NATA Foundation has awarded over $2,284,387 in research grant funding.

The NATAPAC works on behalf of all certified athletic trainers and the people they treat. Its goal is to enhance health care, both for those who provide it and for those who receive care. NATAPAC is the voice of the athletic training profession. This political action committee seeks on behalf of athletic trainers the right to practice to the fullest extent of their scope of practice, as defined by state licensure or regulation, and fair access to the health care market as physical medicine and rehabilitation providers. Like all political action committees, NATAPAC works to effect change by supporting federal candidates for public office whose views and intentions align with NATAPAC goals.

Athletic trainers are also part of the American Medical Association's Health Professions Career and Education Directory. Athletic trainers are assigned National Provider Identifier (NPI) numbers, as all other health care professionals. Additionally, the American Academy of Family Physicians, American Academy of Pediatrics, and American Orthopaedic Society for Sports Medicine, among many others, are all strong clinical and academic supporters of athletic trainers.

The American Medical Association provided Current Procedural Terminology (CPT) codes

(97005, 97006) for athletic training evaluation and reevaluation. Additionally, the American Hospital Association has established Uniform Billing (UB) codes, or revenue codes, for athletic training.

The NATA, founded in 1950, represents more than 33,000 members of this international profession. Of the total membership, 26,000 are certified/licensed athletic trainers, representing about 85% of all athletic trainers practicing in the United States. The remaining 7,000 NATA members are noncertified professionals and nonlicensed students. The NATA accurately claims the distinction of representing the greatest majority of athletic training professionals worldwide.

The NATA is dedicated to enhancing the quality of health care provided by athletic trainers and to advancing the athletic training profession. The NATA represents and supports the members of the athletic training profession through public awareness, legislative and regulatory advocacy, education, and research. Its slogan is "NATA: Health Care for Life and Sport."

Atlantoaxial Instability

Atlantoaxial instability (AAI) is the loss of stability at the junction between the first cervical vertebra (C1, atlas) and the second cervical vertebra (C2, axis). This is usually due to a problem with the ligament that helps stabilize the two bones, but it may also arise from bony defects. The main concern is that excessive movement at the C1-C2 joint may damage the spinal cord.

The diagnosis cannot be made clinically but must be made by radiographs. Once the diagnosis is made, however, the clinical symptoms and signs are more important. Many people with AAI are asymptomatic. However, patients who are symptomatic need prompt and aggressive evaluation and intervention to decrease the risk of permanent neurologic damage.

Anatomy

The odontoid, or *dens*, is a bony prominence arising from C2 that joins C1 near the back of the spinal column. It is held in place by the transverse ligament. This joint rotates when we turn our heads.

AAI is defined by measurements on X-rays. The atlanto-dens interval (ADI) is the primary measurement. AAI is diagnosed in adults with an ADI greater than 2.5 millimeters (mm) and in children with an ADI greater than 4.5 mm.

Many athletes are asymptomatic, and there is no good evidence that people with asymptomatic AAI are more likely to develop symptomatic AAI. Also, the condition may develop and progress over time, so it is worth following patients to inquire about new symptoms.

Causes

Athletes with Down syndrome (Trisomy 21) are potentially at high risk for this injury. The transverse ligament is usually loose, so it cannot hold the dens against C1. However, these patients may also have inadequate bone formation of the dens, C1, and C2. Approximately 20% of patients with Down syndrome have AAI, while only 2% are symptomatic.

Patients with rheumatoid arthritis (RA) have a higher risk for AAI (up to 60%) and symptomatic AAI. Traumatic injury can cause cervical fractures, leading to AAI. Patients with osteogenesis imperfecta, neurofibromatosis, and several rare syndromes have a higher risk for AAI.

Clinical Evaluation

In sports medicine, most cases of AAI will involve clearance of Special Olympics athletes. It may be difficult to get an excellent history and physician exam due to their cognitive delays. The Special Olympics requires all athletes with Down syndrome to have a screening evaluation and radiographs to evaluate for AAI. It is very important to distinguish between symptomatic and asymptomatic AAI by clinical correlation of radiographs with history and physical exam.

History

The symptoms associated with AAI are neck pain, easy fatigability, difficulty walking, abnormal gait, increased clumsiness, and numbness and tingling in the arms. Patients may complain of neck stiffness and decreased neck motion. These symptoms may have been present for some time and can continue to progress.

Physical Exam

Abnormal findings include decreased range of motion in the neck, increased reflexes all over the body, and spasticity of the muscles. A complete neurologic exam should be performed.

Diagnostic Imaging

X-rays should be obtained with the neck in neutral, flexion (45°), and extension positions. The ADI is maximal in flexion and should decrease in extension. There are other methods to measure for AAI, but they are not commonly used by all physicians and not accepted by the Special Olympics.

For patients with symptomatic AAI, magnetic resonance imaging (MRI) should be performed. This allows for detailed evaluation of the spinal cord and spinal canal. It also can be used to measure the space available for cord (SAC), which may be a more accurate predictor of neurologic injury (Figure 1).

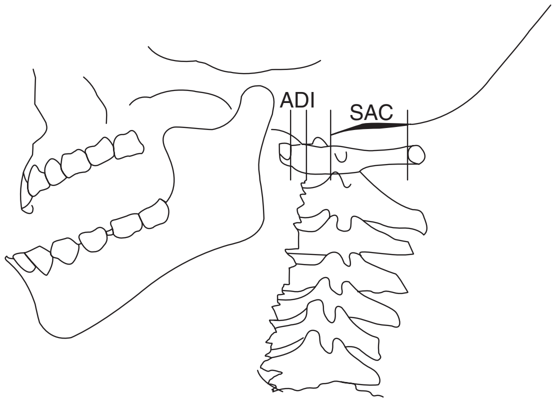

Figure 1 Atlantoaxial Instability: Anatomic Landmarks for Atlanto-Dens Interval (ADI) and Space Available for Cord (SAC)

Treatment

Since AAI can progress over time, at-risk athletes should be followed with regular histories and physical exams.

Special Olympics recommend that athletes with AAI avoid participation in high-risk activities. These include diving, gymnastics, power lifting and squats, alpine skiing, high jump, and pentathlon. They also include butterfly stroke, flip turns, and diving starts in swimming.

These restrictions are controversial since there are no reported cases of patients with asymptomatic AAI (diagnosed by X-ray) sustaining a neurologic injury secondary to sports participation. However, it is still advised that athletes with asymptomatic AAI follow those activity restrictions, but they require no further intervention. They should be followed closely for progression of disease and onset of symptoms.

Patients with symptomatic AAI should undergo MRI evaluation. They should be managed by an experienced neurosurgeon or orthopedist. These athletes will usually need an aggressive surgical approach involving fusion of the vertebra, with ensuing activity limitations.

Attention Focus in Sports

Attention refers to the way in which a person allocates his or her mental processing capacity to the task or tasks at hand. The capacity to do mental processing is not unlimited, so effective allocation of attention is pivotal to successful learning and performance. This is especially true in the sports domain, where poor performance is often attributed to errors of attention. A missed free throw in basketball can be caused by distractions from crowd noise; a defensive player in football can be deceived by an opponent to attend to the wrong cues; or the concentration of a tennis player can waver on an easy smash. These are common occurrences in sport that illustrate the connection between control of attention and successful performance. For different types of sports, and tasks within sports, optimal performance depends on the athlete's ability to either focus attention (so as to apply the maximum mental processing resources to a single element of a task) or divide attention (so as to distribute processing resources concurrently between two or more tasks or elements of a task).

Focusing Attention

The ability to focus attention provides a way of ensuring that only the information that is directly relevant to the task at hand gets processed, while other information that is irrelevant, distracting, or deceptive does not. The information that is relevant may come from sources external to the performer (such as targets, teammates, or opponents) or sources that are internal (such as thoughts, mental images, or kinesthetic feedback from sensory receptors in the body). The golfer attempting to make a crucial putt is more likely to be successful if he or she is able to focus attention only on relevant cues (e.g., the position of the hole, the intended point of contact of the putter with the ball, and the speed and trajectory of the movement of the club) and not on irrelevant or distracting ones (e.g., the spectators, the score, or a previously missed putt). The focusing of attention to ensure the processing of only a limited number of cues (from the near infinite array possible) is often termed *selective attention.*

Studies using methods in which the visibility of particular cues is selectively masked and/or eye movements are recorded have revealed that experts in some sports selectively attend to cues that are different from those used by less skilled athletes. In sports such as tennis, highly skilled players attend to, and are able to pick up information from, cues present in their opponent's movement patterns (e.g., the motion of the opponent's arm, the position of the ball toss, and the opponent's position on court), whereas less skilled players generally rely on later ball flight information to know where to move to hit their return stroke. In learning new movement skills, superior results are consistently achieved when learners focus their attention *externally* on the movement outcome (e.g., the trajectory of the ball) rather than *internally* on the mechanics of the movement (e.g., the swing of the arm). Both of these strategies are typically superior to those in which attention is directed to irrelevant cues.

Dividing Attention

In contrast to the golfer, who needs to retain a singular point of attentional focus while putting, the quarterback in football needs to be able to divide his attention contemporaneously between multiple tasks and multiple sources of relevant information. To be successful, he needs to be able to not only control his own running and throwing movements (through attention to relevant internal and external cues) but also simultaneously process information about the current and future positions of both teammates and opponents. Because processing capacity is limited, dividing attention (or processing resources) between current tasks and competing sources of information is generally difficult, although this difficulty is reduced significantly for more skilful/better-trained athletes and in situations in which one or more of the tasks is relatively simple.

Attempts have been made to measure individual differences in the ability to divide attention between competing tasks using self-report instruments (e.g., the NASA Task Load Index), physiological indicators (e.g., pupil diameter, heart rate variability, and event-related changes in the electrical activity in different brain regions), and behavioral measures (involving the concurrent performance of multiple, usually dual, tasks). In the dual-task method, a secondary task (e.g., a reaction time task) is completed at the same time as a primary task (e.g., dribbling a basketball). In such situations, the more skilled athletes typically show superior performance on the secondary task even if their primary task performance is indistinguishable from that of less skilled athletes. With practice, the control of at least some aspects of the primary task may become automatic, or at least require less than the usual levels of attention, effectively freeing processing resources that can then be applied to, and result in better performance of, the secondary task(s).

Controlled and Automatic Processing

The alterations in the attentional demands of different skills that occur with practice highlight the existence of two fundamentally different types of information processing. *Controlled processing*, which is generally thought to be predominant early in learning, is slow, sequential, deliberate, and conscious and consequently requires substantial mental-processing resources. In contrast, *automatic processing*, which is typically associated with highly skilled acts, is rapid, parallel, and involuntary and occurs below the level of consciousness, requiring relatively little of the brain's information-processing resources. Recent research using functional magnetic resonance imaging (fMRI), which permits high-resolution tracking of blood flow changes within the brain, has attempted to determine those areas of the brain most responsible for these different types of processing.

Explicit and Implicit Motor Learning

How and where attention is directed during the learning of a movement (motor) skill can significantly influence the demands on mental processing capacity that are made when the same skill is later performed under competitive pressure. During the controlled processing phase of skill acquisition, *explicit motor learning* occurs when performers encode and store large amounts of conscious, generic knowledge into long-term memory, whereas in *implicit motor learning* the accrual of such knowledge is meager. Performers who learn a movement skill explicitly generally find it more difficult, under conditions of psychological stress or physiological challenge, to divide their attention between performance of the motor skill and conscious processing of other sources of information related to the situation and the anxiety produced by it. As a consequence, the performance of their motor skills can become disrupted. In contrast, performers who learn implicitly appear to find it much easier to divide their attention effectively when multitasking or when faced with the need to perform their motor skills under stressful or challenging conditions.

Implicit motor learning techniques can be used during the early stages of skill acquisition specifically to distract the attention of the learner away from information that can be employed to test hypotheses about the best way to move successfully. This may then effectively reduce the encoding and storage of conscious generic knowledge about the movements. For example, a beginner golfer who makes a series of putts all of which are successful is unlikely to test hypotheses about the best way to move, given that the movement is already highly effective. Consequently, the golfer with error-free performance in learning will store less conscious generic knowledge in long-term memory than a golfer who makes a series of putts that are unsuccessful. The unsuccessful golfer is likely to deliberately test many hypotheses about how to move as he or she searches for an effective putting technique and will consequently generate and store large amounts of conscious generic knowledge. Developing a variety of strategies to optimize attentional focus for both learning and performance of motor skills presents an ongoing challenge for sports scientists and coaches alike.

Avascular Necrosis of the Femoral Head

Avascular necrosis (AVN), which is also known as osteonecrosis, aseptic necrosis, ischemic necrosis, and osteochondritis dissecans, is a pathological process that results in the death of bone tissue in the affected area. Many medical conditions and treatments have been linked to AVN.

The exact mechanism that causes AVN is not well understood. The process leading to AVN involves compromise of the bone vasculature, which leads to the death of bone and marrow cells and ultimately to mechanical failure of the affected bone. The process of AVN is often progressive and will result in joint destruction within 3 to 5 years if left untreated.

Prevalence

The exact prevalence of AVN is not known. Each year, 10,000 to 20,000 new cases are diagnosed in the United States. Men are eight times more likely than women to be diagnosed, and the average age at diagnosis is less than 40 years.

Causes

A number of traumatic and nontraumatic factors have been linked to AVN. Greater than 90% of reported cases of AVN are due to glucocorticoid use or excessive alcohol intake.

The precise cause of AVN is not completely known. It is thought to result from a combination of metabolic factors, mechanical stress, and local factors in the affected joint that alter the blood supply. AVN most likely begins from an interruption of blood supply to that area, leading to weakened bone that will collapse if stressed.

Glucocorticoids

Many studies have been done that link glucocorticoid use with an increased risk of developing AVN. The exact mechanism by which glucocorticoids increase this risk is not known. One proposed mechanism is that steroids alter the circulating lipids in the blood supply, leading to microemboli that block the arteries supplying the bone. Another theory proposes that steroids cause changes in venous endothelial cells, leading to stasis of blood and increased pressure within the bone, which eventually leads to necrosis.

Patients treated with prolonged courses of high-dose glucocorticoids seem to be at the greatest risk of developing AVN. Patients receiving short-term steroids, including pulse-dosing and steroid injections into the joint, rarely develop AVN.

Alcohol

Excessive alcohol intake and the development of AVN have been well studied in the literature. Studies suggest that fat emboli, venous stasis, and increased cortisol levels associated with alcohol intake contribute to the development of AVN. Studies have clearly documented that a clear dose–response relationship exists between alcohol intake and risk of developing AVN. The more alcohol consumed regularly, the more likely a patient is to develop AVN.

Trauma

Fracture or dislocation of a bone may cause damage to the blood vessels inside the bone. For example, fractures in the subcapital region of the femoral neck (the femur is the thighbone that connects the hip to the knee) frequently interrupt the major part of the blood supply to the head of the femur, which can lead to AVN.

Other Risk Factors

Many other medical conditions have been associated with AVN. These include, but are not limited to, sickle cell hemoglobinopathies, lupus, Gaucher disease, chronic renal failure, pancreatitis, hyperlipidemia, HIV infection, and gout. In addition, there are two types of AVN that are seen only in children. The first is idiopathic osteonecrosis of the femoral head, which is known as Legg-Calvé-Perthes disease (please see separate entry for more details), and the second is osteonecrosis occurring in children, which is associated with a slipped capital femoral epiphysis (please see separate entry for more details).

Symptoms

The most common presenting symptom of AVN is pain. Groin pain is the most common complaint in patients who have AVN of the femoral head. Thigh pain and buttock pain are also associated. Most patients complain of increased pain when bearing weight on the affected joint and during movement of the joint. Two thirds of patients also complain of pain during rest, and one third of patients complain of night pain. Many patients do not present until late in the disease process because pain is not always present in the beginning stages.

Location of Avascular Necrosis

The most common location of AVN is the anterolateral femoral head. AVN has also been seen in the humeral head (the humerus is the arm bone that connects the shoulder to the elbow), femoral condyles, proximal tibia (the top of the shinbone), vertebrae in the spine, and small bones of the hand and foot. Some patients have disease on only one side of the body, but many patients present with disease on both sides (bilateral). Bilateral disease is most commonly seen in disease of the hips, knees, and shoulders.

Diagnosis

When the symptoms suggest AVN, a complete physical exam and imaging studies are done to help make the diagnosis. Findings on physical exam are usually nonspecific. Patients may have pain and some limitation in the range of motion of the affected joint. A limp may be present as the disease progresses to the later stages. Some patients with AVN will have a normal physical exam with no symptoms.

Imaging studies including X-rays, bone scans, and magnetic resonance imaging (MRI) are helpful in making the diagnosis and also to classify and stage the extent of disease. X-rays are the first step in imaging studies. Evaluation of suspected AVN of the femoral head should begin with anterior-posterior and frog-leg views of the hips. It is important to know that X-ray findings can remain normal for months after symptoms of AVN pain begin.

Bone scans are helpful to further evaluate patients with suspected disease who have normal X-rays, unilateral symptoms, and no known risk factors for AVN. The bone scan determines areas of active bone turnover and will show an area of active turnover surrounding a cold area or "dead spot" where bone has died due to AVN. This finding on bone scan is known as the "doughnut sign."

Magnetic resonance imaging (MRI) is much more sensitive than plain X-rays or bone scans and can detect changes early in the course of the disease if the other imaging reports have been negative and AVN is highly indicated.

The diagnosis of AVN is a clinical diagnosis based on symptoms and findings on imaging. Unfortunately, there is no single simple test to determine if AVN is or is not present. The doctor must look at a number of factors and rule out other possible causes before making the diagnosis.

Classification and Staging

Classification and staging of AVN are based primarily on radiographic findings. The greater the extent of bone involved, the more serious the disease and the higher the stage. Stage 0 is normal diagnostic studies and Stage 4 shows late changes in the affected joint.

Treatment

The goal of treatment is to preserve the native joint for as long as possible. The ideal treatment for AVN remains controversial in the current orthopedic literature. There are four therapeutic options: (1) conservative management, (2) joint replacement, (3) core decompression with or without bone grafting, and (4) osteotomy.

Conservative management involves bed rest, partial weight bearing with crutches, weight bearing as tolerated, and the use of nonsteroidal anti-inflammatory agents for pain management. This approach has generally not helped stop the progression of disease. Joint replacement (e.g., a total hip replacement for a patient with AVN of the femoral head) has also been shown to be somewhat ineffective for AVN. Patients who have joint replacement because of AVN tend to do more poorly than patients who have joint replacement for other reasons. Total joint replacement of the shoulder for AVN has been shown to be more successful than hip or knee joint replacement.

Core decompression for AVN was initially used as a diagnostic tool to measure bone marrow pressure and to get bone marrow biopsy specimens. Doctors began to notice that patients had symptomatic pain relief after the "diagnostic" procedure and began to use it as a type of treatment.

Osteotomy is a "joint-sparing" technique that has been used to treat AVN, primarily of the femoral head. The goal of this treatment is to move the area of necrosis away from the major transmitting area of the acetabulum and to redistribute the weight-bearing forces to healthy cartilage and bone. Overall, osteotomies have been successful in treating later-stage AVN of the femoral head.

The optimal treatment for AVN is yet to be determined. The decision depends on the joint involved, the extent of disease, and the other risk factors present in the individual patient.

AVN and Sports Medicine

An athlete who presents with pain in a joint area should be thoroughly evaluated and AVN ruled out, especially if the athlete has any or a combination of the above-listed risk factors,.

Athletes who have AVN, which occurs most commonly as a result of trauma in athletes, will need close follow-up after diagnosis and treatment. These athletes will need comprehensive physical therapy after recovery, especially if they undergo surgery. All athletes should be counseled about lifestyle factors that could put them at higher risk for AVN.

Avulsion Fractures

Avulsion fractures are sports injuries that may occur at any age but are frequently seen in adolescent athletes. They usually involve a fracture of a bone at the insertion site of a tendon or ligament. The mechanism of these injuries is often the exertion of a force on a bone that leads to the fracture and subsequent separation of a piece of the bone from the skeleton. The excessive stretching of the muscle that attaches to an incompletely fused piece of bone can also create an avulsion. The athletes who suffer the most from these injuries are sprinters, jumpers, and those involved in sports with rapid stops and starts, such as football. Avulsion fractures occur most often in athletes aged 14 to 17 years, and with the emergence of competitive athletics among children and teens, these injuries are becoming more common.

Mechanisms

Avulsion fractures can occur at practically any site on the skeleton. The pelvis is a common location as the major muscle groups of the lower extremity attach to small processes on the pelvic bones. The hamstrings commonly generate avulsion fractures, and they attach to the ischial tuberosity, a swelling of bone on the ischium of the pelvis. These muscles contract forcefully during sprinting or jumping. The mechanism for injury is the initial contraction in a sprint, during which the muscles generate enough force to separate a piece of the ischial tuberosity from the pelvis. Similarly, the sartorius muscle, which attaches at the anterior-superior iliac spine of the pelvis, contracts during knee and leg flexion, which makes avulsion possible during running and jumping. Conversely, the rectus femoris is a leg muscle involved in extension of the knee and hip flexion. It can injure the anterior-inferior iliac spine during those same activities. The abdominal muscles can cause avulsion of the iliac crests of the pelvis during exercise as well. This occurs with severe abdominal contractions or rapid twisting of the upper torso. These pelvic injuries significantly limit overall activity, as the lower extremities need to be rested after these types of insults.

Apart from the pelvis, long bones such as the femur and the ulna are also susceptible to avulsion fractures. The iliopsoas muscles can avulse pieces of the lesser trochanter of the femur during rapid hip flexion. The olecranon of the ulna is the insertion point of the triceps brachii muscles. The olecranon can be damaged with repeated, forceful throwing motions, primarily seen in young pitchers (Little League elbow). The glenoid of the scapula is also vulnerable to avulsion from the biceps tendon's insertion at the labrum during rapid arm flexion, as seen with tackling in football. Upper extremity injuries are serious and require long rehabilitation. Nevertheless, they are much rarer, as adolescents tend not to have as well-developed upper extremity as lower extremity muscles.

Avulsion fractures at large joints, such as the knee, are often caused by extrinsic forces on the ligamentous structures. In the knee, the lateral collateral ligament (LCL) and the anterior cruciate ligament (ACL) cause these injuries after severe internal rotation of the tibia with a flexed knee or other mechanisms of knee injury such as direct trauma. One such injury, the LCL-induced avulsion fracture of the tibia, "Segond fracture," is often associated with ACL tear when present in adults but causes isolated avulsion fractures in adolescents. In the case of ACL-induced tears, the tibial eminence, a wide, depressed area on the anterior, proximal portion of the tibia, is avulsed (left photo next page). Avulsion of the proximal fibula is most commonly due to forces exerted on the bone by the LCL and biceps femoris tendon, commonly seen when ACL and posterior cruciate ligament (PCL) tears occur. The presence of the "arcuate" sign on the X-ray is an important predictor of the success of surgical reconstructions of these knee ligaments. If an avulsion of the fibula is present but not identified and addressed, there is an increased likelihood of failure of the reconstruction, leading to chronic knee instability. Nevertheless, with proper immobilization and rehabilitation, chronic instability can be averted.

Avulsion fracture of distal fibula at the insertion of the anterior talofibular ligament

Source: Authors.

Smaller joints and bones, such as the ankle and the fifth metatarsal, are affected as well. The common ankle sprain, which is caused by excessive inversion of the foot, can lead to an avulsion fracture as well. The anterior tibiofibular ligament is the first ankle ligament to tear in common ankle sprains and has been known to avulse pieces of the distal fibula and tibia (right photo). Avulsions of the proximal aspect of the fifth metatarsal are seen in cases of severe plantarflexion (toe-off) and inversion of the ankle. The attachment of the lateral plantar aponeurosis is supposed to be the culprit in these cases, as in sprinting. This type of metatarsal fracture is effectively resolved with conservative therapy. It is important to differentiate this injury from Jones fracture, which often requires surgical repair. From these examples, it is clear that avulsion fractures occur at many sites throughout the body and thus are important pathologies to keep in mind when assessing an injured athlete.

Presentation

Athletes who have avulsion fractures present with localized pain, swelling, limited range of motion, or sudden loss of function of the affected area. They often report a snapping sound or sensation accompanying a movement of significant effort. After the incident, there is usually severe tenderness to palpation, as well as an increase in discomfort with movement of the affected muscle group. The injured athlete will favor a position that maximally stretches the muscle.

Diagnostic Studies

Radiographs of the affected area are routinely ordered. Imaging of the contralateral bone can be helpful in confirming an avulsion fracture, especially in growing children. Initial films do not always capture the fracture, as the fracture may be only minimally displaced or indistinguishable from normal, unfused bone in a child. Repeat films may be required a few weeks after injury for confirmation, as time will allow soft tissue changes to accentuate the fracture. Magnetic resonance imaging is not routinely required and is only used when further evaluation is needed.

Treatment

Treatment for avulsion fractures begins with rest. Athletes need to remain on bed rest or have their movement considerably limited in the early stages of recovery. It is important to place the involved muscle group in a relaxed position and ice the injured area to limit soft tissue swelling. Pain relievers will help keep patients comfortable during recovery. Once the pain has subsided, the patient is permitted to gradually increase the level of activity involving the affected musculature. After full range of motion without pain is achieved, the patient can begin retraining the muscles. A stepwise program that involves resistance exercises for the muscles in isolation is recommended initially. The timetable for return depends on the location and severity of the injury; reports of return to normal activity 4 weeks to 4 months after initiation of a proper rehabilitation program have been documented. Fortunately, good to excellent results can be achieved for most athletes using a nonoperative rehabilitation program.

The role of surgery as a treatment modality is not well defined. Evidence-based criteria for surgical intervention are not yet established, but as a guideline, when a bone fragment is displaced greater than 2 cm, it often requires surgical fixation. Surgical intervention can decrease the likelihood of nonunion of the fragment, preventing chronic pain and functional disability.

Back Injuries, Surgery for

Athletes with back injuries are commonly divided into two groups on the basis of diagnosis: (1) those with stress fractures and (2) those with lumbar disk herniations. Stress fractures of the lumbar spine are termed *spondylolysis*. Spondylolysis is caused by repetitive hyperextension forces on the spine in an area termed the *pars interarticularis*. The *pars* refer to the part, and *interarticularis* refers to the bony area connecting the facet joints. Hyperextension causes tension in this area of the spine, and the repetitive motion eventually leads to a fatigue crack in the spine. The incidence of spondylolysis in the normal population is believed to be around 8%, with a higher incidence in the athletic population. Athletes who are involved in activities that entail hyperextension of the spine are at a greater risk of developing this injury. Gymnasts who perform many back-spring activities and down linemen in football, who rise from a forward stance and are pushed back, represent the athletes who most commonly sustain this injury.

Patients with spondylolysis generally present with significant low back pain related to their sports activities. The examination of these patients will indicate pain in the affected area with hyperextension. Plain X-rays may aid in the diagnosis; however, many times, a computed tomography (CT) scan or magnetic resonance imaging (MRI) is required to make the definitive diagnosis. These studies reveal a fracture of the pars interarticularis, which sometimes is acute; however, often there is evidence that these are long-standing injuries that have recently become symptomatic. Nonoperative treatment of these patients is generally sufficient for resolution of symptoms and return to full sporting activities. It revolves around physical therapy working on strengthening the core musculature of the body and stretching to improve flexibility. The use of bracing is indicated in those patients who have specific symptoms such as pain and spasm of the back. Surgical treatment is deemed appropriate in long-standing stress fractures in which the athlete is unable to become painfree despite physical therapy and bracing.

Herniation of the lumbar disk is the other common type of sports-related back pain; disk herniation is brought about by an increase in pressure and strain on the intervertebral disk. This increase in stress causes a weakening of the ligament surrounding the disk, which results in weakening and failure of the *annulus,* or outer fibrocartilaginous rings, of the disk surrounding the *nucleus pulposus* at the center. The resulting outpouching of the pulposus material causes back pain; however, most symptoms are caused by the disk area that has herniated exiting and touching a nerve root. The resultant pressure on the nerve root leads to radiculopathy.

Pressure against a nerve root causes irritation in the nerve root, which can lead to pain signals down the leg from the irritated nerve, weakness in muscles innervated by that nerve, numbness in areas that are innervated by that nerve, and resultant reflex changes. On examination, the athlete will present with significant pain and, occasionally, listing to one side, which is the body's way of splinting the affected area. Nerve tension signs are physical exam findings that are seen when the nerve is stretched, causing irritation due to pressure by the herniation, as in a straight leg raise test.

Surgical Treatment

Surgical treatment for spondylolysis depends on the location of the fracture. The most common location of a stress fracture is the fifth lumbar vertebra, which is the last bone before the sacrum. Surgical treatment of a stress fracture in this area entails fusing of the bone with the sacrum, termed an L5-S1 fusion. The goal of this operation is to prevent motion at the site of the stress fracture by making that portion of the spine stiff. A *fusion* occurs when two bones that move together in normal circumstances are surgically made to become one bone. This is performed by creating a new bone growth by way of bone grafting. The bones of the fifth lumbar vertebra are made to grow together with the bones of the sacrum by adding a bone graft. Once they become a solid area of bone, they will not move separately, and hence, the fracture cannot move; this eliminates the source of pain for the patient. Surgeons will occasionally use spinal instrumentation in the form of screws and rods during surgery to help internally immobilize the bones. Bones tend to fuse together if there is no motion, and the bone graft matures into solid new bone; local screws into the bone connected to rods help immobilize the area and improve the chance of fusion.

Occasionally, spondylolysis requiring surgical treatment will occur higher in the lumbar spine, such as in the third or fourth lumbar vertebra. In these instances, surgical treatment is aimed at fixing the fracture because motion loss in these areas is more detrimental to an athlete. This procedure entails directly cleaning the area of spondylolysis of scar tissue and placing a bone graft in the fracture site. This is termed a *direct pars repair* and is usually supplemented by a screw across the fracture site to hold the fracture still until the bone graft matures and solidifies.

Surgical treatment of a lumbar disk herniation is performed in a minimally invasive manner by using a microscope and doing a limited surgical dissection. The surgeon makes a small incision over the back in the affected area and moves the muscles out of the way at the correct level. The surgeon then performs a small laminotomy, in which the bone and the ligament are removed to enter the area where the spinal nerves are located. The surgeon then identifies the spinal nerves, gently moves the affected nerve out of the way, and removes the herniated disk fragment. In general, the herniated fragment represents a small overall piece of the disk, and hence its removal does not affect the entire disk.

After Surgery

Recovering from surgical treatment of spondylolysis requires 3 months of absence from any athletic activity. In the first 6 weeks, the patient is required to wear a low-contact, hard-shelled brace during upright activities. After the sixth week, the athlete can start controlled physical therapy aimed at core strengthening, pars spinal muscle strengthening, and lower-limb flexibility. Return to noncontact sports may begin after 3 months; but in general, contact sports require a total of 5 months before return to play. Disk herniation surgery usually requires a minimum of 6 weeks off to minimize the complications of reherniation. Physical therapy may be instituted at 2 weeks after surgery and focuses on core strengthening and flexibility. Return to contact sports may begin after 3 months.

Badminton, Injuries in

Badminton is a court-and-racquet sport requiring high levels of cardiovascular endurance, strength, and dexterity. As Olympians, the athletes participating in this event have elite training and the highest levels of the above characteristics. As a result, they are able to strike the projectile in this game at extremely high velocities. The nature of this sport leaves the participants vulnerable to injury categories that include those related to high-speed projectiles, acute lower and upper extremity trauma, chronic overuse injuries of the upper and lower extremities, and various other injuries. This entry highlights the game and history of badminton and those injuries specific to the game of badminton and others related to racquet sports in general.

The Game

Badminton is a racquet sport played by either two opposing single players or two opposing pairs, on a rectangular court with a net dividing the sides equally. This sport differs from most other racquet sports in the use of a shuttlecock instead of a ball. The shuttlecock has feathers that create a significant drag, decelerating the projectile much more quickly than the traditional projectiles. These projectiles are struck with a lightweight racquet that can be swung quickly, easily providing the force to create an extremely fast-moving object. The objective of the game is to strike the shuttlecock in such a manner as to have the shuttle strike the ground in the opponent's territory.

Equipment

Badminton racquets are lightweight, with top-quality racquets weighing between 80 and 90 g, including the strings. They are composed of many different materials, ranging from carbon fiber composite to solid steel, which may be augmented by a variety of materials. For many years, all badminton racquets were made of wood, which is fairly light and durable. However, carbon fiber composite, such as aluminum, can be much lighter and more durable and, most important, extremely stiff. This stiffness decreases the amount of kinetic energy lost to the racquet when striking the shuttlecock. The strings of the racquet are usually around 0.25 millimeter in width, and the tension ranges from 80 to 130 newtons.

The *shuttlecock*, or birdie, is cone-shaped with a cork base surrounded by a leather or synthetic cover. From this base, a cone-shaped ring of goose feathers arises, creating the drag of this projectile. As in squash, the shuttlecocks come in a range of speeds that are color coded (green is slow, blue is fast, and red the fastest).

Badminton shoes should be comfortable and lightweight, with soles that provide good traction. Unlike tennis and running shoes, the soles should not be elevated. An elevated shoe increases the risk of ankle sprain in this game, which requires very forceful lateral movements.

Injuries

Injuries discussed in this entry will be divided into three categories. First are general injuries related to court games. These tend to result from repetitive stress to individual body parts, leading to overuse injuries or acute injuries related to sudden direction change and other forces applied during play. Second are overuse injuries that are particular to the game of badminton. Third are injuries related to high-speed ballistics. Treatment of these conditions is not covered here since the treatments are generally standard and are covered in other, related entries.

Overuse Injuries in Racquet Sports in General

Most racquet sports are fast-paced matches in which the players start and stop suddenly and change direction, often while swinging racquets of variable weight and size. Injuries generally sustained under these circumstances include both soft tissue and bony injuries to the feet, legs, knees, hips, shoulders, elbows, wrists, and hands. When a muscle—for instance, the gastrocnemius—is loaded concentrically and eccentrically hundreds of times during a game, the weakest point will incur the most damage. For adults, this point is the tendon or the point where the tendon meets the muscle. This includes the Achilles tendon, which is loaded when the athletes push off the ground or land on their toes, which occurs often in badminton (often the athletes are "on their toes" for the entire event). Achilles tendinosis is a common condition in racquet sports. The patellar and quadriceps tendons are loaded with each jump or sudden stop. This results in the common diagnosis of patellar or quadriceps tendinosis. The shoulder and elbow have common overuse syndromes with similar mechanisms, including rotator cuff tendinosis and epicondylitis, respectively. Bony injury can also occur from chronic loads, as in stress reaction where the bone is weakened and, occasionally, fractures from recurrent stress of impact. Joints can be injured as well through chronic stress, as in osteochondritis dissecans, where microstress can cause permanent injury to the cartilage that protects the joints. Awareness of these injuries with limitations of repetitive motions and good injury prevention programs can decrease the incidence of these injuries.

Acute Racquet Sports Injuries

The majority of acute injury in racquet sports is related to the sudden starts and stops, direction change, and jumping involved with the particular sport. Multiple athletes sharing the same court space can increase the risk of blunt trauma, of ankle-type injuries (when one athlete inverts his or her ankle on the other), or of being struck directly with the racquet. The majority of acute injuries involve the lower extremity. In the case of patellar tendon and Achilles tendon rupture, the cause is likely related to the pattern of injury described above, leading to weakened tendons. They are both surgical problems. Other acute injuries in the ankle include fractures and sprains of the stabilizing ligaments. In the knee, twisting injury can lead to tearing of the meniscus and the anterior cruciate ligament. Less commonly, the racquet-sports athlete can have an acute upper extremity injury to the shoulder, elbow, or wrist, including muscle and tendon injury. This may also include rare rotator cuff strains.

Badminton-Specific Injuries

Injuries specific to badminton are upper extremity injuries. Players swing extremely lightweight racquets and use wrist strength to produce quick racquet speed. This "flicking of the wrist" puts significant strain on both the wrist flexor group of muscles and the wrist extensors, causing muscle and tendon tearing. The treatment of these, generally, overuse injuries includes prevention, activity modification, bracing and rehabilitation, and, rarely, surgery. In terms of prevention, the players are encouraged to engage in general upper extremity strength work, focusing on wrist strength, in addition to quality periods of rest and recovery. Once the injury occurs, if it is mild, players can increase their recovery periods and consider bracing, such as a counterforce brace. If the injury is significant, a prolonged period of rest is indicated, from a few days to several weeks, depending on the severity. Rehabilitation will again focus on regaining wrist strength, as well as a number of other modalities provided by the player's athletic trainer or physical therapist. In rare cases of severe recurrent epicondylitis, a debridement procedure can be considered.

Projectile Injuries

Although relatively rare, shuttlecock-related injury can occur to soft tissue. The most devastating and preventable injuries are ocular. If the eye is struck directly by the shuttlecock, a player can sustain permanent visual loss. If the globe of the eye is ruptured, the cornea injured, the lens detached, the retina detached, or any number of other critical structures injured, the player can lose vision. For this reason, it is critical that all levels of players in high-speed racquet sports be required to wear eye protection.

Baseball, Injuries in

In the 1960s, Nolan Ryan, a professional baseball pitcher, began lifting weights as part of his physical conditioning regimen. At that time, most people subscribed to the belief that strength training with weights was deleterious to the baseball player's body. Especially with regard to pitchers, it was believed that weight-lifting programs would produce muscle growth that would impede the player's movements and biomechanics. But within a decade, advancements in sports medicine disproved what everyone had thought to be true. By the end of the century, this transformation had a lasting effect, the likes of which almost no one perceived even a few years earlier.

Baseball is a team sport that requires the individual athlete to run, hit, and throw. Under normal conditions, these activities do not generally tax the human body. But under the conditions of a baseball game, the requirements to throw a ball, swing a bat, and run around the field of play put unusual distress on players' joints and muscles. As a result, there has long been a focus on training methods that help prevent injury. Yet baseball, from the youth to the professional levels, has over time also become increasingly focused on performance.

The shift to performance enhancement poses enormous challenges for ballplayers and the sports medicine practitioners who attempt to keep them in playing condition. Despite the mounting existence and availability of performance-enhancing substances, the care and conditioning of ballplayers was essentially the same in the 1960s as it was at any time prior. But as people in the ranks of medical science and technology began to use their skills to perform more highly specialized work, the product of their work was increasingly applied to baseball and vice versa.

There may have been no greater a period of significant advancements in baseball-specific sports medicine than that which occurred during the two or so decades beginning around 1960. For instance, in 1966, the future Hall-of-Fame pitcher Sandy Koufax abruptly retired due to injury sustained from overuse of his throwing arm. The fastballs and curve balls he threw en route to recording 382 strikeouts in 1965 forced him to retire at age 30, on the heels of the last of his three Cy Young Awards. Throughout his 12-year career, which included winning 25 games three times, the bone spurs, scar tissue, adhesions to the cartilage covering the elbow, circulatory problems in his left (throwing) hand, and arthritis that he developed were treated with ice baths, massage therapy, and ointments. For Koufax and other ballplayers through that era, preventive treatments superseded curative treatments; the player tended to retire when the latter proved no longer effective.

But around the same time, physicians began to pay attention to injuries and ailments in ballplayers of all ages and skill levels. A body of research on baseball-related injuries and ailments—mostly associated with pitching—began to emerge from clinical practices, one of which was the orthopedic practice run by Dr. Robert Kerlan. Kerlan, who as the first team physician in the history of the Los Angeles Dodgers recommended to Koufax that continuing his career past the 1966 season could result in permanent arm damage, later formed a partnership with Dr. Frank Jobe. Together, they devised innovative treatments and procedures that were a significant contribution to the game of baseball. By the mid-1970s, Jobe had invented a surgical procedure that could reconstruct a damaged elbow. The procedure to repair a torn ulnar collateral ligament by harvesting a nonessential tendon from a ballplayer's nonthrowing side wrist, followed by 18 months of recovery, allowed the then Dodgers' pitcher Tommy John to resume a playing career in which he would eventually win a total of 288 games—164 of which came after the operation that today informally bears his name.

Since then, numerous other surgical procedures have been developed to remedy injuries in the shoulder, elbow, and wrist, as well as at other bodily sites that have been compromised by injury.

Common Injuries and Health Care Concerns

The shoulder region and arm are the sites most often considered in the context of baseball injuries. Particularly for pitchers, the repetitive and high-energy forces of the throwing motion place progressive stress on the stabilizing structures of the shoulder. This can lead to instability, especially in the rotator cuff and shoulder capsule ligaments. While an intensive strengthening program can encourage structural stability and proper biomechanics, tissue damage in the shoulder sometimes requires anatomical repair through surgical intervention, followed by a postoperative rehabilitation program.

Yet all regions of the body must be given proper care and attention during baseball-related activities. Because baseball is a sport that involves the use of the entire body, all areas, including the shoulder region and arm, are susceptible to injury: head, neck, and face; thoracic through coccygeal spine; thorax and abdomen; hip and pelvis; thigh, leg, and knee; and lower leg, ankle, and foot. Given baseball's continuous enormous popularity in the United States, there is an overall increased incidence of injury as more people, especially youth, participate in organized and spontaneous baseball games.

Acute baseball-related injuries tend to be caused by the impact of being hit by a ball or bat or by collision and sliding. Severe injuries—and sometimes fatalities—are often the result of blows to the chest and head. This has been a cause of concern in all levels of baseball. So too is the fact that adolescent pitchers sustain chronic injuries to the shoulder and the elbow as a consequence of throwing too many pitches without proper recovery and throwing certain types of pitches. The literature that reports on the veracity of these claims is mixed, although some large-scale investigations have concluded that baseball has a high incidence of injury associated with it, particularly for pitchers who throw with the sidearm style.

But more recently, the prevalence and use of performance-enhancing drugs (PEDs), including steroids and herbal dietary supplements, has been of mounting concern in baseball circles. The abuse of PEDs, especially anabolic-androgenic steroids, is the fastest-growing form of drug abuse in the United States, according to the Food and Drug Administration. On a very basic level, these steroids are the synthetic derivatives of the naturally occurring male anabolic (tissue building) hormone testosterone. By duplicating the effects of testosterone, these steroids, either injected or taken orally, have the capacity to encourage increased muscle strength and muscle growth. This allows the athlete to train harder for longer periods of time. Their frequent enhancement of performance and social recognition, their apparent use by some professional baseball players and other elite athletes, and the likelihood of diminishing results once usage is stopped create an incentive for the user to continue using PEDs. Yet those who persist in taking these substances often evade the fact that these PEDs can cause serious physical and psychological side effects and that injury rates can result from increased loads on bones and joints.

Performance Enhancement and Injury Prevention

Steroids may, at present, be highly equated with performance enhancement, but there are other means through which ballplayers can choose to prepare and modify their bodies ahead of competition. Perhaps the most effective way through which to prevent injury is to develop physical fitness. Athletic trainers and, increasingly, strength and conditioning coaches in many instances now work with ballplayers to devise complete physical conditioning programs. These usually include a regimen of cardiorespiratory fitness, muscular strength and endurance fitness, flexibility, and nutrition and therein variously consist of general and sport-specific conditioning. An increasing number of baseball teams, from youth to professional, have instituted such full-fledged strength and conditioning programs to assist ballplayers in their preparatory and competitive efforts. And some of these programs have increasingly been aided by the advent of sport psychology, which complements the physical conditioning by giving attention to the mental aspects of performance. That is, a good many ballplayers today use modes of training and conditioning that half a century ago had been exceptions to the norm.

For all of these impressive changes that have taken place in and around baseball during that span of time, it stands to reason that injury rates have decreased and careers have been prolonged. But this is too simple an assumption, in large part because the game has changed dramatically in a short time.

In an era of conditioning, pitch counts, player match-ups, a heavy dependency on relief pitchers, the evolution of free agency, player development and procurement strategies, incentive clauses in contracts, and advances in orthopedic surgery and physical therapy, fans marvel at the endurance and durability of modern-day pitchers, who rarely succeed in reaching double digits in complete games during a season. Although there were 29,101 complete games thrown between the 1960 and 2007 Major League Baseball seasons, only 16% of those were pitched after the 1989 season.

Basketball, Injuries in

Basketball is an organized collision sport that is played by millions of people worldwide. Developed in 1891 by Dr. James Naismith as a way to keep his physical education students occupied, basketball has seen an incredible amount of change over time. Originally played with a soccer ball, peach basket, no dribbling, and nine players to a side, the game has evolved to become the fast-paced and dynamic sport it is today. Basketball requires a high level of hand-eye coordination, as well as explosive jumping, cutting, and running maneuvers. As a result, lower extremity injuries to the knee, ankle, and foot are expected. In addition, head injuries, sudden cardiac events, and upper extremity conditions commonly occur. Injury rates for basketball athletes will continue to rise as the popularity of the sport grows.

Epidemiology

Basketball is the third most popular sport offered by U.S. high school athletic programs. Nearly 1 million high school boys and girls participate during each school year. Even among adults, there are more than 500,000 yearly visits to physician offices and emergency rooms for basketball injuries. The injury rates of males and females appear to be equal. When competing in games, athletes are approximately two times more likely to be injured than in the practice setting. Sixty percent of all injuries occur in the lower extremity. The most common areas injured are the ankle, foot, knee, head, and hand. Ligament sprains, muscle strains, contusions, and fractures are the most frequent diagnoses.

Knee Injuries

Knee Sprain

There are four main ligaments of the knee. The medial collateral ligament (MCL) and lateral collateral ligament (LCL) are located on the inner and outer sides of the knee, respectively. Conversely, the anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL) are present within the knee joint. While direct contact to the knee causes most MCL, LCL, and PCL sprains, noncontact injuries after twisting or cutting movements are notorious for causing a torn ACL. Hearing or feeling a "pop" is a classic description of a sprained ACL. Frequent symptoms include swelling within the knee joint and a feeling of instability. Often, associated structures such as the meniscal cartilage and the MCL are injured along with the ACL. Currently, the gold standard for diagnosis of an ACL sprain is a magnetic resonance imaging (MRI) study. When an ACL sprain occurs in isolation, surgical reconstruction is performed for athletes who desire a return to cutting and pivoting sports. The management for all other isolated knee ligament sprains is nonsurgical.

Meniscal Tear

Meniscal tears are an injury to the cartilage of the knee. The meniscus is the cartilage that is attached to the tibia (shinbone) and serves primarily as a shock absorber. Meniscal tears are classically produced by twisting movements at the knee. Pain at the joint line and swelling are common symptoms of a meniscal tear. When mechanical symptoms such as locking or catching of the knee begin, the management of this condition becomes surgical. Depending on the location and quality of the tear, the injured meniscal cartilage can be repaired or resected. For athletes without mechanical symptoms, either nonoperative or operative treatment is appropriate.

Patellar Tendinitis

With a nickname such as "jumper's knee," it is not surprising that patellar tendinitis afflicts a great number of basketball players. The patellar tendon attaches the kneecap to the tibia. It is under the most stress during knee extension, when the tendon is subjected to large weights while jumping and landing. A rise in the volume or the intensity of play, such as early in a season, is a common cause for patellar tendon injuries. Pinpoint pain over the patellar tendon and pain with running and jumping are frequent symptoms. Rest from offending activities, frequent icing, and patellar strapping are initial treatment options.

Ankle and Foot Injuries

Ankle Sprain

Ankle sprain is the most common injury found in basketball players. Nearly 40% of all basketball injuries are to the ankle and foot. Given the amount of running and cutting, as well as the potential for landing on opponents' feet, this is not surprising. An ankle sprain is a stretch or tear of the ligaments that attach the lower leg bones to the bones of the feet. The outer ankle ligaments are affected far more often than those on the inner aspect of the ankle. Pain, swelling, and bruising are frequent consequences of ankle sprain. X-rays may be necessary to exclude a fracture in certain circumstances. Initial treatment includes *r*est, *i*ce, *c*ompression, and *e*levation (RICE) of the ankle. Early attempts at improving range of motion by the prevention of swelling are critical to an efficient recovery. Ankle taping and ankle braces are used to protect an injured ankle or prevent a future sprain.

Achilles Tendinitis

The Achilles tendon attaches the calf muscles to the calcaneus (heel bone). It facilitates heel raising and, thus, is essential in jumping. Achilles tendinitis is an overuse injury that is frequently triggered by increases in the volume and intensity of play. Pain during heel elevation or jumping and pain directly over the Achilles tendon are frequent symptoms. Along with relative rest and icing to initially treat Achilles tendinitis, specific strengthening exercises are crucial to long-term treatment.

Achilles Tendon Rupture

Basketball athletes are notorious for experiencing an acute rupture of the Achilles tendon. While typically pushing off of their toes, the athlete experiences a sensation such as being kicked in the heel. Difficulty pointing the toes or palpation of a large defect in the tendon is indicative of a complete Achilles rupture. Nonoperative management avoids potential wound complications from surgery; however, some physicians advocate surgical repair as it may reduce the risk of repeat rupture of the Achilles tendon.

Jones Fracture

A Jones fracture is an acute fracture at the proximal (closest) aspect of the fifth metatarsal bone. Analogous to ankle sprains, Jones fractures develop after a rolling injury of the foot and ankle. A foot fracture is suspected, though, when bony tenderness is found over the fifth metatarsal bone instead of the expected ankle joint area. Diagnosis of a Jones fracture is critical as the blood supply to that area of the bone is poor and can prevent proper healing. Radiographs of the foot are often sufficient to diagnose the Jones fracture. Treatment decisions are individualized; however, because of an increased chance of nonunion (lack of fracture healing) with nonoperative treatment, many athletes require surgical correction with screw fixation to ensure a good outcome.

Stress Fractures

Due to the frequent pounding from running and jumping, basketball athletes are prone to stress fractures of the lower extremity. To guide treatment, stress fractures are divided into high-risk or low-risk groups depending on the bones' available blood supply and subsequent healing potential. Common low-risk stress fracture locations include the metatarsal (main) bones of the feet and the medial (inside) tibial shaft of the lower leg. High-risk areas consist of the femoral (thighbone) neck, anterior (front) aspect of the tibia, tarsal navicular (small foot bone), and proximal shaft of the fifth metatarsal (outside foot bone). Radiographs can diagnose stress fractures after pain symptoms have been present for approximately 2 weeks; however, many go unnoticed on an X-ray. A bone scan or magnetic resonance imaging (MRI) is an excellent test to detect stress fractures not found on radiographs. Treatment predominantly includes rest from basketball, with a gradual return to the sport. With low-risk stress fractures, complete rest or simply a reduction in volume of play is appropriate. Most high-risk stress fractures, however, require an extended period of non–weight bearing with immobilization (cast) or consideration of surgery.

Medial Tibial Pain Syndrome (Shin Splints)

Media tibial pain syndrome (shin splints) is an exceedingly common diagnosis for those with shin pain. Shin splints and tibial stress fractures both cause pain on the inner tibia; however, the pain of shin splints is spread across a larger area. The diagnosis is made based on the history and physical examination. Imaging studies are used to exclude a stress fracture. Treatment is focused on rest, regaining of strength and flexibility, and adjustments of any of the athlete's biomechanical issues.

Upper Extremity Injuries

Shoulder Injuries

A variety of injuries can occur in the shoulder region. Direct impact to the shoulder can cause dislocations (at the shoulder joint) and separations (a ligament sprain on the top of the shoulder). Overuse injuries often cause irritation within the region of the rotator cuff. Acute and traumatic rotator cuff tears are rare, especially in the young athlete.

Wrist Injuries

An injury to the wrist often begins with a fall on an outstretched hand. Sprains of the wrist ligaments can occur with this mechanism. Initial treatment for sprains includes icing, elevation, and wrist bracing. When acute wrist injuries have persistent pain or swelling, X-rays are necessary to exclude a fracture. Breaking a fall by extending an outstretched hand can cause a fracture of the distal radius (the far end of the outside forearm bone) or the scaphoid (wrist bone). It is important that tenderness over the scaphoid bone and a potential fracture therein is not missed. The scaphoid bone tends to heal relatively poorly, and certain locations of this bone can be slow in healing. When a scaphoid fracture is displaced, surgical management is undertaken. For nondisplaced fractures, a period of nonoperative cast immobilization is attempted. Some physicians, however, advocate initial surgical management of nondisplaced fractures as this may result in a shorter healing time.

Finger Injuries

The "jammed" finger is one of the most common basketball injuries. It typically affects the proximal interphalangeal (PIP) joint (middle knuckle of the hand and fingers). When the basketball comes in direct contact with the tip of a straightened finger, a jammed finger frequently results, leading to pain and swelling at the PIP joint. Ice and buddy taping of the fingers are usually sufficient to treat this joint sprain.

A finger dislocation can happen with a similar mechanism as the jammed finger, though it is a much more urgent and serious injury. Reduction of the dislocated joint back to its normal state is required and commonly relieves pain. After any first-time dislocation, radiographs are necessary to evaluate for an associated fracture. Since soft tissue injury is common around the dislocated joint, swelling and loss of range of motion are seen. If the joint is stable and a significant fracture is not present, buddy taping is performed for 3 to 6 weeks along with early range of motion activities.

Spinal Injuries

The spinal column consists of three main areas: cervical (neck), thoracic (mid back), and lumbar (low back). Muscles surround these areas of the spine and provide stabilization and movement. With frequent jumping and landing, combined with twisting motions, a significant amount of strain is placed on the spinal muscles during basketball. Naturally, muscle strains of all areas of the back occur regularly. Relative rest, stretching, and ice are important initial treatment steps for strains of the neck and low back. Radiation of pain down the arms from a cervical injury or down the legs from a lumbar injury can indicate a more serious injury than a muscle strain. Further medical evaluation is appropriate in those cases.

Cardiac Events

A sudden cardiac event is the collapse of an athlete due to cardiac causes. Highly publicized incidents of collegiate and professional basketball players who have died from heart-related causes while competing have brought a great amount of attention to this topic. Despite this interest, sudden cardiac death remains an exceedingly rare event. A selective list of causes of sudden cardiac events includes hypertrophic cardiomyopathy (congenitally thickened heart wall), anomalous coronary artery (atypical path of the coronary arteries), and aortic stenosis (narrowing of the heart valve). Survival of those athletes who experience a sudden cardiac event has been shown to improve with the prompt use of automated external defibrillators (AEDs). These small, portable devices can be used by lay persons and are increasingly found in basketball gymnasiums, as well as other public places. Both athletes and spectators alike have benefited from the use of a nearby AED to quickly reverse a sudden cardiac event.

Concussion

Concussion is seen among basketball athletes after injuries such as striking the head on the floor or receiving a blow from an opponents' elbow to the head. Symptoms such as headache, nausea, dizziness, and imbalance are but a few of the common complaints of concussion. Memory, concentration, and orientation should be assessed. A graded return-to-play protocol is necessary as concussion features worsen with physical exertion. Those athletes who continue to have symptoms should be withheld from further competition until the symptoms have resolved.

Head and Facial Injuries

In a manner similar to concussion, many other traumatic injuries occur with contact from an elbow, finger, or basketball floor. Nasal, dental, eye, and skin injuries are seen on the basketball court. Nasal fractures most often require reduction based on cosmetic concerns. Two potential complications, difficulty breathing or a septal hematoma (collection of blood within the inner nasal wall), require urgent attention. Face masks are used to permit early return to play. Dental injuries may include loosened or even completely avulsed teeth. Mouthguards can prevent dental injury but are rarely mandatory at any level of basketball. The most common eye injury is abrasion of the cornea (surface layer of the eye). Skin lacerations occur most frequently at the face and more specifically on the chin, eyebrow, and lip. While local pressure and adhesive strips may be sufficient for minor and superficial wounds, sutures (stitches) are the definitive treatment for skin lacerations.

Benefits of Exercise and Sports

The benefits of exercise and sports are much more than just gaining a nice physique. In our modern "connected" life, we tend to ride out our days stuck in one position. This inactivity leads to increased incidence of diabetes, heart disease, and premature death. A new branch of exercise physiology, inactivity physiology, inevitably emerged studying the increasingly chair-bound society. A study of 10,224 healthy men and 3,120 healthy women published in 1989 in the *Journal of American Medical Association* (*JAMA*) demonstrated a marked decrease in mortality with higher fitness levels. In addition to mortality, exercise helps us to have a higher quality of life. Insurance companies are recognizing exercise as a way to cut costs for seniors. Several major health insurance companies are offering free gym memberships to seniors. The program has reportedly cut sedentary behavior down by 70%. This senior population, known as masters athletes, has an improved quality of life and better health due to its dedication to exercising. Exercising is a major factor in delaying the aging process of the heart, lungs, and musculoskeletal system.

The NEAT Way to Increase Metabolism

A study of sedentariness at work demonstrated that people sit an average of 8 to 12 hours a day. The concerning part is that these same people sit for 7 to 9 hours on their leisure days, meaning they are more active when not at work but still are sedentary for the majority of the week. The sedentary lifestyle of work and play has been shown to decrease metabolism. The energy used in normal daily life is known as non–exercise activity thermogenesis, or NEAT. NEAT has recently been targeted as a key to decreasing weight and promoting a healthy lifestyle. NEAT is a factor that can be directly decreased by inactivity. In a study published in *Obesity Management* in 2006, James A. Levine and colleagues have shown that obesity is associated with a lower NEAT level, and obese individuals walk and stand two and a half times less than lean sedentary people. To target this, Levine et al. (2006) have used the approach of STRIPE: *S*elect a NEAT activity, *t*arget-define goals, *r*ewards identified, *i*dentify barriers and remove them, *p*lan a NEAT activity, and *e*valuate adherence and efficacy. Ways to increase a person's NEAT level in the office vary from walking to a coworker's desk instead of calling, climbing the stairs, using a balance ball as an office chair, and taking breaks to stand. A more extreme solution in the office place is to use "active" computer workstations, which consist of computers with stationary bikes and treadmills attached. At home, similar techniques can be applied: playing active video games, watching TV on a treadmill or bike, talking with friends during walks instead of on the phone, using push lawn mowers, and many other small changes can lead to increased NEAT level and weight loss.

Lean people walk 3.5 miles more than the obese in a study on nonexercise, normal-day walking. It makes sense that the obese walk less, but more important, with increased weight gain, walking decreases further. Clearly, this is a double-edged sword because with inactivity comes health concerns that make exercise more difficult to perform safely. However, as James Levine and Selene Yeager state in their 2009 book *Move a Little Lose a Lot*, with small increases in daily activity, the NEAT level, weight loss will ensue, stopping the downward spiral of weight gain and inactivity. The question can then be asked, Do lean people eat less, or is their energy expenditure more? To study this, a group of rats were bred selectively due to their resistance to obesity. The rats and controls were fed high-fat diets. The lean rats did not gain weight, which supported the theory that lean rats had a higher usage of energy. It was found that lean rats and people had a higher daily level of activity, which was measured as endurance capacity. To measure the endurance capacity, a sedentary group of people used a treadmill test to obtain their oxygen consumption, $\dot{V}O_2$max, which is correlated to endurance capacity. Not surprisingly, lean people had a higher $\dot{V}O_2$max, demonstrating that they are more active throughout a normal day; that is, they have a higher NEAT level. This entry is not suggesting that the only cause of obesity is daily activity or endurance capacity, but it is simply testing theories on why lean people despite similar caloric intake remain lean.

Inactivity and Health Problems

A new aspect of physiology has emerged to study this harmful trend of increasingly sedentary living—inactivity physiology. The basic principles of inactivity physiology are that sitting more and performing less nonexercise activity can cause a decrease in fitness and an increase in mortality. Also, the body's response to inactivity varies greatly in comparison with the body's cellular/molecular response to exercise. Furthermore, the response to exercise in an inactive person would differ from the response in a person who had a more active baseline. A few epidemiologic studies have been done demonstrating that inactivity leads to increased risk for cardiovascular disease and death. The British professor Jeremy Noah Morris in the 1950s made the observation that deaths from heart disease were more common in people with sedentary jobs. He then studied a few groups of people to determine if this hypothesis was true. First, he studied the conductors and drivers of London's double-decker buses. He found that the active conductors of the double-decker buses had a lower incidence of coronary heart disease (CHD) than did the sedentary drivers. Then he was able to reproduce this study in active postmen versus sedentary telephonists and other government desk workers. The physique of a conductor was overall leaner and the waist band size smaller than the drivers'. This abdominal obesity became known as central obesity. After accounting for weight, age, and height, the rate of sudden death from coronary artery disease (CAD) was two times higher in the drivers, even if they had a "slim" physique. As expected, the conductors had lower low-density lipoprotein (LDL) cholesterol and triglyceride levels. Further studies of fitness level and heart disease demonstrated that regardless of body mass index (BMI), low fitness levels led to increased risk of CHD and mortality; the authors even stated that a low fitness level was comparable with diabetes as a health morbidity contributor.

In addition to increased cardiovascular morbidity, inactivity has been shown to be detrimental to other areas of health as well. A high level of exercise in postmenopausal women has been shown to decrease breast cancer risks. Maintaining a waist circumference below 102 centimeters and moderate-intensity physical activity are associated with sustaining proper erectile function. Asthma has been shown to decrease physical activity in adults; this population is characterized by a higher number of emergency room visits, greater use of medication/inhalers, sleep issues, and inability to go to work. Interestingly, a prospective study showed that asymptomatic children with low physical fitness had increased development of asthma in adolescence.

It was speculated that inactivity led to an increase in systemic inflammation. Another study demonstrated that tumor necrosis factor alpha and C-reactive protein, inflammatory reactants, increased with inactivity. This systemic inflammatory state is hypothesized to increase the risk for tumor growth, insulin resistance, and CHD. Thus, exercise acts as an anti-inflammatory agent; skeletal muscles release various myokines that have endocrine and paracrine effects on visceral fat and fat oxidation signaling. A molecular study by Marc Hamilton demonstrated that decreasing the daily low-level activity led to a change in the cellular regulation of skeletal muscle lipoprotein lipase, a protein that is important in triglyceride catabolism and for high-density lipoprotein (HDL) cholesterol. Inactivity in essence decreases muscle lipoprotein lipase, decreases HDL concentration, and decreases triglyceride uptake. In this study, when sedentary people added vigorous exercise to their daily routine, it did not have as much effect on the skeletal muscle lipoprotein lipase as did increasing baseline activity. In another study by Hamilton, treadmill walking was shown to raise lipoprotein lipase eight-fold within 4 hours after inactivity. This perhaps is why even low-level exercise, such as walking, is beneficial in preventing heart disease.

Exercise in Seniors

Athletes over 40 years of age, known as *masters athletes*, have been shown to have improved life expectancy, higher life satisfaction, and improved overall health. A survey conducted by the Arthritis Foundation showed that 64% of masters athletes reported feeling an average of 11 years younger than their actual age, while 40% reported having a healthier and more physically fit lifestyle than in their 20s. It is interesting to note the latter fact, that these incredibly active people are more fit as seniors. Moreover, 33% of them boasted that they can beat their children in at least one sport. These people are not the exception but the standard. All individuals have the chance to maintain this high quality of life and functional capacity throughout their life span if they choose to avoid a sedentary lifestyle. The sedentary lifestyle is quite detrimental to aging; it has been shown that the health of sedentary people declines twice as fast as that of their age-matched active counterparts.

Contrary to popular belief that older individuals cannot exercise or remain active due to age, this has not been shown to be true. In a study of track athletes aged 50 to 85 who participated in the 2001 National Summer Senior Games, running times across all distances declined with age. While this trend was expected, the surprising finding was the small degree of performance decline that occurred with age. Until the age of 75, the observed decline was slow and linear, with decreases of less than 2% per year. This decline was not found to be statistically significant. At age 75, however, the rate of decline jumped to approximately 8%. This trend of performance decline with age is shown in Senior Olympians running the 100-meter dash. These results suggest that if disuse and disease are eliminated, individuals should be able to maintain high levels of functional independence until the age of 75. Therefore, the loss of independence before the age of 75 must be attributed to disuse, destructive lifestyle habits, disease, or genetic predisposition. Although it has been shown in multiple studies that at age 75 the aging process becomes a factor in exercise, this still does not stop the Senior Olympians from participating in sports activity. It is not uncommon for competitors to run into their 90s and, more impressively, gain a position on the medal stand.

Health Benefits From Exercise

These masters athletes are quite serious about fitness, although they cannot ward off some aspects of aging with exercise. The good news is that even if aging is inevitable, intense exercise has been shown to slow its process.

Lungs

With age, the efficiency of oxygen delivery decreases, which affects peak performance. Oxygen is a much more efficient energy producer than any other catabolic pathway. This change in performance with aging is attributed to a lower lactate threshold, lower exercise efficiency, and lower $\dot{V}O_2max$. The $\dot{V}O_2max$ is the most important factor, and a reduction in $\dot{V}O_2max$ is the primary reason for a decline in functional endurance with aging. The $\dot{V}O_2max$ decreases 5% to 15% per decade after age 50; this decline is mainly due to changes in cardiac output. An intense endurance workout program can cut this decline of $\dot{V}O_2max$ in half.

The lung tissue also changes with age and body abuse. The lungs become stiffer and cannot expand to hold the amount of air that a more elastic lung can hold. This capacity decreases by 250 milliliters per decade. Also, from age 20 to 70, the maximum breathing capacity declines by 40%. Smoking and asthma can also lead to decrease in the elasticity of the lungs. There is also a decline in the number of lung capillaries, which further decreases oxygen exchange. With the combination of less elasticity and decreased capillaries, the lungs do not exchange oxygen for carbon dioxide in the blood as efficiently. The only way to decrease the damage to the lungs is to stop smoking.

Heart

The heart cannot take a moment's rest in the 80+ years of life; it beats on average 80 times per minute and over 50 years this is 2.1 billion heartbeats. With all that daily work, it is not surprising that the heart ages. The maximum heart rate, heart muscle contractility, and stroke volume all decline with age. Without an aerobic workout program that stresses the heart, the muscle, just like a biceps or quadriceps, can weaken. Other control measures to keep the heart pumping strongly include controlling the blood pressure, reducing emotional stress, and, as always, eating a well-balanced diet. The numbers can be frightening, with 40% of deaths in people aged 65 to 74 resulting from heart disease, which increases to a staggering 60% in people above 80. The cardiac output is only twice the resting capacity in an 80-year-old, while a 20-year-old has 3.4 to 4 times the resting capacity. To increase cardiac output, the heart pumps harder; in an older person, this is a challenge as well because with age the arteries become less elastic and therefore the blood pressure increases. To counteract the higher blood pressure, the left ventricle becomes hypertrophied. This leads to a heart that can be up to 40% larger than in a young person. The heart rate maximum decreases 1 beat/year after age 10, and the heart is not capable of beating as quickly due to the aforementioned reasons. The good news is that the effects of the aging process on the heart can be delayed with an intense endurance workout program. This strengthens the heart, causing the resting heart rate to be lower because the heart muscle is more efficient. The muscle can make more forceful contractions to squeeze out the blood and therefore does not need to squeeze as often.

In addition to the arteries becoming less elastic, they may also harden due to buildup of cholesterol and calcium deposits. High-fat diets and smoking can exacerbate this. The repeated theme of exercise and a well-balanced diet can prevent narrowing of the arteries and help control blood pressure.

Skeletal Muscle

Age-related changes affect a muscle's overall power and strength. The changes seen are due to sarcopenia, the loss of lean muscle mass. This decreases the size of muscle fibers, leads to the loss of muscle cells, and decreases muscle flexibility. Lean muscle mass starts to decrease at age 25 with the loss of muscle fibers and loss of fiber size, mostly fast twitch muscle. By age 80, 50% of lean muscle mass is lost. This dramatically increases with a sedentary lifestyle. More important, with inactivity the muscle becomes replaced with fat. However, an intense endurance workout program can again prevent age-related changes. In a Swedish and Finnish study, the vastus lateralis of 18- to 84-year-old male sprinters was studied, and the researchers found the typical age-related reduction in the size of fast twitch fibers, but these fibers were preserved at a high level in the older runners.

Old muscle has the ability to hypertrophy, just like young muscle, if the muscle is exercised. Multiple studies have shown that high-intensity strength training results in substantial, continual increases in strength. This has been shown true for deconditioned elderly individuals as well. The strength training has been shown to be essential in keeping muscles healthy. A study of masters athletes who mainly take part in aerobic exercise for fitness found muscle composition similar to that of age-matched sedentary controls. However, masters athletes who had workout routines that included weight training had muscle composition similar to controls who were 40 years younger. Other research has shown that regardless of age, if people are using comparable training regimens, it results in similar muscle composition. In essence, the aging process can go seemingly unnoticed with an intense and consistent strength training program.

Bone

The loss of bone with aging is a big concern since it leads to many complications. Bone mineral density decreases with age, but risk factors such as inactivity, smoking, low calcium intake, and low sunlight exposure or vitamin D intake can accelerate bone loss. A decrease in bone mineral density leads to osteoporosis. These soft bones are much more prone to fracture than normal-density bone. A seemingly harmless fall in an osteoporotic person can lead to a complex fracture and quite possibly permanent disability. A once independent elderly person may then end up in a nursing home. Bone loss is inevitable, but osteoporosis is not. After the age of 40, bone is lost at 1.5% to 2% per year, and women lose bone twice as fast as men. The key to bone health is, of course, eating a well-balanced diet rich in calcium and vitamin D but also performing weight-bearing exercises. For example, although swimming is an excellent cardiovascular activity, it does not stress the bones. Bones need a stress or load to maintain density. A study performed at the University of Pittsburgh on bone density in senior athletes found that the women had normal bones, even the Senior Olympians in their 80s. The prevalence of osteoporosis was lower than in the general population at any age.

New Trends in Exercise

Circuit Training

Circuit training has become increasingly popular. Many health clubs have circuit training workout classes or preprinted circuit workouts for members to use. One successful chain of women-only health clubs, Curves, is devoted entirely to circuit training. The workouts are for only 30 minutes, and they combine strength training with aerobic activity.

Dance Exercise

At every health club, there are multiple workout classes that include dance workouts. The themes range from African dance, to flash dance, to Zumba, an increasingly popular style that originated in Colombia. The dance numbers are salsa, meringue, samba, reggaeton, and other Latin rhythms. The class consists of slow- and fast-tempo songs for a strength-training and cardiovascular workout. Moving to the fast beat of the music, the aerobic expenditure can be intense.

Exercise Video Games?

Exercise has even become a trendy subject in the video game world with the advent of interactive video games. One of these gaming systems is the Wii by Nintendo. The Wii holds 48.8% of the world market, and Wii Fit is listed among the top three video games in the past few years. This gaming system requires standing and movement for game play, in contrast to typical video games where people are seated and stationary. The Wii Fit, in particular, has an exercise program that incorporates aerobics, balance, and strength training. In both adults and children, the Nintendo Wii has been scientifically shown to increase energy expenditure. Although traditional exercise such as walking is always beneficial and free, the Nintendo Wii may be an attractive alternative to motivate previously sedentary people.

While our society has become increasingly sedentary, our bodies still need exercise and activity every day. The entire body depends on exercise to keep working efficiently. The lungs, heart, muscles, and bones all benefit from exercise, which can be anything from jogging to taking the stairs at work, push mowing the lawn, or boxing a friend on a video game. Although any extra movement a day can mean pounds lost or a lower resting heart rate, only intense exercise can elevate a person to the level of the masters athlete. These older people have taken the aging process head on and are winning, with better health, longer life, and more satisfaction.

Beta Agonists

Beta agonists are medications commonly used to treat "reactive airway disease," or *asthma*. These medications stimulate the beta-2 receptors, which are found in the lungs in very small airways called alveoli. The beta-2 receptors are present in the muscles that surround the alveoli. When these muscles contract, the alveoli constrict, and less air moves through. This process is called *bronchoconstriction*. These alveoli have very small cross-sectional space so that even a mild constriction can significantly alter the airflow. This is what happens in an asthma exacerbation. The beta agonists relax the muscles that surround the alveoli.

In asthma, there are often triggers that cause bronchoconstriction. Common triggers are exposure to cold, stress, exercise, or allergens such as animal dander, pollen, medications, or food. It is important for anyone with asthma to learn his or her specific triggers and avoid them. Bronchoconstriction can be rapid and deadly, and sometimes beta-agonist treatment is not enough to reverse it. Asthma has an inflammatory component as well, which means that the alveoli swell and mucus is produced. Beta agonists cannot treat this aspect of asthma, and the inflammation will get worse if the asthma is left untreated or if there are repetitive exposures to triggers. In addition, continued use of beta agonists may make them less effective over time.

Any chemicals that stimulate beta receptors are considered beta agonists. Most of the medications that are designed to stimulate beta-2 receptors will also stimulate beta-1 receptors, which are found in the heart and control the heart rate. That is why beta-agonist medications usually increase the heart rate (i.e., stimulation of beta-1 receptors in the heart as an unintended consequence). Epinephrine (adrenaline), caffeine, and cocaine are some examples of beta agonists. Cold medications such as pseudo-ephedrine and some herbal supplements (such as *ma huang*) have beta-agonist properties. One of the most commonly used beta agonists in the treatment of asthma is albuterol. Albuterol is most often inhaled through a metered dose inhaler (MDI, or "puffer"). It is also available in pill form or inhaled in powder form.

Athletes use beta agonists to prevent or treat reactive airway disease. They are sometimes abused to increase the heart rate and get a competitive advantage. Beta agonists were previously thought to have mild anabolic (muscle building) properties, and so their use in competition was strictly prohibited. After further study, there does not appear to be any significant anabolic effect. This fact, and the significant rise of asthma rates worldwide, has contributed to relaxing of the restrictions on beta-agonist use in competition. Certain beta agonists such as formoterol, salbutamol, salmeterol, and terbutaline are permitted but regulated in international competition and during training. These medications are permitted to be taken by inhalation to prevent and/or treat asthma and exercise-related respiratory problems. Athletes still need documented proof that they have reactive airway disease and a prescription in order to compete while taking these medications (therapeutic use exemption).

Beta agonists have a role in treating asthma, but they must be used properly, and an athlete needs to be aware of the risks and side effects. Common side effects include jitteriness, increased heart rate, tremor, and difficulty sleeping. Beta agonists can exacerbate or cause arrhythmias (erratic and sometimes deadly irregular heartbeats).

Beta Blockers

Beta blockers are a group of medications that are typically used to treat hypertension and heart disease but have also occasionally been abused by athletes to gain a competitive advantage. If a medication name ends in "-lol," such as atenolol or carvedilol, it is usually an indication that the medication is in the beta blocker family.

Beta blockers are antagonists (blockers) to beta-1 (and to a lesser degree beta-2) receptors. Stimulation of beta-1 receptors increases the heart rate, and therefore, taking beta blockers will slow the heart rate. In the body, chemicals such as epinephrine (adrenaline) will increase the heart rate in response to fear or excitement or with activity such as exercise by stimulating beta-1 receptors in the heart. Beta blockers are typically used to treat high blood pressure or irregular heartbeats. They have been used for a long time and have saved many lives, especially after someone has had a heart attack.

Beta blockers can also minimize tremors. For this reason, people have used them to control symptoms of stage fright or before public speaking. This is also one of the reasons why they are banned in certain types of athletic competition, such as biathlons. Biathletes have to run or ski to certain checkpoints. They then must shoot targets, sometimes with an air rifle or pistol or with archery. Beta blockers give an advantage by controlling the heart rate and tremors, making it easier to take a steady shot after running or skiing. Athletes who do artistic performances, such as ice skaters, gymnasts, or dancers, may be tempted to use beta blockers to minimize the physical signs of stress and to project confidence.

Common side effects of beta blocker use include dizziness, fatigue, or syncope (passing out). They are especially dangerous in athletes who use them for performance enhancement rather than to treat a medical condition. Exercise increases the need for oxygen, and the heart beats faster to get oxygenated blood to the tissues that need it. If the heart rate is artificially limited, dangerous drops in blood pressure can occur. In addition, beta blockers can induce arrhythmias (erratic and sometimes deadly heart rhythms). Nonselective beta blockers may also induce asthma symptoms since there is a beta receptor in the lung (beta-2 receptor) that needs to be stimulated to keep the airways open. Blocking these receptors causes the tiny muscles around the airway to constrict.

Biceps Tendinitis

Biceps tendinitis is an injury to tendon of the long head of the biceps in the upper arm and shoulder. Although the term *tendinitis* implies acute inflammation, this disorder is usually degenerative in nature, and acute inflammation is relatively rare; thus the term *tendinopathy* is increasingly preferred. Most biceps tendinitis can be thought of as a fraying and irritation of the ropelike biceps tendon as it courses from the anterior or front of the shoulder to deep within the shoulder joint. It is most commonly seen in overhead athletes such as swimmers and tennis players or middle-age patients who do repetitive lifting, pushing, or pulling. Unfortunately, definitive treatment options are limited. Management focuses on symptom relief and physical therapy to correct general shoulder dysfunction.

Anatomy

The shoulder joint consists of the shallow ball-and-socket articulation of the humerus (upper arm bone) and scapula (shoulder blade). In this way, the humerus sits on the scapula like a golf ball on a tee. The scapula moves freely on the posterior chest wall and is connected to the rest of the skeleton only by the clavicle, or collarbone. These relationships allow the shoulder to have tremendous mobility but put a greater strain on the soft tissue structures (muscles, ligaments, and tendons) to maintain stability and function.

One of these soft tissue structures is the tendon of the long head of the biceps, which begins within the shoulder at a bony prominence located at the superior (top) of the glenoid (socket part of the scapula). Here at its origin, the tendon is confluent with glenoid labrum (cartilage rim that deepens the shoulder socket). From the glenoid labrum, it extends as a ropelike structure that courses along the head (ball) of the humerus, exiting the shoulder through a groove in the humerus, where it is held in place by a roof of thick connective tissue. Once outside the shoulder joint, it continues down the arm for several centimeters before it blends into the biceps muscle.

Causes

The exact cause of biceps tendinitis remains controversial. Although tendinitis implies that there is a primary inflammatory cause for this disorder, acute inflammation is not common and likely represents a small subgroup of patients with biceps tendinitis. More commonly, this diagnosis is seen in the setting of biceps tendon degenerative changes. Degenerative changes in the tendon are due to wear and tear from overuse, age, or impingement from the bony structures of the shoulder. These degenerative changes in the tendon are marked by a tendon that is softened, thickened, and frayed. Fluid, debris, and calcification can be seen around the tendon. Occasionally, the biceps tendon can be unstable in the groove of the humerus, moving up and out of its normal position, a condition called *subluxation*.

These degenerative changes in the biceps tendon are often seen alongside other shoulder problems, including rotator cuff tendinitis or tears, shoulder impingement, bursitis, and shoulder instability, suggesting that biceps tendinitis is the result of a more general shoulder dysfunction. This also provides the rationale for treating biceps tendinitis through general shoulder rehabilitation (Figure 1, next page).

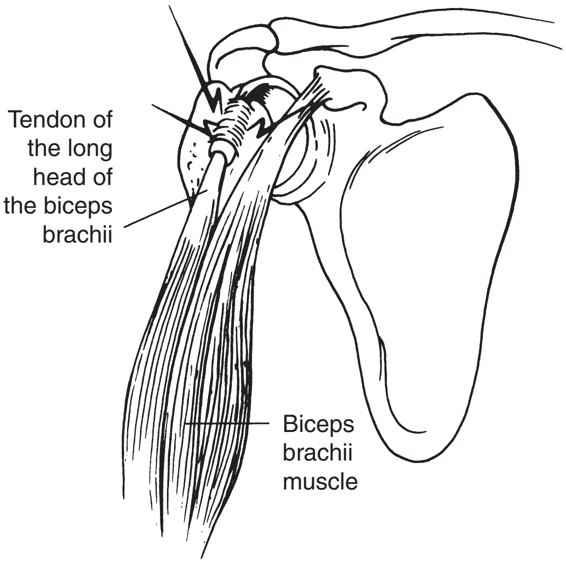

Figure 1 Biceps Tendinitis

Note: The tendon of the long head of the biceps is especially vulnerable to irritation because it passes through a narrow groove in the ball of the humerus.

Symptoms

Patients with biceps tendinitis have pain over the anterior shoulder that can radiate slightly down the arm. They may report a painful clicking or popping sensation in the anterior shoulder. Symptoms are aggravated by reaching, overhead activities, or push/pull movements. Pain may be present at rest and may worsen at night. Patients may report point tenderness over the biceps tendon. Although some patients report a particular event or injury, most cases of biceps tendinitis have an insidious onset.

Diagnosis

There is significant overlap of the symptoms and exam findings of biceps tendinitis and other common shoulder conditions. Moreover, as mentioned above, these conditions commonly coexist in the patient presenting with shoulder pain. Therefore, it is important to consider and evaluate the patient for associated shoulder pathology when symptoms suggest biceps tendinitis. Several clinical tests are used for the diagnosis of biceps tendinitis. These include palpation of the biceps tendon, the Speed test, and the Yergason test.

The biceps tendon should be palpated in both shoulders. Asymmetrical tenderness in the symptomatic shoulder has long been regarded as the hallmark of diagnosis. Palpation of the tendon takes some practice and may be difficult in a heavily muscled or obese patient. Internal and external rotation of the shoulder can help in identification of the biceps tendon and may suggest a subluxating tendon if the tendon can be felt to pop out of the groove. Flexion (bending) and extension (straightening) of the elbow during palpation may reveal crepitus (a tactile creaking).

The Speed test is preformed by having the patient extend the elbow with the palm facing up. The arm should be elevated so that it is slightly less than parallel to the floor. In this position, the patient is asked to resist a downward force applied by the examiner. Pain is considered a positive test. Studies suggest that this test is moderately sensitive for biceps tendinitis but is not specific for the condition. This means that a negative test makes it less likely that the patient has biceps tendinitis but a positive test does not provide much help in determining if a patient has biceps tendinitis.

The Yergason test is conducted by having the patient flex the elbow and rotate the hand from a palm-down position to a palm-up one while the examiner resists the motion. Reproducing pain at the location of the biceps tendon is considered a positive test. Studies on the accuracy of the Yergason test in diagnosing biceps tendinitis suggest that it is reasonably specific but insensitive. Therefore, when positive, the Yergason test helps in confirming the diagnosis of biceps tendinitis, but when negative, it does not exclude the disorder.

X-rays can be used to assess the bony architecture of the shoulder and may provide helpful information to your physician but does not yield a specific diagnosis of biceps tendinitis. Magnetic resonance imaging (MRI) can be used to evaluate the biceps tendon, but MRI is usually reserved for cases of suspected significant rotator cuff or labral pathology. Although not widely available in the United States, musculoskeletal ultrasound is a good choice for evaluating the biceps tendon. It allows for a detailed assessment of the tendon and its surrounding structures while allowing the physician to evaluate the dynamic function of the biceps tendon in the bicipital groove of the humerus.

Treatment

Nonsurgical Treatment

Initial treatment for biceps tendinitis focuses on symptom management and avoidance of aggravating activities. Patients should be temporarily restricted from repetitive or heavy overhead lifting, pushing, pulling, or throwing. A 2-week trial of scheduled nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen or naproxen, is reasonable. Application of ice to the anterior shoulder for 20 minutes/hour, repeated as needed, is helpful for acute exacerbations of symptoms. The patient should not immobilize the shoulder; rather, frequent home rehabilitation exercises should be preformed as soon as tolerated. These can be as simple as repetitive pendulum circles or tracing the alphabet with the hand with the arm hanging straight down. The patient should also begin to slowly walk the hand up a wall to an overhead position; he or she can move closer to the wall if the pain is within tolerable limits. For recalcitrant or severe cases, steroid injections into the biceps tendon sheath or shoulder joint may be administered.

Following resolution of acute symptoms, general shoulder rehabilitation based on a home exercise program or under the guidance of a physical therapist may be prescribed. This will focus on exercises designed to strengthen and improve shoulder positioning in order to maximize function.

Surgical Treatment

Surgery is rarely preformed in patients with biceps tendinitis. Patients with chronic biceps tendon pain that has not responded to aggressive conservative care are sometimes referred for surgery. During surgery, attempts are made to correct the associated shoulder pathology, and the biceps tendon is sometimes cut; this procedure is called *tenodesis*.

Biceps Tendon Rupture

The biceps muscle is an integral component of the upper extremity. Injury to the proximal tendon is relatively common in older people and can often be associated with other shoulder pathologies. Injury to its distal tendon is an uncommon injury; nonetheless, it can produce significant functional disability. Many surgical and nonsurgical treatment options exist for these injuries.

Anatomy

Proximally, or at the shoulder, the biceps muscle has two heads, from which its name is derived. The muscle connects to the bone through its tendon, thereby allowing the body part to move with the contraction of the muscle. The shorter head of the biceps connects to the bony prominence of the scapula, called the *coracoid*. The longer head connects to the top of another part of the scapula called the *glenoid*. The glenoid is the "socket" with which the humeral head articulates, although its shape is closer to a saucer than to a socket. A portion of the biceps tendon travels within the shoulder joint and can easily be visualized during shoulder arthroscopy. The function of the proximal two heads is two-fold. The first is to help flex the shoulder joint, or bring the arm straight out in front of the body. The second is to help keep the humeral head located in the glenoid during movement of the shoulder joint.

Distally, or at the elbow, the biceps muscle forms a single strong tendon. This tendon crosses the elbow joint and thereby imparts two movements: (1) bending of the elbow (flexion) and (2) rotation of the forearm into the palm-up position (supination).

The biceps can be injured at any of these three tendons, as well as at the middle of the muscle belly. Injuries to the muscle belly or to the short head of the biceps tendon are very rare injuries and are not discussed further. The most common injury occurs to the tendon of the long head of the biceps at the shoulder, and the next common injury is to the distal biceps tendon at the elbow.

Causes

Rupture of both types of biceps tendons most commonly occurs from chronic, repetitive injury. This causes degeneration within the tendon, leading to decreased tendon strength. Impaired blood supply to the area of the tendon also contributes to degeneration as this impairs tendon healing. Eventually, a force occurs that exceeds the strength of this weakened tendon and leads to tendon rupture. Injury to the tendon from sharp, penetrating trauma is rarer.

The biceps tendon at the shoulder is intimately associated with other shoulder anatomic structures: the rotator cuff (a group of muscles that surround and control shoulder movement and stability) and the glenoid labrum (a cartilage within the shoulder joint). Repeated and chronic injury to these other structures can irritate and injure the proximal biceps tendon. Rotator cuff impingement, rotator cuff tear, and superior labral tear are commonly associated with proximal biceps injury (see Figure 1).

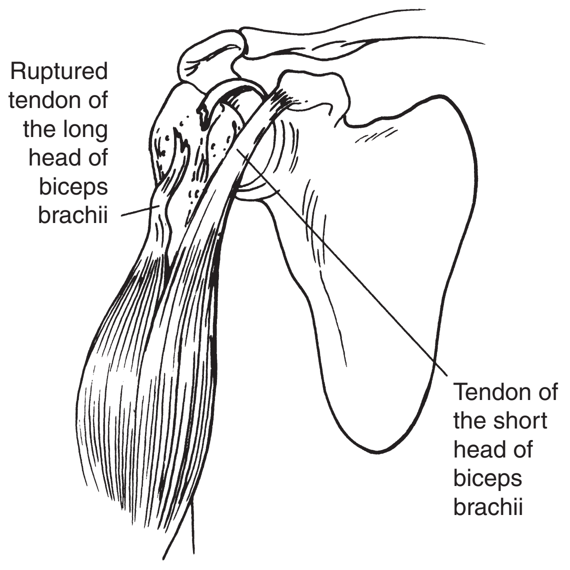

Figure 1 Rupture of the Long Head Tendon of the Biceps

Epidemiology

Injury to the proximal biceps tendon is common in older people, in whom concomitant shoulder pathology is also present. In the athletic population, it is most common in overhead throwing athletes.

Distal tendon injuries occur almost exclusively in men aged 40 to 60 years. Injury occurs typically when a sudden force is applied to a partially bent elbow. Contraction of the biceps occurs to decelerate the arm, and this causes failure of the weakened tendon.

Symptoms

Pathology of the proximal biceps tendon typically presents with pain. The pain is usually located over the tendon in the front of the shoulder. If the injury coexists with other shoulder pathologies, the pain can be located almost anywhere. Any movement that puts strain on the inflamed tendon will aggravate the symptoms. Likewise, tests for rotator cuff and labral injury will be painful, although not always localized to the tendon. Not too uncommonly, a patient will describe a long history of symptoms followed by a "pop" felt in the shoulder. The pain will usually improve after this presumed rupture of the tendon. Bulging of the biceps muscle, also known as the "Popeye muscle," will occur after complete rupture. If the tendon is unstable within its path, often the complaint will be clicking or snapping felt within the shoulder with movement.

Distal biceps rupture is usually dramatic. The history will reveal a story similar to that described above, in which the biceps contracts against a sudden weight. Pain in the front of the elbow is reported and can often be accompanied by bruising or discoloration. A "Popeye muscle" can also be observed. Sometimes people will present weeks after the injury has occurred and will complain of weakness while bending the elbow and while turning the forearm palm up, as when using a screwdriver to drive in a screw.

Diagnosis

Because examination of the shoulder reveals many overlapping symptoms and concomitant pathologies, it can sometimes be difficult to make the diagnosis of biceps tendon injury on history and physical exam. Plain radiographs are typically normal or may suggest some level of impingement syndrome. The study of choice for suspected tendon injury is magnetic resonance imaging (MRI). This has the added advantage of being able to assess the entire shoulder joint for other pathologies. The addition of contrast material into the shoulder joint greatly enhances its diagnostic ability.

Unlike the proximal tendon, complete rupture of the distal biceps tendon can most often be diagnosed by the history and physical exam. MRI can be helpful in the context of partial tears or nontypical presentations.

Treatment

Nonsurgical Treatment

The first line of treatment for proximal tendon derangements is nonoperative. The usual combination of rest, ice, and anti-inflammatory medications can improve symptoms. Physical therapy and occasional corticosteroid injection can be used in specific cases. Most cases will respond well to these modalities. When conservative measures fail, surgery should be considered.

Complete distal tendon injury is usually treated with surgical repair. Partial tears can usually be managed nonoperatively. This modality uses rest, ice, and anti-inflammatory medications to manage local pain symptoms. Continued treatment with physical therapy is aimed at regaining elbow motion as well as muscle strength. Complete tears managed conservatively will result in residual muscle weakness while bending the elbow (flexion) and turning the forearm palm up (supination), as well as early muscle fatigue. Cases that fail nonoperative treatment should be considered for surgery.

Surgical Treatment

Various surgical treatments exist for the treatment of proximal biceps injury. Often the biceps is addressed at the same time as other shoulder pathologies, such as those of the rotator cuff or labrum. For small partial tears, the tendon can be simply debrided—the rough, degenerative portion removed to allow healing of the remaining tissue. For cases where much of the tendon is involved, simple release of the tendon from the glenoid will usually relieve symptoms, although typically some weakness and cosmetic change can occur. In the athletic population, or anyone in whom weakness would be undesirable, significant degeneration of the tendon is treated by releasing the damaged portion and then anchoring the remaining part to the humerus. This is called tenodesis.

Some controversy currently exists regarding the optimal treatment for biceps pathology. The surgeon must tailor treatment to each individual patient, taking into consideration all factors, including the dominant extremity, occupation, age, and other shoulder pathology.

Postoperative physical therapy is necessary following any type of surgical treatment. The goals of therapy are to decrease local symptoms from surgery, regain shoulder motion, and enhance strength. In cases where the biceps tendon is repaired or tenodesed, time must be allowed for healing before significant stresses are put through the tendon.

The treatment of complete distal biceps rupture is usually surgical. While nonoperative treatment is always an option, and is recommended for partial tears, most active patients are unwilling to accept muscle weakness and mild cosmetic deformity. Acute (recent) tears are easier to repair than chronic (old) ones. If much time has passed since the rupture, the muscle retracts, and it becomes difficult to repair directly. In these cases, complicated reconstructions are necessary. Acute tears can be repaired through several different techniques. Drill holes, suture anchors, and EndoButton (Smith & Nephew Endoscopy, Andover, Massachusetts) fixation have all been successfully used to repair the torn distal biceps tendon to the radius through a variety of surgical exposures.

Postoperative physical therapy is required for elbow, wrist, and hand range of motion. Once the tendon is allowed to heal, strengthening of the entire upper extremity can promote faster return to activity.

Complications

Various complications can occur in the treatment of biceps tendon injuries. Nonsurgical treatment can result in continued pain and disability. Surgical treatment can result in shoulder stiffness and pain, failure of the tendon to heal to the humerus (tenodesis), or cosmetic deformity (Popeye muscle).

Nonsurgical treatment of distal biceps rupture can result in the loss of elbow motion or weakness. Surgical complications of distal biceps repair include injury to the sensory or motor nerves around the elbow, rerupture of the tendon, and elbow stiffness from postoperative calcium formation around the elbow (heterotopic ossification).

Biking, Injuries in

Cycling injuries occur as a result of riding a bicycle. This entry will focus on the most common causes of cycling-related injuries, along with some treatment options and recommendations to eliminate pain. The role of bike fit, the changing of a bicycle's positioning to accommodate the rider's posture, will be addressed when appropriate. Pain is the primary restriction to enjoyment of bicycling, and the prevention and rehabilitation of injuries causing pain are important aspects of sports medicine.

Road Rash

"Road rash," or *abrasion*, occurs when skin comes in contact with the pavement. The resultant skin damage is similar to a sunburn or heat burn and is classified as first, second, or third degree depending on the severity.

Treatment

First aid involves cleaning or scrubbing the skin with soap and water. If you are able to clean the area enough to remove any signs of dirt or gravel, then using polysporin antibiotic ointment two to three times daily, with a bandage, is ideal. The goal for healing is to keep the area moist and prevent any scab formation. As with sunburn, using sunscreen to prevent further damage is important. If you are unable to clean the wound adequately or control bleeding or if the pain indicates more than a simple sunburn, then visit a medical professional.

Head Injuries

Head injuries are the most common cause of death and serious injury in cycling, and this risk is decreased greatly by wearing an appropriate helmet. The Insurance Institute for Highway Safety reported that 95% of bicyclists killed in 2006 were not wearing helmets.

Treatment

When a head injury is suspected, do not take aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs; such as ibuprofen) unless directed by a physician. Immediate medical attention should be sought if an injury results in loss of consciousness or memory. Medical attention should also be sought if confusion, dizziness, slurred speech, nausea or vomiting, disorientation, extreme sleepiness, pupil dilation, loss of balance, vision or hearing problems, changes in taste or smell, or other signs develop.

Clavicle Fracture

Any bone can break in a crash, but the most common fracture is of the clavicle (or collarbone). The clavicle is the S-shaped bone that runs from the front of the shoulder to the sternum, and it is usually fractured when a cyclist falls onto an outstretched arm while trying to break a fall.

The risk of a serious or deadly head injury is decreased greatly by wearing an appropriate helmet.

Source: John Rasmussen/iStockphoto.

Treatment

Most collarbone fractures will have significant healing in approximately 6 weeks. Whereas treatment is based on the severity of the fracture (which usually requires almost no treatment), medical attention is recommended at the time of injury. Riding a stationary bicycle is allowed immediately, with outdoor riding often permitted by 6 weeks.

Anterior Knee Pain

Anterior knee pain is often called *chondromalacia patella* and is the most common area of chronic pain in cyclists. There are many possible causes for these symptoms, including the following:

- *Posture:* being “knock-kneed,” “bowlegged,” or having a leg length difference
- *Improper bike fit:* a saddle positioned too far forward or too low, cranks too long for one’s anatomy, or a toe-in or toe-out position of the cleats
- *Use of excessively large gears*
- *Muscle imbalance or inflexibility*

Treatment

First aid involves the RICE (*r*est, *i*ce, *c*ompression, *e*levation) method and acetaminophen for pain relief. Bike-fit strategies include these potential adjustments:

- Raising and/or moving the saddle back decreases knee angle at maximal load.
- Shorter cranks decrease leverage and often result in higher cadence and less resultant force on the knee.
- Adjusting cleat position to minimize sideways force, using arch-supporting orthotics for hyperpronation, and/or shims under the cleat to address any leg length differences ensures proper force distribution.

Rehabilitation exercises consist of hamstring stretches and target strengthening of the medial quadriceps. On-the-bike strategies include standing more during uphill riding, using smaller gearing to increase cadence, and riding on flatter terrain. If pain does not resolve or worsens, visiting a medical professional is recommended.

Tendinitis

Tendinitis is defined as inflammation of a tendon. The areas most susceptible to this are the patella or quadriceps tendon (front of the knee), the hamstrings (back of the knee), the pes anserine group (medial knee), the iliotibial band (ITB; lateral knee), the tibialis anterior (front of shin), and the Achilles tendon (back of the calf).

Common causes for tendinitis include the following:

- *Improper bike fit:* a saddle positioned too high, too far back, too low, or too forward, as well as poorly positioned cleats
- *Pedaling mechanics:* using overly large gears, pulling up or dropping the heel during the pedal stroke, or angling the knees in or out
- *Muscle imbalance and inflexibility:* tight hamstrings and/or weak gluteus muscles
- *Tissue changes posttrauma:* scar tissue, swelling, and/or atrophy from a previous injury

Treatment

First-aid strategies for tendinitis are similar to those for anterior knee pain. Bike-fit strategies include the following:

- Lowering and/or moving the saddle forward for hamstring, ITB, pes anserine group, Achilles tendon, or tibialis anterior symptoms
- Raising and/or moving the saddle back for patellar or quadriceps, or Achilles tendon symptoms
- Proper cleat alignment for appropriate lower leg tracking and force distribution

Pedaling strategies include increasing the cadence by decreasing the gears, practicing single-leg intervals to balance the pedal stroke between the legs, limiting the amount of heel drop, or pulling on the upstroke. Rehabilitation exercises should include stretching tight hamstrings, as these can result in a functionally high saddle position (compared with positioning based on leg length) because of restricted knee extension. Stretching should also target any tight calf, quadriceps, or hip muscles. Strengthening weak gluteus muscles will decrease overdependence on the hamstrings or quadriceps during cycling. If symptoms persist or worsen, visiting a medical professional is recommended.

Neck Pain

Neck pain during riding is reported at the base of the neck or at the base of the skull. If symptoms radiate into the arms (numbness, pain) or lead to weakness, seek a qualified health care provider for advice as this may indicate more serious pathology. Causes include the following:

- *Posture:* a forward head position or insufficient or excessive cervical lordosis (forward curve)
- *Improper bike fit:* stem too long, bars too low, or a forward-tilted saddle
- *Muscle imbalance:* weak or tight cervical and upper back muscles
- *Disk or joint pathology*
- *Inadequate training:* increasing the ride time too fast

Treatment

First aid involves ice or heat, acetaminophen, and rest. Bike-fit strategies include the following:

- Shortening the stem length and/or raising the handlebars lessen forward reach and subsequent neck extension. Riding with the hands on the brake hoods also helps avoid this posture.
- Leveling the saddle to prevent forward leaning prevents neck and shoulder strain from increased load bearing.

Rehabilitation exercises include strengthening of the longus colli, upper trapezius, and periscapular muscles, which support the neck, as well as stretching tight muscles. Building endurance on the bike prevents fatigue-initiated strain, making riding more comfortable. If symptoms persist or worsen, visit a medical professional.

Low Back Pain

Cycling-related back pain may be due to the following causes:

- *Posture:* insufficient or excessive lumbar lordosis or thoracic kyphosis
- *Muscle imbalance:* tight hip flexors and/or hamstrings
- *Improper bike fit:* saddle positioned too low or tilted forward, stem too long, or handlebars too low
- *Poor training/technique*
- *Disk or joint pathology*

Symptoms radiating to the legs or any bowel/bladder changes should be discussed with a health care professional immediately.

Treatment

Core stability exercises targeting the abdominals, back extensors, and hips are strongly recommended for both prevention and rehabilitation. Stretching the iliopsoas and hamstrings should be a regular postride strategy. Fit-related strategies include the following:

- The saddle should be leveled.
- The bar/stem should be adjusted to avoid a long or low reach to the handlebars.
- Leg length difference may be an underlying component and may require shims under the cleat to balance the riding position.

Nerve Compression

Nerve compression in cycling typically involves the ulnar and median nerves in the hand. Ulnar nerve compression results in numbness in the ring and small fingers, which usually clears when riding is stopped. Median nerve compression (or carpal tunnel syndrome) is noted in the thumb through ring fingers, the palm, and occasionally the elbow and shoulder and is often worse at night. The following are some of the causes:

- *Improper bike fit:* excessive forward reach, forward-tilted seat, insufficient handlebar padding, and/or improper brake hood positioning
- *Training/technique:* excessive ride length, riding on rough ground, or overgripping the bars

Treatment

Bike fit strategies are as follows:

- Ensure a proper frame size.
- Adjust the stem/bar height to limit pressure on the hands.
- Level the saddle to prevent forward lean.
- Rotate the bars to raise the brake hoods, or tilt the hoods medially.

Improving padding via gloves or bar tape and adding suspension or using wider tires to reduce vibration into the hands can help. With median nerve pathology, night splints can promote recovery by avoiding compression during sleep. If symptoms do not resolve or worsen, medical attention is recommended.

Saddle Sores

Saddle sores are tender bumps in the buttock and groin area, where saddle pressure is supported. This area, during riding, is typically warm and moist, creating ideal bacterial growth conditions. These bacteria enter the glands and cause local infection. Saddle pressure can also block the pores, entrapping bacteria and inhibiting blood flow. The resultant sore makes cycling extremely uncomfortable.

Treatment

The optimal treatment is prevention: removing the cycling shorts after riding, wearing only clean shorts, replacing the worn chamois (the pad in the cycling shorts), and keeping the area dry. Proper fit to address the pressure on the saddle (height, tilt, saddle type) is an important element, and use of chamois creams to reduce friction is often successful. Gradually increasing the riding time allows tissue to adapt to pressure changes. Once a saddle sore occurs, keep the area clean. After washing, dry the area with baby powder (or its equivalent), and later, apply antibacterial ointment. In severe cases, lancing may be required.

Bioenergetics of Exercise and Training

Human activity, in its various forms, requires energy. Exercise involves the use of energy to perform work that propels the body. Training increases the efficiency of this process in various ways. *Bioenergetics* is the study of the formation, conversion, and use of energy in a biological system. Its application in sports relates to how three energy systems, (1) adenosine triphosphate (ATP)/creatine phosphate (CP), (2) glycolytic/nonoxidative, and (3) oxidative, are used.

Energy is stored in the body as fat, protein (muscle), and glycogen (liver and muscle). It becomes incorporated into the body via ingestion and digestion of food. And when it is metabolized by the three energy systems, the by-products include carbon dioxide and heat.

Different activities use various combinations of these three energy systems. For rapid-power activities (i.e., shot put, weight lifting) that last less than 3 or 4 seconds, the primary energy source is the ATP/CP system. For speed activities that last up to approximately 1 minute or less (e.g., 100-, 400-meter runs), the glycolytic/nonoxidative system uses primarily blood glucose and muscle glycogen. For endurance activities (running a mile or longer), the primary energy system will be oxidative, using muscle and liver glycogen, lipids, and amino acids.

Many activities, of course, use various combinations of the three energy systems, more so than others, responding to the constantly shifting demands of the athlete. A soccer player, for example, will constantly be using the oxidative system to keep running during the game. But sometimes, a sprint may be required to defend or attack, and that effort will tap into the nonoxidative glycolytic system. All three systems are always active, however, with the body constantly replenishing their supply of energy and regulating its use.

Thermodynamics

Thermodynamics is the study of energy exchange and transfer; bioenergetics must follow the laws of thermodynamics, as it applies energy toward biological activity.

The *first law of thermodynamics* is that energy cannot be created or destroyed, it can only be changed from one form to another. This implies that the total energy in the universe remains constant. For example, a sprinter uses energy to sprint. This results in the stored form of energy in the form of ATP and glucose being converted to work to moves the athlete and heat that goes back to the environment. On the other hand, if the ATP or glucose is not used for activity, it will accumulate and be converted to a storage form for the body, that is, fat.

As mentioned, heat is released during metabolism that is required to perform work. Heat can stimulate enzyme activity and contribute to an optimal environment for some enzymes, thus responding to the body's demands. But heat's dissipation through the cooling mechanism also expends energy. Cooling is required because excessive heat can inhibit and slow the activity of the body's metabolic enzymes. In terms of efficiency, energy not devoted directly to performance is considered a loss of efficiency.

Adenosine Triphosphate and Creatine Phosphate

ATP and CP are the basic currency of energy to power muscle contractions. The metabolism of glycogen or fat ultimately produces ATP, which muscles can use. ATP is an immediate energy source and the final pathway toward muscle activity.

The study of muscle physiology shows that ATP combines with actin, myosin, and calcium and becomes hydrolyzed to adenosine diphosphate (ADP), to allow contraction and relaxation of muscle fibers.

CP exists in resting muscle and acts as a source of entry to regenerate ATP. CP plus ADP is converted to ATP and creatine via creatine kinase. The enzymes in the ATP/CP energy system act very quickly and are readily available in the muscle cell cytosol.

The amount of ATP and CP immediately available, however, is limited. Beyond more than 1 minute, the muscle will need other sources of energy.

Nonoxidative, Glycolytic System

Glucose and glycogen, in the blood and muscle, respectively, are broken down via glycolysis and glycogenolysis to form ATP and lactate. This occurs without the use of oxygen within the muscle cell's cytosol, thus it is called the nonoxidative glycolytic system. This system can rapidly supply the required ATP and is in close proximity to the contractile elements of the muscle.

The nonoxidative glycolytic pathway produces two ATP and two lactate molecules from one glucose molecule. Although this process is rapid, the amount available to the athlete is rather limited (approximately 3 grams per kilogram of muscle) and is only adequate for events that take less than 1 minute.

The lactate produced can also accumulate in tissue. Previously believed to be only a harmful by-product, lactate in fact can be metabolized by the body via the oxidative system by cardiac and slow-twitch (Type I) muscle fibers. The hydrogen ions accompanying lactate production do, however, inhibit the glycolytic enzymes and interfere with the coupling of calcium with muscle fibers. This acts as a negative feedback or "brake" to limit muscle activity as nonoxidative conditions persist.

Oxidative System

The primary source of energy for our day-to-day activities, as well as any exercise or sport that requires activity beyond 1 minute, is the oxidative energy system. This system, while not as immediate or rapid as the ATP/CP and glycolytic/nonoxidative energy systems, has an abundance of energy sources. The key is the presence and availability of oxygen. This energy system has components in the cytosol as well as the mitochondria. The process is not as rapid but can produce almost limitless energy.

Muscle and liver glycogen, fats, and proteins are all sources for the oxidative system and are in vast supply in stored forms in the body.

The oxidative system releases much more energy in the form of ATP than the ATP/CP or nonoxidative system. For example, 1 molecule of glucose produces 36 ATP with oxidative process versus only 2 ATP and 2 lactate with the glycolytic process. Even more astounding is the use of fat in the oxidative system. Palmitate, a fatty acid, produces 129 ATP.

Training

Training has definite effects both directly on the energy systems and on which systems are used when. Training goals should be targeted toward a specific type of activity. In general, the overall goal of training is improved efficiency, or the ability of energy from metabolism to produce the work desired.

The effect on the nonoxidative energy systems is minimal, and it is the least with endurance training. Weight lifting and power training can slightly increase the stored levels of ATP and CP.

Endurance training decreases lactate dehydrogenase activity, thus reducing the metabolism of lactate in fast-twitch muscles during nonoxidative forms of activity. It changes the isozyme of lactate dehydrogenase to a type that is similar to that of the heart and thus allows the working muscle to take up and use lactate as an energy source as the heart does. Thus, one of the primary effects of endurance training on the nonoxidative system is actually to convert some of the working muscle cells to use the oxidative system.

Lactate, a by-product of the nonoxidative glycolytic system, is available for use by the heart and these muscles for energy under low-oxygen conditions. Lactate can also be used to form carbohydrate via gluconeogenesis. Elite athletes adapt to training by becoming adept at metabolizing lactate, thus improving their "lactate threshold."

The effect of training on the oxidative system is significant. It improves myocardial contractility and size to better deliver oxygen supplying blood to the body. Blood vessels grow and extend into a process called neovascularization to better deliver blood to muscles in need. The neurohormonal system also responds to training by decreasing its response to sympathetic stimuli, resulting in lowered heart rate and reduced carbohydrate breakdown.

The changes at the muscle cellular level are also equally significant. While specific enzyme rates of activity remain fairly constant, the "engine" of the oxidative system, the mitochondria in muscles, becomes packed with enzymes. Mitochondria also develop more elaborate mitochondrial retinaculum to better perform oxidative production of ATP. Muscles also gain greater densities of mitochondria with endurance training, seen vividly using electron microscopy. Glycolytic muscle fibers can also be converted to oxidative fibers with the stimulus of endurance training.

Neurohormonal changes shift the use of energy stores from carbohydrate to fat, delaying the depletion of carbohydrates and taking advantage of the almost endless energy provided from fat. Endurance training shifts the timing of when the body uses one energy system over the other two. With training, the body will continue to use the oxidative fat-burning system at higher intensities (greater $\dot{V}O_2max$). This delays muscle glycogen depletion and fatigue and is known as the "crossover" concept.

Depending on the sport and the level of development of each energy system, an athlete can improve his or her performance by targeting specific energy systems. If oxygen consumption ($\dot{V}O_2max$) has plateaued, the oxidative system is likely to be maximized. In this case, athletes could improve their performance by improving their ability to exercise under nonoxidative conditions with efforts at or above their lactate thresholds. On the same note, if the event is power related, time spent doing low-intensity aerobic exercise will unlikely benefit the athlete.

Conclusion

Bioenergetics is the study of the transfer of energy in a biological system. Bioenergetics and its application to human movement are subject to the laws of thermodynamics. The application of bioenergetics in sports relates to how it develops the ATP/CP, nonoxidative glycolytic, and oxidative energy systems to respond to the demands of athletic activity. For explosive power sports, the immediate energy source of ATP/CP is used. For rapid activities such as the sprints, the glycolytic system quickly produces adequate ATP and lactate to supply the muscles. And for endurance sports, the oxidative system can supply an almost endless supply of energy. Depending on the type of training, these three metabolic systems are stimulated to various degrees to best address the athlete's needs. An understanding of bioenergetics can help develop and refine training programs toward achieving maximal performance.

Biofeedback

Biofeedback as an area of inquiry and clinical application in medicine, psychology, and education first appeared in the literature in the 1960s. In 1975, Leonard Zaichkowsky first proposed that biofeedback had strong potential to help athletes self-regulate the psychophysiological processes that interfere with optimal performance. Unfortunately, little has been published on the topic until recently. Because of significant improvements in technology, biofeedback is now an exciting methodology for assessing "mind-body" function in athletes and a method of training athletes to self-regulate stress reactions.

Biofeedback is a technology that uses instrumentation to detect and amplify internal physiological processes in order to make this ordinarily unavailable information available to the individual as "feedback" in a form that is *meaningful, rapid, precise,* and *consistent.* With feedback and the other essential ingredient for learning (i.e., practice), athletes can learn to control or self-regulate essential biological functions such as muscle tension, heart rate, respiration rate, skin conductance, and brain activity.

The Problem of Athlete Stress and Dysregulation

Both beginning and experienced athletes often fail to perform optimally because of self-induced pressure. As such, their mind and body are in a state of disequilibrium, and at critical moments, an athlete may not know how to self-regulate his or her thoughts, feelings/emotions, physiological reactions, and motor responses. Biofeedback technology is the single most efficient way to teach self-regulation. Perhaps the greatest feature of biofeedback instrumentation is that most manufacturing companies have developed software that allows for two separate operations: assessment and training. First, we can *measure, assess,* and *profile* baseline psychophysiological activity in athletes under conditions of rest, competition, and recovery. Second, the technology allows us to train athletes to self-regulate specific biological functions (e.g., excessive muscle tension) that tend to interfere with performance.

Modalities of Biofeedback

1. *Electroencephalography (EEG), sometimes called neurofeedback (NF).* EEG is used to measure brain activity (frequency and amplitude), and as such, we can determine if appropriate parts of the brain (e.g., those regulating coordination or spatial awareness) are active during peak performance or inappropriate parts (e.g., language production, and negative self-talk) are active. Multichannel recording can take place, so it is possible to determine what brain activity is associated with successful performance and what brain activity is associated with unsuccessful performance.

2. *Surface electromyography (sEMG).* sEMG refers to surface electromyography and measures muscle activity in microvolts. This form of feedback allows us to determine if muscles not involved in a particular skill need to be relaxed and those muscles involved in a skill need to fire in the right sequence and with the right amplitude. In addition to using sEMG feedback for training purposes, the information can also provide insight into the athlete's strength and conditioning or the effects of an injury rehabilitation program.

3. *Heart rate (HR).* HR is typically measured by standard electrocardiogram (EKG) electrodes or a photoelectric plethysmography sensor attached to a finger. HR is a measure of both exercise demands and thoughts and emotions. HR and a more recent measure, HR variability, play a large role in the psychophysiological training of athletes.

4. *Respiration rate.* Respiration is usually measured by a strain gauge placed in the thoracic or abdominal region (or both). Respiration rate and amplitude reflect response to the stress of exercise, psychological distress, or poorly learned breathing mechanics.

5. *Respiratory sinus arrhythmia (RSA).* RSA is a measure of the synchrony between heart rate and respiration. When an athlete is in a calm and alert state, the HR rises and falls with each inhalation and expiration.

6. *Skin conductance.* Skin conductance measurement refers to measuring the sweat response and is referred to in the literature as electrodermal response, skin conductance, or galvanic skin response. Low, stable skin conductivity is an indicator of strong autonomic nervous system function.

7. *Skin temperature.* Skin temperature is another measure of autonomic nervous system function

and reflects somatic relaxation (vasodilation) or stress (vasoconstriction) in an athlete.

Assessment and Training Protocols Used in Sports

Sport scientists and sport psychologists using biofeedback assessment and training usually start by getting baseline measures of the athlete using a typical protocol of rest (2 minutes), psychological stress (2 minutes), and recovery (2 minutes). The stressor usually involves the use of a standardized test, such as the Wisconsin Card Sort Test, the Stroop Test, Serial 7s, or a sports video of performance stress. These measures create a psychophysiological profile that allows the sports scientist to design a training program that will enable the athlete to cope with pressure and maintain an optimal psychophysiological state. Should attention, cognition, and decision making show the greatest amount of dysregulation, then the focus of training might be on neurofeedback (EEG). In many cases, however, lack of self-regulation skills is demonstrated in all the modalities, and thus training will be necessary for all modalities.

Training self-regulation using neurofeedback or biofeedback usually begins in the laboratory, in the reclining chair where the assessment/profiling took place. The athlete attempts to self-regulate specific physiological functions either by using the creative software provided by the biofeedback manufacturer or by reviewing DVDs of successful and unsuccessful performance. The goal is to become aware of specific biological reactivity to pressure and learn what the optimal values are when the mind and body are in the "zone." For example, athletes quickly learn about what happens to their physiology when they slow their respiration down to 6 to 8 respirations/minute. They can also become aware of what happens when they view "anger" being displayed in a DVD video clip or when they simply image an emotional/traumatic reaction. After training in the laboratory or clinic, the athlete attempts to replicate these ideal performance states on the playing field. Wireless technology enables monitoring of psychophysiological signals that are presented as feedback to both the athlete and the sports scientist. Self-regulation training is learned through this real-time feedback and continued deliberate or intentional practice.

Evidence of the successful application of biofeedback technology to sports is provided in the Further Readings. Additional documentation can also be obtained from the Thought Technology website (http://www.thoughttechnology.com). One reference points to the successful development of the "MindRoom" by Dr. Bruno DeMichelis with the AC Milan football club. A second story makes reference to the successful biofeedback training of the first ever gold medal winner from India, Abhinav Bindra, in air rifle shooting at the 2008 Beijing Olympics.

Biomechanics in Sports Medicine

The quest to understand and explain the causal factors associated with the injury mechanisms underpinning biological failure are linked to understanding the biomechanics of human movement.

This entry examines the role of biomechanics within the discipline of sports medicine and has an overall aim of providing a meaningful examination of biomechanics and its relationship with sports medicine.

To achieve these aims, this entry has been organized into four sections. First, a definition of biomechanics and its theoretical link to sports medicine is provided. This section also highlights some basic principles of describing athletic movement and the variables associated with injury. It concludes with an outline of the implicit use of biomechanics from the clinician's perspective. The second section builds on this base and details the practical, clinically based relationship that the sports medic has with the biomechanist in the diagnosis and rehabilitation process. This section evolves into a more detailed examination of the sports-specific research that drives clinical applications. With the increase in the availability and sophistication of measurement systems in biomechanics and sports medicine, an overview of the grounded scientific methodologies available to the practitioner and researcher is provided in the third section. The final section examines some of the major theoretical issues associated with the occurrence of injury. This fourth section highlights some contemporary issues within sports medicine, biomechanics, and current research in this field. Concluding remarks look to the future of biomechanics and its role within the discipline of sports medicine.

Biomechanics and Sports Medicine Defined

The origins of biomechanics and the theories that underpin this scientific discipline have emerged from the very beginnings of scientific discovery. In fact, the origins of this discipline can be traced back to the seminal work of Sir Isaac Newton. who, from the shoulders of other great scientists, produced the *Philosophiæ Naturalis Principia Mathematica* (*Mathematical Principles of Natural Philosophy*) in July of 1687, which provides the foundation of many concepts in use today. In the late 20th century, classical definitions of biomechanics provided by James Hay, Herbert Hatze, and, more recently, Benno Nigg are similar in that they point to a science that examines the forces acting on and within biological structures and investigates the effects produced by such forces. Today, there are many thousands of researchers involved in biomechanics, working toward enhancing understanding of the topics related to human movement, ranging from injury to clinical assessment, ergonomics, rehabilitation, and sports. In the context of sports medicine, biomechanics encompasses a number of fundamental areas, including the study of the functioning of bodily structures (e.g., muscles, tendons, ligaments, cartilage, and bone) and their responses and adaptations to loading in sporting performances.

While it is not the intention of this entry to provide a detailed account of the biomechanics of the musculoskeletal system, knowledge of some of the key principles is necessary to develop an understanding of the mechanisms that underpin the occurrence of injury.

Key Biomechanical Principles

The constituent components of the human body comprise active (force producing, i.e., muscle) and passive (bone, cartilage, ligaments, tendons, and other soft tissues) structures. The interaction of these biological materials, which makes up the joints and the skeletal system, functions in a synergistic fashion, responding to forces and the environment. In sports, this environment can be more predictable (e.g., landing from an apparatus in gymnastics or performing a pitch in baseball) or less predictable (e.g., cutting in football or being checked in hockey). The nature, etiology, and complexity of an injury are based on a number of anatomical, physiological, biochemical, and biomechanical factors. Understanding the factors associated with the occurrence of sporting injury from a biomechanical perspective requires a detailed understanding of the biology and mechanics of human movement, which lies outside the scope of this entry. But some of the key principles that help provide a context within which it is possible to explain the issues relating to the interface between sports medicine and biomechanics are discussed here.

An understanding of the movement patterns and body positions involved in sporting technique is the first step in explaining how athletes achieve performance and also how these movements and positions predispose them to injury. The description of the geometry of movement is known as kinematics (see Figure 1) and includes variables such as time, displacement, velocity, and acceleration. The forces producing movement are known as kinetics, and these include external forces, such as ground reaction forces in running, air resistance, and gravity, and internal forces, such as joint forces and moments. The characteristics of force, which are linked by many to the occurrence of injury, are highlighted in Figure 1 and include peak force and loading rate.

The calculation of internal joint kinetics (joint forces and joint moment or torques) is based on Newton's second law of linear and angular motion using the iterative process of inverse dynamic modeling. Inverse dynamics requires knowledge of the kinematics of the segments, inertial characteristics, and known external forces, usually ground contact:

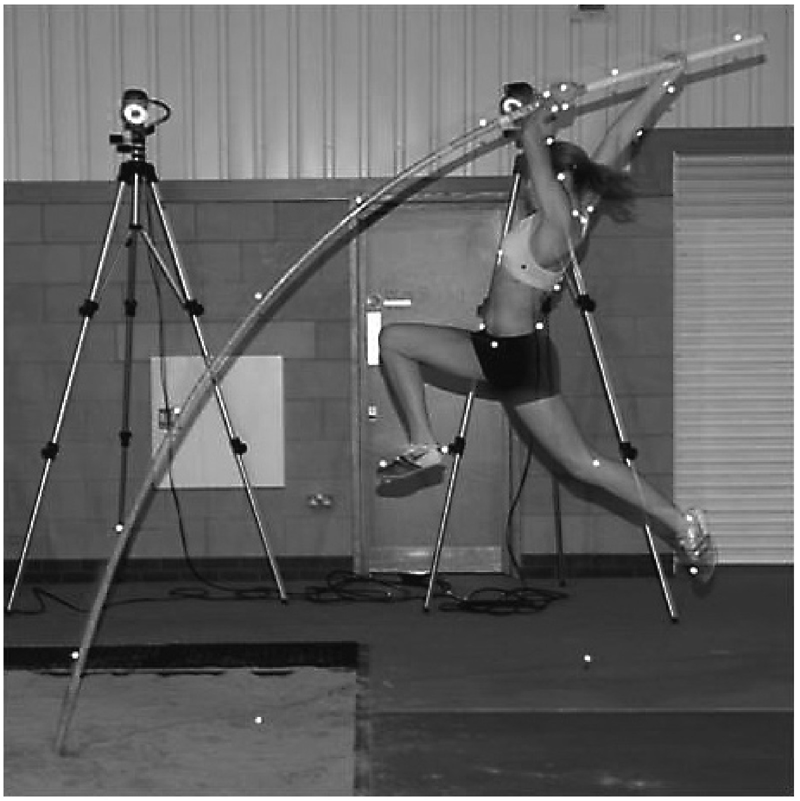
$$\text{Internal joint forces} = \sum F = m \times a$$

and

$$\text{Internal joint torques} = \sum \tau = I \times \alpha,$$

where F = force, m = mass, a = acceleration, τ = torque, I = moment of inertia, and α = angular momentum.

Three-dimensional inverse dynamics provides a measure of the net joint kinetics for extension or flexion, internal or external rotation, and abduction or adduction. These values are very useful in determining whether the technique is overloading the



Kinematics		*Kinetics*	
Temporal characteristics of movement	Timing of phases of a skill	Ground reaction forces	F_z = vertical force F_y = horizontal force F_x = medial lateral force
Displacements	Including joint angles, e.g., extension or flexion, internal or external rotation, abduction and adduction	Force characteristics related to injury	F_{max} = maximum or peak flow F/dt = rate of force application $F \times T$ = impulse
Velocity	Linear and angular: including rate of joint opening and closing	Internal joint kinetics	
Acceleration	Rate of change of velocity		

Figure 1 Key Biomechanical Variables Associated With Describing the Movement Pattern of Performance (Kinematics) and the Forces Involved (Kinetics)

Source: Courtesy of Ray Edwards, Cardiff School of Sport, Biomechanics Laboratory, U.K.

Notes: Also highlighted are the force characteristics that have been associated with injury. In all cases, the displacement, velocity, and acceleration can be either linear or angular.

biological structures of a joint; however, the main problem is in determining what constitutes the limits. Other variables of interest that can be calculated from the joint moments include joint moment power and work, and consequently, a more detailed explanation of the musculoskeletal demands of sporting techniques can be given. The calculation and analysis of joint kinetics require specialist measurement systems and an in-depth biomechanical knowledge of human movement. For the biomechanist and clinician to have confidence in the conclusions drawn, the quality or sensitivity of the result obtained from inverse dynamics need to be quantified. The calculation of joint kinetics can be particularly challenging in a sporting environment; however, the effort is worthwhile in that ecological validity is maintained.

To provide the reader with the underlying theory necessary to develop an understanding of the responses of biological structures to load during sporting activity and to allow the development of a broad conceptual platform from which to build further knowledge, some key concepts are defined and explained in the following section. The magnitude, location, direction, frequency, variability, and rate of loading are key components in the occurrence of injury. The main variables that are highlighted here are load, stiffness, stress, strain, elasticity, and viscoelasticity.

Load

The sum of the forces and torques acting internally and externally on the biological systems of the body or specific tissue is collectively known as *load*. During athletic performance, body segment orientation, which makes up technique, exposes the athlete to these loads, inducing adaptations, which in the most part are desirable. However, when these loads are in excess of the critical limits of the biological structures (accompanied by other contributing factors, e.g., skeletal geometry), trauma can occur. Load affects the nature and severity of injury and can cause failure in two major ways (Figure 2).

Stiffness

The relationship between force and displacement defines the *stiffness* of a tissue. In general, when tissue is deformed within its elastic limit (i.e., the point at which a material subjected to a higher stress will no longer return to its original shape), a linear relationship occurs, with the gradient representing the stiffness. The steeper the slope of the force displacement curve, the stiffer a material will be.

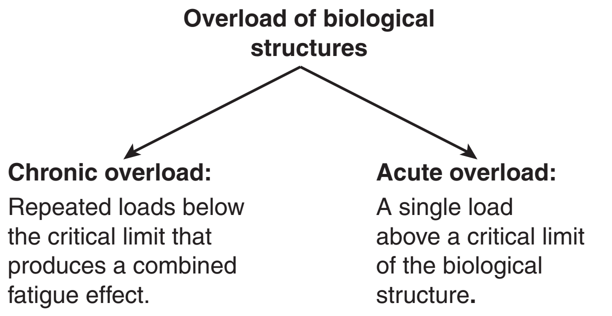


Figure 2 Simple Definition of Overload of Biological Structures

Stress

The internal resistance to load is specific to the tissue experiencing it (bone, skin, cartilage, etc.), and it is this resistance that is termed *stress* or *mechanical stress*. Stress (σ) is defined as the force in newtons (N) per unit area in square meters (m^2):

$$\text{Stress}(\sigma) = \frac{\text{Force}}{\text{Area}} = \text{N/m}^2.$$

Strain

The geometric response of tissue under the influence of load is described as deformation and defined as *strain* (ε):

$$\text{Strain}(\varepsilon) = \frac{\text{Change in length}}{\text{Original length}}.$$

The rate of change of strain over time is also an important mechanical characteristic of biological structures.

The relationship between stress and strain, with regard to load response, is complex for most biological tissues. The ratio of these two parameters defines the elasticity or elastic modulus (E) of the structure:

$$\text{Elastic modulus } (E) = \frac{\text{Stress}}{\text{Strain}}.$$

The two-dimensional loading model is an oversimplification. The compliant yielding phenomenon that characterizes most biological tissue is complex, affected by a number of internal and external factors, and three-dimensional in nature.

Viscoelasticity

The pathomechanics of injury are inherently linked to a tissue's *viscoelastic response*. The viscoelastic characteristics of tissue are related to the constituent matter, specifically the fluid components. The major underlying concept here rests with the fact that the rate of strain causes different stiffness characteristics of the same tissues. In practical terms, what this means is that the faster a tendon is loaded, the stiffer it will become compared with the same tendon loaded slowly. This factor highlights the importance of loading rate as a characteristic of injury potential.

The added complication that a sports medic must take into account is the performance aspects of the athletes in his or her charge. With the complex and specific nature of many sporting techniques, in terms of movement patterns, the loading diagnosis and assessment of injury provide a challenge. Biomechanics within this context can be helpful, to the sports medic, through the development of biomechanically specific tacit knowledge and clinical understanding. The development of a conceptual understanding provides knowledge that practitioners use on a day-to-day basis to inform their decisions and to develop greater knowledge through continued professional development. Examples include the following:

- Peer-reviewed journals provide specific information relating to sporting injury and medicine (including outlets such as the *International Journal of Sports Medicine,* the *American Journal of Sports Medicine,* and the *British Journal of Sports Medicine*).
- International and national conferences—for example, the American College of Sports Medicine (ACSM) and British Association of Sport and Exercise Medicine (BASEM)—have sections dedicated to research in biomechanics and injury. In addition, dedicated conferences on biomechanics and sports have various injury themes that can add to the knowledge base.
- Formally taught courses, generally at the master's level, provide advanced subject-specific knowledge in gaining experience of biomechanical systems, the underlying theory, and its application to sports medicine and injury.

Biomechanists work alongside sports medics in a clinical environment to diagnose, monitor, and understand injury and inform the rehabilitation processes. The ways in which researching biomechanists, often at a university, address sports medicine questions in an ecologically valid setting is dealt with in the following section.

Practical and Clinical Applications

This section details the "day-to-day" methods employed by biomechanists in the assessment of the parameters that play a role in the etiology of injury. Whether it is an analysis of walking, running, or complex gymnastic skills, information regarding the biomechanics of movement can be useful in the search for the causal mechanisms of injury. Understanding the "normal" sporting biomechanics of a skill is the foundation of the application of injury prevention strategies. However, one key principle to consider is the definition of what constitutes "correct" or "normal" biomechanics. An alternative mindset may be to consider the atypical biomechanics of technique that takes into account individual differences in the morphology, physiology, and biological variability of movement. The latter of these issues will be discussed in the final section as an important contemporary issue in relation to the functional aspects of performance and injury reduction. There is evidence to suggest that small changes in the correct or common techniques used in sports activities can lead to injury. The mechanisms that cause this injury are still not well understood, and the issue of which biomechanical variables are responsible for certain sporting injuries is still under much debate. However, with the development of technology and the increased level of fundamental research in the area, more is now understood about the mechanisms of injury. Working with a biomechanist in a clinical environment to diagnose, monitor, and understand injury and also inform rehabilitation may include the analysis of the kinematics of movement, for example, gait, throwing, and running. These analyses may employ simple semiqualitative methods or sophisticated automated motion analysis systems. The measurement of other variables such as ground reaction forces via force plates and pressure distribution through insoles or pressure plates may also be useful. The measurement of external forces can be combined with the inertial characteristics of the athlete and their kinematics to estimate loading at the joints (inverse dynamic analysis). Electromyography can also be used to examine the activation characteristics of specific muscle groups. Variables associated with injury can be measured, analyzed, and monitored by the biomechanists to help inform the decisions of the sports medic. The following section draws on running injuries to illustrate the close relationship between the biomechanist and the clinician.

The Use of Clinical Gait Analysis

The *gait cycle* is the basic measurement unit in gait analysis. From a clinical perspective, gait analysis of walking, running, and sprinting can provide useful information about the occurrence of atypical techniques that produce kinetic and kinematic changes that may influence the type, severity, and nature of injury. The underlying theory that supports this type of analysis will be discussed in the final section of this entry. According to researchers like Professor Tom Novacheck and sports medicine texts, the gait cycle is defined from the discrete variables of foot-ground contact to the next ground contact off of the same foot. The foot contact is vital to the definition of gait. During waking, the heel (subtalar joint) usually may be used by the biomechanist to define foot contact; however, as the speed of movement increases and walking becomes running, different sections of the foot may define the start and end of these phases, including the mid- and forefoot. Indeed, during elite sprinting with velocities in the range of 9 to 12 m/second, the ground contact of the metatarsal-phalangeal joint will be used to define these phases. Copious amounts of literature, from both applied sports biomechanics and clinical biomechanics, detail the key variables used to detect and diagnose the etiology of injury in running. Many disorders of the lower limb have been associated with the orientation of the foot described by its kinematics and the loading of foot and ankle measured via joint kinetics. Literature in this area has highlighted the effect of excessive foot pronation. The impetus behind this view has been the empirical and clinically driven evidence. Nearly a decade ago, Professor Tom Novacheck, stated that there was little grounded scientific evidence to quantitatively support the influence of pronation and that further research into the mechanism associated with injury needed to be carried out. Information gleaned from the analysis of gait can be in the form of kinetic and kinematic profiles detailing specific features of the performance. These may typically include an examination of the level of pronation, inversion, or eversion. Moving up the lower limb to the knee, the clinician would typically be interested in the magnitude of the turning forces at this joint in terms of abduction or adduction, internal or external rotation, and horizontal draw force as an indicator of a potentially hazardous technique. The main issue here is identifying the critical limits of biological structures. The limits of selected biological structures have been reported, but much of this is based on cadaver studies and may have limited use in a sporting or in vivo situation. To overcome these limitations, comparative examinations of the biomechanics of performance are often undertaken, for example, before and after surgery or before and after participation in rehabilitation programs. Feedback to clinicians based on these biomechanical assessments exists on a continuum from qualitative video-based feedback (Example 1) to a more complex and detailed kinematic and kinetic feedback based on automated motion analysis systems (Example 2).

Example 1: Qualitative Video-Based Feedback

A simple analysis of digital video pictures highlighting key instances in the gait cycle is often done by the biomechanist. Comparing the intrasubject variations over a period of time—for example, before and after injury or rehabilitation—will allow the biomechanist to build a picture of the athlete's individualized technique and, using knowledge of the biomechanics of human movement, draw conclusions useful to the clinician. Figure 3 shows some examples of the key variables previously associated with the etiology of injury. Pelvic stability and orientation from simple visual inspection and best-fit angle estimation are shown in Figure 3c. Foot orientation and lower-limb positioning are shown in Figure 4. These images can help indicate a potentially hazardous technique and the mindset of factors that may influence an athlete's predisposition to become injured.

Example 2: Quantitative Feedback

Detailed kinematic and kinetic analysis can provide useful information to the clinician regarding the techniques used in sports performance, and they can highlight areas of concern. A major problem facing the sports medic and the biomechanist is the identification of what could be the causes of injury. This is overcome by a longitudinal approach whereby a profile is built up of the "typical" pattern of movement over time for an individual

Note: Three-dimensional skeletal representation of a cutting movement with synchronized resultant ground reaction force vector (*top left*), internal knee joint force (internal/external rotation) (*top right*), three-dimensional skeletal representation of running with synchronized resultant ground reaction force vector (*bottom left*), and vertical ground reaction force profile (*bottom right*), showing a distinctive high-impact peak followed by a smaller peak approximately 50% through the stance phase.

performer. Then, any changes that occur in both kinematic and kinetic variables of interest may be markers for biological failure. The images in Figure 5 show two types of fine-grained biomechanics data, which includes a three-dimensional (3D) graphical image of the athlete with the force vector. The skeleton represents the movements of the joints and segmental orientations based on the athlete's anthropometric information. The graphs accompanying the images provide accurate information about the biomechanical variables of interest, which include the internal/external knee forces and vertical ground reaction forces. The biomechanist and clinician will use this information to discuss any atypical aspects of technique.

Clinical examination and critical reflection on patterns of injury, combined with epidemiological evidence, may lead to sport-specific research questions. These queries drive targeted research, drawing on the expertise of biomechanists and medical staff, requiring them to work together in an interdisciplinary approach. An example will now be detailed of how this relationship has worked in the sport of football with reference to boot selection and potential knee injury risk.

Sport-Specific Example: Football

Background. The introduction of bladed football boots in the early 1990s appeared under the marketing banner of a new technology that improves performance in kicking, stability, and maneuverability. Soon concerns emerged through the increased incidence of lacerations and compression injuries, with possible links to knee injury. These issues were highlighted when the English Football Association sent a dossier to the Fédération Internationale de Football Association (FIFA) in 2002 outlining their concerns. Clubs, coaches, managers, and players developed mindsets based on their own experiences. The current example details a national team physician who approached a sports biomechanist to address these concerns.

Research Review. Probably the most common injury of the lower limb in sports that require running, cutting, turning, and stopping is anterior cruciate ligament (ACL) injury. In football, lower limb injuries are very common, ranging from acute macrotraumas to chronic overuse injuries. Specifically in football, knee injures account for about 75% of all lower limb injuries. The football boot undersurface and foot fixation are key components that have been associated with knee injury. In football, more than 60% of ACL injuries are noncontact in origin, and it is well-known that internal tibial rotational moments play a major etiological role. Based on ACL critical limits, this study evaluated commercially available studded and bladed football boots to determine whether the type of boot undersurface affects noncontact ACL injury potential when football players sidestep or "cut" as they run.

Method. To address this research question, a sound, rigorous research design was required. Fifteen professional outfield male football players of mean age 19.5 ± 1.4 years, mass of 70.1 ± 7.6 kilograms, and stature of 1.76 ± 0.06 m, without a history of lower limb injury, and with at least two consecutive injury-free seasons participated. Each undertook three trials of a straight-line run (0°) and sidestep cuts at 30° and 60° on an artificial football surface (FieldTurf FTS01, FieldTurf, Montreal, Canada) approved by FIFA with approach velocity from 5.5 to 6.0 m/second (Figure 5). Each participant was tested using two plastic-studded football boots (Adidas Copa Mundial and Nike Air Zoom Total 90 v3 FG) and two plastic-bladed boots (Adidas Predator Pulse FG and Nike Mercurial Vapor v2 FG), all specified by their respective manufacturers for use on the surface (Figure 5). Kinematics (8 camera VICON 612, Vicon Motion Systems Limited, Oxford, U.K.) synchronized with force plate (Kistler 9287BA, Kistler, Alton, U.K.) data provided inputs for the 3D inverse dynamics analyses (Figure 6).

To enable analysis of potential ACL knee injury, mean absolute externally applied internal/external tibia axial moments, abduction/adduction moments, and anterior forces were calculated. All joint kinetics were normalized to body mass.

The results are displayed in the muscle moment profiles, which provide an indication of the continuous change in musculoskeletal loading, as illustrated in Figure 7. Clear differences can be seen in internal tibial and abduction/adduction moments between straight-line running and cutting at 30° and 60° ($p<.01$).

Figure 6 Research Study of Boot Undersurface and ACL Injury Potential

Note: Studded boots: Adidas Copa Mundial and Nike Air Zoom Total 90 v3 FG, bladed boots: Adidas Predator Pulse FG and Nike Mercurial Vapor v2 FG (*top left*); VICON marker placement in a stationary and dynamic situation (*top middle*); VICON output animation (*top right*); and data collection setup showing VICON cameras, the participant, and 3G artificial turf (*bottom image*).

Interestingly, there were no significant differences in key variables between any of the boots, suggesting that the undersurface during this cutting movement was not affected by the use of blades or studs. Therefore, varying the soccer boot type had no effect on knee loading for each maneuver, but sidestep cutting significantly increased internal tibia and abduction moments and anterior joint forces when compared with straight-line running. The clinical relevance of these findings points to the fact that irrespective of the type of soccer boot worn, loading at the knee remains consistent and that player-specific profiles would provide useful information in developing a picture of the typical movement patterns and loadings of these players.

Other important questions also emerged from these investigations, which were used to inform future work on issues surrounding gender, level of performance, fatigue, and anatomical difference. The research described here was collaborative work carried out by Dr. Rajiv Kaila, MRCS, Dr. Gareth Irwin, and Prof. David G. Kerwin at the Cardiff School of Sport and was published by the American Orthopaedic Society for Sports Medicine's *The American Journal of Sports Medicine*. The work also featured in a number of international

conferences—on both medical and sports biomechanics—and in a keynote lecture at the annual conference of the Royal College of Surgeons and the Football Association in 2006. Details of all these have been included in the Further Readings.

A key issue for the clinician is obviously the logistics of employing a biomechanist to undertake such extensive analyses, even in a video-based gait laboratory. The development of technologies has helped this process significantly over the past 5 to 10 years with the availability of measurement systems. The next section will explore these technologies and explain what tools are available to the modern sports medic and biomechanist.

Methodological Approaches and Issues

To fully understand the extent of the integration of biomechanics into sports medicine, one must first appreciate the technologies that are available to the biomechanist. As in all research, the question dictates the method. It is important that the methodological approach is also underpinned by the grounded scientific principles of accuracy, precision, reliability, and validity. The levels of analysis available, in detail and quality, exist on a continuum with the more simplistic qualitative systems at one end and the advanced automated quantitative systems at the other. Accompanying these analyses is a theoretical or modeling approach. Each will be briefly considered here.

Qualitative Analysis

Over the past decade, there has been an increase in computer and video technologies that have provided the opportunity for clinicians and biomechanists to access a whole range of new techniques for analysis. The development in technology has meant that these systems have become readily available to all interested parties. These systems enable discrete high-resolution images to be selected for instant replay, slow motion, and frame-by-frame playback for use by the clinician or biomechanist. These forms of analysis are normally undertaken in the clinic and allow inspection of key phases of performance and also facilitate comparisons across trials. The main strength of such systems is that they supplement and enhance direct observational skills and provide an excellent archive for future trend analyses. The clinician develops an understanding of what he or she considers to be the desired technique and, by using new technologies, has additional ways of comparing current performances with the mental image of the ideal performance.

The accuracy and effectiveness of any decisions made at this level of analysis, however, can only be as good as the mindsets and conceptual understanding of the biomechanists and clinicians involved.

Semiquantitative Analysis

This level of analysis requires a closer working relationship between the biomechanist and the clinician and is the first step to full quantification. More detailed visual analyses provide improved estimates of the key variables associated with injury. Care has to be taken when using semiquantitative analyses as only simple scaling (i.e., using a single object of known length to convert measures in the video image to real distances) can be achieved. Also, movements are largely assumed to occur in a plane when, in reality, they are 3D. These inaccuracies are exaggerated particularly in the estimation of angles. The validity of many measures recorded using semiquantitative (and qualitative) analyses is therefore questionable. Qualitative and semiquantitative analyses then, although visually impressive and informative, do not provide clinicians and biomechanists with the maximum benefit to be derived from such technology.

Quantitative Analysis

The past decade has seen the rapid development of sophisticated automated motion analysis systems. These systems can provide the biomechanist with the opportunity to collect fine–grained, accurate data ranging from linear and angular kinematics to external forces, internal joint forces, and muscle moments. These systems have also enabled users to calculate muscle power and work, in at best real time and usually within a few minutes of collecting the data. The operation of these systems requires a considerable step-up in knowledge and associated analysis procedures. For sports medicine to benefit from the fruits of this category of analysis, close cooperation between clinicians, coaches, and biomechanists is necessary. The computation of angular and linear, planar, and 3D movements (kinematics) and forces (kinetics) has allowed the biomechanist to develop a larger base of experimental investigations that have increased the understanding of injury.

These systems have been combined with other clinical applications such as radiographic imaging, electromyography, and in vivo force measurements to provide further understanding of the biological processes underlying the potential causes of injury. Innovative analysis methods have emerged alongside these advances in technology. Kinematically, these have included examinations of continuous and discrete inter- and intrasegmental coupling as an assessment of coordination. Exciting new advances in the area of motion analysis include the introduction of machine vision technology, which allows the marker free tracking of whole-body movements. In a sporting situation, this is attractive as it maintains ecological validity and therefore increases the meaningfulness of the derived data.

Modeling in Biomechanics

The computer modeling referred to here is the forward dynamic approach. Forward dynamics modeling is a useful tool in the quest to understand and explain the mechanisms underpinning the occurrence of injury. Biomechanists use the Newtonian laws of motion to produce mathematical formulations to define the systems. Then these models make predications about the behaviors of the biological systems under investigation. There are a number of commercially available software packages that allow biomechanists to build their own models based on specific research questions. Gross models of the whole human can provide useful information about the responses to a technique from a biological sense. A major issue surrounding human models is complexity. The athlete can be simplified, but the model still needs to be representative of a system of rigid and wobbling mass parts linked by springs with varying stiffness and damping characteristics. The type of mathematical representation of human muscle is important and should include the complex dynamics of skeletal muscle force profiles. Modeling of tissues can employ finite element analyses. This technique originated from the necessity to solve complex problems relating to the elastic and structural characteristics of materials. These analyses can inform the researcher about load distributions and subsequent biological responses. Modeling plays a major role in sports and represents a powerful tool; it is often considered the only true method for identifying the individualized optimal technique for a particular athlete.

Contemporary Issues

This section provides an overview of two key contemporary issues relating to the biomechanical aspects of injury. As mentioned earlier, the biomechanist can help in the explanation of the underlying mechanisms that cause jury. Although it must be pointed out that prior to the development of measurement techniques such as inverse dynamics, in vitro force analysis, and forward dynamics modeling, the nature and role of the forces responsible for macro- or chronic injury were not known. Indeed, even today the major contributors to this area—for example, Professor Benno Nigg, Calgary, Canada—suggest that there is as yet no evidence that an increased understanding of load during running has reduced the occurrence of injury. While the relationship between load and injury is still not well understood, there are some key principles and more complex theories currently existing that may help explain the biomechanical mechanisms underpinning the occurrence of injury. Several key concepts have emerged that are fundamental to understanding the etiology of injury. The two concepts that are introduced here are variability and muscle tuning.

Variability

Over the past decade, theories have emerged that have linked biomechanics and motor control. The most well-known of these theories is the dynamic systems approach. Dynamic systems theory has been used to examine and explain injury, particularly of the lower extremities during running. The main researchers in this area are Professors Joseph Hamill, Richard van Emmerik, and Bryan Heiderscheit. This new approach builds on the discrete time research that inked variables such as foot pronation and lower limb internal joint rotation to the occurrence of injury. The dynamic systems approach takes into account the relationship within and between segments during performance, which is quantified through the measurement of joint coupling or coordination. The relationship between injury and coordination variability has been suggested in some cases to be inversely proportional. This is due to the fact that the load placed on biological structures is constantly changing and hence structural failure due to chronic overload is less likely to happen; another benefit of this variability is that it increases the possibility of adapting to any changes in the task (cutting, stopping, and accelerating) or the environment (surface and terrain). This conceptual shift toward the belief that coordination variability has a functional role in the prevention of injury has been controversial within traditional clinical sports medicine. Examining the patterns of coordination and coordination variability through continuous profiling of athletes may allow injury potential to be identified and effective rehabilitation modalities to be monitored.

Muscle Tuning

The main research in this area has been conducted by one of the leading biomechanists, Professor Benno Nigg, from Calgary. He proposed this paradigm based on evidence from epidemiological and experimental studies examining forces. His conclusion is that it was not possible to correlate repetitive-impact forces as a major factor in acute or chronic injuries, specifically in running. The new school of thought proposes that the frequency and amplitude of these impact forces provide an input signal into the biological system. These impact forces produce vibrations of the soft tissue, often referred to as wobbling mass. Skeletal muscle responds to these vibrations in an attempt reduce them. This is achieved through a change in the natural frequency and/or damping characteristics of the muscle, a process defined as muscle tuning.

The strength of this paradigm is that it helps explain the role of impact forces in sporting activities and suggests that they are a prime cause of the development of sports injuries. Additionally, the new paradigm highlights the importance of impact forces as stimuli to the bone. It is also suggested that the impact conditions are correlated to the performance, comfort, and work of the athlete.

The importance of the interface between the surface and the performer becomes more apparent due to the noise removal or filtering effects that the materials will have. This is important in sports such as gymnastics, where epiphyseal growth plate injury can occur at the radius in boys while using the pommel horse apparatus. The resulting ulnar growth creates an abnormal variance in length. The material and geometry of the surface are implicitly linked to the occurrence of such injuries.

Conclusion

This entry has provided an overview of the intrinsically symbiotic relationship that biomechanics shares with the discipline of sports medicine. An initial definition of the science of biomechanics accompanied by the fundamental principles of loading provided the reader with a foundation of knowledge to facilitate further understanding of this area. Practical examples of how the biomechanist can support the clinician to help understand and explain the etiology of injury have been presented, ranging from the viewing of basic digital images to the more complex 3D kinematics and kinetics collected using automated systems. A sport-specific example is then presented that highlights the importance of being able to use research to address sport-specific questions in an ecologically sound fashion. The development of technology over the past 10 years has been dramatic, and an overview of the methods available to the biomechanist has been introduced in this entry. Looking to the future, the entry dealt with two complex issues that are the subject of much debate within the clinical and sports biomechanics community.

Possible future developments are likely to include a stronger mutual relationship between sports medicine and biomechanics. The development of technologies such as machine vision and automated motions analysis systems combined with radiographic and inertial scanning devices will allow more accurate and useful explanations of human movement and loading. These descriptions and explanations when set within a sporting context with a high degree of ecological validity will serve to effectively address problems from a question- rather than a discipline-specific perspective. Bringing coaches, sports medicine experts, and biomechanists together in an interdisciplinary approach will allow the development of this field, which continues to develop through internationalization and broadening of the scientific expertise, to build an outward-facing academic discipline.

Black Nail

Black nail (subungual hematoma) is a straightforward nail-bed injury manifested by pain and dark red to black discoloration of the nail bed. Black nail is the result of blunt trauma or crush injury to the nail followed by bleeding from an underlying vessel. The nail bed is vulnerable to injury due to its rich vascular supply and its position between the tough nail and hard bone (the distal phalanx). Black nail is also referred to as *subungual hematoma*, meaning a collection of blood (hematoma) beneath the nail (subungual).

Presentation

Black nail appears as a visible area of bleeding between the nail bed and the fingernail. The degree of discoloration can vary, as can the timing of presentation. If the injury is close to the base of the nail (near the cuticle), discoloration may not be visible for several days. However, if the injury occurs more centrally or toward the end of the nail, the discoloration can be seen the same day. Either way, the red, dark violet, or black discoloration persists until the nail plate grows out. In cases where the bleeding is significant, there is a significant risk of losing the nail. The accumulation of pressure can cause separation of the nail plate and loss of the nail.

Traumatic causes of black nail in sports include dropping a weight onto a nail while weight lifting, being hit by a pitch in baseball or softball, and an opponent applying force down onto one's nail (such as in wrestling). Repetitive stress can also cause nail injury, such as the repeated striking of the toe into the end of the toe box in tennis and jogging and the stress placed onto the toes in dancing, particularly when ballet dancers dance en pointe.

Making the Diagnosis

This is a clinical diagnosis, meaning that extra testing or imaging is typically not necessary. The exceptions to the rule are (1) an unstable fingertip, (2) a mechanism of injury that is indicative of fracture (broken bone), and (3) a dark nail that is not painful and is asymptomatic. In the first two scenarios, radiographs should be done to rule out bone trauma. In the last case, it is important to monitor the discolored nail carefully and chronically in order to differentiate black nail from possible subungual melanoma, an invasive cancer. Subungual melanoma will be asymptomatic and nonpainful; there is also typically no history of a traumatic injury to the nail. If a clinician is worried about melanoma, a biopsy may be done.

Lacerations are complications of nail-bed injuries, and they occur in the nail matrix. The degree of suspicion for a laceration rises when 25% to 50% of the nail is discolored by a subungual hematoma. However, they can only be diagnosed by removing the nail plate and examining the nail matrix. This is done after digital lidocaine is applied to the area to anesthetize the nail bed.

Treatment

The severity of the nail injury determines the appropriate treatment for black nail. Treatment options include observation, drainage, and nail removal. Small hematomas involving less than 25% of the nail bed can simply be observed; intervention is typically not necessary. The blood will be integrated into the nail. As the nail lengthens, the blood will progress with the new growth and eventually be removed when the edge is trimmed.

Black nail involving more than 25% of the nail bed should be drained, because pressure accumulates under the nail and causes discomfort. Pressure from large hematomas can even lead to deformity. Decompression is done by creating a hole in the nail near the center of the hematoma. This can be done by melting a hole with a heated needle, a handheld cautery device, or a carbon dioxide laser; a scalpel blade has also been used. However, care should be taken to avoid putting extra pressure on the nail and subjecting the patient to additional pain. It is important that the hole be large enough to allow blood to drain and to avoid being sealed shut by seared blood under the surface. Decompression provides immediate pain relief and quickens the return to athletics and activity (see Figure 1).

In the case of a broken finger, once the hematoma has been decompressed, it is considered an open fracture. Broad-spectrum antibiotics should be given to cover for possible infection and osteomyelitis. Some sources advocate using sterile technique during the evacuation, including surgical scrub of the injured finger. However, this is not the current standard of care. Some severe fractures require removal of the nail plate, irrigation, debridement, and repair of the nail bed. Any black nail involving a fracture requires immobilization by splinting.

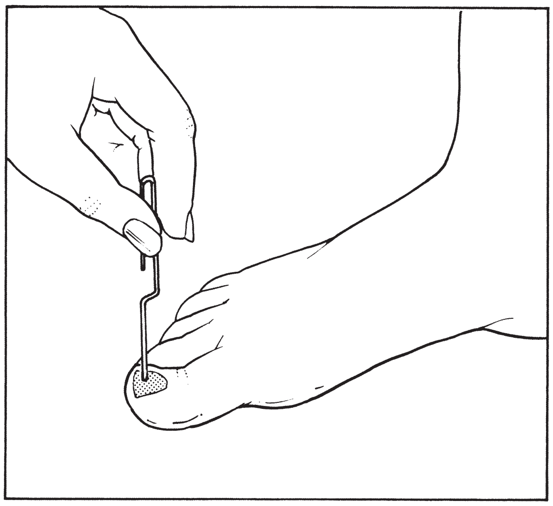

Figure 1 Decompression of a Black Nail

After treatment, the nail should be monitored. The injured nail will eventually detach, and a new nail will grow beneath. In most cases, no further treatment is warranted. Sometimes, the new nail will have bloodstains on it. As with the black nail that does not require treatment, the stains will advance along with nail growth and eventually grow to the nail edge. Complications after decompression include persistent bleeding and development of an ingrown nail. Persistent bleeding raises the suspicion of a nail-bed laceration. As alluded to earlier, the nail should be removed to examine the nail bed and possibly suture the wound. Toe nails are more likely to become ingrown, which results from progressive growth of the lateral nail fold.

Bleeding Disorders

Bleeding is commonly understood as a loss of blood from the vascular system either internally in the body or externally through a natural orifice or break in the skin. Normal bleeding time following most soft tissue injuries is less than 5 minutes. Prolonged bleeding time may indicate a bleeding disorder. This entry focuses on how these disorders may concern people who are active in exercise and sporting activities, identifies the sporting events and activities that are acceptable or unacceptable for people with bleeding disorders, and describes how treatment is rendered and how to monitor these athletes on a continual basis.

Normal Bleeding and Clotting

Blood carries vital nutrients within a liquid made up of plasma, red and white blood cells, and platelets. Plasma, a mixture of water, sugar, fat, and protein, also contains many chemicals that help form the clots necessary to stop bleeding. Red blood cells carry oxygen to all parts of the body. White blood cells fight infections and disease. When an injury occurs, platelets gather at the site of the injury and adhere to the edges of the wound, where they release chemicals that help start the process of clotting so that bleeding will stop.

To understand what is *abnormal* bleeding associated with bleeding disorders, we must first understand the *normal* process of how our bodies bleed and clot. Bleeding occurs in approximately four stages. (This process is the same for both external and internal bleeding.)

Stage 1: The platelets in the blood activate and form a plug over the injured skin or vessel. This plug lasts for 12 to 24 hours.

Stage 2: A substance called Von Willebrand factor reacts with the platelets to increase the "stickiness" of the platelets to each other and the surrounding collagen or tissue.

Stage 3: Further platelet recruitment is involved via local hormone messengers such as fibrinogen and thromboxane.

Stage 4: Activation of the clotting factors, produced by the liver, forms a series of reactions and stabilizes the bleed even further. These factors are XII, XI, IX, and VIII to VII and X, and V. Notably, a deficiency of Factor VIII—which is Hemophilia A—is the most common factor deficiency that causes a bleeding disorder.

Common Types of Bleeding Disorders

The three most common bleeding disorders in athletes are as follows:

1. *Von Willebrand disease* (VWD), an inherited disorder of platelet function (reflected by prolonged bleeding time) and a partial deficiency of functional Factor VIII, which occurs in about 1 in 100 people
2. *Hemophilia,* an inherited deficiency of Factor VIII or IX, which occurs in about 1 in 10,000 people
3. *Immune thrombocytopenic purpura* (ITP), which is an autoimmune or drug-induced disorder

Signs of a Bleeding Disorder

Athletes with bleeding disorders may show the following signs:

- Athletes with VWD usually have mucosal (nasal and gastrointestinal) bleeding. In women, it also includes heavy menstruation.
- Hemophilia in contact athletes is characterized by bleeding into a joint cavity (hemarthrosis), such as the knee, or into muscles. Prolonged bleeding times in the face of a skin injury can occur as well.
- Crops of little red blanched dots on the skin known as petechiae, along with purpura or bruising, may signal thrombocytopenia, low platelets, or ineffective platelet function.

Any bleeding disorder may be worsened by the use of aspirin or anti-inflammatory drugs, which can affect platelet function and therefore prolong bleeding. A physician along with a hematologist can diagnose a bleeding disorder. Routine tests such as cell blood count (CBC) will look for low platelets, anemia (low hemoglobin), prothrombin time (PT), and partial thromboplastin time (PTT). Prolonged PTT can be the initial clue in the diagnosis of hemophilia or VWD. Like hemophilia, VWD will have a prolonged bleeding time.

Treatment

Treatment immediately after an injury includes activating the PRICE regimen: *p*rotect, *r*est, *i*ce, *c*ompression, and *e*levation. Athletes with mild cases of VWD are treated with DDAVP (desmopressin), and those with active bleeding are treated with Factor VIII concentrate.

Treatment for hemophilia is often given when bleeding has started or when the doctor knows that clotting factor replacement will be needed, such as before surgery. This is known as treatment "on demand." Recently, however, doctors have started prescribing clotting factor replacement to young people on a regular basis to try to prevent bleeds from starting. The goal is to ensure that joints and muscles are less likely to be damaged in the future. This preventive type of treatment is known as prophylaxis.

ITP is generally limited to children. Cases usually cease when the offending drug is stopped (e.g., antibiotics such as trimethoprim/sulfamethoxazole or vancomycin, or antacids such as famotidine or ranitidine). However, a case was reported of a professional football player who developed ITP after taking quinine sulfate for muscle cramps. In adolescents and young adults, most cases of ITP are autoimmune related and require corticosteroids, IV (intravenous) immunoglobulin, and, in some cases, a splenectomy.

Activity Prescription

Recent decades have seen a shift in attitudes and approaches to bleeding disorders and sports. Formerly, hemophiliacs were overprotected and told to be as physically inactive as possible. In many cases, physical activity was forbidden. They were kept indoors, often not allowed to go to school, and not allowed to engage in activities that could be perceived as high risk.

The main authority on exercise, the American College of Sports Medicine (ACSM), does not publish guidelines on activity and bleeding disorders. Even the *Preparticipation Physical Evaluation* monograph, a guide that helps physicians screen medical conditions during routine preseason physicals in sports, simply recommends further evaluation for anyone with a bleeding disorder. This leaves the decision of whether to participate to the athlete and his or her health care team: the primary care physician, the hematologist, the athletic trainer, and, in the case of children, the parents.

In general, however, athletes with hemophilia and VWD are precluded from contact sports, specifically collision sports such as football, basketball, soccer, and rugby. The research varies, and some experts believe that contact sports may be allowed in mild cases of ITP if the platelet counts are above 100,000 per cubic millimeter.

There is a consensus among physicians that good physical condition and well-trained musculature in athletes can reduce the incidence of spontaneous bleeding. Rochelle Tiktinsky and colleagues observed a marked decrease in bleeding complications among hemophiliacs after progressive resistance training. It has been demonstrated that physical activity enhances the concentration of various coagulation factors without raising the number of bleeding episodes cased by the training program.

Classifying Sports: Contact Versus Noncontact

The medical and sports industries have created ambiguity in defining who may or may not participate in which sports. Some sports have been ranked as high risk based on the frequency of injuries, even though those injuries are relatively mild. Some sports, such as snowboarding, in which the injuries can be catastrophic, are ranked as medium risk. Interestingly, basketball and soccer both appear on the American Pediatric Society list as "contact" or "collision" sports but are classified as medium risk in most hemophilia publications. The need for clarity and consistency to guide athletes and their health care teams is apparent.

What is more important in identifying risk for an athletic patient with hemophilia or VWD is to match the athlete and the activity according to the biomechanical requirements of the sport and the physical abilities of the participant. This is being done in Germany. Biomechanical analysis, including angular acceleration, is measured for different sports to calculate joint stresses. Children with hemophilia are assessed for balance and coordination, flexibility, muscle strength, endurance, and body mass. The results of the assessment are then compared with the demands of the child's chosen sport. If the analysis shows that the joints and muscles are up to the task, the child is allowed to play. If deficiencies are found in certain areas that the sport requires, the child is advised to choose another sport or to correct those deficiencies before trying to play.

Conclusion

Physical activity is advocated for the general population. It has been linked to favorable effects on heart disease, hypertension, obesity, diabetes, osteoporosis, high cholesterol, and emotional states. Through appropriate participation in sports, people with bleeding disorders can develop good physical condition and motor coordination, which may prevent musculoskeletal problems and speed recovery after joint and muscle bleeds. Participation in activities that are normal and desirable parts of social life confers not only physical but also psychosocial advantages.

In any sport or physical activity, those with bleeding disorders need proper physical conditioning. They must know the rules, have the skills to play, go through proper warm-up, and use appropriate protective equipment. Education concerning the player's bleeding disorder is imperative for the coaches, trainers, and parents. Most important, if an injury does occur, proper treatment must be readily available.

Blisters

Blisters occur where there is excessive friction over the skin. For this reason, they are frequently called *friction blisters.* This differentiates them from blisters caused by heat or solar injury, infection, medications, or other medical conditions. Friction blisters generally occur on the soles and heels of the foot; however, they may also form on the palms in athletes who are active with their hands, such as rowers and gymnasts. Although more common in active populations because of the repetitive movements in athletics, all people are susceptible to friction blisters.

Anatomy

The skin has three layers. The deepest layer is called *subcutaneous tissue* and is composed of adipose (fat), nerves, hair follicles, arteries, veins, and sweat and oil glands. The middle layer is the *dermis.* It has two layers and varies in thickness depending on the location in the body. The deepest layer of the dermis is composed of thick collagen (connective tissue) fibers, which have parallel alignment with the skin surface. This layer sits just on top of the subcutaneous tissue. The thin, more superficial (outer) layer of dermis is also made of collagen fibers, which are randomly arranged. The most superficial layer of the skin is the *epidermis*. The epidermis constantly replenishes keratinocytes (skin cells), which flatten, die, and eventually slough. The overall thickness of the epidermis depends on its location in the body. It is thickest in the palms and soles. The epidermis consists of five layers (from deep to superficial): stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. The *stratum basale* is named for the basal cells that form the base of the epidermis. They lie on top of the dermis, are shaped like columns, and are constantly dividing to replenish the cells lost at the surface. Basal cells divide into keratin-producing cells called *keratinocytes*. These keratinocytes form microscopic spines that link them together; thus, this layer is called the *stratum spinosum*. As the cells migrate toward the skin surface and become progressively flattened, they form a new layer called *stratum granulosum* because the cellular cytoplasm appears granular under microscopy. The cells then die and become the outermost layer, the *stratum corneum*. The *stratum lucidum* is a transition layer between the stratum granulosum and stratum corneum. It is found only in the thick skin of the palms of the hands and soles of the feet. This layer contains an oily substance that provides protection from friction. A friction blister forms when there is breakdown of the spinous bridging in the stratum spinosum. The blister roof and floor contain the normal layers of dermis and epidermis, and the cavity becomes filled with a clear transudate (fluid). If the friction over an area is more intermittent, hyperkeratosis (callus) formation may occur. This thickened area can be somewhat protected from friction blisters. If left to grow thick, however, a friction blister may occur under a callus.

Causes

Any repetitive external force across a localized area of skin can cause a friction blister. Susceptibility is based on the magnitude of frictional forces and the duration of repetition. Athletes are unlikely to stop their activity with the earliest signs of discomfort from friction blisters, thus predisposing them to greater severity. Typical causes are poorly fitting footwear, sweating, heat, and increased level of activity preceding protective callus formation.

Symptoms

Initial symptoms of friction blisters are a localized, mildly erythematous (red) "hot spot" in the area of repetitive friction forces. Slight stinging or burning may be associated with this stage and tends to worsen as the friction forces continue. The localized area becomes progressively more erythematous and painful, and a zone of pallor (white skin) surrounds the area. Eventually, the stratum spinosum splits, filling with a clear transudate. The roof of epidermis skin covering the friction blister becomes raised, tense, and appears white or yellow. A zone of erythema may surround the bullae (fluid filled sac) depending on the amount of irritation. In extreme cases, ulceration may occur in the floor of the bullae, or the protective roof may break, exposing the underlying dermis to infection.

Prevention

Prevention of friction blisters begins with awareness of a localized "hot spot" and then taking appropriate measures to reduce the causative friction force before bullae formation can occur. Choosing appropriate footwear, wearing gloves if using the hands, and gradual entry into new activities are also helpful. Other considerations in preventing friction blisters on the soles and heels are choosing socks that optimize frictional and wicking properties. In general, socks that move moisture away from the skin and can maintain their cushioning despite compression and moisture are the best. These include an outer wool or polypropylene sock combined with a wicking, thin, polyester-base layer sock. Antiperspirants have also been used in the prevention of friction blisters but may be associated with contact dermatitis (skin irritation).

Treatment

Most friction blisters are self-limited and will heal with little intervention once the friction force is removed. If the roof of the bullae remains intact and tense, a doughnut pad can be placed around the site for protection and to relieve discomfort.

The bullae can also be drained using sterile technique; however, the overlying blister roof should not be disrupted as it acts as a protective dressing. If the roof is already removed, the blister should be treated as an abrasion. In this case, an antiseptic and bandage should be applied in addition to doughnut padding. If signs of infection are present, antibiotic treatment may be indicated.

Specialized blister dressings are now available with and without a prescription. They are typically a semipermeable, adhesive film that provides a protective sterile covering for blisters that have lost their roof. In some cases, they are medicated.

Blood Transfusion

Blood transfusion is a life-saving technique that was developed in the 1880s. It is used therapeutically to treat anemia but has also been used by athletes as a performance-enhancing technique.

Anemia is a condition in which there is a decreased amount of red blood cells. It is measured by analyzing a sample of blood and calculating a hematocrit (the proportion of blood that is occupied by packed red blood cells). Anemia can develop from many causes: of these, iron deficiency, kidney failure, and blood loss are among the most common.

It may be surprising to some people that transfusions also have been used by some athletes as performance enhancers. Endurance athletes competing in cycling, marathons, or triathlons have been known to use this technique, known as *blood doping*. Blood doping is a way of artificially increasing the amount of red blood cells in the body's circulation. The red blood cells (and the protein *hemoglobin* inside the cells) carry oxygen to all the tissues of the body. The more the red cells and hemoglobin, the more oxygen can be delivered to the exercising muscles. An athlete with more red blood cells can exercise harder and longer, with quicker recovery, more stamina, and better results—up to a point.

Athletes who engage in blood doping put themselves at risk of disqualification and also put themselves at risk for myriad health problems. This dangerous technique creates polycythemia (increased number of red blood cells) and increases the viscosity of the blood, which leads to sludging. Sludging in the heart can lead to myocardial infarction (heart attack), and in the brain it can cause stroke (cerebrovascular accident, or CVA). Sludging in the veins causes blood clots in the legs or pelvis (deep vein thrombosis, or DVT), and pieces of these clots that break off and go to the lungs can instantly kill the athlete (pulmonary embolism). Blood doping can also cause kidney failure and even iron overload toxicity.

Blood transfusions require needles and IV (intravenous) drips. There is an inherent risk of cellulitis or phlebitis (infection from the IV site). In addition, blood products can carry dozens of viruses, such as hepatitis B virus (HBV), human immunodeficiency virus (HIV), and others. Athletes have tried to minimize this risk by taking their own blood out weeks or months before competition (autologous blood transfusion). They store the blood, give their body enough time to bring their blood levels back to normal, and reinfuse the stored blood just before their event.

With this blood-doping technique, there can be problems with sterility and storage, especially if it is being done surreptitiously. Blood is an excellent culture medium, and even small amounts of bacteria that have contaminated the blood can cause deadly sepsis; so can blood that has been improperly stored.

In endurance sports, such as the Tour de France, strict monitoring of hematocrits is used to detect athletes who are blood doping. A normal hematocrit for an average adult ranges from 32% to

43%. Intense exercise over time can increase it up to around 46% or even 48%. If the hematocrit for an athlete is found to be more than 50%, it may be assumed that he or she has used artificial means. In this case, he or she may be investigated further or disqualified.

Other methods besides blood transfusions are used to raise hematocrits, including the use of erythropoietin (EPO). EPO is a chemical that stimulates the body to make more red blood cells and is discussed at length in a separate entry. In addition, people who live at high altitudes will acclimatize over time and will naturally have higher hematocrits. Athletes have tried to harness this phenomenon. Some will live and sleep at high altitudes (and train at sea level) to achieve this effect on hematocrit. Some use hypoxia tents, where they sleep in an environment of slightly lower than normal oxygen levels. This simulates the low oxygen experienced at high altitude. These are considered legal devices; however, their use as performance-enhancing devices is somewhat controversial. Sports-governing groups continue to investigate their safety and effects. The proper use of hypoxia tents is generally considered safe, and they are not banned in any sport.

Blood-Borne Infections

During participation in athletics, an inherent risk of exposure to, as well as subsequent transmission of, blood-borne viral infections exists for both the athlete and sports medicine team members. Although there are presently no published epidemiologic studies assessing the transmission of viral pathogens such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), or hepatitis C virus (HCV) during athletics, expert opinion estimates the theoretical risk to be exceptionally low. Regardless of the improbability of communication of blood-borne viral infections in sports, the underlying focus should involve preventing the dissemination of blood-borne infections and education of athletes/staff members regarding the potential risks of transmission on and off the field. Emphasis should be placed on off-field conduct and on minimizing risk-taking behaviors, as sexual contact and injection drug use overwhelmingly pose the greatest risks of infection for the athlete. Other challenging facets of blood-borne infections and the athlete involve ethical and legal issues pertaining to disclosure of infection status.

Those involved with the care of the athlete should become more familiar with the following aspects of blood-borne infections in athletic participation:

- Epidemiology and transmission factors associated with HIV, HBV, and HCV infections
- Prevention and educational initiatives involving blood-borne pathogens in the athletic setting
- The role of testing for blood-borne infections in high-risk athletes
- Management issues pertaining to diagnosis and care of the recently infected athlete
- Legal and ethical considerations affecting an athlete infected with a blood-borne pathogen

Epidemiology and Transmission of Blood-Borne Viral Pathogens

Risk of transmission of blood-borne infections can be categorized according to the likelihood of contact and collision in a given sport. Athletes taking part in sports such as wrestling, boxing, and tae kwon do have a higher risk due to significant blood exposure and prolonged close body contact. "Moderate"-risk sports include basketball, field hockey, ice hockey, judo, soccer, and team handball; lowest-risk sports include baseball, gymnastics, and tennis.

Transmission risk during athletic participation stems largely from bleeding wounds or the blood of an infected athlete contaminating the skin or mucous membranes of other athletes/staff members. However, the athlete's greatest risk of acquiring a blood-borne viral infection is through sexual activity and injection drug use rather than through on-field activities. Additionally, the increasing popularity of body piercing and tattooing among adolescents and young adults is another potential means of transmission of viral blood-borne infections. Skin branding, a fashionable practice of college athletes belonging to Greek fraternities, similarly can be complicated by acquisition of blood-borne infections in settings where nonsterile equipment or procedures are used.

Human Immunodeficiency Virus

According to the World Health Organization (WHO), the number of people living with HIV worldwide in 2007 was estimated at 30 to 36 million. These new data represent a significant correction of previous analyses and can be attributed to improved survey data and advances in estimation methodologies. Previous estimations of 36.1 million HIV-infected people in 2000 and 39.5 million in 2006 have been revised to 27.6 million and 32 million infected people, respectively. Globally, it is estimated that 0.8% of the adult population (aged 15–49 years) is infected with HIV.

In 2006, an estimated 56,300 new HIV infections occurred in the United States. Fifty-three percent of all new infections in 2006 occurred in gay and bisexual men, 31% resulted from high-risk heterosexual contact, while 12% of new infections were the result of injection drug use. The number of annual infections peaked in the mid-1980s at approximately 130,000 per year and reached a low of roughly 50,000 in the early 1990s. Incidence appeared to increase in the late 1990s but has stabilized subsequently (in the three most recent periods analyzed, new infections ranged from 55,000 to 58,000 per year).

Presently, no scientific study has specifically investigated transmission rates of HIV among competitive athletes. According to a research conducted by the Centers for Disease Control and Prevention, the risk of HIV transmission during athletic participation is very low. With the exception of boxing, the calculated risk is less than one transmission in 1 million games. To date, transmission of HIV during sports has not been corroborated. In 1990, Torre and colleagues reported one alleged case of HIV seroconversion during a collision between soccer players in Italy. However, the infected athlete's off-field profession (as a drug dependency rehabilitation center worker) and the lack of sufficient documentation to confirm that the transmission occurred during sports participation led public health officials and reviewers to reject the claim as inconclusive and unsubstantiated.

Research conducted with health care workers provides much of the epidemiologic basis for HIV transmission rates and risk. Approximately 1 in 300 needle-stick injuries involving infected blood results in HIV transmission. The risk of transmission from exposure to mucous membranes or nonintact skin has been determined to be 1 in 1,000 exposures, significantly less than the 2 to 3 per 1,000 exposures risk from parenteral (i.e., intravenous, intramuscular, subcutaneous) exposure. Skin and mucous membrane transmission appears to require prolonged exposure to large quantities of blood in addition to a portal of entry (e.g., cuts, abrasions, open wounds), thus making the potential for HIV transmission in typical sports settings unlikely. Casual body contact occurring during athletic participation (e.g., sharing sports equipment, touching, sharing locker room/bathroom facilities, contact with contaminated surfaces such as toilet seats and wrestling mats) poses virtually no risk of HIV transmission to athletes/athletic personnel.

Sexual contact and injection drugs (e.g., anabolic steroids, hormones, vitamins, illicit drugs) present the greatest risk of blood-borne viral pathogen dissemination to athletes. While epidemiologists routinely estimate that transmission of HIV occurs on average once per 1,000 acts of heterosexual intercourse by couples in which only one individual is HIV positive, a recent study has challenged these results. Powers and colleagues found that the estimation of heterosexual infectivity ranges widely, adding that the use of a single value for the heterosexual infectivity of HIV-1 misrepresents important differences associated with transmission cofactors. Additionally, the authors advised that the particular value of one infection per 1,000 contacts between infected and uninfected individuals appears to define a lower boundary, thereby significantly underestimating the infectivity of HIV-1 via heterosexual contact.

Communication of HIV infections among anabolic-androgenic steroid injectors has been well documented in the literature. It should be noted that risk factors other than steroid injecting (e.g., past history of intravenous drug use, needle sharing, imprisonment, number of tattoos received, number of sexual partners) complicate the ability to isolate the risk of steroid injecting for blood-borne pathogen transmission among steroid users. Despite this, steroid-injecting athletes have lower rates of blood-borne infections than intravenous drug users.

While no reports of HIV transmission as a result of blood doping currently exist in the literature, HCV infection as a result of athletes sharing a syringe containing vitamin complexes has been reported.

HIV transmission via body piercing or tattooing remains a potential medical peril, although no published literature currently substantiates this concern. A single case report has documented a possible transmission of HIV-1 during extensive body piercing. No other exposures could be identified in the infected patient. However, as several studies have demonstrated that the presence of body piercings and tattoos may be associated with more risk-taking behavior, caution must be applied when interpreting the significance of such a report.

Hepatitis B Virus

It is estimated that 2 billion people worldwide are infected with HBV; more than 350 million have chronic liver infections. Modes of transmission are identical to HIV, but HBV is 50 to 100 times more infectious, due in part to the virus's stability in the environment (HBV can survive outside the body for more than 7 days) and its high serum concentrations. Infectivity risk estimates, based on occupational exposure data evaluating needle puncture and contaminated–sharp-object injuries, currently place the risk of transmission at 2 to 40 per 100 exposures. The risk of HBV transmission from skin and mucous membrane exposure is generally accepted to be higher than the risk of transmission of other blood-borne pathogens.

While the theoretical transmission rate of HBV during athletic competition has been estimated to be one transmission in every 10,000 to 4.25 million games, numerous documented HBV transmissions have occurred during sports participation. Ringertz and Zetterberg reported an outbreak of HBV infections involving 568 Swedish track-finding (orienteering) athletes from 1957 to 1963. The route of infection was believed to be water contaminated with the blood of HBV-infected athletes, which was used to clean wounds acquired by contact with branches and thorns. In 1980, an asymptomatic high school sumo wrestler in Japan with chronic hepatitis B infection transmitted HBV to his teammates, likely through skin cuts and abrasions. More recently, Tobe and colleagues reported an outbreak of HBV involving 11 athletes on an American football team over a 19-month period (1990–1991). A player with HBV-carrier status (i.e., an individual who harbors and can transmit an infection but is not symptomatic from the infection) was identified as the source of infection; contact with open wounds of the carrier was likely the route of transmission.

Hepatitis C Virus

Worldwide, hepatitis C infections are quite common. Three percent of the global population has been estimated to be infected with HCV. There are nearly 4 million HCV carriers in Europe alone. In the United States, approximately 19,000 new cases of HCV occurred in 2006, the vast majority being asymptomatic and underreported. Nearly 3.2 million Americans have chronic HCV infections. The risk of occupational exposure to HCV is not well established, but the risk of transmission is estimated to be 3 to 10 per 100 exposures through the skin—less than the risk for HBV infection but 10 times greater than that of HIV.

For the athlete, injection drug use represents the primary risk factor for HCV infection. Approximately one third of young (18–30 years old) injection drug users are HCV infected. Additionally, tattooing has been shown in epidemiologic studies to be an independent risk factor for HCV seropositivity. Sexual contact and sharing personal items that are HCV contaminated (e.g., razors, toothbrushes) appear to pose a low risk for HCV transmission.

Case reports involving HCV transmission in weightlifters injecting anabolic-androgenic steroids and soccer players sharing syringes to inject intravenous vitamin complexes have been documented in the literature.

Prevention and Educational Initiatives Involving Blood-Borne Pathogens in Sports

As previously discussed, the primary routes of transmission that place athletes at risk for blood-borne infections are sexual activity and injection drugs rather than on-field sporting activities. It is incumbent on the sports medicine practitioner to educate athletes regarding the detrimental consequences of high-risk behaviors. For many practitioners, the preparticipation physical exam provides an ideal opportunity to counsel athletes on disease transmission issues, dispel myths and misconceptions regarding blood-borne infections, and provide insight and guidance in a nonjudgmental fashion to athletes regarding off-field conduct and risk-taking behaviors.

While the likelihood of on-field transmission of blood-borne infections remains remote, advising the athlete regarding the circumstances in which transmission during athletic activity could occur merits attention. Guidelines addressing preventive measures for reducing blood-borne pathogen transmission in sports have been published by the American Academy of Pediatrics (AAP), the American Medical Society for Sports Medicine (AMSSM), and the American Academy of Sports Medicine (AASM). Since the risk of blood-borne infection in sports is exclusively restricted to contact with blood, body fluids, and other fluids containing blood, the aforementioned guidelines focus on precautions designed to contain bleeding injuries in the context of athletic competition. The following provides a synopsis of the guidelines' recommendations:

- Athletes should be advised that it is their responsibility to report all wounds before or during competition.
- Abrasions, cuts, or oozing wounds that potentially could serve as a source of bleeding or portal of entry for blood-borne pathogens should be covered with an occlusive dressing before and after participation. Caregivers should also cover their own healing wounds to prevent transmission to or from an athlete seeking medical attention.
- Athletes with active bleeding should be removed from participation as soon as possible; bleeding must be controlled, and wounds must be cleansed with soap and water/antiseptic and properly covered before return to competition. Minor cuts or abrasions that are not bleeding do not necessitate stoppage of play; instead, these can be cleansed and covered during breaks in play.
- When managing an acute blood exposure, universal precautions (with the necessary equipment/supplies to implement them) should be practiced by all caregivers. Proper equipment includes latex or vinyl gloves, antiseptic, bleach (1:10 dilution with tap water), alcohol-based disinfectant, receptacles for soiled equipment or uniforms, dressings/bandages, and a "sharps" container for disposal of needles, syringes, or scalpels.
- Equipment and playing surfaces (e.g., wrestling mats) contaminated with blood should be cleaned immediately with disposable towels, then disinfected with a 1:10 bleach solution for at least 30 seconds. The surface should be dry before resuming sports activity.
- Emergency care for life-threatening injuries should not be delayed if gloves or other protective equipment are not available. Breathing (Ambu) bags and oral airways are the preferred equipment for airway management, when available. Mouth-to-mouth resuscitation may be administered when such equipment is not accessible.
- Equipment handlers, laundry personnel, and janitorial staff should be advised to wear gloves when contacting bloody equipment and clothing.

In addition to on-field precautions, sports medicine practitioners should promote HBV immunization among athletes and staff (e.g., coaches, athletic trainers, laundry personnel, janitors). A complete series of HBV vaccine affords vaccinated individuals >95% effectiveness against HBV infection; approximately 5% of HBV vaccine recipients are "nonresponders"—that is, they do not generate an immune response that offers them adequate protection against HBV.

While both the AAP and the American College Health Association have recommended universal hepatitis B vaccine for children, adolescents, and student-athletes since the early 1990s, the sports medicine practitioner should be aware that the increasing reluctance to vaccinate among various parenting communities and subsequent nonmedical vaccine exemptions may affect immunization rates among student-athletes enrolling to their respective institutions.

Role of Testing for Blood-Borne Infections in Sports

The AAP, the AMSSM, and the AASM do not advocate mandatory testing or universal screening of athletes for blood-borne pathogens to determine eligibility for sports participation, citing that such testing "would not effectively prevent infection, promote health, or be easily implemented." The AMSSM and AASM suggest that voluntary testing be offered to athletes and athletic staff who may have potentially been exposed to blood-borne pathogens. Such high-risk individuals would include (1) persons with multiple sexual partners or sexual contacts with at-risk persons; (2) injection drug users (past or present); (3) persons with histories of sexually transmitted infections, including HBV; and (4) persons receiving blood transfusions prior to 1985.

Various organizations involving sports deemed "high risk" for blood-borne pathogen transmission—in particular, the International Boxing Federation and the International Federation of Associated Wrestling Styles—have mandated HIV testing prior to sports participation. Other organizations, such as the International Amateur Boxing Association, only recommend HIV screening as part of their preparticipation physical exams. In the United States, no federal regulations exist pertaining to mandatory HIV screening for boxers. State boxing commissions differ significantly regarding prefight medical requirements, including blood-borne pathogen testing.

Management Issues Involving the Recently Infected Athlete

When implemented, blood-borne pathogen testing should be accompanied by pre- and posttest counseling. In certain cases, such as an athlete with asymptomatic HIV infection, a strategic approach to inform the athlete of (1) his or her infection status, (2) the availability of counseling regarding the psychosocial aspects of the disease, (3) the implications of continued sports participation, and (4) subsequent behavioral modification following infection can be effective as a means of reducing transmission to other susceptible individuals. This can be particularly noteworthy in the setting of the acutely infected athlete, who has a higher risk of transmitting his or her infection via sexual contact due to substantially higher viral loads.

Because infected athletes have a very low probability of infecting other athletes, all athletes with blood-borne pathogens (i.e., HIV, HBV, HCV) should be allowed to participate in all competitive sports. Particular attention has been drawn to boxing and wrestling—sports with the greatest potential for contamination of injured skin by blood. Sports medicine practitioners may choose to encourage infected athletes participating in such high-risk sports to pursue other relatively low-risk sporting activities. Doing so may provide further protection to the infected athlete by minimizing exposure to additional blood-borne pathogens.

Continued participation in sports by the infected athlete is a personal and individual decision. Moderate-intensity exercise has been shown to provide both psychological and immunological benefits to HIV-infected patients, and no evidence exists that intensive training negatively affects asymptomatic HBV carriers. The sports medicine practitioner can play a pivotal role in advising the infected athlete on the decision to continue competing. Referral to an infectious-disease specialist is an essential component of managing the infected athlete; it is particularly important when attempting to determine the individual's state of health and the likelihood of deterioration when exposed to the potentially detrimental psychological and physical stressors that accompany competitive sports.

Athletes acutely infected with blood-borne infections often experience prolonged febrile illnesses accompanied by flulike symptoms. Hospitalization may be required for illnesses such as pharyngitis, diarrhea, and hepatitis/jaundice—conditions typically managed in an outpatient setting in healthy individuals.

Treatments for blood-borne infections may also affect the infected athlete's energy level and/or performance. Interferon, a treatment generally recommended in the setting of HCV to delay the onset of cirrhosis, causes a multitude of side effects, including fatigue, headaches, anxiety, depression, insomnia, and muscle aches—symptom constellations that can make athletic competition extremely difficult.

An athlete who acquires a blood-borne viral infection such as HIV, HBV, or HCV unequivocally undergoes psychological adjustments such as depression during the acute phase of his or her illness that often overshadows every other aspect of his or her life. Sports medicine practitioners need to recognize the challenges athletes face when coping with their illnesses and assist infected athletes with obtaining the proper mental health services necessary to maintain a positive outlook on their futures and to guide them through the inevitable uncertainties they encounter.

Legal and Ethical Considerations Involving the Infected Athlete

When faced with an athlete recently infected with a blood-borne pathogen, it is the responsibility of the sports medicine practitioner to maintain confidentiality about the athlete's infection. With the exception of mandatory reporting to state and public health departments by physicians ordering testing, the athlete and parent/guardian (if the patient is a minor) must give informed consent for medical personnel to disclose information to sports organizations and institutions. It is advised that the sports medicine practitioner familiarize himself or herself with individual states' regulations concerning confidentiality and reporting of blood-borne pathogens. As of April 2008, all 50 states, the District of Columbia, and five dependent areas—American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the U.S. Virgin Islands—use the same confidential name-based reporting system to collect HIV and AIDS data.

The legal responsibility to warn fellow athletes and staff members of infection status remains the obligation of the infected athlete, not the physician caring for the infected athlete. While it is understandable that sports medicine practitioners may feel a conflict between keeping an athletes' infection status confidential and informing other athletes/staff members, the AMSSM and AASM position statement is unwaveringly decisive regarding this ethical conundrum: The physician may not disclose the infected athlete's status to other physicians, coaches, trainers, teammates, or opponents.

As previously stated, athletes infected with blood-borne pathogens may not be excluded by an institution or sports organization from athletic participation on the basis of their infection status. Both the Americans with Disabilities Act of 1990 and the Rehabilitation Act of 1973—federal laws applicable to virtually all professional, intercollegiate, and interscholastic sports programs—prohibit discrimination against persons who have physical abnormalities or impairments. Excluding an athlete with a blood-borne infection because his or her physical condition increases the risk of personal harm must be based on "reasonable medical judgments given the state of medical knowledge." Furthermore, the theoretically harmful effects of the prolonged physical exertion inherent to athletic competition on an infected athlete's immune system have not been upheld by the legal system as grounds for exclusion from sports.

Apart from the legal decisions pertaining to participation involving the infected athlete, there are ethical decisions regarding the athlete's state of health. When advising an infected athlete regarding the potential risks and benefits of engaging in sports competition, the sports medicine practitioner, in conjunction with the athlete and the athlete's personal physician, should provide individualized recommendations based on the clinical status of the athlete, the nature and intensity of training and competition inherent to the athlete's sport, and the risk of both transmission and susceptibility of the infected athlete to blood-borne infections in his or her given sport.

Body Composition (Body Mass Index)

Body composition (body mass index, BMI) is a method used to quantify the percentage of each body component as it constitutes the whole. There are numerous ways to divide the body's components, but the most common method is to divide the body into fat mass and lean body mass (bone, muscle, blood, organs). Alternatively, the body can be divided into water, protein, carbohydrate (glycogen), minerals, and fat. More detailed divisions such as these are most often used for research purposes. Differing body compositions explain why individuals of the same height and weight may still differ in their shape and leanness. Body composition both positively and negatively influences athletic performance in sports and is directly related to many health issues in the general and athletic population.

There are numerous methods for determining an individual's body composition. Methods vary by their reliability, ease of use, cost, and availability. The most frequent method for evaluating body fat is measuring the amount of fat under the skin at various sites using special tools called skin calipers. This method is widely used in health clubs, athletic departments, and medical offices; however, the measurements obtained with this method are the least accurate and are assessor dependent. Another commonly accessible method is measuring the bioelectrical impedance. This method is often used on home digital body weight scales and estimates body fat percentage by calculating the resistance of an electrical current as it flows through the body.

More sophisticated measurements include underwater weighing, air displacement, dual-energy X-ray absorptiometry (DXA), and advanced imaging such as magnetic resonance imaging (MRI) and computed tomography (CT). These more accurate techniques require expensive medical equipment and are commonly reserved for research. Despite the cost, air displacement is becoming more commonly accessible at health and fitness centers as well as sports medicine centers. This method calculates the body's density and body fat percentage by measuring the weight and the amount of air the individual displaces inside the closed unit. The Bod Pod is the most common of air displacement devices found in clinical and research facilities.

BMI is commonly used as a measure of obesity in adults. It is calculated by dividing body weight (in kilograms) by height (in meters) squared. Normal weight is classified by a BMI between 18.5 and 24.9. Individuals classified as overweight have scores between 25 and 29.9, and obesity is defined in individuals with values of 30 and above. Elevated BMI has been linked to multiple medical conditions, including heart disease, diabetes, high cholesterol, and high blood pressure. Unfortunately, while BMI is a fast, easy, inexpensive, and reproducible method, it is not the most reliable measure to evaluate an athlete's body composition. BMI does not directly measure body fat percentage, and thus it can classify a very muscular individual as being obese when in fact he or she may have very little body fat. Therefore, BMI measurements in athletes should be used with caution.

In many sports, performance is directly affected by body size and composition. Scoring in sports such as diving, gymnastics, and competitive cheerleading is subjective and can be affected by the aesthetic build of the competitor. Similarly, sports such as running focus on weight and body composition. Runners may concentrate on losing body weight as a way to increase speed, because many believe that thinner is always faster. Unfortunately, many competitors, especially females, focus on weight loss and unhealthy eating habits, causing hormone imbalances, menstrual irregularities, bone loss, and impaired performance. Other sports, including wrestling, boxing, and weight lifting, use weight classes. For these sports, participants not only focus on weight loss, but also often resort to unhealthy training and dieting methods to decrease their body mass in a short period of time in order to conform to the prescribed weight classes for competition.

There are also sports that center on gaining weight, both lean mass and fat mass. Training and eating to produce mass is undesirable in most sports but can be advantageous for sports such as sumo wrestling and American football (linemen). These individuals do put themselves at risk of developing the same medical complications of overweight and obese individuals as described earlier. Counseling athletes to focus on maximizing lean mass rather than fat mass and counseling them about healthy modifications once their athletic careers are completed are vital. As we have described, body composition is often a focus of athletes, coaches, and their medical professionals, and there are many reasons for altering one's body composition. The constant drive for athletes to reach their ultimate potential often leads them to extreme measures to reach the "ideal" body type or body composition for their sport/position.

Bowel Injury

Bowel injury is infrequent in sports and most commonly occurs as a result of a forceful blow to a small area over the small intestine. Injury can also result from lack of blood supply, but such acircumstance seems to have some genetic predisposition accompanied by vigorous endurance exercise.

Bowel Injury Resulting From Abdominal Trauma

Epidemiology

Traumatic injuries to the bowel are more common in contact sports (e.g., soccer, rugby, football), sports involving high velocity (e.g., skiing), and sports with a high frequency of falls (e.g., equestrian). Blunt abdominal trauma causing jejunal rupture has been described following a punch to the abdomen as well as following blunt trauma to the abdomen. Perforation of the gastrointestinal tract is reported in 4% to 9% of patients who present at hospital with blunt abdominal trauma. While most of these injuries are a result of motor vehicle accidents, bicycle handlebar injuries have been reported to account for 14% to 20% of the cases. Cases of duodenal rupture following sport-related blunt injury have been described during cycling, hockey, skating, soccer, and American football. Three cases of jejunal rupture during participation in American football and soccer have been reported so far.

Anatomy and Pathophysiology

The abdomen is relatively poorly protected, with superficial rectus abdominus and transverse abdominus muscles providing some limited coverage. When a direct blow lands on a small area of abdomen, enough force to eviscerate the bowel can be transferred. Such an event can occur when a bicycle handlebar is spun 90° and jabs someone in the epigastric region, resulting in duodenal injury (see photos, next page).

The mechanism of bowel rupture is variable and controversial. Direct compression with tearing between two opposing surfaces, such as the abdominal wall and spine, is thought to be the most likely cause of bowel injury. Fixed areas of the bowel, such as the duodenum, proximal jejunum, terminal ileum, or areas with adhesions are at increased risk.

Bicycle handlebar trauma to epigastric region of the abdomen

Source: Courtesy of David Mooney, M.D., Children's Hospital Boston.

Clinical Presentation

Athletes with abdominal trauma usually complain of abdominal pain. It may be important to determine how quickly the pain develops, whether it is local or diffuse, and if it progresses to involve the entire abdomen. Injury to the abdominal wall usually produces local pain, whereas injury to the internal organs such as the bowel often initially causes localized pain that may spread to the entire abdomen if intraperitoneal irritation develops.

Physical findings may be limited, despite the propensity for life-threatening injury, hence a high index of suspicion for bowel injury is necessary. Abdominal guarding, rigidity, rebound tenderness, and pain with laughing, coughing, jumping, or bouncing are other signs of intraperitoneal irritation. Radiation of pain to the left shoulder (Kehr sign) due to blood irritating the diaphragm is called the Cullen sign, a bluish periumbilical discoloration suggesting hemoperitoneum, and it may be present. Signs of injury may develop over time, requiring serial examination to elucidate.

Persistent abdominal pain should alert the practitioner to other symptoms of chemical or bacterial peritonitis, including fever, nausea, and vomiting. In addition to the tenderness and guarding noted above, loss of bowel sounds on auscultation can be a sensitive (though certainly not specific) finding for injury to the bowel. Diagnosis of peritonitis due to bowel perforation is often delayed because there is usually no associated major blood loss. The small intestine is the most common site of such perforation, and peritonism may not be evident initially because the content of the small bowel is of a neutral pH, low bacterial density, and low enzymatic activity. Studies have reported that only 38% to 54% of cases had signs of peritonism at presentation.

Evaluation

If an injury to the bowel is suspected, athletes should not be allowed to continue participation and should be transported immediately to a facility with hemodynamic monitoring and imaging capability. In transit, signs of cardiovascular shock might become apparent, necessitating fluid resuscitation with intravenous access.

Once in a suitable setting such as an Emergency Room, erect chest X-ray may reveal air beneath the diaphragm, although computed tomography (CT) is the most sensitive diagnostic imaging method. A plain radiograph is also unreliable in the diagnosis of bowel perforation as there is no pneumoperitoneum in 54% to 85% of cases. The small bowel contains little air, unlike the stomach or colon, in which perforation more frequently results in appreciable pneumoperitoneum.

Patients with significant blunt abdominal trauma should have baseline hematological and biochemical laboratory tests performed, including a complete blood count and determination of serum electrolytes, glucose, amylase, and, in the female athlete, human chorionogonadotrophic hormone to determine pregnancy.

Patients are triaged based on their hemodynamic status. As is the case with the solid abdominal organs, diagnostic peritoneal lavage (DPL) and laparotomy are indicated in hemodynamically unstable patients suspected of having an injury to the bowel. Nasogastric tube placement may be helpful to check for blood in the stomach.

With the increasing availability of bedside ultrasonography and rapid access to CT, a decrease in the frequency of DPL use has been noted. Ultrasonography has been shown to have equal sensitivity and specificity to DPL in diagnosing intraperitoneal free fluid. Ultrasonography has the added advantage of being a virtually dynamic investigation and can be repeated at frequent intervals. Its sensitivity for identifying intestinal injuries is lesser, however, than for detecting splenic or liver injury.

Unfortunately, laparotomy is often required to make an accurate diagnosis and definitively treat individuals with injury to the stomach and intestine.

Differential Diagnosis With Abdominal Trauma

A less severe abdominal blow more commonly results in the "wind being knocked out" of an athlete. In this case, mild trauma irritates abdominal musculature such as the diaphragm, inducing a brief period of dyspnea, which resolves with loosening of restrictive clothing and hip flexion for a few minutes.

Bowel Injury Resulting From Endurance Activities

Epidemiology

Estimates of the incidence of blood passed per rectum, indirectly indicating bowel injury after a marathon race, range from 8% to 85%. With longer distances, such as in ultramarathon events, the incidence increases. Sixteen percent of runners in one study reported having bloody diarrhea on at least one occasion after a race or hard run, and 30% to 81% reported gastrointestinal (GI) complaints during long runs and races.

Pathophysiology

With exercise, blood flow is preferentially redirected to the working skeletal muscle, and flow to the GI tract can be reduced by as much as 80%. This relative ischemia can compromise gut function on a spectrum from mild cases, manifested by commonly experienced GI symptoms such as cramping, to severe cases of ischemic colitis. With aerobic training, this decrease in blood flow becomes less, although it does not reliably predict which runners will become symptomatic. There is no clear evidence that less fit individuals are more prone to symptomatic ischemia.

Nonsteroidal anti-inflammatory drug (NSAID) use has been associated with GI bleeding in athletes and may increase the incidence of GI complaints.

An alternative theory to explain a GI injury is that it results from repetitive mechanical microtrauma suffered by the gut from the impact of foot strike while running during gait cycle activity.

Presentation

Athletes can present to the medical tent after a race with bloating, cramps, nausea, vomiting, diarrhea, and fecal incontinence from running. Relevant history questions particular to an event include prior episodes of GI complaints with activity, as well as the timing of symptoms. Performance indicators, such as finish time compared with previous marathon race attempts, will give an idea of the level of exertion during the race. Environmental factors, as well as the amount of fluid ingested, should be taken into consideration because dehydration exacerbates the low-flow state and increases GI complaints.

The presence of bloody bowel movements after an endurance event should raise the possibility of ischemic colitis.

Evaluation

Fluid resuscitation is the first priority in the acute management of suspected endurance event–induced bowel injury. Cardiovascular volume status should be estimated from blood pressure and heart rate; body weight is probably the most accurate predictor of fluid loss if a pre-event weight is available. Transfer of any athlete with bleeding per rectum to a tertiary care facility is warranted. A colonoscopy can be undertaken once the patient has been stabilized.

Prevention

The use of cimetidine before and during a race has been shown to reduce the incidence of bloody stools afterward. The use of NSAIDs before endurance events should also be discouraged.

Bowlegs (Genu Varum)

Genu varum (bowlegs) is an angular deformity of the knees. It is common for young children and younger athletes to be sent to an orthopedist for evaluation, but most patients are within the normal limits. Although most bowlegs will resolve on their own, it is important to identify patients outside the normal limits who may need further evaluation. It is also important to give families reassurance about patients within normal limits (see Figure 1).

Figure 1 Bowlegs (Genu Varum)

Note: Athletes with bowlegs are at greater risk of sustaining problems on the outer side of the knee. However, many athletes with bowlegs participate in distance running without such problems.

Normal Development of the Legs

While developing, the fetus is usually positioned with hips and knees flexed in the uterus. The feet and tibia can be internally rotated (pointed in). This positioning causes a tightening of the medial ligaments of the knee, leading to bowlegs at birth. The bowlegged position at birth is normally the maximum for a person.

As the child begins to walk and grow, the ligament tightening begins to stretch, allowing the knees to straighten out. Between 18 and 22 months, the angular deformity begins to correct, and the legs will appear straight.

This straightening will continue over the next 3 years and actually lead to an overcorrection, causing genu valgum (knock-knees). This is usually most evident at about 4 years of age. As the child continues to age and grow, the genu valgum begins to correct. By about 7 years of age and into adulthood, most people will retain a slight valgus deformity of about 5° to 8°.

Clinical Evaluation

History

One of the most important things to consider is the patient's age. It has been noted that the persistence of bowlegs beyond 2 years of age is likely to be abnormal. It is important to identify whether the deformity worsens as the child grows. Reviewing old photographs of the child's legs will be helpful in the evaluation. Pain is an uncommon complaint.

Dietary history can reveal important information about nutritional deficiency being a potential cause. Family history, specifically for Blount disease, and past medical history should also be reviewed.

Physical Exam

A physical exam should begin with plotting overall height, as short stature is common with rickets and skeletal dysplasia. It is important to identify if the bowing is on both sides or is unilateral. In most cases, asymmetric bowing indicates abnormality.

With the patella facing forward, measure the angle of the knee. Measuring the intercondylar distance (between the two medial femoral condyles) and intermalleolar distance (between the two medial malleoli) can provide objective information to assess the deformity. All these measurements can be plotted on charts to help identify normal versus abnormal angular deformities.

The child may need to return every 3 to 6 months for repeat measurements in order to ensure that the deformity is not worsening. It is important to take the measurements in the same posture (lying down or standing) each time for consistency.

Radiographs

Ideally, X-rays should be taken in the standing position with kneecaps facing forward. If the feet are facing forward instead of the kneecaps, it can exaggerate the appearance of the bowlegs. X-rays should cover the region from the hips to the ankles.

X-rays should be obtained for children with bowlegs who are above 2 years of age or for children with pain, severe deformity, or unilateral bowing.

Diagnosis and Treatment

Physiologic Bowlegs

Physiologic bowlegs are symmetric bowing seen in children below the age of 2 years. Parents will usually report that the condition improves as the child grows. The patient will generally have a normal height and normal screening measurements. The family should be reassured, and the measurements should be taken every 3 to 6 months if needed.

Blount Disease

Blount disease, also known as tibia vara, is a disorder that causes irregularity at the growth plate of the medial, proximal tibia. The cause is unknown, but it appears to be related to damage from mechanical stress to the growth plate. The risk factors are positive family history, African American origin, and obesity. The clinician should be highly suspicious of Blount disease in children who have unilateral deformities and are early walkers.

Early or infantile Blount disease usually occurs in obese, female African Americans younger than 3 years old. Adolescent Blount disease occurs more often in obese, male African Americans older than 8 years of age. Many patients will describe a history of bowlegs that never improved and rapidly worsened during a growth spurt. X-rays show abnormalities of the medial proximal tibia.

Treatment of Blount disease requires prompt recognition and referral to an orthopedist. Bracing may help in patients younger than 3 years of age who have mild Blount disease. If the disease is severe or the patient is nonresponsive to bracing, the surgeon may perform a proximal tibial osteotomy (removal of a wedge of bone). In adolescent Blount disease, the surgeon may consider stapling or a hemiepiphysiodesis, too.

The prognosis of Blount disease depends on severity. Younger children may have recurrence as they age through childhood. If the deformity is not fully corrected, it can lead to degenerative arthritis.

Other Causes

Rickets is a nutritional deficiency that can cause bowlegs. This disorder is described in the entry Knock-Knees (Genu Valgum).

Focal fibrocartilage dysplasia is an unusual cause of unilateral genu varum that usually resolves with conservative treatment. This is a small bony defect at the medial tibial metaphysics (just under the growth plate). However, if it does not resolve, surgical intervention is necessary.

Achondroplasia is a genetic condition more commonly known as *dwarfism*. The genu varum in this case is caused by abnormal bone growth. This usually will not improve with bracing and requires surgery.

Boxing, Injuries in

All contact sporting events carry a risk of injury. Of all sporting events, boxing ranks first in the potential for injury, with 5.2 injuries per 1,000 athlete exposures. Although amateur and professional boxing activities appear similar, they differ in scoring and types of injuries.

In amateur boxing, injuries are fewer and less severe because amateur boxers are required to wear more padding, along with protective headgear. Additionally, amateur boxing is scored differently than professional boxing. In amateur events, points are scored on skillful punches, with less emphasis given for the knockout.

As amateur boxers wear more padding, have protective headgear, and fight fewer rounds, it is the professional boxers who have the higher risk for injury. Science has determined that the force of a professional boxer's punch is equivalent to being struck with a 13-pound bowling ball traveling at 20 miles per hour.

Many health professionals and organizations have concerns about the safety of the sport, especially the trauma to the brain. Although boxing ranks high as a dangerous sport, the death rate is actually lower than for some other sports. However, the long-term effects of boxing suggest that 15% to 40% of professional boxers exhibit evidence of brain injury that includes memory loss, unsteadiness, speech difficulties, and increased stiffness as a consequence of cumulative head trauma.

Head and Face Injuries

Excluding minor injuries, head and brain injuries are the most common for the boxer. The most common of these are brain *concussions*. Concussions are transient alterations of brain function, with or without loss of consciousness, that resolve without evidence of any permanent brain damage. Concussions differ in severity based on the duration of unconsciousness and the degree of amnesia or memory lapse.

Brain injuries in boxing are divided into two major types: acute immediate injury and chronic, where the injury develops over a period of time. Acute brain injury is more severe and life threatening when it results from a ruptured brain blood vessel due to a boxer's punch to the head. This ruptured brain blood vessel spills blood within the brain cavity, resulting in increased pressure that pushes on vital centers of brain function. The repetitive and cumulative effects of taking punches to the head result in chronic head injury, commonly referred to as "punch drunkenness." Symptoms of punch drunkenness include inhibited thinking ability, headaches, and blurred vision or memory loss.

Punches to the face and head can result in injuries to the eyes, nose, facial bones, and jaw. Most injuries occur from the glove impact and result in regional contusions on the face and head. The more serious facial injuries occur from the gloved knuckle or thumb. Eye injuries hold the highest risk of permanent injury and may be career ending. A strong punch to the eye may detach the retina and require surgical repair. Other ocular boxing injuries include corneal abrasions, orbital blowout fractures, and intraocular bleeding.

Facial lacerations and facial bone fractures are a common injury resulting from a punch or head butt. These lacerations are usually minor, with the exception of an upper eyelid laceration. An upper lid laceration should be evaluated for underlying damage to the forehead bone along the tarsal plate, and if a fracture is suspected, this clinical situation requires immediate medical intervention.

Injuries to the nose include fractures of the nasal bones and damage to the nasal septum cartilage. Septal deviation may cause obstruction of the nasal passages and impede breathing. Surgery may be required to open the nasal passages.

On rare occasions, the mandible or jawbone may be broken with a strong punch. Suspected fractures require immediate medical evaluation and may necessitate surgical stabilization. Broken teeth are the most common dental injury.

Ribs and Abdomen Injuries

Rib injuries are fairly common. Besides being quite painful, a broken or fractured rib may be very dangerous in that it may pierce the lung, causing it to collapse. Just below the lower ribs, the spleen is vulnerable and could rupture from a forceful punch. Ruptured spleens often require surgical removal as they can cause extensive internal bleeding, resulting in quick death. Liver bruising and kidney bruising may occur but rarely require any surgical intervention.

Upper Extremity Injuries

The shoulders, upper arms, forearms, and wrists are sites of frequent injury for the boxer during training inside and outside the ring. The most common of these are hand injuries. The "boxer's fracture" is a fracture at the base of the little finger. Most of these boxer's fractures can be treated without surgery by first aligning the bones and then applying an immobilizing splint. If alignment cannot be corrected, then surgical correction may be required.

Fracture of the long bones of the ring and middle fingers, the metacarpals, is more serious with regard to reestablishing alignment. If the alignment of these bones is not adequately achieved, surgical pinning should be considered. Boxers can sustain serious hand and knuckle injuries by throwing an awkward punch causing injury to the knuckle, commonly called a "boxer's knuckle." A boxer's knuckle results in a tear to the protective sheath of the extensor tendon overlying each knuckle, most often involving the index and the middle fingers. Typically, pain is the complaint in the area of the tear overlying the affected knuckle. Examination will reveal weakness when attempting to extend the affected finger, and palpation may identify a depression within the extensor hood. Tendon tears necessitate surgical repair followed by casting the wrist and hand for 6 weeks. After the cast is removed, rehabilitation must provide full range of motion and muscle strength before the boxer is allowed to punch.

Studies and Statistics

The U.S. Olympic Training Center in Colorado Springs, Colorado, collected and analyzed records of amateur boxing injuries from 1977 through 1992. This study found that only a relatively small percentage (6.1%) of these injuries were classified as serious. The breakdown of the frequency of injuries found that upper extremity injuries were the most frequent at 25%, followed by head and facial injuries representing 19%. Lower extremities accounted for 15%, with spinal injuries representing 9% of all injuries. This study found that contusions represented 24.9%; muscle strains, 20.8%; joint sprains, 17.5%; concussions, 6.1%; and fractures, 4.9%.

Another amateur boxing study reported that 48% of all competition injuries were the result of a punch to the head. An 8-year study of instructional boxing in the U.S. Marine Corps basic training found that within a group of 180,000 participants only three sustained serious acute brain injuries, constituting an extremely small proportion (0.3%) of the approximately 1,000 boxing-related injuries that occurred during the survey period. This study may underrepresent the true incidence rates, as those events were largely noncompetitive and involved more sparring and training rather than the actual matches.

Boxing Injuries and Death

Accurate evaluation of boxing-related deaths is difficult. Differences in the regulations of amateur and professional boxing, poor reporting of worldwide boxing-related injuries and deaths, illegal boxing events, and lack of medical data contribute to poor statistical analysis. Recent U.S. statistics on sports-related deaths found boxing to rate eighth overall in incidence rates. Horse racing was the highest at 128 fatalities per 100,000 participants, followed by skydiving at 123, hang gliding at 55, mountaineering at 51, scuba diving at 11, motorcycle racing at 7, college football at 3, and boxing at 1.3.

Professional Boxing Injuries

There are relatively few boxing studies and even fewer in professional boxing. A study of professional boxing event injuries was done over a 2-year period from 2001 to 2003 in Nevada. The study found an injury rate of 17.1 per 100 boxer matches. The breakdown of injuries found facial lacerations accounting for 51% of all injuries, followed by 17% hand injuries, 14% eye injuries, and 5% nose injuries. Male boxers were three times more likely to sustain injuries than female boxers in this study. Boxers who lost by knockouts or technical knockouts doubled their risk of injury when compared with their winning opponent. Weight and age were not factors in predicting the risk of injury.

Long-Term Injury in Boxing

Concern over the medical consequences of long-term head trauma creates controversy over the safety of the sport. The American Medical Association (AMA) takes a strong position, opposing all forms of boxing. The AMA recommends the prohibition of all forms of boxing for people below the age of 18 years. To improve the safety of boxing and minimize the risk of injury, the AMA provides recommendations that most state boxing commissions have incorporated into their licensing and regulations.

Unlike many other contact sports, head injuries in boxing are not accidental. Although amateur boxing mandates protective headgear to minimize brain trauma, clinical studies have found evidence that participation in amateur boxing matches can diminish neurocognitive functioning. On the other hand, professional boxers, who do not use protective headgear, sustain multiple head blows resulting in cumulative head injury. A limited study of 42 professional boxing volunteers evaluated multiple neurocognitive variables to assess the degree of brain injury. The results identified that the amount of sparring by the boxers was an important factor in the decline of neurocognitive performance. The study found neurocognitive impairments in areas of attention, concentration, and memory. Interestingly, performance on the neuropsychological tests showed no association with the professional boxer's age, boxing record (wins, losses, or total number of bouts), length of career, or history of knockout or technical knockout.

"Punch drunk syndrome," or dementia pugilistica, is a medical condition caused by repeated brain trauma, such as in boxing. The symptoms include dementia, memory loss, confusion, psychosis, and abnormal movement, similar to the symptoms seen in Alzheimer disease. The risk of a boxer developing this condition correlates with the number of matches and the length of the boxer's career. This condition affects 17% of professional boxers.

Consequently, older boxers are more vulnerable to diseases of the brain and progression of aging of the brain. Alzheimer-like dementias and Parkinsonian diseases are the more common presentations and are more prevalent among former boxers than within the age-matched population. Diagnostic imaging reveals a greater degree of changes in the brain, showing a thinner surface gray matter, a decrease in the brain's white matter, and enlarged brain ventricles.

Boxing is one of the oldest sports. Unfortunately, little has been done to identify and track injuries in training and events. Better data collection systems should be mandated to assess the actual risk of injury for both amateur and professional boxers. Based on clinical data, changes related to safe participation can be instituted.

Bracing

The use of braces as a support for joints while an athlete is participating in sports has been a very common and well-established practice during the past 30 to 40 years. Today, bracing has grown into a large industry in the United States. However, there is conflicting evidence as to the effectiveness of braces in sports activity.

Bracing is thought to influence the efficacy and performance of a joint in multiple ways. It is widely thought that there are structural benefits in bracing a joint. These benefits include limiting the range of motion of a joint; this becomes important particularly when forces applied to a joint may cause the joint to exceed its normal range of motion, thereby creating the potential for injury. It is also thought that a brace, in the face of an injury force, may help dissipate and limit the force applied to the joint. Finally, it is thought that bracing may provide some benefit by limiting the ground reaction forces that are applied to a joint during sports activities.

There is also evidence for other types of benefits from braces. It is widely accepted that braces can affect the kinesthesia of a joint, or the sensation of muscle movement that one experiences during sports activity. It is thought that this, coupled with the proprioceptive benefit that braces provide, leads to an increased sense of joint position and function, thereby leading to increased performance. There is evidence that braces also affect the neuromuscular responses of the muscle groups that are affected by a brace; studies have shown that muscle groups may have decreased strength of contraction as well as a slowed response with bracing.

These neuromuscular responses highlight one of the difficulties in determining the effectiveness of braces as a class. In some instances (e.g., injury), it is advantageous for an athlete to have decreased contraction of muscles and increased periods of muscle rest. However, in the case of athletes trying to perform at their peak, this would not be a desired side effect of a brace. Research into the neuromuscular response of muscles with both acute and chronic brace use has been common over the past two decades; however, there have been conflicting results, making it unclear whether the use of braces is beneficial or harmful with regard to athletic performance.

In fact, research on the use of braces has its own limitations. In general, most research that is done with bracing involves the use of cadavers rather than live subjects. This type of research is often used to show the restriction in the range of motion of a joint while using a brace; however, cadaveric tissue does not respond in the same way as a live tissue would, as there are, among other problems, changes in the skin, in the muscles themselves, and, most important, in the neuromuscular response. However, there are also difficulties in using live subjects. These include the difficulties in finding an effective placebo for a brace, as well as the difficulties in standardizing brace-fitting as well as research protocols.

There are multiple types of braces available today. However, these types can be divided into three main categories to describe their use in sports: (1) prophylactic, (2) functional, and (3) rehabilitative (postsurgical). Prophylactic braces are those applied prior to injury to attempt to limit the number of injuries suffered during participation in sports. The use of braces to prevent injury has been common in some sports, such as the use of ankle braces in basketball and volleyball and the use of knee braces in football. Here, the use of braces has been a supplement to the use of taping for the same purposes. In many ways, bracing may be more cost-effective than taping, particularly when the salaries and time of those who apply the taping is figured into the total cost. There has been some research done in this field to support the use of such braces as prophylaxis, particularly in jumping sports such as basketball and volleyball. There is some limited research to support the use of knee braces by football players, but their effectiveness seems to be limited by the position played (braces may be effective for offensive linemen but not for wide receivers). There is also evidence that braces may be effective in preventing some types of injuries while not preventing others (prophylactic braces appear to limit the number of medial collateral ligament [MCL] injuries in offensive linemen while not changing the rate of anterior cruciate ligament [ACL] tears).

Functional braces are a very broad category, as almost all braces are desired to be “functional.” In general terms, these are used to provide support to a joint or body area that has suffered some sort of injury. These braces, along with prophylactic braces, can be prefabricated and obtained over the counter. These can also be custom made to the desired fit of an athlete.

Elbow braces are frequently used by racquet sport players.

Source: Julian Rovagnati/iStockphoto.

Rehabilitative braces are very commonly used, particularly following surgical repair of injuries. The use of braces such as this allow athletes to return to sports earlier while providing the support required for participation. There has been a fair amount of data published to support the use of braces in a rehabilitative phase, which would fit well with our current ideas about injury and rehabilitation. On most occasions, these braces are custom made to fit the needs of the patient.

In spite of all the aforementioned difficulties, braces are widely used in sports. Athletes will often use any item that they believe will provide them with a competitive advantage, either in performance enhancement or in injury prevention. The most commonly used braces are those for the lower extremity, particularly for the knees and ankles. In general, upper extremity braces are more difficult to use and apply and are typically not as comfortable for use in sports. Braces are also used in general sports medicine practice as well as for a variety of conditions. Some of these include carpal tunnel (cock-up wrist braces), lateral epicondylitis (tennis elbow strap), patellar tendinosis (patellar tendon strap), and chondromalacia patella (patellar tracking brace). While there is not much research that supports their use in sports, athletes will continue to make use of any devices available that they believe will enhance their performance and enjoyment of the game.

British Association of Sport and Exercise Medicine

The British Association of Sport and Exercise Medicine (BASEM) was founded in 1953 by a group of doctors, sports scientists, and those from allied disciplines who were involved in the care of individuals and teams in international sports. Their initial objectives, which have remained largely unchanged since that time, were to represent the professional needs of those doctors working in the specialty of Sport and Exercise Medicine (SEM), to advise on career structures, and to provide support and education for those health care professionals involved in the care of athletes and individuals undertaking, or aspiring to undertake, regular physical activity at all levels. They promoted the adoption of evidence-based practice in all areas of SEM and hoped to encourage the highest standards of clinical practice in the care of the exercising individual.

Meeting in London, the founders gained charitable status for the organization and produced guiding rules, "The Articles and Memorandum of Association," which are regularly updated (available at the association's website: http://www.basem.co.uk). The aims are to support and encourage research in SEM and to promote the adoption of exercise and physical activity by all sections of the population for their general well-being and for the prevention and treatment of illness.

The founding members agreed to assist and advise all relevant authorities to adopt policies that encourage and promote physical activity in schools, the workplace, and the home, and to collaborate with other associations, both nationally and internationally, in furthering the specialty of SEM and the aims of BASEM.

The pioneers' first conference in 1962 was held at Loughborough University, and early figures involved included Arthur (later Lord) Porritt, John Williams, and Henry Robson. Later in the decade, they introduced the *British Journal of Sport and Exercise Medicine*. Since 1996, this has been jointly owned with the British Medical Association. Produced monthly, it now has the highest impact factor of any sports medicine journal in the world. (A complete set of BASEM journals is available for study through the library of the University of Bath.)

The BASEM provides the medical practitioners for all elite sports teams within the United Kingdom and has close links with the British Olympic and Commonwealth Games Associations.

With the foundation of the British Association of Sport and Exercise Sciences (BASES) in the 1980s, the membership of more than 1,000 members became increasingly medically orientated, and in 2004, the BASEM was voted to become a doctor-only organization. This allowed it to re-amalgamate with the U.K. Association of Doctors in Sport (UKADIS), which had broken away from the parent organization in 1997.

The campaign by BASEM for professional recognition in the United Kingdom took a giant step forward in 2005 with the formation of a Faculty of Sport and Exercise Medicine under the auspices of the Royal College of Surgeons in Edinburgh.

The association holds an annual Congress, to which the leading researchers and specialists are invited to speak, and since 2004, a Spring Meeting, which is more cutting-edge. There are other training courses for aspiring SEM doctors. Details of the activities and membership of the association are available on the organization's website.

Bruised Foot

A *bruise,* or contusion, of the foot is a common sports injury caused when blood vessels are damaged or broken as a result of a blow to the skin. This injury can be caused by a high-impact direct blow or from lower-impact repetitive forces. Contusions can affect the skin, muscle, and even bone in higher-impact injuries. Most contusions heal quickly without any interference in sports activity; however, more severe contusions can take longer to heal and keep the athlete sidelined for several months.

Diagnosis

History

The diagnosis of a bruised foot should begin with the history of the injury. The athlete may relate sudden onset with a blunt force trauma, such as the foot getting stepped on or kicked during a contact sport. Alternatively, the athlete may relate a slow and gradual onset with chronic repetitive stress to a specific area, such as the ball of the foot during running.

Physical Examination

Next, the physical examination of the foot should be performed. Physical examination may demonstrate purplish or bluish discoloration, and swelling may be evident. The purple discoloration is due to leaking of blood from disrupted blood vessels into the skin. In more severe cases, a lump may be felt in the injured area. This is called a hematoma and is the result of a pool of blood collecting under the skin.

Palpation of the bruised area tends to be painful, and a gentle touch should be used to prevent further injury to the disrupted blood vessels. Passive and active range of motion of the adjacent joints should be attempted to rule out fractures, muscle rupture, and tendon injuries.

In the foot, the most common areas of increased pressure with athletic activity include the heel and the ball of the foot. In particular, pain under the ball of the foot is commonly called a "stone bruise," or metatarsalgia. This is occasionally accompanied by swelling and is the result of chronic repetitive stress.

Imaging Studies

Radiographs

The bruised foot is largely a soft tissue injury. However, if the history of the injury or physical examination suggests the possibility of a fracture in addition to the contusion, plain radiographs of the foot should be taken.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is rapidly becoming the imaging modality of choice with soft tissue injuries. In the bruised foot, an MRI scan should be ordered only when there is concern with stress or occult fractures or when the symptoms are not responding to treatment.

Because of its ability to evaluate edema, or swelling, in the deeper tissues, MRI can be useful in detecting bone bruises. Bone bruises result from trabecular microfractures, causing increased fluid changes on the MRI scan.

Treatment

Initial Treatment

Initial treatment of the bruised foot consists of the RICE (*r*est, *i*ce, *c*ompression, *e*levation) formula:

Rest: The injured area should be protected from further trauma. Depending on the severity of the contusion, the athlete may need to stop participating in sports or is even placed on crutches.

Ice: The contusion should be iced to decrease the inflammation that accompanies the injury.

Compression: The injured foot should be placed in a compressive-type dressing, such as an elasticized wrap. The elastic bandage should be applied starting from the toes and gently advanced toward the ankle and up the lower leg to move the swelling up toward the torso.

Elevation: The affected foot should be elevated above the level of the heart to assist in decreasing the swelling.

The pain from the contusion is usually treated with over-the-counter or prescription-strength nonsteroidal anti-inflammatory drugs (NSAIDs). These medications also help decrease the swelling and inflammation associated with the contusion.

Occasionally, a large hematoma will not resolve on its own and will cause persistent pain symptoms. In these instances, it may be necessary for the hematoma to be drained with a simple procedure.

Return to Sports

An athlete may return to sports once the pain symptoms resolve and the strength and motion to the foot have returned. Depending on the nature of the injury, supportive foot devices called orthotics or special padding may be used to prevent recurrence of the bruised foot.

Bruised Ribs

Ribs serve as the key protector for the vital organs in the torso. The human body has 12 ribs on each side, which are divided into different categories based on their function during the motions of inspiration and expiration (inhaling and exhaling). Ribs 1 through 5 typically function in a pump-handle motion. Ribs 6 through 10 function in a bucket-handle motion. Finally, Ribs 11 and 12 typically move in a caliper motion. Furthermore, ribs are defined and divided by their means of attachment to the torso. Ribs 1 through 7 are deemed "true" ribs as they directly connect to the sternum (breastbone) via cartilage (costochondral area). Ribs 8 through 10 are called "false" ribs as they do not directly connect to the sternum and only connect to the cartilage. Ribs 11 and 12 are called "floating" ribs as they do not connect to the sternum or cartilage. Understanding these terms is important to diagnose and treat bruised ribs. When injured, ribs may be strained, broken, bruised, separated, locked down, or locked up. The small intercostal muscles surrounding the ribs may take substantial time to return to normal. Quick diagnosis and treatment lead to quicker return to play.

Mechanism of Injury

An injury typically occurs with a direct blow to the ribs or the cartilage. Broken ribs commonly occur as a fracture of the bony prominence in the middle of the rib, which is normally in the midaxillary line (the area directly below the armpit). Costochondral separation describes an injury that divides the ribs from the cartilage and can occur from landing hard on the feet or even a forceful sneeze or cough. Bruised ribs indicate an injury to the bones, intercostal muscles, or cartilage.

Symptoms

An athlete develops pain directly over the rib or in the area in between the ribs. Pain can also occur with a deep inspiration, hard cough, or sharp movement. In addition, sudden shortness of breath could indicate a rib fracture that could have punctured a lung.

Diagnosis

The sports medicine physician can perform a physical exam, including auscultation (listening to the lungs), percussion (tapping on the lungs), palpation (touching the ribs), and examination of the entire length of the ribs. Ecchymosis (bruising) near the site of injury can provide a clue in the diagnosis. A chest X-ray may be ordered to confirm the diagnosis or to evaluate more complex cases.

Treatment

Treatment of bruised ribs depends on the type of injury. First and foremost, patients should rest. Ice, nature's anti-inflammatory, should be applied intermittently for 20 minutes at a time throughout the day. Nonsteroidal anti-inflammatory drugs, such as ibuprofen or naproxen sodium, may help over the first 10 days of the injury. A sports medicine physician may recommend a rib belt for compression to decrease the symptoms. The rib belt's compression decreases the movement of the injured rib, allowing the intercostal musculature to heal.

Additional therapy may include osteopathic manipulative therapy (OMT), especially if an athlete presents with a locked-down or locked-up rib. Ribs become "locked" when there is a spasm of the surrounding rib intercostal muscles, thus preventing the rib from moving up during inspiration. A sports medicine physician may perform various osteopathic manipulative techniques, such as the high-velocity, low-amplitude technique, underneath the rib that is locked down to break the spasm. A myofascial release (the area between the muscle and the bone) is then performed passively with direct palpation in between the rib muscles to decrease the local rib spasm. The patient would then continue applying ice and taking anti-inflammatory medicine as previously stated.

Return to Sports

Return to sports depends on multiple variables. First, return to play is based on the type of rib injury. A broken rib injury typically takes 4 to 6 weeks to heal completely, thus allowing the athlete to safely return to play. A repeat X-ray may be required prior to clearance for return to play. Occasionally, if there is evidence of healing, the athlete may return sooner with protection over the affected area. Return to play with bruised ribs or a costochondral separation is based more on the symptoms of the individual athlete. Once the athlete experiences decreased symptoms such as minimal pain and normal respirations, return to play may be considered. The timeline for a returning athlete also depends on the sport. Athletes participating in contact sports may have a more delayed return based on the type of rib injury and the risk of further reinjury. Contact sport athletes may require a rib belt or padding if early return to play is considered.

Prevention

Rib injuries can rarely be prevented as they are typically caused by trauma. Contact sport athletes may consider appropriate rib padding to prevent the impact of repeated blows to the rib area.

Bulimia Nervosa

It has often been noted that contemporary American popular culture is marked by an obsession with thinness and weight loss. At the same time, there is a worldwide epidemic of overweight and obesity. Many people strive to lose weight for health or aesthetic reasons. Most use healthy methods such as decreasing their caloric intake and/or increasing their physical activity. Some use unhealthy methods such as abusing stimulants, laxatives, or diuretics or intentionally acquiring gastrointestinal infections. For some people, weight loss becomes an obsession, marked by persistent and pervasive worries about body image, weight, or athletic performance. Some of these people develop maladaptive eating, exercise, or other behavioral patterns that can lead to serious health problems or even death. These patients are said to have an *eating disorder*. The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV*) identifies three distinct types of eating disorders: anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified (ED-NOS). Anorexia and eating disorders are discussed elsewhere.

Epidemiology

Compared with anorexia nervosa, bulimia nervosa has been recognized as a diagnosis for a shorter period of time, and the diagnostic criteria have changed from previous editions of the *DSM*. For this reason, incidence and prevalence data are difficult to interpret. Bulimia is clearly more common in women and in college students. Prevalence rates are likely between 1% and 1.5% of women. This compares with a lifetime prevalence of 0.9% for anorexia nervosa in women.

Diagnosis

The lay public commonly defines *bulimia* as forced vomiting after meals. This is an incomplete and misleading definition. While vomiting may be associated with bulimia, the hallmark of the disorder is really a sense of lack of control over eating and the use of excessive compensatory behaviors to prevent weight gain. The *DSM-IV* definition of bulimia nervosa is outlined below (American Psychiatric Association, 1994, p. 549):

- There are recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  - o eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances, and
  - o a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- There is recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercising.

- The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- Self-evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.
- Specific types are as follows:
  - *Purging type:* The person regularly engages in self-induced vomiting or the misuse of laxatives or diuretics.
  - *Nonpurging type:* The person uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not regularly engage in self-induced vomiting or the misuse of laxatives or diuretics.

Patients with bulimia nervosa rarely complain to their health care provider without the encouragement of friends or family members. In addition, they are often of normal weight, appear healthy, and have normal menstrual periods, which may mislead the examiner into thinking that they have healthy eating habits. The astute clinician may notice physical examination findings suggestive of purging behavior, such as erosions of the dental enamel, hypertrophy of the parotid glands, calluses on the dorsum of the fingers (the Russell sign), or damaged fingernails. Electrolyte abnormalities can be seen with laxative or diuretic abuse. Frequent stress fractures or other musculoskeletal injuries may occur in those who engage in excessive exercise.

Because identifying patients with bulimia nervosa (or other eating disorders) can be challenging, several screening tools have been developed. Among the most common are the SCOFF and *E*ating Disorder *S*creen for *P*rimary Care (ESP) questionnaires and the Eating Attitudes Test (EAT). Each has good sensitivity and specificity for eating disorders in general. However, additional interviewing and a good rapport with the patient are required for the clinician to make a definitive diagnosis of bulimia.

Vital sign abnormalities, such as low heart rate, orthostasis, and low body temperature, may be seen in patients who are severely malnourished due to an eating disorder. Rarely, fatal bradyarrhythmias may occur in the setting of profound malnutrition (especially protein and phosphorus depletion) and electrolyte abnormalities.

Laboratory evaluation for electrolyte abnormalities is necessary in patients who have been abusing laxatives or diuretics, have significant malnutrition, or vomit frequently. In addition, it may be useful to assess for other conditions that can mimic eating disorders, such as new-onset diabetes mellitus, adrenal insufficiency, gastrointestinal disease, or thyroid disease.

Other psychiatric illnesses, especially major depression, can be confused with eating disorders. This is more common with anorexia but can occur with bulimia nervosa as well. It is important to have the patient evaluated by a psychiatrist or psychologist with substantial experience with eating disorders to help assess for comorbid psychiatric illness early in the treatment course in order to maximize the patient's likelihood of recovery.

Treatment

A multidisciplinary team consisting of a medical provider, a dietitian, and a mental health provider should work together to treat patients with bulimia nervosa. While the disease can be difficult to manage, cognitive behavioral therapy, other psychotherapies, antidepressant medications, and a combination of antidepressant medication with psychotherapy have all been shown to provide some benefit. Patients with severe malnutrition may be at risk for refeeding syndrome and should be managed in a medical ward or in the ICU (intensive care unit), with frequent monitoring of their cardiac function and electrolytes. While a complete discussion of the treatment of bulimia is outside the scope of this entry, the American Psychiatric Association and the Society for Adolescent Health and Medicine have published detailed treatment guidelines for adolescents and adults with eating disorders.

Bunions

A bunion, also called *hallux valgus*, is an enlargement on the inside of the big toe joint, resulting in the big toe leaning toward the second toe. This deformity is a common and usually an inherited trait. The resultant malalignment of the big toe joint and the bony prominence result in a painful deformity that makes wearing shoes difficult, necessitating treatment. While bunions are not associated with narrow shoes or high heels, there is a higher incidence in females. Most bunions can be treated successfully with conservative or surgical intervention.

Diagnosis

History

Bunions are a common foot deformity that has been estimated to affect approximately 1% of the population. The incidence of the deformity has been found to increase with age due to the progressive nature of the deformity. The deformity begins with a leaning of the big toe, gradually changing the angle of the bones over the years and slowly producing the characteristic bump on the side of the big toe (Figure 1).

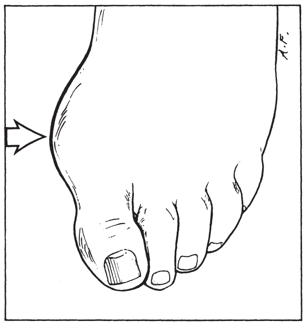

Figure 1 A Typical Bunion

Bunions have been thought to be caused by a variety of underlying conditions, such as faulty biomechanics of the foot, neuromuscular disorders, and arthritic conditions. The prevailing theory is that the deformity is caused by an inherited faulty mechanical structure of the foot. Thus, it is not the bunion itself that is inherited but certain foot types that make a person prone to developing a bunion.

The pain symptoms associated with bunions typically appear at later stages, well after the deformity becomes evident. These pain symptoms are typically aggravated by activity such as walking or running, as well as by shoes that create pressure along the bony prominence. However, some people with bunion deformities may never experience pain symptoms.

Although wearing narrow shoes that crowd the toes is not the cause of the bunion deformity, it can aggravate the pain symptom, causing symptoms sooner. Most individuals complain of pain in the area of the bony prominence. These pain symptoms are usually aggravated by pressure in the area. Occasionally, compression of a nerve by the bunion area will cause symptoms of tingling and numbness.

Bunion deformities in the athlete and the dancer may be particularly painful due to the snug fit of athletic shoes such as cleats and pointed shoes. Additionally, the strenuous activities may aggravate the area, creating a chronic inflammatory condition. Bunions are particularly prevalent in ballet dancers, and it is felt that while ballet itself is not the cause of the deformity, the forces through the foot during dancing produce an environment in which bunions may develop.

Physical Examination

Bunions can be recognized on visual examination of the foot. There is a characteristic prominence to the inside of the big toe joint with leaning of the big toe toward the second toe. In early deformities, the big toe joint is flexible and the deformity can be manually reduced. In later stages, the joint may stiffen, and range of motion diminishes.

In many individuals with bunions, there may be an associated hypermobility noted in the foot that may be a contributing factor to the development of the bunion. These individuals may exhibit a flat foot deformity. However, not all bunions are associated with flat feet.

Initial examination of the bunion may involve determining the area of pain, which is usually located at the bony prominence of the big toe joint. Signs of inflammation, such as swelling, redness, and increased warmth, may also be noted in this area. Examination of the motion of the joints in the foot may also be performed to determine the stage of the deformity.

Imaging Studies: Radiography

Radiographic evaluation of the bunion includes examination of the alignment of the bones involved in the deformity. The angle formed by the first metatarsal and the second metatarsal is measured to determine the severity of the bunion deformity. The angle formed by the first metatarsal with the proximal phalanx in the big toe is also measured to determine the extent of the big toe angulation toward the second toe.

The first metatarsophalangeal joint is evaluated for congruency. As the bunion deformity progresses, the joint will become less congruous. The position of the sesamoid bones will also start to shift laterally as the bunion deformity progresses. The subluxation of the sesamoid bones generally results in joint incongruity. Evaluation of these radiographic parameters will enable the doctor to determine how severe the deformity is and will give some guidance in selecting treatment options.

Treatment

Initial Treatment

Initial treatment is typically aimed at easing the pain of the bunion. This can be achieved through methods to alleviate the inflammation associated with the bony prominence or the impinged nerve. However, it is important to note that conservative treatment will not correct the bony deformity or halt its progression. Thus, after the pain symptoms resolve, the bony deformity persists and can result in recurrence of the pain symptoms.

Treatment options include the following:

- *Changes in footwear:* The patient may be recommended shoes that have a wide toe box and asked to forgo those with pointed toes or high heels, which may aggravate the condition.
- *Padding:* Pads placed over the area of the bunion can help minimize pain. These bunion pads are typically found in drugstores.
- *Activity modifications:* Activity that causes bunion pain should be avoided, such as certain sports activities.
- *Medications:* Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, may help relieve pain.
- *Icing:* Applying an ice pack several times a day helps reduce inflammation and pain.
- *Injection therapy:* Although rarely used in bunion treatment, injections of corticosteroids may be useful in treating the inflamed bursa (fluid-filled sac located in a joint) sometimes seen with bunions.
- *Orthotic devices:* In some cases, custom orthotic devices may be provided to decrease the pain symptoms as well as to decrease the motion that may be aggravating the bunion.
- *Physical therapy:* Physical therapy may help relieve the pain symptoms associated with inflammation of the joint.

Surgical Treatment

In athletes and dancers, surgical intervention is typically considered the last resort, given the amount of time needed for recovery as well as the residual stiffness experienced after surgery. However, in some instances, the bunion deformity will be painful or large enough so that conservative care may not be sufficient to relieve the symptoms. Additionally, subluxation of the sesamoids resulting in incongruity of the joint may make surgical relocation necessary. In these cases, surgery may be required to treat the bunion deformity.

The type of surgical treatment will depend on the severity of the deformity. Most procedures used for treating hallux valgus involve performing an osteotomy and soft tissue balancing procedures to realign the joints in the proper position. Following surgery, it may take several months before the athlete can return to his or her sport.

Prevention

It is unclear as to whether the bunion deformity can be prevented. However, the pain symptoms associated with the bunion can be prevented by wearing appropriate shoes to remove the pressure from the deformity. Additionally, avoidance of activities that aggravate the symptoms will help decrease pain.

Return to Sports

An athlete may return to sports once the pain symptoms stop. If conservative care is given, the pain symptoms may recur due to the continued bunion deformity. However, the use of appropriate shoes to accommodate the deformity and inserts to reduce the biomechanical stress may reduce the recurrence rate.

Burnout in Sports

Athlete burnout is a negative experiential syndrome. The most widely employed description of the syndrome has come from the work of Dr. Tom Raedeke. He has demonstrated that the athlete burnout syndrome is characterized by an enduring experience of three key symptoms: (1) emotional and physical exhaustion, (2) sport devaluation, and (3) reduced accomplishment. This sport-specific conceptualization is grounded in Christina Maslach's research in other work settings and has been modified to have particular relevance to sports. Unfortunately, in addition to this syndrome, the term *burnout* is often loosely employed to cover a variety of other potentially interrelated experiences, including sport dropout and overtraining-related underperformance (i.e., "overtraining syndrome"). Although interrelated to some degree, the burnout and overtraining syndromes, in particular, differ in diagnosis and treatment, and it is important that they are not confused.

Researchers have found that a relatively small proportion of athletes involved in serious competition experience burnout to an extent that results in negative performance and personal welfare outcomes. Consequently, the early identification and treatment of burnout is important from both athlete welfare and performance perspectives. Readers should be mindful that athlete burnout is currently a developing area of research. Current knowledge on potential antecedents, early signs, symptoms, consequences, and treatment is outlined in this entry; further research advances are likely to emerge.

Potential Antecedents

Burnout is proposed to be the result of excessive psychological and physical demands. As such, athletes at the highest risk of experiencing the burnout syndrome tend to be involved in serious organized sports with demanding competitive schedules and regimens of formalized training. In contrast, athlete burnout is unlikely to be an issue of particular relevance among recreational sports participants.

The ongoing demands of sports differ in important ways from those found in other settings in which burnout has been studied. Moreover, there is also variation in the demands associated with athlete burnout across different sports. As a consequence, identification of a comprehensive list of potential antecedents is not possible. To date, some common antecedents identified across sports settings include intense competitive involvement, high competition load, heavy training, injury, demanding travel schedules, media and public demands, pressure to perform, risk of nonselection or deselection from a team, poor performance, and playing in underrecognized but physically demanding positions that are important to team performance.

Demands outside an individual's direct sports involvement have also been associated with athlete burnout. For example, financial stressors and concerns about not being able to fulfill educational and nonsport career aspirations may color the way athletes view their sports involvements. These perceptions may lead athletes to believe that they are effectively trapped by (or within) their sports involvements, which can, in turn, initiate or exacerbate feelings of exhaustion, alienation, and cynicism about those sporting involvements.

Possible Early Signs

Identification of early signs indicating risk for athlete burnout enables a proactive approach to the management of the syndrome. It may be considered normal for athletes involved in intense competition to intermittently present with some early signs. Nonetheless, once presentation of a sign (or signs) becomes more frequent, the athlete would be considered at risk of experiencing burnout.

Early signs of risk for athlete burnout can be found in the increase in ongoing difficulties in meeting sporting and personal obligations. Athletes at risk of suffering from burnout may also exhibit strained social interaction and communication patterns or report being unhappy with their social lives. Early signs might also manifest in the form of restricted participation in previously valued alternate activities, particularly when the athlete attributes this change to exhaustion. Finally, an athlete at risk of burnout may report feeling that he or she is not receiving adequate support from significant others, including the coaching and support staff, other players, spouses, and friends. As these are the athlete's perceptions, the beliefs may or may not accurately represent the situation.

Symptoms

In essence, a syndrome is a group of symptoms that present as defining features for a condition. In the case of athlete burnout, the symptoms are most logically grouped by the key characteristics—emotional and physical exhaustion, sport devaluation, or reduced accomplishment. Large variations in athletes' stress perceptions and experiences have been well documented; as a result, *representative* symptoms are identified here. The chronological order in which the burnout characteristics emerge is yet to be established. Preliminary evidence suggests that physical and emotional exhaustion may result in performance declines, subsequent feelings of reduced accomplishment, and, finally, devaluation of the sport. Alternatively, based on current research, it is equally plausible that poor performance may result in feelings of reduced accomplishment, while subsequent redoubling of efforts to rectify performance may then lead to sport devaluation.

Emotional and Physical Exhaustion

Athletes suffering from burnout experience a prolonged sense of being both emotionally and physically exhausted. This feeling of exhaustion is *not transient,* as is often experienced during episodes of demanding competition or training, which subsequently recedes after relatively short periods of rest. Instead, burnout-related exhaustion is *chronic.* These prolonged feelings of exhaustion have been associated with factors such as ongoing and unrelenting exposure to emotionally and physically draining competitive circumstances (sometimes intensified by media scrutiny), demanding and/or extended travel schedules, and intense training regimens. Athletes experiencing burnout typically report that they do not feel emotionally and/or physically refreshed after routine breaks in competition and training. Moreover, they often feel unable to "turn the experience around."

Reduced Accomplishment

A lingering (or enduring) sense of reduced accomplishment, especially among athletes who have no objective reason to feel this way, can be a key symptom of burnout. Athletes experiencing burnout may perceive that their contributions to the team are relatively unimportant, even in instances when, objectively, their contributions are substantial. Independent of their own perceptions of contribution, athletes may also feel that significant others within the team environment do not value their contributions. For athletes suffering from burnout, these feelings are not transitory and often include misgivings about their ability to perform as they would like in the future. It is not at all unusual for these athletes to feel that their careers are not progressing as they would like. These feelings of reduced accomplishment are often closely related to feelings of sport devaluation.

Sport Devaluation

Players experiencing burnout will typically devalue their sports participation to the point where they question the value of their participation. This devaluation allows athletes to psychologically distance themselves from the formerly valued activity in a way that protects their self-esteem. It is much easier to back away from commitments that are of lesser importance than those that have very high personal value. As such, some symptoms include doubts about the cost-benefit ratio associated with their athletic involvement (e.g., "Is this really worth it?" "Why am I doing this?") and loss of enjoyment of the sport and the desire to train and compete. These reservations can result in an unwillingness to examine poor performances for future improvement and a decreased enthusiasm for the challenging training required to extend skills and physical capabilities.

Consequences

Preliminary research has associated athlete burnout with negative consequences such as decreased motivation/commitment (including psychological and sometimes physical withdrawal), decreased performance levels, impaired health, personal dysfunction, insomnia, misuse of alcohol and drugs, as well as marital and family problems.

The consequences of athlete burnout are likely to exacerbate the negative way in which these athletes view their sports participation. For example, athletes experiencing a loss of enthusiasm may be reluctant to complete the repetitions necessary to perfect moves or lack the motivation to self-initiate individual training sessions, resulting in decreased performance levels and nonselection. In turn, nonselection has consequences for financial remuneration and athlete confidence and is, in and of itself, a recognized antecedent.

Diagnosis

Although measures of athlete burnout have been developed and validated for research purposes, no tools currently exist to assist in the clinical diagnosis of athlete burnout. Current definitions suggest that an enduring experience of all three burnout characteristics is required. This is not to say that the chronic experience of just one characteristic will not result in potential negative welfare and performance consequences; it is only to suggest that a diagnosis of burnout may not be warranted if all three syndrome characteristics are not evident. Athletes displaying symptoms relating to all three characteristics over a prolonged period, however, should be regarded as potentially progressing into or experiencing burnout. Of course, any burnout diagnosis would involve assessments ruling out other potentially related conditions of concern (e.g., depression, overtraining syndrome).

Perhaps one of the most challenging aspects of identifying that an athlete is experiencing burnout is the differentiation between burnout and overtraining syndrome. While researchers are still working on clear delineations of these phenomena, two key issues are clear. Clearly, the stress of training demands can exacerbate athletes' progression into burnout, but it is also the case that athletes can progress into burnout without any involvement of overtraining. In contrast, overtraining syndrome, by definition, requires athlete overtraining. Moreover, preliminary evidence suggests that burnout is associated with shifts toward motivated sports participation, while overtraining syndrome is brought on and maintained by high levels of training motivation and commitment.

Treatment

To date, researchers have presented a number of potential strategies for assisting athletes with burnout. Intervention evidence is available from burnout research in other workplace settings, but refinement of athlete-specific strategies into well-tested intervention programs has yet to occur. As a result, the current discussion is limited to a description of approaches and proposed strategies that may be suitable for athletes.

Strategies can be implemented to both manage and/or prevent burnout. These strategies to prevent and/or manage burnout can be implemented at personal (e.g., skills) or organizational (e.g., management strategies) levels. Overall, workplace burnout intervention research has had a bias toward examining personal strategies rather than organizational strategies because personal-level interventions are easily implemented and have lower organizational costs. These strategies have tended to concentrate on the management of symptoms and early signs, rather than on prevention. The primary assumption of these personal management interventions is that individuals are aware (or can be made aware) that they are experiencing (or are at risk of experiencing) burnout and, furthermore, that they are interested in implementing strategies to address that concern. Despite the negative consequences of stress potentially making it harder for participants to use strategies, personal-level management strategies have had demonstrated success in preventing and reducing burnout outside sports.

Some specific personal management strategies evaluated as effective in past research include common stress management techniques such as cognitive restructuring, development of time management skills, and relaxation exercises. These types of personal management strategies can be employed to equip athletes for dealing with potential burnout antecedents such as injury, poor performance, and perceived risk of nonselection. Organizational-level strategies with a potential to manage burnout might include efforts to enhance athletes' perceptions of autonomy, choice, and control over their careers; career opportunities, training, and development of competencies beyond sports; and support of the athletes' relational and familial responsibilities. Organizational-level strategies could also address potential antecedents relating to season and rest break structure (time off training and competition). While these organizational-level strategies are yet to be evaluated in sports, studies in nonsport settings have produced some positive results.

Bursitis

Bursitis is inflammation of a bursa. *Bursae* (plural for bursa) are lubricating sacs that overlie bony prominences to prevent friction between skin and bone and between tendons or ligaments and bones. There are approximately 160 bursae located throughout the body. The largest joints—shoulder, hip, knee, and elbow—are the sites of the major bursae and are the areas most commonly affected with bursitis. Symptoms of bursitis include stiffness after inactivity and pain with movement of the adjacent joint.

Anatomy

Bursae are small sacs lined with synovium, a thin membrane that secretes a clear, viscous (thick) lubricating substance called synovial fluid. They are located in areas of friction where skin, tendons, and ligaments move across bony prominences. If bursitis becomes chronic, the synovial fluid within the bursa can become thickened and calcified from prolonged swelling. The most commonly affected bursae are the subacromial, olecranon, trochanteric, prepatellar, infrapatellar, pes anserine, and retrocalcaneal.

The subacromial bursa is located in the shoulder, just inferior (below) to the acromion of the scapula (shoulder blade) and above the rotator cuff. The olecranon bursa is located just under the skin at the posterior (back) elbow at the olecranon of the ulnar bone. The trochanteric bursa lies over the greater trochanter of the lateral (outer) hip. The prepatellar bursa is located between the skin and the patella (knee cap) and the infrapatellar bursa is just inferior (toward the foot) to the patella, surrounding the patellar tendon. The pes anserine bursa is located on the medial (inner) leg, just inferior to the knee. It lies between the tibia bone and the attachment of three muscle tendons: semitendinosus of the hamstrings, gracilis, and sartorius.

Symptoms

Initially, symptoms of bursitis will be noticed only during activity or when pressure is applied directly over the bursa. For example, it is common for people with trochanteric bursitis to complain of hip pain when they lie on the affected side. Pain is also noted to worsen after a period of inactivity, such as stepping out of a car after a long trip. Edema (swelling), erythema (redness), and radiating pain to adjacent structures may also occur. As the inflammation progresses, symptoms become more severe, occurring at rest or with minimal movement. This is seen in subacromial bursitis, in which patients commonly report pain that awakens them at night. Prolonged inflammation can lead to thickening of the synovium, calcification of the synovial fluid, and chronic swelling. In these cases, the bursa is no longer acting as a lubricating pad. Partial tears or complete rupture of adjacent muscles or tendons may then occur from excess friction. In this case, weakness would be reported in addition to pain.

Causes

Bursitis can be caused any mechanism that can irritate a bursa. The most common cause is trauma, either repetitive or acute. Examples of areas of repetitive trauma are the acromial bursa of the shoulder in throwing athletes and the knee or hip in runners. Bursitis from acute trauma is more commonly seen over bony prominences such as the greater trochanter or olecranon after a fall. Other causes include infection, gout, and rheumatoid arthritis, as well as other medical conditions that involve the immune system.

Treatment

Treatment of bursitis is most successful during the earliest stages of the inflammatory process. Conservative management includes ice, nonsteroidal anti-inflammatory medications such as ibuprofen, and avoidance of activities that cause pain or irritation to the affected bursa. If symptoms become chronic or severe or if there is excessive edema, an inflamed bursa can be aspirated (fluid removed with a needle) and then injected with a corticosteroid, with or without a local anesthetic. In cases where there is no history of trauma, diagnostic aspiration may be indicated to evaluate the fluid for infection or systemic disease processes. In rare cases where conservative treatment fails and patients have severe, recurrent symptoms, surgical excision (removal) of the bursa may be necessary.

C

Caffeine and Exercise

Caffeine (1,3,7-trimethyl-1H-purine-2,6(3H,7H)-dione) is the world's most widely used ergogenic (external influences that positively affect mental or physical performance) pharmacological aid. Caffeine has been used for over 5,000 years, dating back to when the Chinese first discovered tea. Today, the substance is primarily consumed in the form of coffee and other beverages. Caffeine is found in coffee beans, the tea bush, the kola nut, guarana berries, yerba mate, and cocoa. Caffeine is commonly used in pill form (NoDoz®), is sometimes used in combination with over-the-counter pain relief medication (Excedrin®), and has recently been incorporated into the growing market of energy drinks (Red Bull®, Monster®). Historically, the stimulant has been used to increase alertness and reduce physical fatigue; however, more research is being done to elucidate the effects of caffeine on athletic performance.

The effective ergogenic dose of caffeine has been reported to be 3 to 9 milligrams/kilogram (mg/kg) of body weight. Caffeine is primarily absorbed in the stomach and small intestine and has peak blood concentrations at about 45 minutes after intake. The chemical is distributed throughout all tissues of the body and is capable of crossing the blood-brain barrier. In healthy adults, caffeine has a half-life of about 3 to 4 hours. However, oral contraceptives, pregnancy, and liver failure can extend the half-life substantially. Caffeine is metabolized in the liver by a cytochrome P450 oxidase enzyme system (1A2). The three metabolic by-products, paraxanthine (80%), theobromine (10%), and theophylline (4%), have various effects on the body. These metabolites are broken down and excreted in the urine.

General Cardiovascular Effects

Caffeine and its metabolites have effects on the cardiovascular system that are thought to enhance athletic performance. Theobromine is a vasodilator that helps increase oxygen and nutrient delivery to muscle and brain tissues. Theophylline increases heart rate and heart contractility and, therefore, increases cardiac output (the amount of volume pumped by the heart per unit time). Large overdoses of caffeine can create cardiac complications, including heart palpitations and heart attack.

General Respiratory Effects

In addition to the vascular effects, caffeine also contributes to an increase in respiratory function. Theophylline acts as a smooth muscle relaxant of the bronchioles and, thus, increases lung ventilation and oxygen saturation. Caffeine is being researched as a potential drug for use in athletes with exercise-induced asthma. Caffeine is also thought to stimulate the respiratory center of the medulla and, thus, increase the ventilation rate. Caffeine can therefore increase respiratory readiness and prepare the body for athletic activity by increasing overall blood oxygen concentrations.

Dehydration and Renal Effects

One of the common worries about the consumption of caffeine is dehydration. While caffeine has shown mild diuretic (water excretion) effects on the kidney, consuming caffeinated beverages does not show a significant increase in overall fluid loss in a 24-hour period. Therefore, athletes should not increase their fluid intake when using moderate amounts of caffeine (<456 mg). However, when large ergogenic doses are taken, the risk of fluid loss is higher, and more water should be consumed to prevent hypovolemia (a drop in blood pressure). Regardless of caffeine intake, athletes should always monitor fluid intake during heavy training regimens.

Effects on Endurance and Aerobic Exercise

Because of the proven cardiovascular and respiratory effects of caffeine, the effects on endurance athletes (swimming, running, cycling) are being researched in depth. Athletes in endurance sports report an increase in performance in long-distance events, with very little side effects. These athletes typically consume caffeine in a beverage or gel form and report doses of 3.8 mg/kg of body weight. Caffeine has also been shown to increase the time needed to reach the maximum rate of ventilation in endurance athletes during aerobic threshold training. Athletes therefore do not reach their maximum ventilation rate until later in the exercise. The vasodilation of peripheral blood vessels helps decrease total vascular resistance, thus increasing muscle and brain perfusion. This allows oxygen and nutrients to be delivered to the muscles, heart, and brain more efficiently, thus promoting faster recovery. Finally, while caffeine has been shown to shift metabolism toward breaking down fats, the long-term effects of caffeine use in endurance athletes has not been shown to include a change in body composition. In general, caffeine can be used to increase mental performance and concentration during all types of athletic events.

Effects on High-Resistance, Explosive, and Anaerobic Exercise

Acute dosing of caffeine prior to explosive training (weight lifting, sprinting) has shown beneficial effects as well. Caffeine is thought to increase muscle contractility by enhancing the release of calcium and increasing neuromuscular transmission. Agility and focus during sports have been shown to increase when taking effective doses of caffeine. In addition, caffeine has been shown to replenish muscle glycogen stores faster when co-ingested with carbohydrates. This allows the athlete to perform explosive exercise for a longer duration of time. In addition, because of the effects of theophylline, cardiovascular output can be increased rapidly while working with increased muscle after load or contraction. However, overall maximal speed and power have not been shown to benefit from caffeine dosing.

Effects on Recovery After Exercise

Several studies have shown that caffeine in combination with complex carbohydrates (energy drinks, sugar, juices) allows for muscle glycogen to be replenished faster. The increased glycogen stores allow for increased performance in the next workout cycle. Caffeine also changes the body's metabolism to use more fats. Fats have more energy per gram and can therefore fuel athletes for greater endurance.

Effects on Concentration and Memory

Caffeine has many effects on the central nervous system (CNS). Caffeine and its metabolites have been shown to change chemical signaling in the brain. The changes allow for faster recognition of stimuli and increased processing of information. This can have a beneficial effect on concentration during sports competitions. For example, caffeine has been shown to increase the focus level in sports such as tennis and soccer. In other studies, consistent low doses of caffeine have been associated with decreased function in the long-term memory centers of the brain. These processes are yet to be fully elucidated.

Tolerance, Addiction, and Overuse

Because caffeine has an effect on some neurotransmitters in the CNS, over time and with consistent dosing (a cup of coffee a day), caffeine can induce tolerance adaptation. In this type of tolerance, the body adapts itself to the current dose, and thus higher doses are required to elicit an ergogenic effect. At the same time, a sudden decrease in caffeine usage will create withdrawal symptoms, because of the way the body has adjusted to a baseline caffeine intake. Caffeine tolerance has been induced when taking more than 300 mg/day for about 7 days. Therefore, to optimize the effect of caffeine for a sporting event, abstinence from caffeine for several days is thought to increase the acute dosing effects.

Withdrawal symptoms include headache, irritability, inability to focus, and stomachaches. These symptoms typically occur 12 to 24 hours after a previous dosage. Resolution of withdrawal can typically take 1 to 5 days.

Caffeine abuse and overuse is known as caffeinism. One can become caffeine dependent and take large doses daily. Symptoms include nervousness, irritability, anxiety, tremulousness, muscle twitching (hyperreflexia), insomnia, headaches, respiratory alkalosis, and heart palpitations. Neurological disorders include caffeine-induced anxiety disorder and caffeine-induced sleep disorder.

Athletic Regulations

Historically, caffeine and ephedrine have been consumed in combination by elite athletes; this combination has been banned by all sporting and athletic organizations. Caffeine use, however, is still permitted in major sporting events. The International Olympic Committee (IOC) has set limitations on the use of caffeine to less than 12 micrograms/milliliter (μg/ml) in the urine. The National Collegiate Association of Athletics (NCAA) has set the limitation slightly higher at 15 μg/ml in urine testing. These doses are about the equivalent of 800 mg of caffeine, which is above the dose needed to create an ergogenic effect. For reference, a single cup of coffee contains about 120 mg of caffeine.

Coffee Versus Caffeine

Some of the acute ergogenic effects of caffeine have not been reproduced when drinking the equivalent doses of coffee. Further studies are being done to tease out the benefits of coffee intake versus caffeine intake.

Calcium in the Athlete's Diet

Calcium is the most prevalent mineral found in the human body. Calcium is chemically classified as an alkaline earth metal, which is a substance that forms ions. Ions have an electrical charge, thus they bind with the free electrons in these metals. The metallic bond formed by such metals tends to make these elements good conductors of both heat and electricity.

Calcium is not often found in its pure state in nature, as its ability to bond causes it to readily form compound substances such as calcium carbonate, or calcite, the essential component of limestone. Minerals are substances that are mined from the earth; although it is not extracted in its pure form, calcium is defined as a mineral for the purposes of understanding its role in the function of the body.

The Function of Calcium

Calcium is an essential mineral that is important for bone health. It is also important for normal enzyme activity and muscle function. Approximately 90% of the total body calcium is stored in the bones and teeth. This results in approximately 2.2 pounds (lb; 1 kilogram [kg]) to 3 lb (1.4 kg) of calcium contained in the body of an average healthy adult. Calcium is constantly being turned over in bone, with resorption and deposition happening simultaneously to maintain it in an active steady state. It is required for bodily functions such as muscle contraction, blood clotting, central nervous system activity, and regulation of heart rate. Calcium is lost through sweat, urine, and feces. Daily intake of calcium is necessary to replenish the body and maintain the calcium stores. Absorption of calcium in the gastrointestinal tract depends on the availability of active 1,25-dihydroxyvitamin D (1,25-Vit D-OH). Vitamin D is regulated by the parathyroid hormone (PTH) and parathyroid gland. Low calcium levels trigger PTH release and vitamin D conversion in the kidney, which, in turn, increases absorption of calcium from the gut and also from bone.

Healthy bone development, maintenance, and repair are directly related to optimum levels of calcium. Bones are constructed of calcium phosphate and collagen protein. The bone components form a mesh of the very hard calcium phosphate and the softer collagen. Bone metabolism is a very active process in the body, with cells known as osteoblasts (bone-formation cells) and osteocytes (bone-lining cells) continually processing calcium for bone construction. Bone metabolism is not a protected process in the body as calcium is removed from the processes of bone formation when it is needed for other essential functions such as muscle contractions. Bone formation and bone mineralization are compromised when the calcium level is low due to poor dietary intake. Similarly, too little vitamin D will inhibit calcium utilization, which leads to a similar consequence. Excess intake of calcium leads to the risk of the formation of calcium oxalate, a compound that forms in the kidneys and is the chief component of kidney stones.

Table 1 Recommended Daily Intake of Calcium

Age (years)	*Daily Requirements (mg/day)*
6–10	800–1,300
11–18	1,200–1,500
19–50	1,000
Over 50	1,200

Recommended Daily Calcium and Vitamin D Intake

There are variations in the recommendations of daily calcium intake. Children from 6 to 10 years of age require 800 to 1,300 milligrams (mg)/day, and children from 11 to 18 years of age require 1,200 to 1,500 mg/day. Adults from 19 to 50 years of age require 1,000 mg/day, and people over the age of 50 need 1,200 mg/day. The tolerable upper limit for calcium intake is 2,500 mg/day for all age-groups. Calcium supplementation has been recommended, especially in women, to augment dietary calcium intake. Calcium carbonate and calcium citrate are the most common forms of supplements available commercially. Calcium carbonate generally contains about 40% elemental calcium, while calcium citrate generally contains approximately 21%. In general, calcium carbonate costs less and is best absorbed with meals. Calcium citrate can be taken anytime and is preferred in patients with chronic constipation. Patients who take H2 blockers for gastroesophageal reflux or other stomach acid disorders often tolerate calcium citrate better. Doses are generally 500 to 1,000 mg daily and should be divided into two or more doses spread throughout the day to improve absorption (Table 1).

What Should Athletes Know About Calcium Supplements?

The amount of calcium in supplements varies from 200 to 600 mg and should be printed on the label. Serving sizes vary and are often two tablets at a time. Most often, chewable tablets are absorbed better than pills that are swallowed whole.

Vitamin D is required for adequate calcium absorption, regulation of serum calcium and phosphorus, and promotion of bone health. It is estimated that only 50% of girls aged 9 to 13 years and 32% of girls aged 14 to 18 years get the recommended daily intake of 400 international units (IU) of vitamin D. Vitamin D intake should range from 400 to 1,000 IU/day from food plus supplements. Adequate dietary calcium intake in the absence of adequate vitamin D adversely affects bone health.

Calcium is present in a wide variety of foods and beverages, with cow's milk, soy milk, yogurt, and cheese serving as the major dietary sources for Americans. Certain vegetables such as broccoli and spinach, tofu, salmon, sardines, fortified juices, and grains also serve as good dietary sources of calcium (Table 2). Improvement in vitamin D levels is achieved by eating vitamin D–rich and–fortified foods, taking calcium and vitamin D supplements, taking yearly vitamin D injections, and getting regular exposure to sunlight.

Adverse Effects of Inadequate Calcium Intake on Bone Density

Low calcium intake is an epidemic in our adolescent youth population. It is estimated that only 13.5% of girls and 36.3% of boys get the recommended daily intake of calcium. Inadequate dietary calcium intake in this age-group, particularly in females, is of great concern with regard to bone

Table 2 Examples of Nutritional Sources of Calcium

Food Source	*Serving Size (g or ml)*	*Calcium Content (mg)*
Milk (whole, low fat, skim, chocolate)	240 ml (1 cup)	275–300
Calcium-fortified fruit punch or orange juice	240 ml (1 cup)	300
Broccoli	85 g (1½ cup)	40
Cheddar cheese	45 g (1.5 oz)	300
Cottage cheese	240 g (1 cup)	160
Part-skim mozzarella	45 g (1.5 oz)	300
Chinese cabbage leaves or mustard greens	85 g (1½ cup)	240
Kale	85 g	60
Nuts (almonds)	35 g (½ cup)	160
Pudding (chocolate)	35 g (½ cup)	160
Salmon	100 g	140
Soybeans	35 g (½ cup)	200
Spinach	85 g	115
Tofu with calcium	120 g	260
Vanilla ice cream	35 g (½ cup)	85
Yogurt (nonfat and low fat)	240 g (8 oz)	400–450
Yogurt (frozen)	240 g (8 oz)	100

Note: 1 ounce (oz) = 29.57 ml.

mineral density (BMD). Ninety percent of peak bone mass is attained by age 18. Testosterone helps build bone mass, but low calcium levels and estrogen deficiency (as seen in disordered eating and eating disorder patients) in females lead to low peak bone mass and increased bone fragility (i.e., increased risk of stress fractures). Prepubertal gender differences are virtually nonexistent; adolescent pubertal stages correlate to accelerated gains in BMD. Failure to attain adequate peak bone mass is a major risk factor in the development of osteoporosis as well as the rate of bone loss. Regular weight-bearing exercise promotes the development of peak bone mass but cannot compensate for chronic calcium, estrogen, or vitamin D deficiencies. It is generally accepted that low bone density and subsequent osteoporosis can be prevented with proper education and good dietary habits; however, this must be accomplished in the adolescent years. Once a skeletally mature young woman has reached peak bone density, she can only maintain or lose it throughout the rest of her life. It is extremely difficult to see improvements in BMD in adult women despite adequate calcium and vitamin D intake, weight-bearing exercise, and even medications or estrogen supplementation. It is estimated that more than 2 million osteoporotic fractures occur each year in the United States. The number of fragility fractures in athletes resulting from low bone density is not known.

Calf Strain

A common athletic injury, *calf strain* involves a tear in the muscles of the lower leg or calf. With appropriate treatment, the strain usually heals well on its own. Occasionally, severe strain can lead to complications, resulting in chronic symptoms or surgery. Calf strain is seen most often in active adults who engage in sports that require quick starts, stops, and changes in direction.

Anatomy

The calf muscle is actually three separate muscles: the gastrocnemius, soleus, and plantaris. Each muscle has a different origin around the knee, but they all unite in the posterior (back) ankle to form the Achilles tendon. The Achilles tendon then inserts onto the heel just below the ankle joint. The calf muscles plantarflex the ankle (point the toes).

The *gastrocnemius* begins above the knee on the femur (upper leg bone) and is a powerful muscle used for sprinting and jumping. The *soleus* starts below the knee on the tibia (large lower leg bone) and is more of an endurance muscle used for prolonged repetitive motions such as walking or running. The *plantaris* is a small, almost vestigial muscle that begins above the knee. It contributes little to movement but can sometimes become injured and symptomatic.

Causes

Like the fraying of a rope under tension, calf strains are caused by a tearing of the muscle due to the application of a force across the muscle that is greater than the muscle can withstand. The degree of muscle tearing depends on the force applied and the strength of the muscle to withstand that force. Like a braided rope, the thicker the rope, the greater the strength, but at some point if enough force is placed across the rope, it will begin to fail. First, some strands will fray, weakening the rope, and eventually the entire rope will fail.

Calf strains most commonly occur in the medial (inside) aspect of the gastrocnemius muscle. This injury is often called "tennis leg" because it was first described in the late 1800s in conjunction with lawn tennis. The gastrocnemius is at high risk for strain because it crosses two joints (allowing for greater stretch of the muscle across two fulcrums), and it has a high density of Type 2 muscle fiber (fast twitch), which allow the muscle to generate a quick, powerful contraction. This combination of stretching the muscle and then contracting it quickly is similar to the action of a whip and leads to high degrees of force across the muscle and risks muscle strain. For this reason, calf strains have historically been given the moniker of *coup de fouet,* or snap of the whip.

Strains of the soleus are less common. The soleus begins below the knee and crosses only the ankle. The soleus is predominately made up of Type 1 muscle fiber (slow twitch). These factors make the soleus at low risk for strain.

Symptoms

Symptoms of calf strain should be unilateral. They should localize to the calf or posterior knee. The symptom onset should correlate to an injury or activity. They should be reproducible on muscle testing during the physical exam.

Strains of the gastrocnemius are often quite dramatic. They usually occur during a sporting activity immediately following a quick powerful striating of the knee with the foot on the ground and the ankle bent (dorsiflexed). Injury often results in immediate pain and disability. Significant swelling and bruising occur over a period of hours. Patients may experience a tearing sensation. They will find it difficult to walk, and they may adopt a flexed hip and knee position with little ankle movement. Pain is usually localized to the inside of the calf about halfway up the leg.

Strains of the soleus are less striking. They often present weeks after the injury. Patients will complain of ongoing calf tightness, stiffness, and pain associated with running or walking. Swelling and bruising are usually subtle if present. Pain is often localized to the outside of the lower leg (lateral).

Strains of the plantaris present similarly to gastrocnemius strains. However, due to the small size of the muscle and its limited role in knee and ankle function, symptoms will be relatively milder. Plantaris strains usually localize to the lateral (outer) aspect of the calf, close to the knee.

Diagnosis

Calf strains can typically be diagnosed through the history and physical exam. When the diagnosis is in doubt or additional information is needed to guide recommendation for rehabilitation and return to play, imaging such as a magnetic resonance imaging (MRI) scan or an ultrasound may be ordered.

When the symptoms suggest calf strain, a focused physical exam is the first step toward making a diagnosis. Circumferential measurements should be made of each calf if asymmetry is in doubt. The calf should be palpated along its entire length, making note of localized tenderness, swelling, defects, and masses. The physical exam can also be helpful in isolating the calf muscles that have been injured. With the knee fully flexed, the soleus is relatively isolated in testing calf muscle strength, range of motion, and symptom re-creation. The gastrocnemius can be relatively isolated by repeating this testing with the knee fully extended (or straight). More subtle symptoms can often be elicited by re-creating function movements such as running, calf raises, or single-leg hopping. If tolerated, a Thompson test can be performed by squeezing the calf and observing for passive plantarflexion of the ankle; this test is used to help rule out complete rupture of the Achilles tendon.

Calf strains are classified by the muscle injured and the degree of injury. The degree of injury is correlated with a three-part scale based on function, physical exam finding, and amount of tissue damaged. Grade 1 strains are mild, usually allow continuation of activity, and show localized tenderness and swelling on exam but normal strength and range of motion. Grade 1 strains correspond to an injury of less than 10% of the muscle. Grade 2 strains are moderate, preventing normal activity and showing loss of strength and range of motion on exam. Grade 2 strains correspond to an injury of 10% to 50% of the muscle. Grade 3 strains result in immediate severe pain and disability, loss of muscle function, and clear, palpable defect on exam. Grade 3 strains correspond to an injury of 50% to 100% of the muscle.

Treatment

Early appropriate treatment can significantly decrease the duration and amount of disability. Complete recovery of strength and flexibility should be achieved prior to return to full activity. Premature return may cause prolonged or recurrent symptoms. The vast majority of calf strains are treated nonsurgically.

Immediate treatment is aimed at limiting bleeding, reducing pain, and preventing complications. Over the first 3 to 5 days, the muscle is rested by placing it in a relaxed position and avoiding movement. This can be accomplished by placing a wedge under the heel and using crutches to assist in walking. Regular ice should be applied to the injured area for 20 minutes every hour, which provides pain relief and limits swelling and bleeding. Use of a compressive wrap helps immobilize the muscle and aids in reduction of swelling and bleeding. Avoid use of nonsteroidal anti-inflammatory drugs such as aspirin, ibuprofen, and naprosyn in the first 24 to 72 hours, due to the risk of increased bleeding in the injured muscle. Acetaminophen (Tylenol®) or narcotic pain medication is frequently prescribed. Moist heat and massage early in the healing process are believed to increase the chance of hemorrhage and are generally discouraged.

Although rare, myositis ossificans and compartment syndrome can complicate acute strains. If symptoms worsen despite appropriate treatment, prompt reexamination should be done to assess for these complications.

Following successful acute treatment, rehabilitation can be started. Rehabilitative exercises should isolate the specific muscle injured. A rehabilitation program should have a logical progression from passive stretching and range-of-motion exercises to strengthening. Ten days after the injury, if the developing scar has the same tensile strength as the adjacent muscle, further progression of exercises can begin. Isometric, isotonic, and then dynamic training exercises can be added in a consecutive manner as each type of exercise is completed without pain. The addition of physical therapy modalities, including massage, ultrasound, and electrical stimulation, could also be considered at this stage.

Surgery

Surgical consultation should be considered for Grade 3 strains (50–100% disruption of muscle) and for cases of prolonged (4–6 months) pain with evidence of fixed muscle contracture. Contractures suggest the presence of painful and restrictive adhesions within the calf that may be amenable to surgical intervention. The presence of a very large intramuscular hematoma may impair clinical progress and is also an indication for surgical referral.

Calluses

A *callus* is a broad-based, thickened patch of skin that forms in response to repeated pressure or friction forces, often a consequence of excessive weight bearing or frequent rubbing of the skin by footwear. It is an accumulation of dead skin cells at the surface layer of the skin that harden and thicken to protect the body. This thickening is called *hyperkeratosis*. Calluses can form over any bony prominence, though they are typically found on the palms of the hands and soles of the feet. The ball of the foot, the heel, and the underside of the big toe are commonly affected. Calluses are generally not harmful or painful and are also referred to as a *tyloma* or a *clavus*.

Causes

A wide variety of factors may lead to the development of a callus.

- Extrinsic factors include poorly fitting footwear (such as shoes that are too tight or have a small toe box), walking barefoot, thin-soled shoes, high heels, thick socks or socks with seams by the toes, prolonged standing, and repetitive activity (i.e., athletics, manual labor). Athletes develop calluses due to repetitive motion and recurrent pressure on the same spot. For instance, cyclists develop calluses on their palms from holding the handlebar grips. Rowers form calluses on several areas of the hand due to friction between the oar and the hand. Runners develop foot calluses from repetitive pounding on hard road surfaces. Dancers and gymnasts develop calluses on their feet from distinctive weight-bearing positions. Wrestlers can have knee calluses from pressure exerted on the mat. Surfers who paddle on their knees develop large, calcified calluses ("surf knots") on their knees.
- Intrinsic factors include foot deformities (high-arched feet, claw toe, hammer toe, mallet toe, short first metatarsal, bunions, malalignment of the metatarsal bones, flat feet, loss of fat pad on the underside of the foot, malunion of fracture), poor foot mechanics or abnormal gait, and obesity.

Presentation

A callus presents as a broad-based, diffuse area of hard growth with relatively even thickness, usually at the ball of the foot. It lacks a distinct border. The affected skin is rough and discolored and can vary in color from white to gray-yellow or brown. Calluses are more common in women than in men.

Calluses are often painless and can actually be advantageous to some athletes. Boxers and martial artists build up calluses on their hands to become more resistant to pain from impact. Dancers develop calluses from dancing barefoot, and yet the calluses can facilitate performing turns. Although typically benign, pressure or friction can precipitate pain. Discomfort, for foot calluses specifically, is amplified by thin-soled and high-heeled shoes. Relief comes with rest.

Some calluses develop a deep-seated core known as a *nucleation*, and patients will complain of pain when pressure is applied. This type of callus is referred to as *intractable plantar keratosis*.

Making the Diagnosis

Calluses are diagnosed based on findings on clinical exam. The location and characteristics of lesions are noted, and the affected area is palpated to feel for a prominent bone underneath the skin surface. X-rays may be done to look at the underlying bony structures that may be the cause of calluses.

Clinicians assess for any contributing factors, such as footwear, repetitive activities, medical history, and previous surgery. Foot mechanics are evaluated by observing a patient's gait. It is important to look for the underlying source of increased mechanical stress on the affected body part in order to construct an effective management plan.

Other conditions that can resemble calluses include warts, tumors of the skin and subcutaneous tissues, and a reaction to a foreign body embedded in the skin (e.g., a wood sliver or piece of glass). Genetic and metabolic disorders of the skin can also cause skin thickening, which can be mistaken for a callus.

Treatment

Recent literature suggests that the principles of callus treatment are four-fold: (1) relieve symptoms; (2) determine the underlying cause of mechanical stress; (3) construct a conservative management plan, including counseling regarding proper footwear; and (4) consider surgery if there is no improvement with conservative measures.

Self-Care

Preventive care for calluses includes avoiding high-heeled and thin-soled shoes. It is recommended that patients wear shoes with good arch support and a shock-absorbing rubber sole. An insole that absorbs shear forces inside the shoe can also reduce the risk of developing a callus and the discomfort that occurs after callus formation.

Protective and palliative care includes moisturizing and padding callused skin. Regular moisturizer use is important for keeping callused skin moist and supple. Moisturizer should be applied at least twice a day. Warm-water soaks are also effective for softening the skin. Epsom salts and essential oils can be added for additional benefit. Once the skin is softened, a pumice stone or foot file can be used to gently file away at the callus, lifting the dead skin and stimulating fresh growth underneath. Caution must be exercised, however, when trying to trim or shave off callused skin on one's own with scissors or sharp blades. This should only be done by clinicians due to the risk of injury and subsequent infection, particularly in people with reduced peripheral sensation, such as diabetics with neuropathy. Nonmedicated pads can be applied around a callus to relieve pressure. It is best to start with a thin pad and gradually build it up to one's comfort. Moleskin pads can also be applied to areas that tend to callus to prevent friction and pressure.

Clinical Interventions

Clinical interventions include topical medications, orthotics, debridement, and surgical correction of a deformity or bony prominence.

Orthotics may be used to change foot mechanics by correcting functional problems and/or redistributing body weight. The goal of orthotics, like various other therapies for calluses, is to reduce pressure and friction and allow the skin to rest. Orthotics should be made with shock-absorbing materials and materials that reduce shearing in the shoe. Nonmedicated pads or moleskin can also be applied around or over the callus, respectively, to relieve pressure.

Debridement (shaving down) of the callus helps even out the skin surface and reduce thickening and abnormal pressure distribution. A small amount of callus is left to provide the bony area with some padding. Keratinolytic medications are used topically on calluses and facilitate debridement. They help reduce a callus by causing the skin to swell, soften, crumble, and then flake away. Examples of keratolytics include urea, alpha-hydroxy acids (lactic acid, glycolic acid), and beta-hydroxy acids (salicylic acid). However, complications can arise if a foot callus becomes too large. There is a risk of it beginning to move with the shoe rather than with the foot, with consequent blister formation. This is detrimental to athletic performance because the blister is difficult to drain.

In cases resistant to conservative measures, surgical correction of a deformity may be necessary. Examples include surgical realignment of the metatarsal bones and removal of bony prominences. Risks of an invasive treatment include infection as well as formation of scar tissue.

Cannabinoids

Cannabinoids are substances that come from the plant *Cannabis sativa* and are among the most commonly used illegal drugs around the world. The drug is also known as *marijuana* or *ganja*. Marijuana does not have any known performance-enhancing effects for athletes, but its use is banned in and out of competition.

The psychoactive chemical in cannabis is THC (delta-9-tetrahydrocannabinol). There are dozens of colorful slang terms for marijuana, ranging from common terms such as *weed* or *pot* to references to the amounts that are sold or how much it costs. References used in buying marijuana can be interesting and obscure. One might hear someone asking how much a certain piece of clothing costs when talking in code about buying drugs. A "shirt" might refer to ⅛ ounce (oz; 3.5 gram [g]), whereas "pants" are ¼ oz (7 g), and a "jacket" is 1 oz (28 g). Another popular code is any number of references to "420," which is rumored to have come from the legend of a group of kids in California in the 1970s who smoked marijuana every day at 4:20 p.m.

Cannabis can be prepared into a concentrated resin (hashish) and smoked, vaporized, or ingested (alone or baked and cooked into food products). Usually, however, the dried leaves of the plant are smoked in a pipe or a rolled cigarette. It is typically used as a recreational drug, but there are some medical applications. Accepted medical use includes preparations of THC to stimulate appetite and relieve nausea in patients receiving chemotherapy. Marijuana has also been used to treat conditions such as chronic pain and glaucoma. Medical use of cannabis remain controversial, in part because of the suspicion that many people who are using the drug under the guise of medical treatment do not have the condition that they claim or could do well enough with other, more traditional treatments.

Research has not indicated that users develop a strong physical dependence on cannabinoids, and there are no significant physical withdrawal symptoms once they are stopped. There can be psychological dependence, however. In addition, chronic users may incur significant health risks, particularly from the effects of smoke inhalation, beyond the threat of consequences from law enforcement. For most major sports, including Olympic sports, drug testing panels include a test for cannabinoids. A positive test in competition will result in disqualification and possibly other sanctions. Cannabis is fat soluble and may be detected by modern tests for up to 4 weeks after use.

Side effects can include difficulty in concentrating, impaired motor skills, dry mouth, and depression or apathy. In addition, smoking the drug can cause cough, impair lung capacity, and contribute to cancer. Panic attacks, paranoia, and anxiety are common side effects while the drug is being used.

Over the past three decades, marijuana has been cultivated to make it much more potent. In addition, as with any illicit drug, the purity of each dose cannot be guaranteed. Unexpected exposure to drugs such as phencyclidine (PCP; aka Angel Dust) or gamma hydroxybutyrate (GHB; a date rape drug) when smoking or ingesting marijuana has been reported.

Carbohydrates in the Athlete's Diet

Carbohydrates (CHOs) are the most important source of energy in a balanced daily diet. Carbohydrate intake must be balanced with adequate amounts of protein, fat, and water intake.

In athletes, carbohydrates are the primary fuel source to maintain blood glucose for energy during exercise. Adequate carbohydrate intake also helps spare muscle from catabolic activity and muscle breakdown. After carbohydrates are ingested, they are broken down into smaller sugars (glucose, fructose, and galactose) that get absorbed and used as energy. The body is capable of storing excess carbohydrates in the form of glycogen in the muscles and liver. The body's glycogen capacity is approximately 300 to 400 grams (g). Subsequent excesses are then converted to fat and stored. Conversely, in the setting of inadequate intake, an energy imbalance can result with adverse affects on athletic performance as well as overall health.

Simple Versus Complex Carbohydrates

One gram of carbohydrate provides 4 calories (cal; 16.75 joules [J]) of energy. General guidelines recommend that 6 to 10 g of CHOs per kilogram (kg) of body weight be consumed daily by both adult and adolescent athletes. However, additional recommendations suggest that an adult athlete's diet consist of 60% to 65% CHOs, whereas an adolescent athlete's diet should have 55% to 60% CHOs. Carbohydrates are divided into simple (monosaccharides) and complex (polysaccharides) types. Simple sugars are absorbed and converted to energy very quickly and provide a rapid source of energy. Fruit, 100% natural fruit juice, and sports drinks are good sources of simple carbohydrates. The rise in blood glucose levels is indicated by a food's glycemic index (GI), and the faster and higher the blood glucose rises, the higher the GI will be. A limit of dietary intake of simple sugars is recommended. It is more beneficial to consume lower GI (complex) carbohydrates. Complex carbohydrates take longer to be broken down and absorbed and, therefore, provide energy at a slower rate than simple sugars. Breads, rice, and pasta are common examples of complex carbohydrates. Starch and fiber are also considered complex carbohydrates; however, fiber cannot be digested or used for energy. The most important CHO energy source in an athlete's diet is starch because it is broken down and stored as glycogen. Foods high in starch include whole grain breads, cereals, pasta, and grains (Table 1).

How Important Is Glycogen?

Glycogen is the source of energy most often used for exercise. It can be released up to three times faster than energy from any other source and, therefore, needs to be readily accessible. During training and competition, an athlete's glycogen stores are depleted. To replenish them, the athlete needs to consider the speed at which carbohydrate is converted into blood glucose and transported to the muscles. An intake of between 30 and 60 g of carbohydrate an hour is recommended to maximize the amount muscles can adsorb from the bloodstream during exercise. Greater amounts have no further benefit. During high intensity exercise, carbohydrates are the main fuel for the muscles. Glycogen stores will be kept well stocked if high levels of carbohydrate are consumed before, during prolonged exercise, and after training in the immediate postexercise period.

Athletic performance is limited by the availability of blood glucose and glycogen. It is needed for any short, intense bouts of exercise from sprinting to weight lifting because it is immediately accessible. Glycogen also supplies energy during the first few minutes of any sport. During long, slow-duration exercise, fat (and protein) can help fuel activity, but glycogen is still needed to help break down the fat into energy substrate (Table 2).

Athletes often talk about carbohydrate loading and carbohydrate depletion, which refers to the amount of carbohydrate energy we can store in our muscles. This is generally around 2,000 carbohydrate calories, but we can change this number through depletion and loading. During depletion (from diet, exercise, or a combination of both), we use up the stored carbohydrate. If we don't replenish these stores, we can run out of fuel for immediate exercise. Carbohydrate loading is an attempt to increase CHO stores by eating large amounts of carbohydrates. Our maximal carbohydrate storage is approximately 15 g/kg of body weight. So a 175-pound (79 kg) athlete could store up to 1,200 g of carbohydrate (4,800 cal or 20,096.64 J); enough energy to fuel high-intensity exercise for quite some time.

How Is Energy Created During Exercise?

Anaerobic Metabolism

It is necessary to continually create adenosine triphosphate (ATP) during exercise, both aerobically and anaerobically. The ATP-CP (adenosine

Table 1 Carbohydrate Content in Common Foods

Food	*Amount*	*CHO (g)*
O-shaped cereal, corn pops	1 cup	23–28
Oatmeal	1 cup	26
Bagel	2 oz	31
Granola, low fat	1 cup	82
Graham crackers	2 squares	11
Popcorn	1 cup	6
Pretzels	1 oz	21
Raisins	½ cup	62
Apple	Medium	21
Banana	Medium	27
Orange	Medium	16
Orange juice	½ cup	12
Soda	8 oz	27
Sports drink	8 oz	14
Rice	1 cup cooked	50
Spaghetti	1 cup cooked	34
Beans	½ cup	20–24
Yogurt, fruit	8 oz	42
Yogurt frozen	8 oz	34

Note: CHO, carbohydrate; 1 ounce (oz) = 29.57 ml.

Table 2 Recommended CHO Intake Before, During, and After Exercise for an Average Pediatric Athlete and an Adult Athlete

Timing	*Amount of CHO (g/kg body weight)*	*40-kg Athlete (Total CHO/kcal)*	*70-kg Athlete (Total CHO/kcal)*
Pre-exercise (3–4 hours)	4	160 g/640 kcal	280 g/1,120 kcal
Pre-exercise (1–2 hours)	0.5–1	20–40 g/80–160 kcal	35–70 g/140–280 kcal
During exercise	0.7 every 20 minutes after 1 hour of exercise	28 g/112 kcal	49 g/196 kcal
Postexercise	1–1.5	40–60 g/160–240 kcal	70–105 g/280–420 kcal

Note: 1 kilocalorie (kcal) = 4,200 joules.

triphosphate–creatine phosphate) energy pathway supplies about 10 seconds worth of energy used in short bursts or in sprints. It uses ATP stored in muscle and then uses CP to resynthesize ATP until CP is used up. Then the body must use another pathway to create energy.

Glycolysis is the second anaerobic energy pathway that creates ATP exclusively from carbohydrates and creates lactic acid as a by-product. Glycolysis provides energy through the partial breakdown of glucose and is best for short, high-intensity bursts of exercise. Lactic acid builds up quickly, resulting in muscle pain, burning, and fatigue that reaches a certain threshold and results in cessation of exercise.

Aerobic Metabolism

Aerobic metabolism fuels most of the energy needed for long-duration activity. It uses oxygen to convert nutrients (carbohydrates, fats, and protein) to ATP. This system is slower than the anaerobic systems because it relies on the circulatory system to transport oxygen to the working muscles before it creates ATP. Aerobic metabolism is used primarily during endurance exercise. Fat is a great fuel for endurance events, but it is simply not adequate for high-intensity exercises such as sprints or intervals. If you are exercising at a low intensity (or below 50% of max heart rate), you have enough stored fat to fuel activity for hours or even days as long as there is sufficient oxygen to allow fat metabolism to occur. A balanced diet of CHO, protein, and fat provides enough substrate for the body to use both anaerobic and aerobic metabolism efficiently in the appropriate exercise setting.

What Is the Ideal Precompetition Meal?

Precompetition meals are essential to maintain energy levels during sustained exercise. Consuming 1 to 4.5 g of CHO/kg of body weight 1 to 4 hours preactivity is ideal for maintaining blood glucose levels during exercise by ensuring adequate CHO availability. The meal composition should be relatively high CHO, low fat, and limited protein. The GI of foods also affects athletic performance. High-GI foods may cause a rapid increase in serum blood glucose, which in turn triggers an insulin response to counteract the rapid glucose rise. Conversely, low-GI foods provide sustained energy release without rapid increases and decreases in serum blood glucose and energy substrate. Low-GI foods include whole grain products, vegetables, beans, milk, low-fat yogurt, and some fruits (Table 3).

Table 3 Sample Precompetition Meals

Toast and jelly
Baked potato
Spaghetti with tomato sauce
Cereal with skim milk
Low-fat yogurt with fruit

What Does Our Body Need After Exercise?

It is important to consume carbohydrate within minutes of cessation of exercise to restore glycogen. About 100 to 200 g of CHO within 2 hours of endurance exercise is essential to build adequate glycogen stores. Furthermore, complex carbohydrate ingestion may be preferred, and simple carbohydrate ingestion should be limited. Combining protein with carbohydrate (CHO + AA) in the postexercise meal consumed within 2 hours of cessation of exercise nearly doubles the insulin response. As a result, a significantly larger amount of glycogen stores are replenished. The ideal carbohydrate to protein ratio is 4:1 g. Excessive protein intake postexercise can slow glycogen replacement and rehydration. Protein intake provides the necessary amino acids to rebuild muscles broken down during intense exercise and improves muscle hydration. Consumption of CHO + AA postexercise improved postexercise recovery, thus, preventing decline in endurance performance heavy exercise bouts in the consecutive day. What research has failed to demonstrate is an actual improvement in exercise performance in endurance athletes following protein or CHO + AA supplementation. Thus, the optimal intake of CHO/protein quantities is likely individual and is affected by personal tolerance, dietary practices, metabolism, and exercise type as well as length. Further research is needed to establish optimal CHO/protein types, amounts, and timing with regard to specific types of exercise.

Conclusion

Sports nutrition is built on an understanding of how nutrients such as carbohydrate, fat, and protein contribute to the fuel supply needed by the body to perform exercise. In athletes, carbohydrates are the primary fuel source to maintain blood glucose for energy during exercise. Adequate carbohydrate intake also helps spare muscle from catabolic activity and muscle breakdown. Energy is used by the body in the form of ATP. Muscle contraction occurs via anaerobic and aerobic metabolism of ATP. Athletes who maintain ideal health and fitness are able to supply the body with adequate carbohydrate before, during, and after exercise. The optimal quantities, types, and timing of CHO, and all nutrients, intake is likely varied among athletes. Dietary intake of CHOs and other nutrients for energy substrate is preferred over commercial supplementation whenever possible.

Cardiac Injuries (Commotio Cordis, Myocardial Contusion)

Sudden death in athletes who otherwise appear healthy has often been attributed to an underlying structural or electrical defect in the individual's heart. This is not unjustified, as many sudden deaths in apparently healthy athletes have eventually been linked to an undiagnosed cardiac condition. The medical community and even the media are growing in awareness of several of these cardiac conditions, most notably hypertrophic cardiomyopathy and long QT syndrome. Not surprisingly, vigilant screening aimed at detecting these potentially lethal conditions is part of the standard of care with regard to medical preparticipation exams of athletes.

However, sudden cardiac death in the athlete has also been observed when no previous heart defect was noted. In fact, it is well recognized that blunt, nonpenetrating, and seemingly innocuous blows to the chest may result in sudden death during competitive or even recreational sports activities. *Commotio cordis* (Latin for commotion of the heart) is the term commonly used to describe these cases of sudden cardiac death caused by chest blows. In reality, however, there are a small percentage of cases in which an individual is fortunate enough to survive a commotio cordis event.

Commotio cordis is a cardiac contusion brought about by sudden, nonpenetrating precordial trauma or impact, which causes arrhythmias (ventricular fibrillation [VF]) and, subsequently, sudden cardiac death without any evidence of cardiac injury on autopsy.

Epidemiology

Accurate demographics pertaining to commotio cordis are somewhat limited by the relatively small number of cases compared with other known sports-related disease entities. A lack of recognition of commotio cordis and underreporting are also likely contributing factors. It is considered the second most common cause of sudden cardiac death after hypertrophic cardiomyopathy.

One commonly used source for confirmed cases of commotio cordis is the U.S. Commotio Cordis Registry (Minneapolis, Minnesota). The registry compiles information from a number of sources, including the media and the Internet, the U.S. Consumer Product Safety Commission, and interested medical and nonmedical parties. Based on this registry and as of September 1, 2001, there were 128 confirmed cases of commotio cordis in the United States.

Inclusion criteria in this registry consisted of four items. First, an eye-witnessed event of a blunt, nonpenetrating blow to the chest should immediately precede cardiovascular collapse. Second, detailed documentation of the circumstances should be available. Third, there should be no structural damage to the sternum, ribs, and the heart itself. Finally, there should be no underlying cardiovascular abnormality.

Using these criteria, the registry data revealed that the vast majority of commotio cordis events occurred in young (mean age 13.6 years) males (95% confirmed cases) playing organized sports. The registry showed that 87% of cases occurred in Caucasians. Age of incidence ranged from 3 months to 45 years; however, commotio cordis most frequently occurred in male children from age 4 to 16 years. Only 22% of cases occurred in patients aged 18 or older.

While several sports were represented, baseball, softball, and hockey in descending order accounted for most of the cases. The registry also noted that both fatal and nonfatal events took place, with approximately only one survivor for every five deaths. Additionally, the registry found that commotio cordis events occurred even with protective equipment, including chest protectors and balls specifically designed to reduce risk of injury (Table 1).

Pathophysiology

When an electrocardiogram (EKG) could be recorded after a collapse from commotio cordis, the most common arrhythmias were either VF or asystole. It is presumed that individuals dying from commotio cordis typically will sustain trauma-induced VF prior to their death. Two factors play a role in this sequence of events: the timing and hardness of the impact.

The electrophysiologic consequences of chest wall impact depend on the timing of impact during the cardiac cycle. Specifically, based on animal models, it is thought that chest wall trauma delivered during the upstroke of the T wave results in VF. Others believe that trauma-induced precipitation of premature contractions predisposes to eventual VF in commotio cordis.

In a 2001 study published in the *Journal of the American College of Cardiology,* Link et al. used a pig model to demonstrate that impact with a wooden object, convex in shape and weighing 150 grams (reproduction of a regulation baseball), to the precordium, directly over the left ventricle, within the window from 30 to 15 milliseconds (ms) before T wave peak on EKG, produced VF—nine episodes of VF on 10 impacts. This small window represents approximately 3% of the cardiac cycle in individuals whose heart rate is 120 beats per minute. VF was not preceded by ventricular tachycardia, conduction abnormalities, or ST changes on EKG, evidence that the mechanism of injury is secondary to electrical conduction etiology rather than myocardial ischemia. VF was not elicited by impacts during other times in the cardiac cycle.

Seven impacts delivered during the T wave but outside the 30- to 15-ms window before T wave peak resulted in only two episodes of polymorphic ventricular tachycardia.

When 10 impacts were delivered during the QRS complex, 4 resulted in transient complete heart block for up to 7 sinus beats, and with return of sinus rhythm, subjects developed ST elevation and left–bundle-branch block for up to 120 seconds. The other 6 resulted in ST-segment elevation and left–bundle-branch block.

Another pig study by Link et al., in 1998, using baseballs of differing consistencies affecting the precordium at 30 miles/hour (48.28 kilometers/hour). They showed that the force of precordial trauma was inversely related to fatal outcome and the harder the consistency of the baseball, the higher the incidence of VF.

With the softest-consistency baseball, two episodes of VF were elicited in 26 impacts (8%) in 12 animals. With the medium-soft ball, six episodes of VF were elicited on 27 impacts (22%) in 12 animals. With the hard ball, six episodes were elicited with 21 impacts (29%) in 12 animals. Finally, with a regulation baseball, eight episodes were elicited in 23 impacts (35%) in 12 animals.

Chest wall biomechanics should also be taken into account. Younger athletes with narrower anteroposterior diameter of the thorax and increased compliance of the chest are more susceptible to commotio cordis.

In a 2000 study published in *Circulation,* Bode et al. used a rabbit model to elicit VF from sudden myocardial stretch. VF induction was secondary to a rapid rise in left ventricular pressure from impact, with resulting potassium-ATP (adenosine triphosphate) channel activation and subsequently premature ventricular depolarization and development of VF.

History

Commotio cordis occurs typically, as previously stated, in a sport that involves a projectile device. Most cases of commotio cordis fall into two categories of presentation. In one situation, sudden death will occur immediately on impact. In the other, the individual may collapse and then make purposeful movements or gestures prior to death. In the second situation, it is thought that a brief period of a perfusing arrhythmia, such as ventricular tachycardia, may precede VF.

Treatment

We have few data on the benefits of treatment as death occurs in the majority of cases. As of September of 2001, there were two cases of spontaneous resuscitation from presumed aborted commotio cordis. Otherwise, nonfatal commotio cordis events (21 people, or 16%, of all cases through September of 2001) were only observed when prompt cardiopulmonary resuscitation and defibrillation were employed.

Commotio cordis should be treated as a cardiopulmonary emergency. While maintaining airway, initiating oxygenation, and delivering chest compressions, the most critical component in this case is early defibrillation (less than 4 to 8 minutes from the time of collapse). Successful resuscitation relies on early defibrillation. Spontaneous termination of ventricular arrhythmias rarely occurs.

In the pig models, defibrillation within 1 minute of VF resulted in a 100% survival rate, and defibrillation within 2 minutes resulted in an 80% survival rate. Defibrillation at 4 minutes resulted in no survivals, unless cardiopulmonary resuscitation (CPR) was instituted after the defibrillation, which increased survival to 65%.

In general, out-of-hospital defibrillation occurs within 3 minutes of cardiac arrest and produces a survival rate of 50%. Every minute's delay after the initial 3 minutes results in a 10% decrease of survival rate. Emergency medical services usually arrive after 5 minutes of cardiac arrest; therefore, the use of automated external defibrillators (AEDs) may save many lives.

AEDs and their availability is the gold standard of treatment. Until further research can help identify and prevent those at risk for commotio cordis, the paradigm for dealing with commotio cordis is rapid defibrillation. In 2001, AEDs were modified so as to be able to deliver appropriate voltages to children less than 8 years old or weighing less than 55 pounds (24.95 kg).

Prevention

The use of appropriate protective equipment should be encouraged in all age-groups. However, it is known that commotio cordis occurs despite the use of protective gear.

In one study, 38% of athletes who experience commotio cordis had been wearing chest protectors at the time of impact. Of those athletes who experienced commotio cordis after sustaining an impact, 22% were struck by objects directly on their chest protectors, while 78% of the athletes did not have adequate coverage because of migration of chest protectors over the precordial area.

In another swine model, chest protectors were not shown to significantly decrease the incidence of VF from impacts from baseballs and lacrosse balls when compared with controls without chest protectors. This lack of benefit from chest protectors may be due to the poor fit of the protective gear for children of different ages and sizes or the materials used. Moreover, the use of balls with softer cores can provide a similar benefit. Age-appropriate baseballs of diminished hardness should be used for children under the age of 13 years. Whether chest pads or soft-core balls provide adequate protection against commotio cordis is still a matter of debate.

Cardiovascular and Respiratory Anatomy and Physiology: Responses to Exercise

The capacity for exercise is the net effect of a synchronized response of the cardiovascular and respiratory systems. Understanding the anatomy and physiology of each system is key to understanding how the systems interface at rest and with exercise.

Anatomy and Physiology

Cardiovascular

The heart is a muscular organ roughly the size of a human fist, which is located slightly left of center beneath the sternum and ribcage within the chest cavity. Its job is to receive deoxygenated blood from the body and pump it to the lungs and to receive oxygenated blood from the lungs and pump it to the body, and the organs and muscles use this supply of oxygen and nutrients to function. The human heart has four chambers (Figure 1): right atria, right ventricle, left atria, and left ventricle. The normal path of blood flow is as follows: Blood flow returns from the body via two large veins, called the superior and

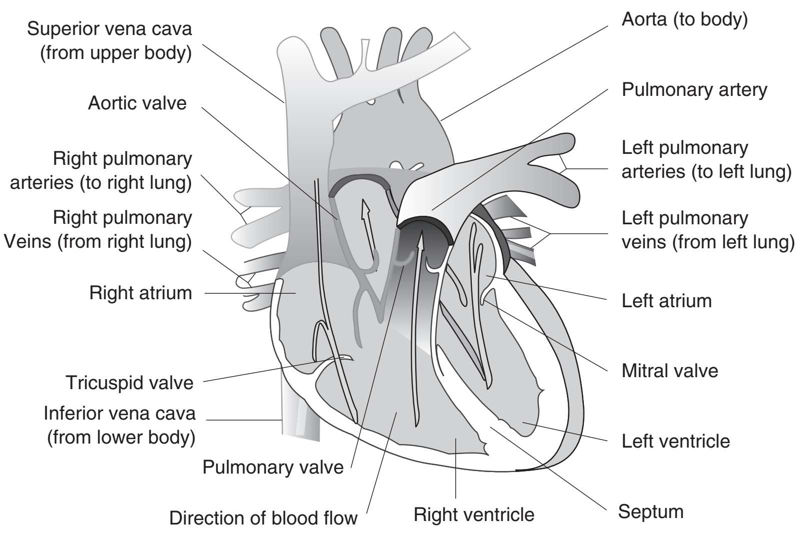

Figure 1 Cardiac Anatomy

inferior vena cava, and collects in the right atria before passing through the tricuspid valve into the right ventricle. It is then pumped through the pulmonary valve into the pulmonary artery, which takes blood into the dense capillary network of the lungs. Here, blood picks up oxygen and releases carbon dioxide before returning via the pulmonary vein to the left atria. From the left atria, blood flows through the mitral valve into the left ventricle before being pumped through the aortic valve into the aorta, a large artery that carries blood away from the heart toward the peripheral organs.

Embedded in the myocardium (heart muscle) is a conducting system that propagates an electrical impulse from its point of origin in the sinoatrial (SA) node in the wall of the right atrium through both atria and ventricles, causing the coordinated, rhythmic muscular contraction that propels blood through vessels as outlined earlier. Pathways involving the parasympathetic and sympathetic nervous systems affect the rate at which the SA node generates an impulse. Parasympathetic activity decreases the heart rate, while sympathetic activity increases it. The actual heart rate is the net effect of these "up and down" messages.

The amount of blood the heart pumps in a minute is known as the cardiac output. The cardiac output is a product of the stroke volume (volume of blood pumped per contraction) and the heart rate (number of times the heart beats per minute). A normal resting heart rate is approximately 70 beats/minute, and a typical stroke volume is approximately 70 milliliters (ml)/minute; thus, a standard reference for cardiac output is roughly 5 liters (L)/minute. Of course, this is just a general reference value, and the actual cardiac output of a specific individual will vary.

Although the heart is the organ responsible for pumping blood, heart muscle also requires oxygenated blood and nutrients. These are supplied via coronary arteries that arise from the aorta.

Respiratory

Within the area bounded by the ribs, sternum, spine, and diaphragm are the lungs (Figure 2). This framework, known as the thorax or thoracic cavity, supports the lungs and helps keep them open; if the lungs were to be removed from the thoracic cavity, they would partially collapse. The right lung has three lobes: the upper, the middle, and the lower. On the left, there are two lobes, the upper and the lower, and a third significant section of the upper lobe, known as the lingula. The lungs are surrounded by a specialized skinlike surface known as the visceral pleura, and the lobes are separated and defined by inflections of the pleura. A similar surface, the parietal pleura, lines the thoracic cavity. During respiration, these two surfaces, lubricated by a small amount of fluid, slide smoothly over each other.

The airways. The nose and the mouth connect to the trachea or windpipe, which branches within the thoracic cavity to the left and right main-stem bronchi. Each main bronchus then divides further into the lobar bronchi, which in turn subdivide for 15 to 20 generations until the smallest conducting airway is reached at the level of the terminal bronchiole. The volume of air in the conducting airways is known as anatomic "dead space" because no gas exchange occurs. This volume is roughly 150 ml in the average adult. The terminal bronchioles then divide further into respiratory bronchioles and alveolar ducts before ending in alveoli. Although some gas exchange can occur at the level of the respiratory bronchiole and alveolar duct, the alveoli are uniquely designed for this purpose. The walls of an average adult's

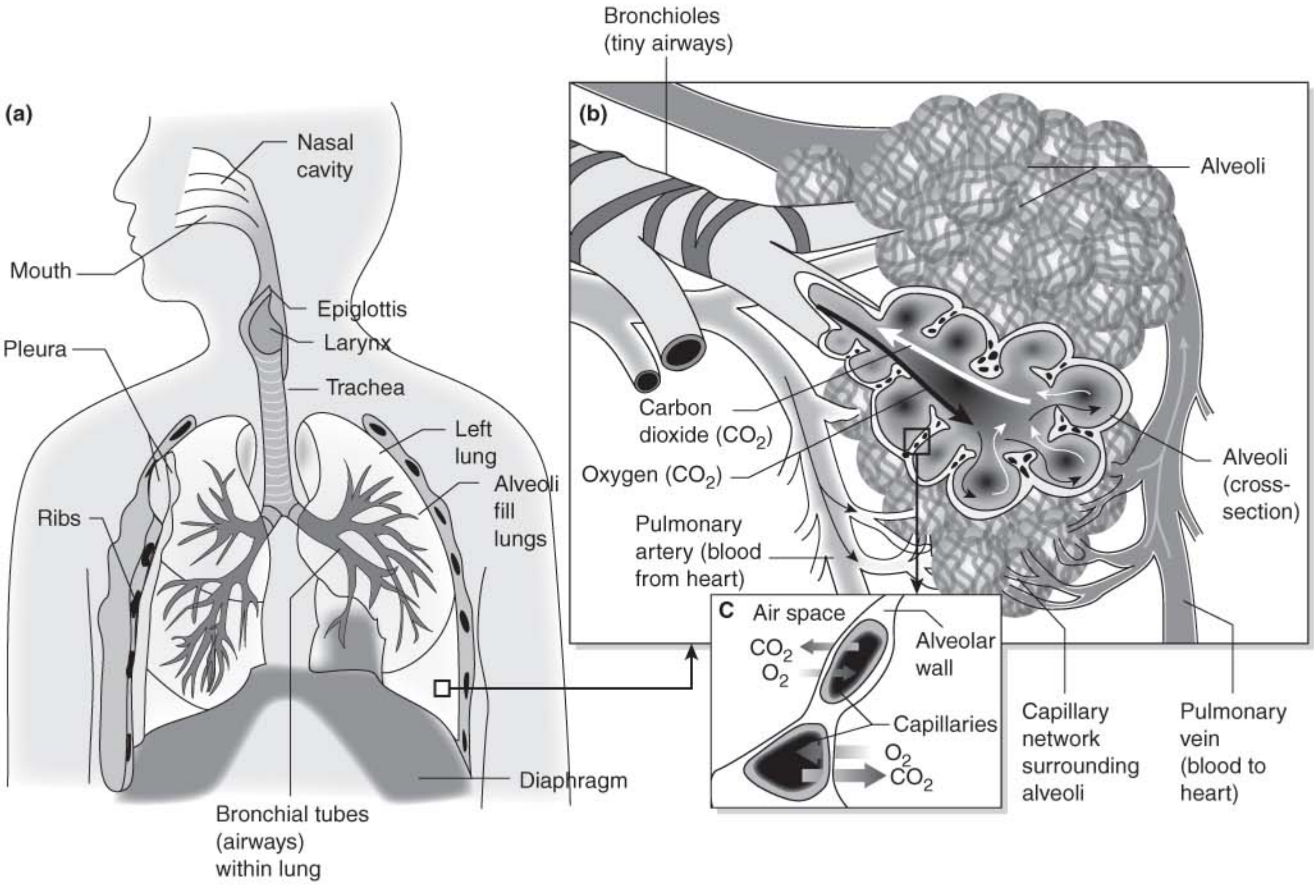

Figure 2 Anatomy of the Lung

300 million alveoli are very thin and surrounded by capillaries, thus creating a surface area approximately equivalent to the size of a tennis court for efficient gas exchange. The volume of each breath is the tidal volume; the maximal volume of air in a single breath is the vital capacity, the amount of air in the alveoli is termed the alveolar volume; and the amount of air available for ventilation in a minute is the minute ventilation. Recall though that in each breath, there is an obligatory 150 ml of dead space. Thus,

$$\text{Minute ventilation} = \text{Breathing frequency} \times (\text{Tidal volume} - \text{Dead space}).$$

The muscles of respiration include the *intercostal muscles* and the *diaphragm*. The intercostals are located between the ribs and contract to move the ribs from their somewhat slanted position to a position more perpendicular to the axis of the spine. The diaphragm is a long flat muscle located at the base of the ribs with attachments to the ribs, xiphoid process, and lumbar spine; it separates the abdominal cavity from the chest cavity. At rest, it has a dome shape, with the convex portion of the dome on the thoracic side of the muscle. With respiration, the diaphragm flattens. The actions of the intercostal muscles to rotate the ribs and the flattening of the diaphragm function to increase intrathoracic volume, which, in turn, creates negative pressure inside the chest cavity and causes air to flow into the lungs. At end inspiration, pressure in the lung is atmospheric, and the driving force for air movement is satisfied. To initiate exhalation, the intercostals and the diaphragm relax. Their movement toward their natural resting position increases the intrathoracic pressure, causing air to be expelled from the lungs. It is important to note that at rest, exhalation is a passive process.

The lung has two networks of blood vessels: the *bronchial* circulation and the *pulmonary* circulation. The bronchial vessels arise from the aorta and bring oxygenated blood and nutrients to the lung tissue, while the pulmonary vessels carry blood to and from the heart for gas exchange. Blood flow through the pulmonary vessels is not uniform. Instead, it is stratified as a result of gravity such that the base of the lung receives the most blood flow and the apex receives the least.

Exercise

Exercising muscle demands a greater supply of oxygen to meet the needs of increased aerobic work. The respiratory and cardiovascular systems are remarkably well equipped to quickly and efficiently respond to this demand.

Cardiovascular

Heart rate increases during exercise as the result of an increase in sympathetic input and a decrease in parasympathetic input. In fact, just thinking about exercise will increase your heart rate, priming you for activity. Cardiac filling and ejection fraction also increase, thus cardiac output also increases, which improves the blood supply to the exercising muscle. The amount of cardiac output that a given subject is capable of producing is the result of a combination of genetics and training. Endurance athletes, for example, may increase their cardiac output to as much as 30 to 40 L. As subjects approach their maximal heart rate, there is less time between contractions for the heart to fill with blood. Reduced ventricular filling time limits increases in stroke volume, and increasing cardiac output becomes dependent on heart rate.

Peripherally, there is also vasodilatation of the vascular beds in the working muscles, as well as vasoconstriction in other organs, such that a greater percentage of the cardiac output is directed toward the exercising muscle. At rest, only about 15% of the cardiac output is directed to muscle; however, with intense aerobic exercise in trained athletes, muscles may receive as much as 60% to 70% of the cardiac output.

Respiratory

This increase in cardiac output also requires the lungs to accommodate markedly increased blood flow. Fortunately, with exercise, pulmonary vessels dilate and distend, resulting in a decline in vascular resistance. This enables the lung to accept the increased blood volume pumped by the heart without significantly increasing pulmonary vascular pressure or sacrificing gas exchange.

During exercise, minute ventilation increases due to an increase in both tidal volume and respiratory rate. With intense exercise, tidal volume may be up to 70% of the vital capacity. Respiratory rate, which was ±12 at rest, can be as high as 55 in healthy adults and >60 in children. Accessory muscles of respiration, including the abdominal, neck, and other chest wall muscles, are recruited during both inspiration and expiration. Exhalation, which was passive at rest, becomes an active process.

With exercise, carbon dioxide production increases in working muscle. However, the rise in ventilation is well matched to metabolic demand, and as a result, arterial carbon dioxide levels remain constant. Oxygen saturation also typically remains constant; however, highly trained athletes may desaturate during exercise as a result of ventilation/perfusion mismatch and diffusion limitation.

While the human body is capable of responding rapidly to increased work demands, this capacity is not unlimited. Typically, at maximal exercise, individuals are limited by cardiovascular capacity. Although training will improve the capacity to pump blood to the working muscles, ultimately, training cannot completely overcome this limitation, and most athletes remain cardiovascularly limited and have a respiratory reserve at maximal exercise.

Careers in Sports Medicine

The athlete is at the center of the sports medicine environment. Athletic success may be measured by wins and losses, individual or team championships, or merely active participation. The professionals who serve athletes should have the health, safety, and participation success of athletes as their priority.

Certified Athletic Trainer

The certified athletic trainer (ATC) may be described as the "hub of the wheel" in the treatment of competitive athletes. The ATC works with the athlete on a daily basis and is often the link between the athlete and the physician, coaching staff, physical therapist, and media.

Certification for an athletic trainer includes earning a bachelor's or master's degree from an accredited athletic training curriculum. Formal training in injury/illness prevention, emergency and first aid, triage of injury/illness, therapeutic modalities, rehabilitation, and return-to-play decisions are part of the athletic trainer's educational background. Close to 70% of athletic trainers have a master's or a doctoral degree.

Physician

Physicians play a crucial role in the treatment of athletes and in assisting them in accomplishing their athletic goals. Physicians from any branch of medicine may be important in the athlete's life, but primary care and orthopedic surgeons are the main contributors. Physicians may complete their education in an allopathic (MD) or osteopathic (DO) medical school.

Primary Care

Primary care team physicians come from the specialties of family medicine, internal medicine, pediatrics, emergency medicine, and physical medicine and rehabilitation. At the intercollegiate and professional levels, the primary care team physicians, in collaboration with the athletic training staff, coordinate preparticipation physical exams and care for general medical issues and nonsurgical musculoskeletal injuries. Often, the primary care team physician evaluates the injuries and illness triaged by the athletic training staff, treats those in his or her specialty, and coordinates referral to the orthopedic surgeon or sports medicine advisory staff.

Completion of a primary care sports medicine fellowship and obtaining a Certification of Added Qualifications in Sports Medicine along with clinical experience distinguishes the physician as one qualified to appropriately treat athletes.

Family Medicine

Family physicians treat the total health of the individual and family primarily in an outpatient setting. Family practitioners receive training in internal medicine, pediatrics, surgery, obstetrics and gynecology, and electives in many other medical specialties.

Internal Medicine

Internists primarily treat older adults. They are trained to diagnose and care for severe chronic illnesses and conditions in which several illnesses occur at the same time. Internists do much of their work in hospitals because of the severity of their patients' illnesses.

Pediatrics

Pediatricians diagnose and treat conditions in infants, children, and adolescents. Many pediatricians limit their practice to treating 14- to 18-year-olds.

Emergency Medicine

Emergency medicine physicians diagnose and treat acute illnesses and injuries that need immediate medical attention. They are competent in a variety of medical fields and are educated in numerous procedural skills to stabilize patients for further care. They treat most of their patients in hospital emergency rooms.

Physical Medicine and Rehabilitation

Physiatrists are physicians who treat disability caused by sports injury, spinal cord injury, brain injury, or other conditions causing pain. They restore function by designing treatment strategies through the combined use of medications, physical modalities, electrodiagnostics, physical training with therapeutic exercise, modification of movement and activities, adaptive equipment and assistive devices, orthotics (braces), prostheses, and experiential training approaches.

Orthopedic Surgery

Orthopedists are surgeons who specialize in the musculoskeletal system. Many orthopedists elect to subspecialize in a branch of orthopedic surgery, such as surgical sports medicine, hand surgery, shoulder and ankle surgery, foot and ankle surgery, pediatric orthopedics, orthopedic trauma, or total joint reconstruction.

Sports Medicine Advisory Team

Many sports organizations use a "sports medicine advisory team," though the terminology may differ depending on the institution. This is a group of physicians chosen by the primary members of the sports medicine team (athletic trainer, primary care team physician, and orthopedic surgeon). It comprises physicians who provide expertise beyond the specialties of the primary members. This includes dentists, cardiologists, pulmonologists, gastroenterologists, neurologists, neurosurgeons, and radiologists, among others. Because of the urgency to return athletes to the field of play, these individuals agree to see athletes on a timely basis and communicate promptly to the health care team.

Undergraduate and medical school, residency and fellowship training, and specialty certification examinations all provide the educational foundation for physicians and allied health professionals, but experience in the treatment of athletes is the most important factor in successful sports medicine care.

Other Allied Health Professionals

Physical Therapists

Physical therapy or "physiotherapy" is the specialty that uses functional movement to restore health. This includes range of motion, strength, balance, proprioception, joint mobilization and manipulation, neuromuscular reeducation, therapeutic exercise, and use of modalities to prevent, treat, or rehabilitate injury.

Chiropractors

Chiropractors are health care professionals who diagnose and treat mechanical disorders of the musculoskeletal system, with special emphasis on the spine. They use manual therapy, soft tissue and spinal manipulation, exercise, and lifestyle counseling without the use of medicine or surgery.

Sport Psychologists

Sport psychologists use mental factors to manage emotions and increase performance or overcome poor performance. The skills used include relaxation, goal setting, self-awareness, concentration, control, relaxation, self-talk, and use of rituals.

Nurse Practitioners

Nurse practitioners (NPs) are registered nurses who have completed advanced nursing education and training to diagnose, manage, and treat medical conditions. Generally, they have completed a master's degree. Many are certified in specialty care. They can practice independently or in conjunction with a physician.

Physician's Assistants

Physician's assistants (PAs) are clinical practitioners who practice medicine under the supervision of a licensed physician. PA school is 2 to 3 years in duration, as opposed to the traditional 4 years of medical school. In addition, PAs are not required to do a residency like physicians are.

Medical Assistants

Medical assistants (MAs) are health care workers who perform clinical or administrative functions in the office of a health care professional. They are not licensed to treat patients but often assist the physician in coordinating the care of the patient. They receive their formal education in vocational schools, technical institutes, or community colleges or through online educational programs.

Nutritionists and Dietitians

Sports nutritionists assist athletes with regard to diet and nutrition. Whereas special licensing is not required to provide nutritional advice, dietitians are professionals who have passed an exam and have completed strict criteria to be registered with the American Dietetic Association. Athletes require nutritional balance to perform at their best; this involves optimal caloric intake, correction of nutritional deficits, and nutrient manipulation.

Radiologic Technologists

Radiographers are health care professionals who create medical images of the body to assist the health care providers in diagnosis of and treatment of injury and illness. Examples include diagnostic radiography (X-ray), ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine.

Exercise Physiologists

Exercise physiology is a health care discipline that studies how exercise affects the function and structure of the human body. Exercise physiologists design physical fitness programs to prevent disease and disability, do exercise testing and cardiac rehabilitation, and are involved in research activities to improve performance.

Carpal Fractures

The *carpal bones* allow the wrist to move and rotate both horizontally and vertically. Within the wrist, these bones form two rows. The most proximal row, which is closest to the forearm, has four bones in it. These bones, starting from the lateral side of the wrist and moving medially, include the scaphoid, lunate, triquetrum, and pisiform. The distal row, which is closest to the metacarpals, includes the trapezium, trapezoid, capitate, and hamate. All have multiple ligaments that attach to them on the front, or palmar surface, and the back, or dorsal surface.

The carpal bones can be fractured from a direct strike or from falling on an outstretched hand. For instance, football linemen can fracture their scaphoid or dislocate their carpal bones when pushing off or against defending players. Patients who sustain carpal fractures often have considerable pain in their wrist and/or hand area. There can be swelling and bruising associated with this injury. Patients may be unwilling to move their wrist or fingers.

If this type of injury is suspected, initial management of the patient is to apply a splint to the affected wrist so that it is immobilized. Ice and elevation of the extremity to the level of the heart or just slightly above often help keep swelling under control. If a carpal fracture is suspected, an X-ray must be obtained.

Specific Types of Carpal Fractures

Scaphoid

In athletes, the carpal bone that is most commonly fractured is the scaphoid. The scaphoid is located on the thumb side of the hand, within the anatomic snuffbox. These fractures most often occur from a fall on an extended wrist, which is not uncommon in soccer and football. Scaphoid fractures are less common in children, but they certainly can occur. Often this fracture does not seem like a serious injury and is initially written off as a wrist sprain. Any tenderness in the anatomic snuffbox, however, should raise suspicion for a scaphoid fracture. If an athlete has been diagnosed with a wrist sprain and does not seem to be getting better, there may be an underlying fracture.

The scaphoid gets its blood supply through ligaments that attach to it. The blood supply is better to the more distal part of the scaphoid. Blood supply to the more proximal part of the scaphoid is precarious, especially after fracture.

If there is a suspicion of scaphoid fracture, then an X-ray of the hand should be performed. Sometimes, even though an athlete has a scaphoid fracture, the X-ray does not initially show the fracture. Any contact sports athlete or any athlete who has sustained a recent fall and is complaining of radial-side wrist pain should be considered to have a scaphoid fracture until studies have proven otherwise. If the initial X-ray does not show a fracture but a scaphoid fracture is suspected from exam, the wrist is still put in a splint to immobilize the suspected fracture. Other imaging modalities that may help diagnose a fracture are computed tomography (CT) and magnetic resonance imaging (MRI).

If a scaphoid fracture is diagnosed, it should initially be immobilized in a thumb spica splint. Either this will need to be transitioned into a thumb spica cast in 1 to 2 weeks, when swelling subsides, or operative intervention may be needed depending on the location of the fracture or how displaced the fracture is within the scaphoid. This decision will ultimately be made by an orthopedic surgeon, and the athlete should be referred to an orthopedic surgeon if a scaphoid fracture is noted.

Lunate

Lunate fractures are rather rare. The lunate is the bone immediately adjacent to the scaphoid. Acute lunate fractures that are displaced often need surgical intervention to decrease the chance of osteonecrosis and make the wrist more stable. Some lunate fractures can be treated in a cast.

Some athletes may develop avascular necrosis of the lunate, presumably from repetitive trauma to the bone. This has more of an insidious onset and does not have to be related to a specific traumatic event. Its treatment depends on the changes to the lunate, but often surgical intervention is needed.

Triquetrum

Triquetral fractures are often associated with other wrist injuries. This fracture usually happens when the wrist twists or rotates forcefully, causing the bone to shear across the surfaces of the other bones in the wrist. This type of fracture can also happen when an athlete falls with the wrist extended, and it occurs often in skaters.

There are different types of triquetral fractures, some of which need surgical intervention and others that can be treated in a cast. Often, CT scans need to be obtained along with X-rays to fully assess the extent of the fracture. The triquetrum can also dislocate, but this is very rare. If the triquetrum is dislocated, it should be reduced in the emergency department by a trained physician.

Pisiform

Fractures of the pisiform are relatively uncommon, representing only 1% of all carpal bone fractures. Most commonly, this fracture occurs when there is a direct blow overlying the pisiform. Sometimes pisiform fractures can be initially overlooked because most of the time there is some other injury in the wrist, hand, or arm that distracts the patient and the physician from the pain associated with the pisiform fracture. Sometimes, CT scans along with X-rays need to be obtained so that better bony detail can be seen. This aids in the decision-making process for treatment of pisiform fractures. Often pisiform fractures can be treated with a cast, and if they continue to cause chronic pain and disability, then surgery can be performed to remove the pisiform. This causes minimal, if any, disability for the athlete, and the wrist will function fine without the pisiform.

Trapezium

Trapezium fractures are rare and often occur with the first metacarpal and/or the radius broken as well. These fractures can occur from direct injury, such as a direct blow to the trapezium, or by an avulsion mechanism from ligaments pulling on the bone. Patients with these fractures are very tender over the trapezium. On physical exam, this can sometimes be confused with the tenderness associated with scaphoid fractures because of the close proximity of the two bones. Most of the time, these types of fractures can be treated in a thumb spica cast. Usually, the cast is left on for 4 to 6 weeks, and then, removable bracing is worn for a few weeks. Sometimes, these fractures require surgery. These fractures can cause early arthritis at the base of the thumb joint, and later in life, people with these fractures may need further intervention for the arthritis that they develop.

Trapezoid Fractures

The trapezoid is protected in the wrist because it has a lot of strong ligaments that attach to it and keep it in place. Therefore, it is rarely fractured. Sometimes, a trapezoid fracture occurs when a metacarpal is fractured or when the metacarpal bone dislocates and directly impacts the trapezoid. If there is an isolated fracture of the trapezoid that is nondisplaced, it can be treated nonoperatively in a cast. Fractures that are displaced may very well need surgery.

Capitate Fractures

Capitate fractures are often difficult to diagnose and require a high index of suspicion. CT scans and MRI can be helpful in diagnosing these fractures. If these fractures are nondisplaced, they can be treated in a cast; however, displaced fractures often require surgical intervention to ensure proper healing.

Hamate Fractures

Hamate fractures cause pain on the ulnar half of the wrist. There is often swelling and tenderness over the hamate. Often several X-rays with different views of the hand have to be taken to adequately visualize a hamate fracture, and these fractures can be very subtle. Usually, if only the hamate is injured, this fracture can be casted. If the wrist feels unstable or the fracture is displaced, surgery may be needed.

There is a part of the hamate called the hook of the hamate. These fractures can easily be missed even if they are suspected. Athletes with this type of fracture usually have persistent ulnar-sided wrist pain and pain when swinging a golf club, tennis racquet, badminton racquet, or baseball bat or when playing handball. These fractures usually occur in athletes who play baseball, golf, or racquet sports because of how the bat, club, or racquet is held in the hand. These fractures can often be treated in a cast.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most common nerve injury in the upper extremity and one of the most common nerve injuries overall. It is an injury to the median nerve at the wrist, initially causing numbness, tingling, or painful sensations in the thumb, index, middle, and half of the ring fingers. As the injury progresses, it may eventually produce weakness within the affected hand. CTS is more common in women and people who perform repetitive tasks using the wrist. Interestingly, it does not seem to correlate to handedness and is often seen in both hands. However, when present in both hands, it is generally worse in the dominant hand.

Besides our senses, our hands are the primary tools we use to manipulate and interact with our environment. While CTS is not fatal, it can lead to loss of hand function, which can greatly affect the quality of life. For athletes, difficulty or pain in using their hands can greatly impair performance as well as enjoyment of their sport.

Anatomy

The carpal tunnel is located at the wrist. Three of the four walls of the tunnel are created by the carpal (wrist) bones. The remaining wall is made of a thick band of soft tissue called the flexor retinaculum or transverse carpal ligament. Inside the tunnel, there are 10 structures: two tendons that flex each of the four fingers (the flexor digitorum superficialis and flexor digitorum profundus), one that flexes the thumb (flexor pollicis longus), and, last, the median nerve.

Causes

Compression of the nerve within the tunnel has classically been thought to cause CTS. This is partially correct, although the exact mechanism that causes CTS remains subject to debate. Compression of the wrist elevates pressure within the carpal tunnel; studies have documented nearly three to four times greater elevation in pressure with wrist flexion compared with rest. It is thought that the pressure results in ischemia (obstructed blood flow) to the nerve. The lack of blood flow to the nerve produces local injury, which results in slowed transmission over that area of the nerve. This impaired signal transduction produces the classic CTS symptoms. Of all the structures traveling through the tunnel, the median nerve is the most sensitive to changes in blood flow.

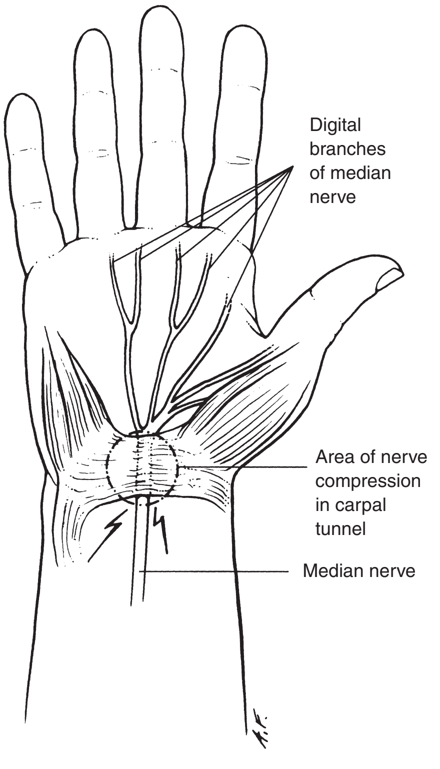

Figure 1 Carpal Tunnel Syndrome

Notes: A buildup of pressure in the carpal tunnel on the underside of the wrist can compress the median nerve that travels through this narrow channel. Carpal tunnel syndrome is the most common nerve entrapment problem in sports.

There are several risks for development of CTS, including genetic, social, and vocational. Some specific factors include diabetes, hypothyroid, wrist fractures, tumors within the tunnel, wheelchair use, and pregnancy. Environmental factors can also increase the risk of CTS. These include vibration, extreme or awkward wrist positioning (wrist flexion, wrist extension, or forceful movement at the wrist), and pressure over the carpal tunnel. There is a great deal of debate as to whether keyboard use increases the risk. Recent studies indicate that there does not appear to be any increased risk for athletes versus the general population. It is important to note that the above factors may be associated with CTS but do not and should not imply causation.

Direct trauma to the wrist can create an acute CTS, and although it is uncommon, it is important to consider in athletes participating in contact sports. More often, the repetitive movements at the wrist in sports create symptoms over time; this is most commonly seen in racquetball, tennis, golf, and bowling.

Symptoms

The median nerve is responsible for supplying innervation to several muscles within the forearm and the hand. The nerve also provides sensation to the thumb, index, middle, and half of the ring fingers. Typically, the first CTS symptoms are *paresthesias* (an unpleasant sensation described as numbness, tingling, or "falling asleep"). Most commonly, this affects the thumb, index, and middle fingers. As CTS progresses to involve the portion of the nerve controlling the muscles, there may be weakness in the hand, most often manifested as a tendency to drop objects. As the ischemia continues, the autonomic nerve fibers can also be affected. Frequently, this is reported as a change in temperature (being hot or cold all the time) or skin color or a feeling of swelling and tightness. It is speculated that when the autonomic fibers are affected, the distribution of paresthesias becomes vague, affecting the entire hand.

Pain can also be reported, most frequently at the wrist, and can extend into the forearm or palm. This pain is not reproducible with palpation to the area. As paresthesias progress, they can transition to a painful sensation (dysesthesia).

CTS symptoms are often present at night, awakening patients due to the paresthesias within the hand. Frequently, they will wake to shake their hand for relief (flick sign). Other activities, including driving, tight gripping, or holding a vibrating object can also produce symptoms.

Diagnosis

CTS is diagnosed by history and physical evaluation; electromyography (EMG) is used to confirm and grade the diagnosis. There are examination maneuvers that are suggestive but not diagnostic for CTS. Tinel and Phalen tests are two such tests that may reproduce symptoms, although the sensitivity and specificity of these is not high. In fact, studies have shown that the presence of a flick sign in the history is as specific and sensitive as Tinel or Phalen testing.

Imaging studies are of limited benefit. Magnetic resonance imaging (MRI) can be helpful in identifying tumors within the tunnel. Occasionally, MRI does show signal abnormality within the nerve, although this does not correlate to diagnosis or severity.

Electrodiagnostic testing consists of nerve conduction studies (NCS) and an electromyographic needle examination. Electrodiagnostic testing is typically referred to as EMG testing. NCS measure several characteristics of the nerve: onset, amplitude, and speed of response. Comparing these characteristics (especially the onset of response) of the median nerve with preestablished normal values, as well as with nerves (in the arm) that do not travel through the carpal tunnel, can assist in diagnosing and grading CTS. These characteristics of nerve function can be affected by age, height, temperature, and other factors that must be accounted for at the time of the study. The electromyographic testing involves a small disposable needle that is used to test muscles innervated by the median nerve after it travels through the carpal tunnel. This is helpful in grading and assessing the severity of the CTS. At the time of this writing, there is no widely accepted grading for EMG, and each individual EMG lab has its own differentiation criteria for mild, moderate, and severe CTS.

It is important to note that the above symptoms correlate to "textbook" cases of CTS, which are relatively uncommon. The range of symptoms and findings is quite large and often misleading in the diagnosis of CTS. Failure to diagnose can lead to irreversible nerve damage, and for this reason, EMG testing is strongly recommended.

Nonsurgical Treatment

A variety of oral medications, icing, and physical therapy techniques have been studied for the management of CTS; however, none have been shown to be effective. Modification of behavior to avoid activities that produce symptoms is the mainstay of initial treatment. Carpal tunnel splints that keep the wrist in a neutral position are available and can provide a great deal of relief from symptoms. For athletes, splinting at rest is tolerated; however, with activity, splinting is generally poorly tolerated. Prolonged rest (avoidance of painful behaviors) may help with the immediate symptoms but does not change the underlying pathology, and symptoms typically return with resumption of activity.

Injection of a steroid, which is an anti-inflammatory medication, within the carpal tunnel has been shown to be effective in symptom relief and can retard progression of CTS on EMG studies.

Surgical Treatment

Despite conservative treatment options, CTS can progress. If one continues to have symptoms despite conservative treatment, surgery is often recommended. Surgery is nonemergent and can be scheduled during a period of downtime (off-season), unless there are severe findings on testing. Surgical release of the transverse carpal ligament can be performed open or endoscopically (minimally invasive). Functional outcomes and relief of symptoms are nearly identical in the two procedures. Endoscopic release is associated with a slightly quicker return to full activity (including work) but also an increased risk of nerve injury. Return to full activity after surgery depends on surgeon preference and is tailored to each individual case but is generally within 2 to 4 weeks. In athletes, frequent pressure loads are placed in this high-tension area, and return to full athletic activity usually takes several weeks longer. Recurrence after surgery is extremely uncommon.

Casting and Immobilization

This entry describes casting and immobilization techniques for the injured athlete. Of the various types of casting and splinting materials used to immobilize the affected area, the two most commonly used today are plaster of paris and fiberglass. These materials come in both individual rolls (approximately 5 yards [4.57 meters] in length) and prefabricated layered rolls with padding that can be cut to length. These are available in various widths so that the affected part of the body is immobilized properly.

Splints are used immediately after the injury occurs or following surgery. Splinting is a way to immobilize the affected area and allow for swelling without compromising circulation. The splint, unlike a cast, is not circumferential and is usually placed on both the medial and the lateral side of the affected area and held in place with an elastic wrap. Many physicians prefer to use plaster of paris for splinting, owing to the greater moldability of plaster compared with fiberglass. This is true when one is trying to reduce or realign a fracture. Plaster allows a nice mold, relatively smooth against the skin, in whatever position is needed, whereas fiberglass tends to harden, with bumps and ridges that could cause irritation and other problems in the skin.

A cast is usually applied 7 to 10 days after the injury. This allows the swelling of the surrounding soft tissue to go down so that a solid cast can be applied for the remainder of the time needed for the injury to heal. If a cast is applied initially, it is a common practice to "bivalve" or split the cast with a cast saw to allow for swelling. The patient would then return for a final layer of material to make the cast solid.

In applying either a splint or a cast, the position of the affected area is extremely important. This is usually in an anatomic or neutral position, unless specified otherwise by the physician. *Note:* Sometimes the athlete is given approval by the doctor to return to sports while in the cast (usually a hand or arm cast). This could change the normal length or position of the cast. An example of this would be to apply a cast that would allow a hockey player to fit the cast or splint inside his or her glove and still be able to have a grip.

Types of Immobilization

The four basic types of casts or splints are short arm, long arm, short leg, and long leg. A short arm cast is mainly used for injuries that involve stable fractures, dislocations, or ligament or tendon injury in the distal radius, ulna, wrist, or fingers. A long arm cast is applied for the unstable injuries described above but includes the elbow or humerus. Including the elbow in the cast or splint will limit the flexion and extension of the elbow and also limit the pronation and supination of the forearm. A short leg cast is used for injuries that involve stable fractures of the distal ends of the tibia and fibula, tarsals, metatarsals, and toes. A long leg cast is applied for the unstable injuries described above but includes the knee or distal femur. Including the knee in the cast or splint will limit the flexion and extension of the knee as well as medial and lateral rotation of the lower leg.

Positioning the Patient

Positioning for a short arm or long arm cast or splint is basically the same. The patient should be sitting down, facing you with the affected arm at a 90° angle at the elbow. The wrist should be in a neutral position, with a slight extension as if shaking hands. The fingers should be spread apart to ensure that the cast is not wrapped too tightly through the hand. Certain types of fractures might require you to change the described position, but this would be specified by the physician ordering the cast or splint. Examples are certain angulations of fractures that tend to shift or unstable fractures that need to be in a position other than neutral.

Positioning for a short leg or long leg cast or splint requires having the patient lie down on his or her back with the knee slightly flexed, thus allowing the calf muscles and Achilles tendon to relax. The ankle should be at a 90° angle or neutral unless otherwise noted by the physician.

Materials Needed

The following materials are needed for casting:

- *Gloves.* The use of gloves prevents chemicals from the plaster or fiberglass from getting on your hands. It also allows you to mold the cast or splint easily.
- *Bucket.* Fill a bucket with tap water. (Warm water will cause the material to set faster.)
- *Stockinet.* This is the first layer applied to the skin. It must lie on the skin smoothly, with no wrinkles. It should be longer than the cast or splint; the ends should be folded back to make a soft cull to keep the cast or splint from rubbing against the skin.
- *Cotton rolls (Webril).* Soft cotton provides the padding between the skin and the casting or splinting material. It should be in no fewer than three to four layers. This should be applied with continuous wrapping and a 50% overlay coverage. Some extra strips should be applied where the ends of the cast or splint will be, as well as over any bony prominences.
- *Waterproof padding.* This is applied in the same manner, only no stockinet is used. It is applied in at least two layers, with extra padding at the ends and over bony prominences. This type of padding is only used with fiberglass, since plaster must not get wet. This allows the patient to shower to rinse away dirt, sweat, and dead, dried skin.
- *Plaster rolls.* These come in different widths, usually 2, 3, 4, or 6 inches (in.; 1 in. = 2.54 centimeters) wide. It is applied with the same type of coverage as the cotton roll and is usually three to four layers thick for casts. If used for splints, it is folded over on itself in the desired length and should be 10 to 15 layers thick for maximum strength.
- *Fiberglass rolls.* The same as described for plaster rolls, only 6 to 10 layers are required for splinting.
- *Bandage scissors.* These are used to cut material to conform around the web space in the thumb and also to cut off excess material and for trimming the cast or splint.
- *Tape.* This is used to cover any rough edges around the toes or thumb. It also can be used on the ends of a cast or splint.
- *Moleskin.* This is a thin adhesive felt that can be cut to size and made to adhere to the outer layer of the cast or splint, where any friction might occur.
- *Cast spreader.* This is used to split a bivalve cast. It allows for swelling.
- *Cast saw.* This is used to trim, bivalve, or remove the cast.
- *Cast knife.* This is used to trim any rough edges of the splint or cast.

Application of Cast and Splint

After positioning the patient as needed, the first layer that is applied is the stockinet. Choose the appropriate size for the affected area. Slide the stockinet over the arm or leg. If the arm is being immobilized, use your scissors to cut a slit for the thumb to come through. On a long arm cast, cut along the crease in the elbow to remove the doubled-up portion of the stockinet. On a leg cast, this cut should be made on the anterior crease of the ankle. The ends should be about 1 to 2 in. longer than where the cast or splint will stop. Remember that the stockinet will be folded over to make a cuff. This will secure the cotton padding and provide a nice cuff so that the cast or splint will not rub on the skin and cause irritation. The next layer applied is the cotton padding. This should be applied in a continuous smooth layer overlapping 50% of the coverage until the area to be casted or splinted has three to four layers of padding. Extra strips of padding are applied at the ends of the cast as well as on any bony prominences (e.g., the thumb, elbow, malleoli, or heel).

Note: If waterproof padding is used, it is applied in the same manner as the cotton padding without the stockinet.

The third and final layer of the cast or splint is either plaster or fiberglass. After donning gloves, open the roll of plaster or fiberglass. While holding onto the roll of material, dip the entire roll into the water until all the bubbles are gone. Squeeze the roll slightly (the more water that is removed from the roll, the faster the cast or splint will set). Begin to wrap the area from distal to proximal, overwrapping a 25% to 50% coverage until three to four layers are applied. This application also needs to be smooth and wrinkle-free. It is very important not to *pull* the material but to *roll* the material on the affected area. On reaching the ends of the area being covered, leave ½ in. of the padding exposed. This will be captured when the stockinet is pulled back over the material to make a cuff. One final layer of material is used to lock down the stockinet and give the cast a smooth finish.

Catastrophic Injuries

Catastrophic sports injuries in any sport are rare but tragic events. This entry reviews the nature of catastrophic sports injuries; the research findings of the National Center for Catastrophic Sports Injury Research (NCCSI), including 25 years of data collection; and the recommendations of the NCCSI and other organizations for prevention of catastrophic injuries in athletes.

The American Football Coaches Association (AFCA) initiated the First Annual Survey of Football Fatalities in 1931, and since 1965, this research has been continued at the University of North Carolina at Chapel Hill. In 1977, the National Collegiate Athletic Association (NCAA) initiated a National Survey of Catastrophic Football Injuries, and as a result, important contributions to the sport of football have been made. Most notable have been the rule changes in 1976 (which eliminated the head as a primary and initial contact area for blocking and tackling), the football helmet standard, improved medical care for the participants, and better coaching techniques.

Due to the success of these projects, research was expanded to include other sports for both men and women, and in 1982, the NCCSI was established at the University of North Carolina at Chapel Hill. Today, the NCCSI conducts research and collects data especially pertaining to the sports of baseball, ice hockey, tennis, basketball, lacrosse, swimming, cross-country running, skiing, volleyball, field hockey, soccer, water polo, football, softball, wrestling, gymnastics, and track-and-field events.

The decision to expand sports research and encompass other sports was based primarily on the following facts:

1. Research based on reliable data is essential if progress is to be made in sports safety.
2. There is a dearth of information on injuries in all sports.
3. There is a lack of injury information in women's sports.

It should also be noted that due to this research, there has been a dramatic reduction in direct fatalities at all levels of play, culminating with no fatalities in 1990. This indisputably illustrates the importance of data collection and analysis and the role that they play in injury prevention.

Definitions

The NCCSI uses the following definitions for its research.

A *catastrophic sports injury* is a sports injury that results in brain or spinal cord injury or skull or spinal fracture. It can be further subclassified as *nonfatal* or *serious*. A nonfatal injury is an injury that results in permanent severe functional (brain or spinal cord) disability, whereas a serious injury is one in which no permanent functional disability occurs, although this may be transient. An example of a serious catastrophic sports injury is a fractured cervical vertebra without permanent paralysis, whereas the same injury with quadriplegia would be classified as nonfatal.

Fatalities are classified as either *direct* (those injuries that result directly from participation in the skills of the sport) or *indirect* (those injuries that are caused by systemic failure as a result of exertion while participating in a sport activity or by a complication that is secondary to a nonfatal injury). The death of an athlete due to cardiac arrhythmias while performing a sporting activity is an example of an indirect fatality.

Research and Data Collection

The NCCSI compiles data through the assistance of coaches, trainers, athletic directors, executive officers of state and national athletic organizations, a national newspaper clipping service, and professional associates of the researchers. After notification of a possible catastrophic sports injury, the NCCSI directly contacts the athlete's coach, trainer, or athletic director. The data collected include demographics, the type and mechanism of injury, the sports equipment involved, and the immediate and subsequent medical care provided. Autopsy reports are used, if necessary. This data collection is supported by the AFCA, NCAA, and the National Federation of State High School Associations (NFHS).

Summary of Data

For the 25-year period from the fall of 1982 through the spring of 2007, there have been 1,068 direct catastrophic injuries in high school and college sports. High school sports were associated with 149 fatalities, 369 nonfatal injuries, and 346 serious injuries, for a total of 864. College sports accounted for 22 fatalities, 63 nonfatal injuries, and 119 serious injuries, for a total of 204. During this same period, there have been a total of 541 indirect injuries, and all but 11 have resulted in death. Of the indirect injuries, 439 were at the high school level and 102 at the college level. It should be noted that high school annual athletic participation (for sports with catastrophic injuries) for 2006–2007 includes approximately 7,445,742 athletes (4,605,347 males and 2,840,395 females). NCAA participation (for sports with catastrophic injuries) for 2006–2007 was 404,728 athletes (245,512 males and 159,216 females).

During the period from the fall of 1982 through the spring of 2007, there were 147,115,293 high school athletes participating in sports that are monitored by the NCCSI. Using these participation numbers would give a high school direct catastrophic injury rate of 0.59 per 100,000 participants. The indirect injury rate is 0.30 per 100,000 participants. If both direct and indirect injuries were combined, the injury rate would be 0.89 per 100,000. This means that approximately 1 high school athlete out of every 100,000 participating would receive some type of catastrophic injury. The combined fatality rate would be 0.39 per 100,000, the nonfatal rate 0.25, and the serious injury rate 0.24.

During this same period, there were approximately 8,029,283 college participants, with a total direct catastrophic injury rate of 2.54 per 100,000 participants. The indirect injury rate is 1.27 per 100,000 participants. If both indirect and direct injuries were combined, the injury rate would be 3.81. The combined fatality rate would be 1.51, the nonfatal rate 0.81, and the serious injury rate 1.49.

High School Sports

Fall

From the fall of 1982 through 2007, high school fall sports resulted in 623 direct fatalities and catastrophic injuries (Table 1), of which 603 were related to football (~97%). Indirect fatalities and catastrophic injuries (Table 2) totaled 230, of which 171 were related to football (~75%). While football had the highest incidence of catastrophic injuries among fall sports, the incidence per 100,000 athletes was still less than 1 (Tables 3 and 4).

Winter

High school winter sports led to a total of 123 direct fatalities and catastrophic injuries (Table 1), of which 58 were related to wresting (~47%) and 19 were related to basketball and ice hockey (~15% each). Indirect fatalities and catastrophic injuries (Table 2) totaled 149, of which 114 were

Note: F = female; M = male; NA = not applicable or not available.

related to basketball (~76%). Although wrestling accounted for the greatest number of direct catastrophic injuries, the incidence rate was less than 1 per 100,000 athletes (Table 3), as were those of basketball and swimming. In contrast, gymnastics and ice hockey had the highest incidence rates per 100,000 (>2 for male gymnasts with direct nonfatal injuries and >1 for male ice hockey players with direct nonfatal and serious injuries).

Spring

From 1982 through 2007, there were 118 direct fatalities and catastrophic injuries in high school spring sports (Table 1), of which 59 were related to track-and-field events (50%) and 47 were related to baseball (~40%). Of the 33 direct fatalities, 20 occurred in track-and-field events (~61%). Of the 58 indirect fatalities (Table 2), 34 were in track-and-field events (~59%) and 14 in baseball (~24%). Direct and indirect fatality and catastrophic injury incidence rates per 100,000 participants (Tables 3 and 4) were <1 for all spring sports, with the highest incidence of indirect fatalities seen in male lacrosse players (0.9 per 100,000 athletes).

College Sports

Fall

During the fall period from 1982 to 2007, there were 139 direct fatalities and catastrophic injuries in college sports (Table 1), of which 133 were related to football (~96%). Of the 49 indirect fatalities, 41 were related to football (~84%; Table 2). The incidence per 100,000 participants for football-related direct fatalities was <1 (Table 3), although the rates were 1.89 and 4.8 for direct nonfatal and direct serious injuries, respectively. The indirect fatality and catastrophic injury incidence per 100,000 athletes (Table 4) was <1 for all sports except for female soccer players (1 fatality per 100,000 athletes) and male football players (2.21 fatalities per 100,000 athletes).

Winter

College winter sports caused 30 direct fatalities and catastrophic injuries (Table 1), 12 of which occurred in ice hockey (40%) and 9 in basketball (30%). There were 41 indirect fatalities (Table 2), of which 28 were related to basketball (~68%). Incidence rates per 100,000 athletes (Table 3) for direct fatalities and catastrophic injuries ranged from 0 (basketball-related direct fatalities in females) to 20.07 (gymnastics-related nonfatal direct catastrophic injuries in males). Indirect fatality rates per 100,000 athletes ranged from 0 in gymnastics (male) to 6.99 in male basketball players and 6.99 in male skiers (Table 4).

Spring

Spring sports among college athletes had 35 direct and catastrophic injuries (Table 1). Of these, 12 were reported in baseball (~34%), 11 in lacrosse (~31%), and 10 in track-and-field events (~28%). The 10 indirect fatalities (Table 2) included 3 in rowing and 2 each in baseball, lacrosse, and tennis. The rate of direct and indirect fatalities and catastrophic injuries was <1 per 100,000 athletes in all college spring sports except lacrosse (Tables 3 and 4).

Injury Prevention in Sports

The data and trends obtained from 1982 through 2007 provide the background for considering sport-specific and general recommendations to help reduce fatality and catastrophic injury rates. Additionally, fatalities and catastrophic injuries in female athletes, especially cheerleaders, deserve particular attention.

Sport-Specific Prevention Recommendations

Football

While the numbers of football-related fatalities and catastrophic injuries have decreased dramatically since 1976, there is still room for improvement, and therefore, further steps are warranted. These steps should emphasize the preventive measures that have already been successful:

1. Continued enforcement of the ban on initial contact with the head in blocking and tackling, along with coaching in the proper skills of blocking and tackling
2. Ongoing research on helmet safety, continuing the effort that led to the establishment of a helmet standard by the National Operating Committee on Standards for Athletic Equipment

3. Improved medical care for injured athletes, including the hiring of athletic trainers and the writing of emergency plans for catastrophic injuries at all high schools and colleges

Specific recommendations from the NCCSI were outlined in the 2007 Annual Survey of Football Injury Research (1931–2007). These recommendations include the following:

1. Mandatory medical examinations and medical history should be taken before allowing an athlete to participate in football. The NCAA recommends a thorough medical examination when the athlete first enters the college athletic program and an annual health history update with use of referral exams when warranted. If the physician or coach has any questions about the athlete's readiness to participate, the athlete should not be allowed to play. High school coaches should follow the recommendations set by their State High School Athletic Associations.
2. All personnel concerned with training football athletes should emphasize proper, gradual, and complete physical conditioning. Particular emphasis should be placed on neck-strengthening exercises.
3. A physician should be present at all games and practice sessions. If it is impossible for a physician to be present at all practice sessions, emergency measures must be provided. Written emergency procedures are recommended for both coaches and medical staff.
4. All personnel associated with football participation should be cognizant of the problems and safety measures related to physical activity in hot weather.
5. Each institution should strive to have a team trainer who is a regular member of the faculty and is adequately prepared and qualified.
6. A cooperative liaison should be maintained by all groups interested in the field of athletic medicine (coaches, trainers, physicians, manufacturers, administrators, etc.).
7. There should be strict enforcement of game rules, and administrative regulations should be enforced to protect the health of the athlete. Coaches and school officials must support the game officials in their conduct of athletic contests.
8. There should be a renewed emphasis on employing well-trained athletic personnel, providing excellent facilities, and securing the safest and best equipment possible.
9. There should be continued research concerning the safety factor in football (rules, facilities, equipment, etc.).
10. Coaches should continue to teach and emphasize the proper fundamentals of blocking and tackling to help reduce head and neck fatalities.
11. Strict enforcement of the rules of the game by both coaches and officials will help reduce serious injuries. Be aware of the 2005 rule change to the 1976 definition of spearing.
12. When a player experiences or shows signs of head trauma (loss of consciousness, visual disturbances, headache, inability to walk correctly, obvious disorientation, memory loss), he or she should receive immediate medical attention and should not be allowed to return to practice or the game without permission from the proper medical authorities.
13. The number of indirect heart-related deaths has increased over the years, and it is recommended that schools have automated external defibrillators (AEDs) available for emergency situations.

Other recommendations from the NCCSI were outlined in the 2007 Annual Survey of Catastrophic Football Injuries (1977–2007). These recommendations include the following:

1. Brain and spinal injuries in football have been dramatically reduced since the rules were changed in 1976 to prohibit butt blocking and face tackling and other techniques in which the helmet and face mask purposely received the brunt of the initial impact. There are still a small number of football players who became paralyzed due to cervical cord injury. Because head contact largely caused these injuries, it is important to remember to keep the head and the face out of the way during blocking and tackling. Coaches should drill the players in the proper execution of the fundamentals of football—particularly blocking and tackling. Shoulder block and tackle with the head up. Keep the head out of range of the football.
2. Preseason physical exams should be taken for all participants. Identify during the physical exam

those athletes with a history of previous brain or spinal injuries. If the physician has any questions about the athlete's readiness to participate, the athlete should not be allowed to play.

3. Athletes must be given proper conditioning exercises that will strengthen their necks to enable them to hold their heads firmly erect while making contact during a tackle or block. Strengthening of the neck muscles may also protect the neck from injury.
4. Coaches and officials should discourage the players from using their heads as battering rams when blocking, tackling, and ball carrying. The rules prohibiting spearing should be enforced in practice and in games. The players should be taught to respect the helmet as a protective device and that the helmet should not be used as a weapon. Ball carriers should also be taught not to lower their heads when making contact with the tackler.
5. Football officials can play a major role in reducing catastrophic football injuries. The use of the helmet/face mask to make initial contact while blocking and tackling is illegal and should be called for a penalty. If more of these penalties are called, there is no doubt that both players and coaches will get the message and discontinue this type of play. A reduction in helmet/face mask contact will result in a reduction of catastrophic football injuries.
6. All coaches, physicians, and trainers should take special care to see that the players' equipment is properly fitted, particularly the helmet.
7. It is important, whenever possible, for a physician to be on the field of play during games and practice. When this is not possible, arrangements must be made in advance to obtain a physician's immediate services when emergencies arise. Each institution should have a team trainer who is a regular member of the institution's staff and who is qualified in the emergency care of injuries, both in treating and in preventing them.
8. Coaches must be prepared for a possible catastrophic head or neck injury. The entire staff must know what to do. Being prepared and knowing what to do may be the difference that prevents permanent disability. Have a written emergency plan and give copies to all personnel.
9. When a player experiences or shows signs of head trauma (loss of consciousness, visual disturbances, headache, inability to walk correctly, obvious disorientation, memory loss), he or she should receive immediate medical attention and should not be allowed to return to practice or games without permission from the proper medical authorities.
10. Coaches should encourage players to let them know if they have any of the aforementioned symptoms (especially those that are not apparent to others, e.g., headaches) and instruct them on why it is important to do so.
11. Both past and present data show that the football helmet does not cause cervical spine injuries but that poorly executed tackling and blocking are the major problem.

Although catastrophic injuries in football may never be totally eliminated, continued research has resulted in rule changes, equipment standards, improved medical care, and changes in the fundamental techniques of the game.

Soccer

It should be noted that from 1979 to 2008, according to the U.S. Consumer Product Safety Commission (CPSC), there have been 34 deaths and 51 injuries from movable soccer goals. Safety measures include anchoring the goals, warning players to avoid climbing on them, and using proper moving, maintenance, and storage techniques. Guidelines for movable soccer goal safety are available from the CPSC at http://www.cpsc.gov/cpscpub/pubs/5118.html.

Wrestling

High school and college wrestling resulted in 82 direct fatalities and catastrophic injuries between 1982 and 2007. Since only four of these occurred at the college level, continued research should focus on high school wrestling. High school coaches should be well versed in the skills of the sport as well as proper conditioning techniques and safety measures; physical education teachers also need training in wrestling skills. Physical education classes should include full-speed wrestling only if sufficient time is available to teach conditioning and skills. Another important issue is improper weight reduction, which can lead to serious injury or death. During the 1997–1998 academic year, there were three college wrestlers who died of heat stroke complications while trying to make weight for a match. These were the first wrestling deaths associated with weight reduction; however, there is no information on the number of wrestlers who had medical problems associated with weight loss but recovered. Making weight has always been a part of the wrestling culture, but it is dangerous and life threatening. A significant rule change approved by the NFHS Board of Directors in April 2005 states that in 2006–2007 stronger guidelines discouraging rapid weight loss will take effect. The revised rule states that specific gravity should not exceed 1.025, body fat assessment should be no lower than 7% in males and 12% in females, and a monitored, weekly weight loss plan should not exceed 1.5% per week.

Gymnastics

Since male and female gymnasts have high injury rates in high school (13 out of 20) and college, injury mechanisms and preventive measures should be investigated further at both levels. Both levels have seen a dramatic reduction in participation, and this trend may continue, particularly in private clubs.

Ice Hockey

While the absolute number of ice hockey injuries in high school and college is low (31 direct and 6 indirect fatalities and catastrophic injuries), the fatality and catastrophic injury rates per 100,000 participants are higher than in many other sports (1.05 indirect fatalities per 100,000 male college ice hockey players and 4.18 direct nonfatal and 7.32 direct serious catastrophic injuries per 100,000 male college ice hockey players). Catastrophic injuries in ice hockey usually occur when an athlete is struck from behind or falls and hits the crown of his or her head on the boards, resulting in a fractured cervical vertebrae and paralysis. Tator and colleagues, who did an extensive survey on catastrophic injuries in Canadian ice hockey that was published in the *Canadian Journal of Surgery* in 1999, recommended the following:

1. Enforce current rules, and consider new rules against pushing or checking from behind.
2. Develop conditioning programs to help players strengthen their neck muscles.
3. Instruct players about the risk of neck injury.
4. Continue epidemiologic research.

Swimming

All catastrophic injuries in swimming have occurred when swimmers struck their head on the pool bottom while doing a racing dive in the shallow end. After the swimming community was made aware of this fact, the rules were changed. Rules to ensure that there is adequate depth when swimmers enter the water were created by the NFHS Swimming and Diving Rules Committee in the early 1990s. The NFHS Swimming and Diving Rules Book (Rule 2–7-2) states that in pools with water depth less than 3.5 feet (ft; 1 ft = 30.48 centimeters [cm]) at the starting end, swimmers will have to start the race in the water. The rules read that in 4 ft or more of water, swimmers may use a starting platform up to a maximum of 30 inches (in.; 1 in. = 2.54 cm) above the water and the pool depth shall be measured for a distance of 16 ft 5 in. from the end wall. Between 3.5 and 4 ft, swimmers start from the pool deck or in the water. The NCAA and USA Swimming have or are in the process of changing the standard for the use of starting blocks to a minimum depth of 5 ft. In April 1995, the NFHS revised Rule 2–7-2, which now states that starting platforms shall be securely attached to the deck or wall in pools with water depth of 4 ft or more in the starting end. If they are not, they shall not be used, and deck or in-water starts will be required. These new rules point out the importance of constant data collection and analysis. Rules and equipment changes for safety reasons must be based on reliable injury data. The NCCSI has not received any information concerning direct catastrophic swimming injuries in high school or college during the 2006–2007 season. NFHS guidelines for swimming are available at http://www.nfhs.org.

Baseball

From 1982 to 2007, high school baseball has caused 47 direct fatalities and catastrophic injuries. Most of these injuries occurred during a head-first slide or when a player was struck with a thrown or batted ball. If the head-first slide is to be allowed in high school, coaches must teach players the safest ways to execute this maneuver. Proper protection should be provided for the pitcher during batting practice, and he or she should always wear a helmet. This should also be true for the batting practice coach. During the 2007 baseball season, three high school pitchers were struck in the head with batted balls. One pitcher recovered, one injury was nonfatal at the time of writing, and one pitcher died. One injury took place in a scrimmage game, one in batting practice, and one in a batting cage. A new rule in fast-pitch softball will require players to wear batting helmets equipped with face masks/guards that meet the standards set by the National Operating Committee for Standards in Athletic Equipment (NOCSAE). The rule came into effect on January 1, 2006.

Track-and-Field Events

From 1982 through 2007, high school track-and-field events resulted in 20 direct fatalities and 39 catastrophic injuries. The pole vault was associated with the majority of the fatal track injuries. There have been 18 high school and college fatal pole-vaulting injuries from 1983 to 2006. In addition to the fatalities, there were also 11 permanent disabilities (8 in high school and 3 in college) and 7 serious injuries (5 high school, 1 college, and 1 middle school). All 36 of these accidents involved the vaulter bouncing out of or landing out of the pit area. The three pole-vaulting deaths in 1983 were a major concern, and immediate measures were taken by the NFHS. Beginning with the 1987 season, all individual units in the pole vault–landing area had to include a common cover or pad extending over all sections of the pit. Additional recommendations have been added since. Another contentious issue is that of pole vaulters being required to wear helmets. While many high school associations have or are considering mandatory use of the helmet, the NCAA has reserved it as a personal option to be decided by the athlete.

There have also been 23 accidents in high school track involving participants being struck by a thrown discus, shot put, or javelin. Good risk management and safety precautions must be stressed for these events in both practice and competitive meets to prevent this type of accident. The NFHS put a new rule in place for the 1993 track season that fenced off the back and sides of the discus circle to help eliminate this type of accident.

Lacrosse

Only one direct death (and no catastrophic injuries) has occurred in high school lacrosse. The fatality occurred when a player struck an opponent with the top of his helmet. This technique is prohibited by the lacrosse rules and should be strictly enforced. Lacrosse has been a fairly safe sport when considering the fact that high school lacrosse has been involved in only nine direct catastrophic injuries in 25 years. A possible new area of concern is the recent lacrosse deaths associated with players being struck in the chest with the ball, causing death, a phenomenon known as *commotio cordis*.

Commotio cordis is the uneventful consequence of a concussion of the heart from nonpenetrating blunt trauma to the anterior chest. On occasion, it can lead to fatal cardiac arrest, due to either myocardial trauma or the mechanoelectrical triggering of a ventricular tachyarrhythmia. Commotio cordis was first described in 1932 in large rabbits, but later on, it came to the attention of clinicians who encountered children dying suddenly from a chest blow while engaging in sports activities. Although reported at a wide range of ages (3 months to 50 years), commotio cordis typically afflicts children and adolescents (mean age 13 years) because the young have narrow, pliable chest walls that facilitate transmission of energy from the chest impact to the myocardium. Most events are caused by blows from "projectiles," such as baseballs or lacrosse balls, with a substantial proportion occurring despite the use of a chest protector. Activation of the sympathetic nervous system has been proposed as a potential mechanism of sudden death in commotio cordis. However, in an experimental model, autonomic blockade has no effect on the frequency of sudden cardiac death (SCD), polymorphic ventricular tachycardia, or ST segment elevation. It has been further confirmed that vagotonic and sympathetic surges do not provide a major pathogenetic contribution to the syndrome of SCD due to chest blows. Therefore, commotio cordis can cause SCD by acute initiation of ventricular fibrillation. Particularly, baseball impacts induce ventricular fibrillation when directed at the center of the left ventricle during the vulnerable part of repolarization just prior to the T-wave peak.

There have been seven cases of commotio cordis (two high school, one high school club, three college, and one summer camp) since 1996. Currently, there is research being funded by the NOCSAE for the study of chest protectors to help reduce commotio cordis–related fatalities. Following injury to a female lacrosse player in 2003, protective eyewear was required for all high school participants in the states that follow NFHS rules and for all competitors at the NCAA championships. In 2005, the requirement was extended to the entire season for all NCAA teams. Early reports indicate a major reduction in eye injuries for female lacrosse players. Injury rates are slightly higher in college lacrosse, but the participation figures are so low that even one injury will increase the incidence rate dramatically. It is important to point out that there have been nine male and two female college lacrosse players with catastrophic injuries during the past 25 years. There were no direct or indirect injuries to college lacrosse players in the 2006–2007 academic year.

Cheerleading

The NCCSI has been collecting cheerleading catastrophic injury data during the past 25 years (see Tables 1 and 2). There were two college and one high school cheerleading catastrophic injuries during 2006–2007. Cheerleading has changed dramatically and now has two distinctive purposes: (1) of a service-oriented leader of cheer on the sideline and (2) as a highly skilled competing athlete.

A number of high schools and colleges across the United States have limited the types of stunts that can be attempted by their cheerleaders. Rules and safety guidelines now apply to both practice and competition. As stated in the *25th Annual Report on Catastrophic Injuries,* published by the NCCSI in 2007, high school and college cheerleaders account for more than half of the catastrophic injuries to female athletes. Inexperienced and untrained coaches should not attempt to teach stunts with a higher level of difficulty than their team is capable of achieving or they have the knowledge and ability to teach. The following is a list of sample guidelines that may help prevent cheerleading injuries:

1. Cheerleaders should have a medical examination done before they are allowed to participate. A complete medical history should be included.
2. Cheerleaders should be trained by a qualified coach with training in gymnastics and partner stunting. This person should also be trained in the proper methods for spotting and other safety factors.
3. Cheerleaders should be exposed to proper conditioning programs and trained in proper spotting techniques.
4. Cheerleaders should receive proper training before attempting gymnastics and partner-type stunts and should not attempt stunts they are not capable of completing. A qualification system demonstrating mastery of stunts is recommended.
5. Coaches should supervise all practice sessions in a safe facility.
6. Mini trampolines and flips or falls off of pyramids and shoulders should be prohibited.
7. Too high pyramids should not be performed without mats and other safety precautions.
8. If it is not possible to have a physician or certified athletic trainer at games and practice sessions, emergency procedures must be provided. The emergency procedure should be in writing and available to all staff and athletes.
9. There should be continued research concerning safety in cheerleading.
10. When a cheerleader experiences or shows signs of head trauma (loss of consciousness, visual disturbances, headache, inability to walk correctly, obvious disorientation, memory loss), she or he should receive immediate medical attention and should not be allowed to practice or cheer without permission from the proper medical authorities.
11. Cheerleading coaches should have some type of safety certification. The American Association of Cheerleading Coaches and Advisors offers this certification.

It is the opinion of the NCCSI that following cheerleading rules and safety manual guidelines that are written by cheerleading experts is an

Catastrophic Injury Prevention Recommendations

- All athletes should be required to undergo a preparticipation physical examination.
- All schools should provide teams with a qualified trainer; accessible, written emergency procedures; and excellent and safe facilities and equipment.
- Coaches should be well trained in physical conditioning, the skills of their sport, and the risks of injury and be able to teach these effectively to young athletes.
- Game officials must enforce the rules strictly, and coaches should support officials' efforts to conduct safe competitions.
- In addition, continued sports-related research will provide the injury data and analysis necessary to formulate changes in rules, facilities, and equipment to help prevent tragedies.

excellent way to help prevent injuries during cheerleading. The new restrictions can be found on the American Association of Cheerleading Coaches and Administrators (AACCA) website, http://www.aacca.org.

General Prevention Recommendations

Besides the above-mentioned sport-specific considerations, the data collected by the NCCSI also suggest the above general safety recommendations.

Cervical and Thoracic Disk Disease

The spine, commonly known as the "backbone," extends from the skull to the pelvis and forms the vertical axis of the skeleton. The cervical spine is the portion of the spine that is located in the neck. The thoracic spine is the portion of the spine that is located in the middle back, from the base of the neck to the lowest rib. Cervical disk disease is common, accounting for more than one-third of all spinal disk disease. Thoracic disk disease is less common than cervical disk disease, probably because the ribs limit the amount of movement between these vertebrae, thus decreasing the risk for injury. It accounts for less than 1% of all disk disease.

Anatomy and Pathology

The spine is actually a series of 24 small bones called vertebrae and two large bones called the sacrum and coccyx. The coccyx is commonly referred to as the tailbone. Every vertebra has an anterior vertebral body and a posterior bony arch. The spinal cord extends from the brainstem to the coccyx and passes through this arch with nerves exiting at every level. The cervical spine refers to the 1st through 7th vertebrae. It starts at the base of the skull and ends at the shoulders. The term *thoracic spine* refers to the 12 vertebrae below the cervical vertebrae. It starts at the shoulders and ends at the lower back. The last thoracic vertebra is adjacent to the lowest rib. In between each vertebral body is a gelatin-like cushion, or *disk*, known as the *intervertebral disk*. Each vertebra articulates with the adjacent vertebrae in a tripod fashion, with the disk in front and the two facet joints on the posterior bony arch. The disk comprises an outer annulus and an inner gelatinous component called the *nucleus pulposus* (nucleus). The outer annulus consists of concentric layers of ligamentous sheaths surrounding the nucleus. The majority of load-bearing forces go through the disk, which is there for stability and fluidity of motion. The inner nucleus has some substances that are inflammatory and cause pain when leaked beyond the annulus. The nerve roots exit the spine at each level to innervate specific muscle groups in the extremities and trunk. The cervical nerve roots innervate the muscles of the upper extremities, and the thoracic nerves innervate the chest and abdominal muscles. These nerve roots also serve to give sensation to specific areas on the trunk and extremities. When these nerves are irritated, they tend to send pain in the direction of this sensory distribution and may be associated with specific muscle weakness in this distribution. These radiating symptoms are called radicular symptoms.

When a disk has an acute herniation, the inner nucleus breaks through the ligamentous annulus and may directly compress a nerve root. The herniated disk may cause radicular symptoms due to the mechanical bulk of the disk on the nerve root or the chemical inflammation around the nerve root.

In contrast, disk degeneration is a slow process that involves gradual dehydration of the normally hydrated nucleus as well as breakdown of the surrounding ligamentous annulus. This will appear on a magnetic resonance imaging (MRI) scan as darkening and a diminished disk height. This is believed to be a normal process of aging and is often not associated with any symptoms. Several bony changes may also occur concomitantly. The vertebral bodies above and below the disk may exhibit some swelling, called bony edema, that is seen on an MRI scan. This finding may be associated with pain. Another bony finding with disk degeneration is called the *disk-osteophyte complex*. In this situation, a very slow and gradual disk herniation causes a coexisting bone spur that may press on the nerve root along with the disk material.

Clinical Presentation

Disk degeneration is a common finding, with 25% of those under 30 and 75% of those above 50 showing these changes without any correlation of pain. However, symptomatic disk disease will present differently based on the nature of the disease and its location. The symptoms may be more central (axial pain) or peripheral (radicular pain). Axial pain refers to pain in the posterior head, neck, and shoulders. Radicular pain reflects symptoms in the arms and upper back. It may be associated with numbness, tingling, or a feeling of "pins and needles" in the arms. This phenomenon is known as *paresthesias*. Most readers will be familiar with this as the sensation they experience after sitting with their legs crossed for an extended period or after banging their funny bone. Weakness of the arms may also occur. This indicates that the nerves that supply power to the arm have been affected. Thoracic disk disease will usually manifest as pain in the upper and mid back with some possible radiation to the chest and abdomen. In severe cases, the nerves to the legs may be affected as well as those that control bowel and bladder function.

Clinical Evaluation

History

Cervical disk herniation will usually result in neck pain. If the herniation occurs at or below the fourth cervical vertebra, it may be associated with shoulder or arm pain. In addition, herniation at or below this level may cause paresthesias—numbness, tingling, or a feeling of "pins and needles"—in the arms. Weakness of the shoulder or arm muscles may also occur.

Patients with thoracic disk herniation will most commonly complain of pain. Less commonly, they may have paresthesias, weakness of the core musculature, or a frequent urge to urinate.

Physical Examination

The physical examination begins with inspection: looking for swelling, bruising, abrasion, lacerations, or other evidence of injury. Feeling or palpating the back of the neck and thoracic portion of the spine may reveal tenderness. As disk herniation is often associated with nerve involvement, testing of the sensation, reflexes, and strength of the neck, shoulder, arm, and back is used to help determine whether a nerve is involved. Often, the particular location of the involved nerve can be determined. In patients who show no positive findings in these components of the physical examination, the clinician places the neck or back in various positions and ask the patient if these positions re-create the symptoms. These are called provocative maneuvers and can help determine the underlying cause of the symptoms.

Diagnostic Tests

The information obtained from the history and physical examination is used to decide whether diagnostic tests are necessary. Sometimes, pictures of the spine, the intervertebral disks, the surrounding muscles, and other tissues are useful. X-rays, computed tomography (CT) scans, and MRI scans are all types of images that may be helpful. Electromyograms and nerve conduction studies may sometimes be useful in assessing whether any nerve damage has occurred.

Treatment

Many cervical and thoracic spine injuries can be prevented, in particular by strengthening and increasing the flexibility of the muscles that support the neck and thoracic spine.

However, when symptoms occur, they are initially treated with relative rest by removing the athlete from play and other activities that stress the affected portion of the spine. In addition, immobilization in a brace or collar may be employed for very short periods. Anti-inflammatory medications, the application of ice or heat, and massage may be added to the therapy. Sometimes, traction may be applied to the spine by pulling gently on the head or hips of the patient to take some of the pressure off of the affected disks.

Once the patient's acute pain has resolved or significantly improved, physical therapy focused on strengthening and stretching the muscles that support the neck and thoracic spine will be recommended. If patients have symptoms that persist or recur frequently, injections of corticosteroids into the area of disk disease may be helpful. At times, if none of the above treatments are effective, surgical procedures may be considered.

Return to Sports

Generally accepted guidelines or standards for returning the athlete to sports after management of cervical or thoracic disk disease are incomplete. However, the athlete should be completely symptom-free and should demonstrate a full and painless range of motion and full strength, along with a normal neurologic examination. The physician will also need to determine that there is no severe narrowing (stenosis) around the spinal cord. If all of these are felt to be satisfactory, most athletes may return to play.

Cervical and Thoracic Fractures and Traumatic Instability

While the assessment of each and every athletic injury requires thorough evaluation, the evaluation of possible spinal cord injuries should be especially meticulous and careful. Because the consequences of spinal cord injury can be devastating, there should be little margin for error in its treatment, beginning the instant the injury is sustained. A wide range of such injuries can occur, from sprains to fracture-dislocations with resultant paralysis. This entry will focus on cervical fractures, thoracic fractures, and traumatic instability of the spine.

Initial Evaluation

Any athlete who is suspected of having a spinal cord injury on the field should not be moved until he or she has been adequately immobilized. Symptoms that could indicate spinal cord injury include paresthesias, or numbness, tingling, or "pins and needles"; weakness in the extremities; radiating pain from the site of injury to other body parts; midline neck or back pain; inability to move body parts; or decreased level of consciousness. Athletes who are unconscious should be treated as if they have sustained a spinal cord injury. Athletes should be evaluated for neurological and respiratory compromise. Emergency medical services should be notified, and the patient should be transported to a hospital for further evaluation.

If a spinal cord injury is suspected, adequate immobilization consists of cervical spine (C spine) in-line immobilization with placement of a rigid cervical collar. A logroll maneuver should be used to place the patient on a long spine board. If the injury is sustained during football play, the helmet should *not* be removed if the shoulder pads are on because this hyperextends—stretches beyond the normal range of motion—the neck, and is unacceptable for immobilization purposes. The face mask can be removed using a proper face mask removal tool. Shoulder pads should not be removed on site.

Cervical Spine Fractures, Dislocations, and Instability

C-spine injuries can involve the vertebrae, intervertebral disks, spinal cord, nerves, or ligamentous supporting structures. The C spine consists of seven vertebrae, numbered C1 through C7. C1 is often referred to as the atlas, and C2 is referred to as the axis. There are a wide range of injuries that can occur, from sprains to fracture-dislocations with resultant paralysis. Dislocations and fractures can be categorized as stable or unstable.

Appropriate work-up of possible C-spine injuries includes X-rays and, possibly, computed tomography (CT) and magnetic resonance imaging (MRI) scans. CT scans are best used to provide fine bony detail, whereas MRI scans are superior for assessment of soft tissue injury.

Upper C-spine injuries occur at the junction of the occiput and C spine or the C1 and C2 vertebrae. Two serious types of instability that can occur in this area include occipitocervical injuries and atlantoaxial instability.

Occipitocervical injuries rarely occur in sports and most often are the result of high-speed motor vehicle accidents. These are devastating injuries, and most individuals do not survive. Rigid immobilization until surgery can be performed is mandatory.

Atlantoaxial instability is characterized by excessive movement between the atlas, C1, and the axis, C2. The alar and transverse ligaments are responsible for atlantoaxial stability, and flexion injuries can rupture these structures, causing resultant impingement of the spinal cord. Athletes with this injury complain of neck pain; often torticollis with limited neck motion and can have neurological symptoms. Diagnosis can be made with X-rays of the C spine, and often a CT scan is needed as well.

Common fractures in the upper C spine consist of C1 fractures, odontoid fractures, and hangman's fractures. C1 ring fractures often can be treated with rigid immobilization; the type of rigid immobilization varies from cervical collars to halo vest immobilization depending on the type of fracture that has occurred. Jefferson fractures are a subtype of C1 fractures, which are typified by a four-part break in C1 involving both the anterior and the posterior arches. These fractures can be unstable, and often more aggressive treatment is required, including operative intervention.

Middle and Lower C-Spine Fractures and Dislocations

Fractures and dislocations to the C3-C7 vertebrae can cause a variety of symptoms, including neck pain, transient paresthesias, paralysis, respiratory compromise, and neurogenic shock. Generally, these injuries can consist of facet fracture-dislocations, vertebral fractures, and spinous process fractures. Advanced imaging, such as CT and MRI scans, are often necessary in identifying these injuries.

Facet fracture-dislocations often need reduction by a trained orthopedist or neurosurgeon. Reductions are necessary, especially in patients with incomplete or complete spinal cord deficits, but they have the potential to cause neurological deficit. Therefore, reductions should be performed on awake patients so that feedback and a physical exam can be performed if necessary. Bilateral facet dislocations always require surgical stabilization.

There are a variety of fractures associated with axial load injuries, including burst, compression, and teardrop fractures. These injuries affect the anterior column of the vertebral column. The treatment required for an axial load injury is determined by neurological status and stability. If there is a spinal cord injury, often surgical intervention is required.

Spinous process fractures can be part of an unstable cervical spine fracture pattern or can be a relatively benign injury. These types of fractures usually occur when the neck is hyperextended or hyperflexed. Flexion-extension X-rays may be needed to identify unstable fracture patterns.

Thoracic Trauma

The thoracic spine is composed of the 12 thoracic vertebrae and is the middle segment of the vertebral column, located between the cervical and the lumbar vertebrae. All the thoracic vertebrae except for the 11th and 12th articulate with the ribs.

There are multiple types of injury patterns that can occur in the thoracic spine. The *three-column* concept is often referred to when describing spinal fractures. The spinal column can be divided into three sections: the anterior column, the middle column, and the posterior column. The anterior column is composed of the anterior longitudinal ligament and the anterior half of the vertebral body, disk, and annulus. The middle column is composed of the posterior half of the vertebral body, disk, annulus, and posterior longitudinal ligament. The posterior column is composed of the facet joints, the ligamentum flavum, and the posterior elements. In general, fractures are considered stable only if the anterior column is involved. The greater the number of columns that are involved, the more unstable is the injury.

The specific types of injuries to the thoracic spine include compression fractures, stable burst fractures, unstable burst fractures, flexion-distraction (chance) injuries, and fracture-dislocations. *Compression fractures* are vertebral body fractures that affect only the anterior column of the spine. They are often stable and most of the time

Type of Fracture	*Columns Involved*	*Stability*
Compression	Anterior	Often stable
Burst	Anterior, posterior	Sometimes stable
Chance	Anterior, middle, posterior	Likely unstable

can be treated with brace immobilization. *Stable burst fractures* involve the posterior cortex, facet joints, and lamina but do not have any displaced fractures. Often, these can be treated with custom-fit orthoses. *Unstable burst fractures* affect the middle and anterior columns, have displaced fractures of the facet joints and lamina, and often require surgical stabilization. *Chance fractures* are flexion-distraction injuries that affect the anterior, middle, and posterior columns. Casting, bracing, or surgery is necessary for a chance fracture. *Fracture-dislocations* of the vertebrae almost always require surgical stabilization.

Thoracic fractures that do not require surgical stabilization are often treated in orthoses. The main function of an orthosis is to provide stability by limiting trunk motion and motion among the vertebrae.

Nonoperative treatment of single-column injuries often involves the use of an extension orthosis to limit flexion. Isolated posterior element fractures, such as spinous process fractures, are typically stable, and thus, they are treated symptomatically and conservatively with mobilization and pain control.

Injuries involving two columns require more rigid immobilization than single-column injuries. Thoracolumbosacral orthoses provide good immobilization if the injury is in the lower thoracic spine, that is, T7 and distal. For more proximal thoracic injuries, the brace is extended to a cervical thoracolumbosacral orthosis or a halo with vest.

Conclusion

The overall prognosis for spinal injuries depends on the level of neurologic compromise. Fracture patterns vary from stable with no neurologic injury or sequelae to devastating injuries that are fatal. The initial treatment is crucial, and if a spinal cord injury is suspected, spinal immobilization is prudent. Diagnosis of vertebral fractures and spinal cord injuries is made by careful physical exam, including a detailed neurologic exam, and various imaging modalities that may include but not be limited to X-ray, to identify basic fractures; MRI, to look for soft tissue and spinal cord injury; and CT scan, to detect occult fractures. Treatment options range from symptomatic treatment of pain to external bracing to surgical stabilization. Overall, outcome is related to the specific fracture pattern and the spinal cord injury that is sustained.

Cervical and Thoracic Spine Injuries

Cervical and thoracic spine injuries are not uncommon in sports. Cervical spine injuries are especially common in collision sports such as football and ice hockey, occurring in 10% to 15% of U.S. football players. Fortunately, most of these injuries are self-limited, and full recovery is usually achieved. Devastating injuries, however, do occur. Between 1982 and 1994, there were more than 300 catastrophic injuries involving the cervical spine. Approximately 7% of all cases of spinal cord injury are related to athletics.

Anatomy

The spinal column, or "backbone," is actually a series of 24 small bones called vertebrae and two large bones, the sacrum and the coccyx (often referred to as the "tailbone"). The cervical spine refers to the 1st through 7th vertebrae. It starts at the base of the skull and ends at the shoulders. The 12 thoracic vertebrae continue at the shoulders and end at the lumbar spine (5 vertebrae). In between each anterior vertebra is a cushion of fibrocartilage known as the *intervertebral disk*. Posteriorly, there is a bony arch that conveys and protects the spinal cord. The spinal nerves exit at each level to innervate the muscles and sensation to the shoulders, arms, and trunk. The stability of the spinal cord depends on the integrity of the anterior and posterior columns.

Clinical Evaluation

Field Evaluation and Early Treatment

Spinal injuries can be extremely serious. At the time of injury, a clinician (doctor, nurse, athletic trainer, emergency medical technician, etc.) needs to assess the degree of injury. In the case of an unconscious or obtunded athlete, spinal injury is presumed. In the conscious and alert athlete, any spinal pain, tenderness, or neurologic deficit will mandate appropriate spinal care. In these circumstances, it is important to use a well-practiced technique of immobilization on a spine board and transfer the patient to the nearest emergency department.

If the athlete is wearing a chin strap, helmet, and shoulder pads, it is best to leave these in place. The helmet is immobilized by taping blocks on the sides. However, prior to transport, the face mask should be removed to allow for airway management if this is needed. Helmet removal places the spine at risk unless the helmet is removed in unison with the shoulder pads in a well-rehearsed fashion.

For athletes without helmets and pads, the cervical spine should be immobilized by placing a hard cervical collar without moving the head.

History

The mechanism of injury should be determined from the patient's account and any available witnesses. The athlete will report any symptoms he or she is having, including pain at the site of injury; radiating pain that moves from the site of injury to other areas of the body; numbness or inability to feel in parts of the body, or a "tingling" or a feeling of "pins and needles," known as *paresthesias*; weakness of parts of the body; or an inability to move parts of the body.

Physical Examination

The physical examination will start with inspection, looking for swelling, bruising, abrasions, lacerations, or other evidence of injury. Next, palpation of the affected area, looking for warmth or areas of tenderness, is usually performed. The athlete may be asked to move various parts of the body, possibly pressing them against the examiner, who tries to resist the movement. This allows the examiner to gauge the patient's strength. Parts of sensation may be tested by asking the patient if he or she can feel the examiner lightly touching the patient or to distinguish between one and two sharp points. These tests give the examiner a sense of whether a nerve has been damaged.

Diagnostic Tests

The information obtained from the history and physical examination is used to decide whether any diagnostic tests are necessary. Plain X-rays are useful to determine many obvious fractures and misalignment. Computed tomography (CT) is very helpful in detecting occult fractures, while magnetic resonance imaging (MRI) is useful in detecting soft tissue and spinal cord injury. In children, an MRI scan is helpful in fractures because the bones have not fully calcified yet. Electromyograms and nerve conduction studies may be useful in assessing whether any nerve damage has occurred, but usually, these are not helpful in the first 2 weeks after injury.

Prevention of Injury

Many cervical and thoracic spine injuries can be prevented. Strengthening and increasing the flexibility of the muscles that support the spine can help in prevention. In addition, the athletic equipment used in various sports, particularly collision sports such as football and ice hockey, is designed to reduce the risk of spine injury, as well as other potentially catastrophic injuries. Perhaps, the most useful strategy for preventing cervical and thoracic spine injury is to develop safety rules and properly enforce them. A classic example of this is in

American (U.S.) football. Prior to 1976, players used to straighten their spine and head and strike their opponents with the crown of the head, a technique known as "spear tackling." This was disallowed in 1976. Since that time, the number of cervical spine injuries has decreased by approximately 66%.

Return to Sports

Returning to athletics after a cervical or thoracic spine injury depends on the type and degree of injury. These injuries may be chronic overuse or acute injuries. At a minimum, the patient should be symptom-free and able to perform the duties of his or her sport without having to change the technique. Unfortunately, some spinal injuries will preclude patients from athletics that pose an increased risk of contact or collision. Some specific injuries are discussed below.

Stingers and Burners

"Stingers" or burners are common in collision sports such as football and rugby. These injuries result from the nerves of the arm being stretched or compressed. The nerves that supply the arm originate from the spinal cord and course through the neck and down the arm. When an athlete is struck on the head, neck, or shoulder, the neck will often bend to the side. This results in stretching of the nerves on the side that is struck or compression of the nerves on the opposite side. When the nerve is damaged in such a way, it will often result in a burning or stinging sensation down the arm. In addition, the muscles of the arm and shoulder may become weak. Eventually, nerve function returns with normal sensation and strength.

Stingers or burners always occur in one arm only. If the same sensation develops in both arms or in one or both legs, it may indicate an injury to the spinal cord, and the athlete should seek immediate medical attention.

When burners or stingers occur, the athlete should be removed from play and examined by a clinician. Before returning to play, the athlete's symptoms must be completely resolved. The symptoms should have occurred only in one arm. There must be no remaining burning or stinging. There must be no tenderness or pain along the cervical spine or neck. There must be a full, pain-free range of motion of the shoulder, arm, and neck. And the athlete's original strength should have returned. The symptoms associated with burners or stingers usually resolve within 1 to 2 minutes. They may, however, persist for days to weeks. Persistent symptoms, recurrent injuries, symptoms in both arms, decreased pain-free range of motion, or decreased strength requires further evaluation.

Transient Quadriplegia

Transient quadriplegia is a type of neurapraxia or bruise to the spinal cord. It occurs in the cervical spine. This results in burning, tingling, or complete loss of sensation in the arms and legs, with associated weakness. At times, total paralysis may be seen. By definition, these episodes are temporary, lasting anywhere from 10 minutes to 2 days. X-rays will usually be normal. It is believed to occur as two of the bones within the spine pinch the spinal cord. These athletes should be evaluated by a spine specialist as they are at risk for permanent injury and return to play is doubtful.

Cervical Degeneration

Force repeatedly applied along the length of the spine can result in cervical degeneration. This can be seen in athletes who frequently employ "spear tackling." This behavior can lead to narrowing of the cervical spinal canal, the area in which the spinal cord resides. It can also result in straightening of the cervical spine from its normal curved structure. This is referred to as *loss of the normal lordosis*. This increases the risk of permanent nerve and spinal cord damage. These athletes should be removed from play until the normal curvature of the cervical spine returns.

Unstable Cervical Spine Fractures

The cervical spine is most at risk of fracturing when the head is flexed slightly forward, thereby straightening the normal cervical lordosis. Catastrophic cervical fractures with spinal cord injury occur when impact forces to the top of the head are applied in this flexed posture. The now illegal maneuver called "spear tackling" refers to an athlete straightening the spine and driving through an opponent head first. Similarly, the ice hockey player must practice "heads-up hockey" when going into the boards to avoid straightening the cervical spine.

Athletes with stable spine fractures that are proven radiographically to have healed and manifest no instability on dynamic flexion and extension lateral X-rays are often cleared for return to play.

Thoracic Spine Fractures

Although less common than cervical or lumbar (lower back) spine injuries, fractures of the thoracic spine do occur. They are associated with axial loading of the spine, when a force is applied to the length of the spine. Minimal fractures are braced for 6 to 8 weeks and then conditioned before return to play. Except for minimal fractures, advanced imaging with CT or MRI may be needed to confirm cord stability.

Scheuermann Kyphosis

This is an injury pattern of adolescence. The growth cartilage of the vertebral bodies becomes more compressed, causing a humped back (forward-flexed thoracic spine). It is important to detect as it is reversible if spinal growth remains. If detected while the athlete is still growing, extension strengthening and bracing may be effective in correcting the posture.

Cervical Brachialgia

Cervical brachialgia is a term that is not commonly used in the modern medical literature. It alone is not a specific diagnosis but refers to pain in the area of the neck or shoulder that may radiate down the arm. Cervical brachialgia is due to irritation of the nerves of the arm, somewhere between their origin in the cervical spine and their ultimate position in the arm.

Anatomy

The nerves that supply the arm originate in the brain. The nerves supplying the right arm start in the left side of the brain, and vice versa. They leave the brain and travel down the spinal cord, a collection of nerves enclosed by the bones of the vertebral column. These bones, the vertebrae, are made up of an anterior vertebral body and a posterior bony arch. The vertebral bodies are separated by the intervertebral disk. The posterior arch articulates with the vertebrae above and below by two facet joints. At each level, a nerve exits to innervate a specific muscle group and sensory pattern. These nerves exit in the nerve tunnels formed by the disk in the front and the facet joints behind. There are seven cervical vertebrae and eight cervical nerves (C1-C8). The cervical nerves emerge above their corresponding vertebrae, except for C8, which exits below the seventh vertebra. For example, C3 exits between C2 and C3. This is distinct from the thoracic and lumbar spine, where the nerve exits below its named vertebra.

The lower part of the cervical spine comprises the nerves that form the brachial plexus. The brachial plexus innervates the shoulder and the arm. These nerve roots include C5, C6, C7, C8, and T1. From here, they travel through a series of muscles called the scalene and then underneath the collar bone, or clavicle, and into the upper part of the arm, making their way down the arm and ultimately to the hand. The arteries and veins to the arm follow a similar pathway and may also be involved.

Clinical Evaluation

History

Patients may complain of pain in the neck and shoulder and down the arm. The symptoms are usually only on one side. The pain may continue into the fingers. At times, it may involve the upper back and chest as well. It may be described as a sharp, stabbing, or burning sensation or numbness. It can be exacerbated by changes in position. There may be a history of sports activity, such as in the throwing athlete. There may also be a known acute traumatic event, such as a fall on the shoulder. However, there may be no preceding overuse pattern of injury. The pain may precede the neurologic symptoms of numbness or weakness, which may confuse the initial diagnosis.

Physical Examination

Patients with cervical brachialgia often hold their heads flexed forward. The muscles of the neck and shoulder are often in spasm and can be tender to the touch. The range of motion of the neck may be limited. Most of the time, they will not have tenderness over the bones of the spine, or vertebrae. A thorough neurologic examination is important. However, the initial neurologic findings may be minimal to none and can lead the examiner to feel that there is a muscle overuse injury pattern. Once the neurologic manifestations occur, there may be weakness of the shoulder girdle muscles, such as the deltoids, as well as the muscles of the arm, wrist, and hand.

Diagnostic Tests

There are some tests that might be useful in discovering the cause of cervical brachialgia. Potential causes of cervical brachialgia are discussed below. X-rays may show abnormalities of the bones, arthritis, or fractures that are contributing to the patient's symptoms. They may also reveal whether a cervical rib (see next section) is adding some compression to the nerves as they exit the shoulder. A chest X-ray will indicate if there is a cause from the upper chest.

Computed tomography (CT) may be useful in the posttraumatic setting to better detect fractures and misalignment. It may help in detecting any degenerative changes of the facet joints as well.

Magnetic resonance imaging (MRI) allows physicians to see abnormal positions of the disks, tumors, and other soft tissues that might be affecting the nerves. At times, there are fibrous bands that may also compress the nerves. It is important to perform MRI scans in functional positions of compression. Many overhead athletes will have normal anatomy until the arm is placed in a functional position of compression. This refers to the arm being held out in an externally rotated position to detect impingement of the nerves and vessels. If done in this manner, MRI scans may also show the blood vessels and any aneurysms causing pain.

Electromyography and nerve conduction tests are often useful in delineating a compressed nerve in the shoulder girdle. They will be normal when the cause is more central in the spinal canal. These studies are not usually useful in the first few weeks.

Potential Etiologies

In some patients, cervical brachialgia results from the presence of a "cervical rib." A cervical rib is an extra rib that arises from the portion of the spine in the neck, as opposed to the normal thoracic spine in the chest. This extra, or "supernumerary," rib may compress the nerve as it exits the spinal cord in the neck and travels down the arm.

For other patients, arthritis or degeneration of the joints between the bones of the spine may result in similar pinching or impingement on the nerves, resulting in pain. A frequent cause of this is facet joint degeneration, which impinges on the exiting nerve. The swelling or displacement of bones that is associated with fractures that have healed may result in similar irritation. The intervertebral disks may degenerate near the exiting nerve and cause gradually increasing irritation to the exiting nerve. Alternately, acute herniated disks may compress the nerve, resulting in shoulder pain.

Tumors in the brain or spinal cord may produce cervical brachialgia by interfering with the normal processing of the nerve. Tumors of the upper chest may also manifest with brachialgia. Aneurysms, a ballooning outward of the walls of the arteries, may also press against the nerve and cause cervical brachialgia.

A bacterial abscess around the spinal cord (epidural abscess) is an uncommon but potential cause of brachialgia. Systemic disease, such as temporal arteritis or lymphoma, may also cause these symptoms in the older athlete. Finally, there are postviral syndromes that mediate a presumed abnormal immunologic response whereby the body temporarily attacks the cervical nerve roots. This is called Parsonage-Turner syndrome. This may cause pain and weakness of the shoulder and arm.

Sometimes, simple muscle tendon overuse may produce brachialgia. Common offenders are the trapezius from the top of the scapula to the spine as well as the levator scapula, the muscle from the upper, inner scapula to the cervical spine.

Treatment

Cervical brachialgia is addressed by first defining the etiology and treating the underlying cause. Some mechanical issues such as spinal degeneration are treated with physical therapy aimed at strengthening the neck muscles and upper trunk postural muscles. Surgical options are possible for significant nerve impingement or for addressing more ominous causes such as tumors. When muscle tendon overuse is detected, the sport-specific biomechanics must be addressed, along with a full, closed-chain analysis to detect weakness more proximally on the kinetic chain (muscle linkages from the legs through the back to the shoulder). When the diagnosis is felt to be a postviral syndrome, the athlete is encouraged to strengthen the surrounding unaffected muscle groups while waiting for the nerves to recover.

Return-to-Sports Criteria

The athlete's return to competition is highly dependent on the cause of the cervical brachialgia. It also depends on the sport played. For contact sports, the athlete must manifest a full cervical range of motion and a normal neurologic examination, including regaining of original strength and the absence of pain. If surgical interventions are undertaken, the athlete must demonstrate the same as well as surgical stability of the spinal cord in the appropriate cases. For noncontact activity, the athlete should minimize overhead activity until the shoulder girdle, including the rotator cuff, is strong enough to protect the shoulder from further injury.

Cervical Disk Degeneration

Neck pain is a common musculoskeletal complaint. It affects at least 50% of the population over a life span. There are multiple causes of neck pain, but the cervical disk is a very common source. The disk is the cushion pad between each vertebral body, as described below. The cervical disk may degenerate as part of the normal aging process without any symptoms. *Degeneration* describes the natural process of disk dehydration, with consequent loss of height. Under the age of 40, magnetic resonance imaging (MRI) may show degenerative disk changes in 25% of the population. Over the age of 40, these changes are noted in at least 60% of people and often without any symptoms.

A number of factors have been related to cervical disk degeneration, including genetics, smoking, a sedentary lifestyle, repetitive motion, and nutrition. Athletic activity certainly may contribute to the process, such as head impacts in football and rugby. Neck hyperextension in competitive cycling is another mechanism with a shear force to the disk.

Anatomy and Pathology

The cervical spine is similar to the lumbar and thoracic spine, with the anterior vertebral bodies separated by the intervertebral disk and a posterior bony arch containing the spinal cord. The posterior arch is separated from the contiguous levels by two facet joints at each level (Figure 1). The facet joints in the cervical spine are unique, with a horizontal plane that allows a large amount of head rotation.

The disk is composed of an outer ligamentous annulus. This is a well-organized series of collagen layers that surround the gelatinous and highly aqueous nucleus pulposus (Figure 2). The nucleus has multiple substances that are highly inflammatory when exposed to the nerve roots. The purpose of the disk is to allow for shock absorption and fluidity of motion. The degenerative process of the disk involves gradual disk dehydration with loss of disk height and increasing spinal stiffness. This is due to gradual fissuring of the annulus and loss of the gelatinous nucleus, resulting in more contact with the bony prominences of the vertebrae with spur formation.

A unique anatomical finding in the cervical spine is a bony prominence on the posterior part of the vertebral body called the uncinate process (Figure 3). During childhood, this forms an articulation with the vertebral body above and is referred to as the joint of Luschka. As it is positioned in front of the spinal nerve exit (neuroforamina), degeneration here may cause a bone spur foramation impinging the nerve from the front. The facet joint is just posterior to the spinal nerve. As the disk height collapses, facet joint degeneration occurs with spur formation and impingement of the exiting nerve from behind. Each spinal nerve exits in the canal formed by its vertebrae and the upper contiguous vertebrae. For instance, the sixth cervical nerve (C6) exits from the C5-C6 foramina, while C7 exits from C6-C7.

Disk degeneration is often asymptomatic and of no clinical significance. However, the disk degeneration may cause symptoms by several mechanisms. If the degeneration is more rapid and there has not been time to develop the stabilizing bony

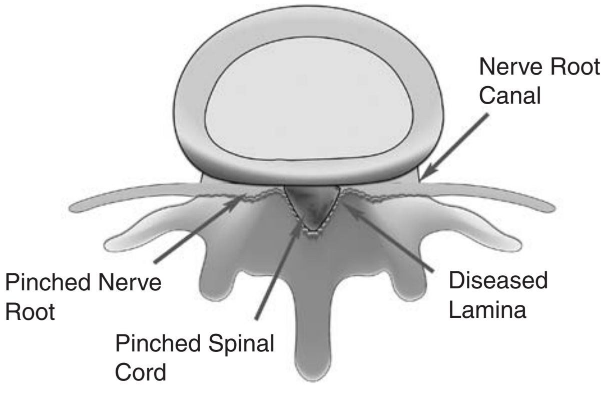

Figure 4 Mechanism of Nerve Impingement in the Spinal Column With Spondylosis

Source: Illustration by Michael d'Hemecourt.

spurs, instability may occur with excess motion. A second mechanism is an internal disk derangement. Here, there is no outward abnormality of the disk. The fibers of the annulus suffer microtears near the outer edge of the disk, which has a density of pain fibers. Often, no findings are seen on an MRI scan. These two mechanisms cause central neck pain without radiation.

The third mechanism involves nerve impingement with peripheral symptoms (radicular symptoms). The diffuse degeneration of the disk and bony prominences is often referred to as *spondylosis,* which may lead to *stenosis,* a narrowing around the nerves. Stenosis is subdivided into lateral stenosis, around the exiting nerve roots, and central stenosis, which is narrowing in the spinal canal around the spinal cord (Figure 4). Lateral stenosis may result in radicular symptoms of pain and weakness into the upper extremity. This is often reversible. Conversely, central stenosis may cause irreparable degeneration of the spinal cord, referred to as *spondylolytic myelopathy*. The spinal cord has no regeneration potential for nerve injury.

Clinical Presentation

Athletes with cervical disk degeneration may present with neck pain only. There is often pain with certain motions, such as heading the ball in soccer or sustaining impact from a football. Pain may also be further aggravated in certain postures, such as computer keyboard work with extreme cervical hyperextension. The physical examination often reveals diminished range of motion and tenderness of the facet joints, as these are easily palpated off the midline of the posterior cervical spine. Pain may be aggravated in neck flexion and extension.

When the spinal nerves are inflamed or impinged, there is radiation down a specific pattern into the upper extremities. For instance, the sixth cervical nerve will send pain to the thumb and outer aspect of the forearm. The interscapular region is also a common area of pain radiation from multiple levels. Radicular symptoms are often exaggerated with a Spurling maneuver. Here, the athlete is asked to extend the neck and rotate to the involved side. With lateral stenosis, the radicular symptoms will be reproduced. The same radicular symptoms are often relieved with arm elevation on the affected side. It is very important to perform a thorough neurologic examination.

Players of contact sports, such as football and rugby, will often experience a stinger syndrome with transient pain, numbness, and weakness in the arm. In the adolescent athlete, this is usually a stretching phenomenon of the nerves as they traverse the shoulder. Conversely, in the college and professional-level athlete, there is often compression in the neuroforamina due to some ongoing lateral stenosis.

Finally, chronic central stenosis may cause spinal cord degeneration, or myelopathy. Patients will present with an unsteady gait and diffuse weakness of the upper and/or lower extremities. There may also be a loss of ability to hold bowel or bladder function. Hyperreflexia and spasticity may also be seen.

Evaluation

Plain radiographs are critical to look for loss of disk height and instability. Lateral views with flexion and extension are best to detect instability. This would be manifested by one vertebra moving more than 3 millimeters (mm) over the lower vertebrae on flexion and correcting on extension. MRI is very valuable for contact sports as it will detect disk involvement and any related spinal stenosis. The normal canal diameter should be 12 mm. Occasionally, dynamic MRI with flexion and extension will reveal functional stenosis not present in the neutral position.

Since there may be multilevel disk degeneration with peripheral symptoms, electromyograms (EMG) and nerve conduction studies may be helpful in delineating the exact level of involvement. However, EMGs are very good at detecting muscle weakness but not very helpful with sensory changes.

Treatment

Conservative management is usually effective with cervical disk degeneration, particularly with nonradiating pain syndromes. The natural history of radicular symptoms is also quite good and is also usually treated nonoperatively. During the acute phase, analgesics are prescribed with 3 to 4 days of rest. Use of a cervical collar should be limited to a maximum of 4 days. During the acute and subacute phases, modalities such as traction preceded by muscle relaxation through heat application may be very helpful. Once the symptoms have begun to abate, upper trunk postural stability is initiated along with aerobic conditioning. Once the peripheral symptoms have resolved, cervical strengthening is also undertaken.

Medications that are most helpful are nonsteroidal anti-inflammatories, mild analgesics such as tramadol, and sleeping aids. Sleeping aids may include the muscle relaxant cyclobenzaprine or tricyclic antidepressants. Corticosteroids (such as a 7-day prednisone taper) can be very helpful in relieving the radicular symptoms, and epidural corticosteroid injections are also quite effective.

Complementary assistance with acupuncture, mobilization, and massage may be effective in the short term, although it is without proven long-term benefits.

Surgical intervention should be considered if there are progressive neurologic deficits, bowel/bladder dysfunction (emergent), and symptoms refractory to conservative care.

Return to Sports

Athletes with cervical disk degeneration frequently have concerns about return to play. For noncontact sports, the questions usually involve function and pain tolerance. Exercise is important for spinal health and is encouraged. The more significant question is return to contact sports and the risk of catastrophic nerve injury. The presence of disk degeneration or herniation is not a problem as long as symptoms have resolved and there is full range of motion and neurologic function. If the athlete has central spinal stenosis and transient neurologic symptoms that have cleared, there remains a relative contraindication to return until the stenosis has been resolved surgically. A single-level fusion is not a contraindication for contact sports but a two-level fusion is a contraindication.

Cervical Facet Syndrome

Neck pain is a common musculoskeletal complaint with a prevalence that has been estimated to be 14% or higher. Neck pain can be divided into two types: (1) those syndromes that cause central neck pain (axial pain) and (2) those that cause pain radiation to the extremities or neurologic injuries. The causes of neurologic injuries include disk herniation and severe narrowing around the nerves in the spinal canal or in the nerve channels (neuroforamina), where the nerves exit the spine. These nerve injuries are discussed in other entries of this encyclopedia.

Axial pain syndromes are caused mostly by mechanical problems of the soft tissues or bony articulations, such as unstable disk degeneration, also called *degenerative disk disease*. Several joints in the cervical spine also may cause pain due to degeneration. These joints are articulation points between the vertebrae above and below. They are the facet joints on the back of the spine and the uncovertebral joints on the front of the spine (Figure 1).

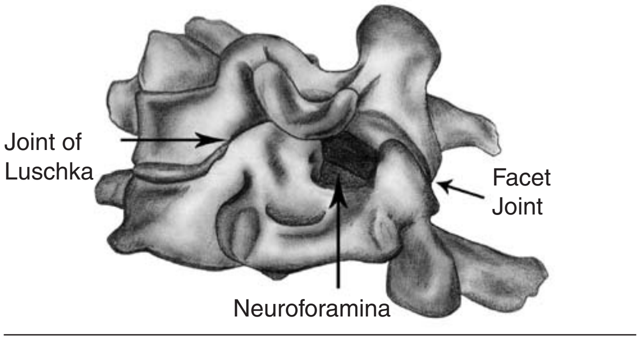

Figure 1 Cervical Vertebrae, Lower Cervical Spine

Source: Illustration by Michael d'Hemecourt.

Facet joint pain is one of the most common causes of axial pain generation. Other causes of axial pain include cervical spondylosis, which is a diffuse degeneration including the disk, as well as bony structures such as the facets. Whiplash syndrome is another cause of axial pain, most commonly due to injury to the facets, but it may involve the disk and some ligamentous structures. Myofascial pain involves tight painful muscle bands with trigger points. This may be related to fibromyalgia. Finally, certain rheumatologic diseases may be responsible for axial neck pain. Rheumatoid arthritis, spondyloarthritis, and polymyalgia rheumatica are some examples. They are often associated with other systemic manifestations of joint and muscle pain.

Anatomy and Biomechanics

The cervical spine may be viewed as the upper and lower cervical spine because of significant differences in anatomy between the two. The upper cervical spine (Figure 2) involves the atlas (C1) and the axis (C2). The atlas articulates with the occiput by two concave joints upward. This articulation allows much flexion and extension (nodding) as well as lateral flexion. The atlas is the most unusual as it is without a vertebral body. The body has become part of the axis called the *dens* or *odontoid process*. The dens articulates with the atlas and is held in place by the transverse atlantal ligament. This allows for about 50% of the cervical rotation.

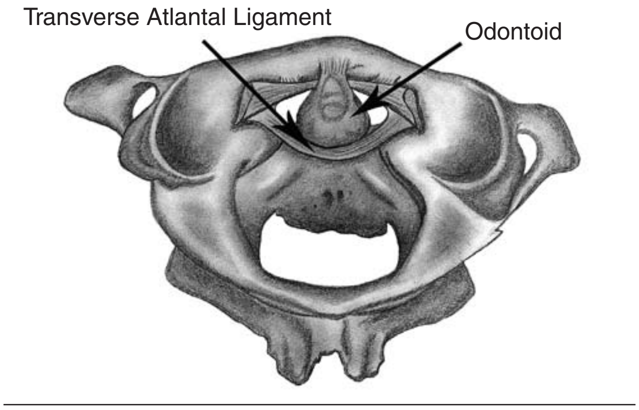

Figure 2 Upper Cervical Spine, Showing Atlanto-Axial Articulation

Source: Illustration by Michael d'Hemecourt.

Below C2, the vertebral bodies are separated by the intervertebral disk anteriorly and the facet joints posteriorly. The facet joints are also called the zygapophyseal joints and are named by the levels that articulate, such as C2-C3. These are located just posterior to the neuroforamina for the exiting spinal nerves (see Figure 1). Facets are normal joints lined with hyaline cartilage on the surfaces, a joint capsule for stability, and synovium to produce the synovial fluid. The cervical vertebral bodies are also unique because of the shape at the top, which is concave upward, while the vertebral body above has a depression to allow for this. By the age of 8, this becomes an articulation similar to a joint and is called the joint of Luschka, or the uncovertebral joint. Note that this is just anterior to the neuroforamina. Degenerative processes of the facets and uncovertebral joints may encroach on the exiting nerve roots.

In the cervical spine, the facet joints are in a more horizontal plane, at about 45° from the horizontal. This allows a coupled motion of lateral flexion and rotation. When there is lateral flexion to one side, there is a simultaneous rotation to that side.

As previously mentioned, degenerative processes of any of these structures can cause axial pain. However, several studies that have differentiated chronic cervical pain, by applying anesthetic injections selectively, demonstrated that the facets may be responsible for up to 60% of chronic cervical pain. Similar selective injection studies on patients with more than 3 months of cervical pain from a whiplash type of mechanism also demonstrated the facet joint as a predominant area of pain generation. Other areas of pain generation were tears to the ligaments of the disk and ligaments from the dens to the occiput (alar ligaments).

Clinical Presentation

Cervical facet syndrome can present with an acute extension or rotational injury as well as a chronic overuse pattern. In the acute setting, an athlete may present with acute pain, spasm, and tenderness of the facet joints. There may be a transient "stinger"-type syndrome due to the involved nerve compression anterior to the facet joint. The athlete will often be limited in extension. The Spurling maneuver—extension and rotation of the spine to the affected side—will often cause neck pain.

In the chronic setting, there is often a limitation to a full range of motion, especially in extension. Settings that often increase the cervical lordosis or extension, such as keyboard work, may aggravate the pain. With the athlete supine and the cervical muscles relaxed, the facet joints are usually easily palpated for specific tenderness at the affected level. The neurologic examination is often normal unless there is an associated injury with instability.

Facet joint pain has characteristic referral patterns depending on the facet level involved. This has been demonstrated by provocative injections into facet joints. The C2-C3 facets refer pain to the occiput and upper neck. C3-C4 facets refer pain to the posterior neck, while C4-C5 facets refer pain to the upper shoulder. C5-C6 facets also refer pain to the shoulder and upper scapula. Pain in the lower scapula is referred from C6-C7.

Evaluation

The evaluation of facet pain in the athlete usually requires ruling out other diagnoses as well as instability. A magnetic resonance imaging (MRI) scan may show some associated disk degeneration that is often not significant. In the acute setting, a computed tomography (CT) scan may show an occult fracture or a partial dislocation of a facet joint. Dynamic lateral radiographs in neutral, flexion, and extension are often needed in the contact athlete to ensure that there is no instability. This would be manifested by more than 3.5 millimeters (mm) of translation on these dynamic studies or more than 11° of angulation.

In an athlete with a stinger-type injury that coexists, MRI should be considered if the symptoms last for more than a few minutes or if there are any associated bilateral or leg symptoms. Dynamic lateral radiographs should also be done. Electromyography is considered if there are persistent neurologic symptoms.

Treatment

Rehabilitation is divided into acute, subacute, rehabilitative, and sports-specific phases. During the acute phase of the first few days, use of ice and minimal mobilization are appropriate. Modalities such as ultrasound and cryotherapy may serve well here. After the first few days, the athlete is started on some upper trunk postural stability and isometric strengthening for the cervical spine. The longest phase is the rehabilitative phase, for progressive strengthening of the upper trunk as well as the cervical spine muscles as tolerated. Resisted chin tucks are often well started at this phase. The sports-specific phase will gradually reintroduce the motions that are required by the sport, and that may be aggravating. It is important to look at sports-specific techniques.

Medications can often be helpful. Since there is often an associated inflammatory component, anti-inflammatory medication is very useful for a short course. If sleep is a problem, a tricyclic antidepressant such as amitriptyline is useful. If there is a neuropathic pain component, antiseizure medication such as gabapentin may be helpful.

Facet manipulation using osteopathic mobilization may be very helpful. This will often involve muscle energy techniques. Acupuncture can also be a strong complementary addition to the care of cervical spine pain.

More invasive interventions are usually withheld for refractory cases. Corticosteroid injection into the cervical facet joints is not strongly supported in the literature. However, diagnostic anesthetic blocks of the median nerve branches that innervate the joints may indicate that a radiofrequency neurotomy be done percutaneously. This involves burning the sensory nerves and may provide relief for 6 to 9 months. This is not a common procedure for an athlete.

Return-to-Sports Criteria

For the athlete involved in a collision sport, it is important to perform the imaging studies mentioned above to rule out instability or significant encroachment on the spinal canal. Even with normal studies, the athlete should also demonstrate a normal neurologic examination, full range of pain-free motion, and normal biomechanics of cervical spine motion.

Cervical Nerve Stretch Syndrome

Cervical nerve stretch syndrome is a fairly common sports injury resulting from trauma to the shoulder or neck. It is an injury to the upper extremity peripheral nerves, manifested most commonly as a shooting or burning pain that radiates down the arm on the affected side (hence the terms *stinger* and *burner*). It is most frequently reported in football players but can also occur in those participating in cycling (in crashes), ice hockey, gymnastics, wrestling, and other contact sports.

Anatomy

The *brachial plexus* is a network of nerves that originate from the lower cervical and upper thoracic portions of the spinal cord to provide motor and sensory innervation to the upper extremities (one on each side for each arm). The plexus starts off as the five nerve roots (C5, C6, C7, C8, and T1) exiting from the spinal canal. C5 and C6 combine to form the superior trunk, C8 and T1 form the inferior trunk, and C7 is renamed the middle trunk. From there, each trunk splits into an anterior and posterior division. These six divisions are then regrouped into cords. The posterior divisions of all trunks form the posterior cord, the anterior divisions from the superior and middle trunks form the lateral cord, and the remaining anterior division of the inferior trunk is renamed the medial cord. Along the way, through this organization and reorganization of the nerve roots, several nerves arise to provide specific motor and sensory information to the arm and hand. This complex arrangement of the innervation explains the generalized nature of the symptoms of a stinger.

Pathophysiology

The injury is typically the result of a traction or stretch mechanism applied to the neck and/or shoulder. Sometimes direct trauma to the area can elicit similar symptoms. Football seems to be the most common sport in which this injury takes place, since players frequently apply traction on each other in blocking and tackling. A similar mechanism can occur when falling to one's side, particularly at speed. For example, as a crashing cyclist hits the ground, one's shoulder may be drawn down toward the feet while the head is pushed to the other direction, stretching the brachial plexus from both ends. Although less common, direct trauma can cause similar symptoms by "bruising" the nerves of the plexus or by compressing them through swelling of the surrounding soft tissue.

The most common symptoms of cervical nerve stretch syndrome are burning and/or shooting pain radiating down the arm and into the hand, similar to when one's arm has "fallen asleep." However, depending on the severity of the injury and what parts of the plexus are affected, there may also be associated numbness or weakness in the arm and hand. Depending on severity, symptoms may last anywhere from a couple of minutes to several weeks. However, a burner or stinger does not usually lead to permanent deficits.

Diagnosis

Sometimes, a burner can be diagnosed before a player even approaches a physician or athletic trainer. Frequently, immediately after the injury, a player may shake his or her arms as if to try to "wake up" the limb. Otherwise, history and physical exam are key. Before that, however, the examiner should make sure that the athlete's cervical spine is stable by asking appropriate questions regarding neck pain and examining the neck. If stable, the examiner may proceed; otherwise, cervical spine immobilization should be applied immediately.

It may be difficult to elicit specific details leading up to the injury, but a general sense of how the player was hit or fell coupled with a description of subsequent symptoms should lead one toward a diagnosis of cervical nerve stretch syndrome. It is important to get as much detail as possible with regard to symptom history, as this may help in estimation of recovery time, management, and evaluation of progress.

The physical exam should be detailed as well. First, inspect the affected and unaffected sides for asymmetry of musculature that might indicate previous injury or increased risk for injury (decreased muscle mass may allow for more traction to occur by not providing enough counteractive reflex contraction). Palpation of the shoulder and clavicle should be performed to rule out more serious injuries such as dislocation or fracture, especially if visual inspection reveals an obvious deformity. Next, if the cervical spine has been cleared, assess the neck in a more detailed fashion for range of motion, paying particular attention to maneuvers that trigger symptoms. Special maneuvers such as the Spurling test or Tinel sign may give clues as to where in the plexus the injury has occurred.

Of particular importance are motor and sensory exams to attempt to uncover any specific deficits that may point to a particular nerve or nerve root. Again, these findings also have implications in management and monitoring progress. In particular, one can test every nerve root of the brachial plexus with a detailed motor exam.

Although an X-ray would be useful if a fracture is suspected, imaging is generally not indicated in the acute phase. However, X-rays of the cervical spine may uncover underlying conditions, such as arthritis or neural foraminal narrowing (the openings in the spinal column where nerve roots exit the vertebral canal), that could augment the symptoms of cervical nerve stretch syndrome. A magnetic resonance imaging (MRI) scan might be indicated if involvement of the spinal cord, rather than simply the nerve roots or plexus, is suspected.

Also potentially useful is electromyography (EMG), a test that evaluates nerve conduction and, as such, may help define the location and severity of the injury. EMG testing should be limited to patients with persistent symptoms lasting 3 or more weeks. If performed before this time, testing may be falsely negative, since conduction delays can take several weeks to appear on EMG testing.

Management

Apart from pain control measures such as medication and rest, management focuses on prevention as recurrences are common. The first focus is improving flexibility and strength of the neck, shoulder, and arm. The left and right sides should be treated equally as any predisposing condition could be present bilaterally and to prevent creating any new asymmetry. A physical therapist might best be able to work closely with the patient in establishing an effective rehabilitation plan.

An emphasis on proper posture in daily activity might help minimize symptoms. Specifically, maintaining a head-up and chest-out posture helps reduce compression at the neural foramina in the neck and opens the thoracic outlet (the passage between the chest and neck used by the brachial plexus as well as several blood vessels).

In collision sports such as ice hockey and football, where pads are part of the requisite gear, additional safety equipment may be helpful in reducing the risk of injury. Lifters or extra air pads can be placed under shoulder pads to elevate them into a position to limit excessive flexion and extension of the neck and, thus, reduce the risk of sustaining a stinger. Care must be taken to ensure that the shoulder pads fit well and will stay in proper position through multiple collisions to prevent other injuries from occurring. Another alternative is a neck roll, a soft supplemental collar that attaches to the top of the shoulder pads. Again, the goal is to reduce excessive flexion and extension of the neck; however, installation is easier, with less shoulder pad adjustment required. A third device that to some degree applies both principles is the cowboy collar. This is a device that fits underneath the shoulder pads and secures separately to the chest (providing some shoulder pad elevation in the process) and incorporates a firm, raised collar that rises above the shoulder pads, engaging the sides and back of the helmet to guard against excessive neck motion.

All these devices have been shown to reduce excessive flexion and extension. As such, a decision as to which device to use should be player specific, taking into account player comfort, predisposition to injury, the position played, and the amount of head and neck mobility required to play at an optimal level, as well as the potential risk for other injuries in general due to reduced visibility (e.g., a player not being able to prepare for a hit because he or she isn't able to scan his or her surroundings).

Prognosis and Return to Sports

The symptoms of a burner can last several minutes to several weeks. A key determining factor in duration of symptoms is the degree of injury. The nerve is made up of neurons (nerve cells) and myelin cells, which surround and protect the nerve cells in the form of a sheath. These can be thought of as an electrical wire and the surrounding insulation, respectively. In a burner that lasts only minutes, the likely injury is a stretch to the nerve momentarily disrupting conduction without damage to either type of cell. In a Grade 1 injury, the myelin cells are damaged with little or no damage to the nerve cells. That is, the insulation is cut, exposing the electrical wire and creating a short circuit. The sheath is able to repair itself over time, and as such, symptoms will resolve over days to weeks. A Grade 2 injury of the nerve involves damage to both the myelin sheath and the underlying nerve cell but with preservation of other connective tissue structures. With the connective tissue structure intact, the nerve is able to regenerate in the correct location to resume function; however, this may take longer than recovery from a Grade 1 injury as peripheral nerves grow at a rate of only 1 millimeter/day (mm/day). A Grade 3 injury is complete disruption of the myelin sheath, nerve cells, and surrounding support structure. Without the connective tissue or myelin to guide it, the separated ends of the nerve cells cannot find each other to reconnect, so this is considered a permanent injury to the nerve, from which recovery of function is not possible. This is fortunately a rare occurrence in sports and actually would not be considered a burner or stinger. In addition to their particular symptoms, burners and stingers are partially defined by being temporary conditions.

Regarding return-to-play decisions, the keys are frequent reexaminations and resolution of symptoms. For a first-time injury, it is prudent to keep a player out for the remainder of that practice or competition, even if symptoms resolve quickly, until a more in-depth evaluation of technique, anatomy, and other predisposing factors can be performed. The athlete should be reexamined weekly to ensure improvement of symptoms. Once the symptoms have resolved, and not before then, a player can be cleared to return in a graduated fashion, starting with conditioning and progressing to full practices and then competition. However, regular reexamination should continue, and symptom recurrence needs to be addressed through physical therapy, technique and posture analysis, and equipment changes. In addition, participation needs to be reduced or withheld in case of symptom recurrence.

Unfortunately, even after careful rehabilitation, recurrence is common. Although permanent damage from recurrent burners is unlikely, they sometimes occur with increasing frequency or with progressively lesser insults. If this is the scenario despite proper management, a player may need to weigh the risks and benefits of continued participation. This last point highlights the importance of early detection of high-risk athletes to initiate a prevention plan.

Cheerleading, Injuries in

Cheerleading, defined as an athletic activity by the American Association of Cheerleading Coaches and Administrators (AACCA), is a unique combination of athletic ability, strength, and spirit that exists both as a school-related activity and as an independent, competitive industry for both youth and adult participants.

The development of cheerleading, as it exists today in the United States, can be traced to the 1800s, starting as an organized yell at a Princeton University football game and later as a group of dedicated supporters yelling or "cheering" their football team in Minnesota. Throughout the years, it has undergone many changes, and today it most commonly exists as an integral part of the local, school, and professional sports climate. It also has a separate existence as an independent competitive athletic industry that developed in the 1980s, which makes up more than half of the estimated 3 million members of the cheerleading nation. Cheerleading has been transformed from an activity in which participants once stood at the base of the stands and led fans in vocal cheering to a strenuous physical activity that is part gymnastics and part dance and requires skill and agility to participate. With its growing popularity has come an increased awareness of the injuries sustained and the need for more stringent guidelines for its participants.

Organization

Traditionally, cheerleaders are the ever-present supporters of school, local, and professional football and basketball teams. Many people know someone who wanted to grow up to be a Dallas Cowboys Cheerleader or a Laker Girl. Children (both boys and girls) are introduced to the activity as young as age 5 or 6, and participation at the school level is often linked with social acceptance. With school-sponsored squads, often the cost of participation is included in the school's athletic program. Other forms of spirit organizations, such as pep squads, pom-pom teams, and twirlers, are not included in the activity of cheerleading.

Cheerleading as an independent athletic industry, however, is less well-known outside the sports community, but its popularity is increasing. Cheerleader organizations, developed in the 1980s, are fee based and extracurricular. The cost per participant can vary from several hundred to several thousand dollars and often does not include travel costs for local and national competitions among the different squads. This domain has grown into a multimillion-dollar industry and captures a wide audience through media and television exposure.

Nearly all organizations are structured to include a coach, team captain, cocaptain, and members. The coaches, usually an adult male or female with prior experience in the cheerleading activity, may be part of the school staff or hired independently. The level of training at the coaching level varies widely and is not regulated at most local or state levels. There are no federal regulations regarding the qualifications of coaches, and in many instances, it is a volunteer position. Coaches are responsible for designing practice routines and exercise regimens, and ensuring the safety of the members of the squad. They should also have training in first aid and a working knowledge of the anatomy and severity of injury. Guidelines, developed by the AACCA, exist, but their degree of enforcement is not known. Captains and cocaptains are participants, or members, of the squad who serve as leaders among their peer group and often are responsible for major decisions made within the squad. They often run practice time and drills prior to sporting events or competitions and determine the members of the squad through tryouts.

Terminology

With the development of cheerleading has come descriptive terminology for the various positions and maneuvers, including, but not limited to, the following:

Maneuvers

Squads: Groups of participants, consisting of both male and female members

Members: Individuals in the squad

Routine: a sequence of moves, usually a choreographed dance combination

Stunt: a maneuver requiring tumbling, mounting, or tossing

Tumbling: forward or backward rolling or flipping

Flying: a skill in which a member is thrown or "tossed" into the air by a vaulter

Vault: using one's hands to propel a member into the air

Pyramid: a stunt involving multiple base members and flyers (may be more than the height of two persons)

Toss: to disengage a member from either a pyramid or a base arrangement

Mount: a skill in which a person is supported by the base (can be more than one person's height)

Dismount: to return all members to floor position

Positions

Base: bottom person in a stunt

Flyer: person who is elevated into the air or thrown from a mount

Spotter: person who helps with persons mounting or dismounting

An understanding of these terms is essential while assessing injuries incurred by those participating in this activity.

Controversies and Injuries

As an athletic activity, routines require skill in dance and gymnastics combined with strength and agility. Participants undergo rigorous training, not unlike that expected of other athletes in competitive sports. Because cheerleading is not governed by any regulated sports commission, there are no rules as to how many hours a squad can practice or how strenuous the training should be. Lack of classification of this activity as a "sport" may have also hindered accurate reporting of injuries sustained during participation. Over the past several years, the complicated routines that make cheerleading unique have come under scrutiny. This is largely due to an increase in the report of injuries to the National Electronic Injury Surveillance System (NEISS) and the National Center for Catastrophic Sports Injury Research (NCCSI). These data were then published in the *American Journal of Sports Medicine* in 2003, bringing public awareness to the inherent dangers of this activity. Many of these injuries were found to be associated with risky maneuvers that were being performed by participants whose level of training was not quantifiable. While these data were reported by participants in school-related cheerleading organizations, they may grossly underrepresent the actual number of injuries sustained by participants of the independent side of this activity. Advocates for regulation of the activity founded AACCA and the National Cheer Safety Foundation (NCSF), which put forth guidelines for coaches and participants in an effort to make cheerleading safer. These guidelines suggest appropriate trainer requirements and certification, safety measures for the use of mats and thickness of mats, and possible limitations on the height of tosses and pyramids. Other well-established organizations, such as the National Cheerleaders Association (NCA), have adopted these guidelines and also serve as major organizers of camps, competitions, and conferences locally and nationally for participants and coaches.

While the majority of injuries sustained in the practice of cheerleading are classified as minor and include sprains, strains, and contusions, injuries such as cervical spine fractures, injury to abdominal organs, and concussions have been reported with increasing frequency. Catastrophic injuries, including severe closed head injuries, spinal cord trauma, and death, have been found to be associated most closely with skills such as flying and tossing.

Participation in any sport or activity carries with it an inherent risk for injury; cheerleading is no different. Participants, coaches, and parents must use common sense both in practice and in competition. While no formal regulations exist at the present, it is only a matter of time before the growth of the activity necessitates more stringent guidelines for both the trainers and the trainees.

Chest and Chest Wall Injuries

Chest pain can be a common complaint in athletes. It is usually the result of musculoskeletal injuries. However, it is important to keep in mind other causes of chest pain. For instance, in older athletes, chest pain may result from a heart attack or other cardiac (heart) causes. The widely publicized deaths of popular college and professional athletes over recent decades have served to demonstrate that even elite athletes can have significant cardiac disease. In the presence of associated symptoms such as shortness of breath or palpitations or when there is a family history or previous medical history of heart disease, a cardiac origin of chest pain is more likely. Chest pain can also be caused by gastroesophageal reflux (GER; heartburn), gastric ulcer, pneumonia, or cancer. In addition, chest pain may be referred from the upper back.

Traumatic chest injuries typically result from rapid deceleration or high-energy impact. These injuries occur most often in high-speed and high-energy contact and high-altitude sports, including skiing, hockey, boxing, bicycling, and football. “Extreme sports” increase the potential for high-energy impacts and serious consequences because of the lack of appropriate safety precautions and remoteness from medical facilities. Significant chest wall trauma is a medical emergency.

Overuse injuries to the chest wall can also occur during sports. For instance, rib stress fractures can occur in tennis, golf, rowing, baseball pitching, and gymnastics.

Lower chest wall trauma can result in injuries to the upper abdominal organs, such as the spleen. Conversely, abdominal impact can result in a chest injury, such as pneumothorax (air in the chest cavity outside the lungs). Therefore, it is important to look for coexisting injuries in the setting of trauma.

Epidemiology

In the younger patient population (age <35 years), cardiac causes of chest pain are uncommon, occurring in less than 6% of the cases. In this age-group, particularly among athletes, chest wall conditions such as musculoskeletal strain and costochondritis predominate. In the older patient population (age >35 years), cardiac etiologies become more prevalent. Ischemic heart disease remains the leading cause of death in the United States.

Anatomy

The chest or thoracic cavity contains the heart, lungs, and great blood vessels. Two layers of pleurae, a pain-sensitive lining, surround the lungs, which are protected by the ribs and thoracic muscles. The lungs surround a central cavity, the mediastinum, which contains the heart, proximal aorta, and vena cava and is lined by a protective tissue, the pericardium. The diaphragm divides the thoracic and abdominal cavities. The position of the diaphragm changes with breathing. During expiration, the diaphragm may be as high as the fourth anterior rib. The spleen, liver, pancreas, and bowel may therefore be injured with lower chest wall trauma.

There are 12 ribs that are anchored to the spine posteriorly. The first seven ribs are attached anteriorly to the sternum with cartilage. The 8th, 9th, and 10th ribs articulate with the cartilage above them. Ribs 11 and 12 are not fixed anteriorly and are called “floating ribs.” The 10th rib is the lowest anterior rib seen. The tip of the 12th rib is at the level of the second lumbar vertebrae. Intercostal muscles run in between the ribs. The scapula protects the posterior ribs and thoracic vertebrae.

In younger children, the bony chest wall is very flexible. As children get older, the bones of the chest wall become more rigid and are, therefore, more vulnerable to fracture. The bones of children mature to adult bones by about 8 years of age.

Evaluation of Injuries

A good starting point in evaluating chest pain in athletes is to first determine whether the pain has a traumatic or nontraumatic cause. The list of nontraumatic causes of chest pain is extensive, but certain historical clues help limit the possibilities. The list of traumatic causes of chest pain is less extensive. The vast majority of traumatic injuries to the chest and thorax are typically mild, but the clinician must be wary of which causes have the potential to be catastrophic if unrecognized or if the diagnosis and treatment are delayed.

Significant injuries to the chest are medical emergencies and may result in shock. On the field, an injured athlete should have his or her airway, breathing, and circulation assessed and supported as necessary by qualified personnel. If there is significant compromise of the airway or breathing, the athlete should be intubated by a trained physician or paramedic. Intravenous access should be established with a large-bore cannula in two separate sites, and normal saline should be infused rapidly. The athlete should then be transported by an ambulance to a trauma center.

Details of Injury

History taking in the evaluation of chest pain should include questions about location, radiation, duration, character, severity, and associated symptoms. Athletes who have sustained a chest injury may present with chest wall pain and possibly shortness of breath. The mechanism of injury is typically a direct impact. In cases of chronic injuries, the onset may be more insidious. Determining the type of sport, the position played, and details of the training regimen, including any increases in training or recent changes to training, is important to help determine the cause of the athlete's symptoms. Previous medical problems may elucidate recurrent injuries.

When there is no history of trauma, it is important to distinguish between musculoskeletal causes and heart, lung, or gastrointestinal (GI) causes of chest pain. The type and location of pain may help distinguish between different causes of chest pain. Other associated symptoms such as sweating, irregular heartbeat (palpitations), or shortness of breath may indicate a heart problem. A productive cough or chest pain associated with breathing may indicate a respiratory cause of chest pain, whereas burning retrosternal (behind the breastbone) pain and indigestion may indicate heartburn or stomach ulcer.

Physical Findings

Physical examination of the thorax should begin with an assessment of general appearance and a complete set of vital signs, including pulse oximetry. A low oximetry reading (<90%) and low blood pressure coupled with an elevated pulse and respiratory rate denote the likelihood of serious cardiopulmonary compromise. Assessment of airway, breathing, and circulation of any athlete who has sustained a chest injury should be done by qualified personnel. There may be bruising at the site of injury or possibly an obvious deformity, such as a flail chest (ribs moving with breathing). If there are severe chest injuries, the athlete may have difficulty breathing and may have an increased heart rate and decreased blood pressure. There may be decreased breath sounds on auscultation of the lungs, and there may be abnormal heart sounds. There may be localized tenderness to palpation over an injured rib, which may indicate a rib fracture or muscular injury. Because upper abdominal organs may also be injured as a result of trauma to the lower chest wall, there may be tenderness to palpation or bruising of the abdomen as well. Percussion is most useful in assessing the status of the lungs and its surrounding pleural cavity. Dullness on percussion suggests a pleural effusion or consolidated pneumonia. Hyperresonance suggests a large pneumothorax. Auscultation with a stethoscope provides crucial clues regarding the clinical status of the lungs, heart, and pericardial cavity, the specifics of which are beyond the scope of this entry.

Investigations

Investigations in the setting of a chest injury include X-rays and possibly computed tomography (CT) or magnetic resonance imaging (MRI). Plain chest X-rays may indicate bony injury, such as rib fractures, or lung injuries, such as pneumothorax. An erect chest film may show free air under the diaphragm, suggesting bowel perforation. If a heart injury is suspected, an electrocardiogram (EKG) should be performed to assess for arrhythmias. An echocardiogram (ECG) may be necessary if there is significant cardiac injury. A CT scan may be necessary to further delineate the extent of lung injury.

Types of Injury

Table 1 lists the different sports-related chest and chest wall injuries.

Table 1 Sports-Related Chest and Chest Wall Injuries

Chest Injuries	*Chest Wall Injuries*
Pneumothorax	Rib fractures
Pulmonary contusion	Rib stress fractures
Hemothorax	Rib tip syndrome
Commotio cordis	Costochondritis
Myocardial contusion	Sternal fractures
	Scapular fractures

Nontraumatic Causes of Chest Pain

Nontraumatic musculoskeletal causes of chest pain in the athlete often result from training errors and overuse. Musculoskeletal pain is frequently described as sharp and may be exacerbated by chest wall expansion, as occurs with inspiration. Palpation of the chest wall may not necessarily reproduce the pain. The most commonly encountered entity in this category is the benign condition of costochondritis.

Costochondritis is a clinical diagnosis usually made based on the history and physical examination alone. It is an inflammation of the costochondral junction (where the ribs meet the sternum) presenting as localized pain and tenderness exacerbated by respiratory and exertional efforts. As it pertains to the athlete, repetitive minor trauma or unaccustomed activity has been proposed as the most likely initiating event. Treatment includes the correction of training errors and gentle stretching of the pectoralis muscle group. An athlete diagnosed with costochondritis can typically return to play once inspiration and truncal range of motion are pain-free.

The most common GI cause of chest pain is GER, better known as heartburn. Simply put, GER is the abnormal back flow of the stomach's highly acidic digestive juices into the esophagus. The resultant symptoms vary but typically include burning central-chest pain associated with belching. Less common but significant symptoms include cough and hoarseness triggered by micro-aspiration.

Exercise-induced reflux is fairly common in patients who suffer from GER at rest, but reflux only with exercise may occur in many athletes. GER increases with the intensity of exercise and is noted to be worse with endurance activities. GER has been reported in up to 90% of fed runners during and immediately following exercise. Dehydration tends to worsen the symptoms. The specific cause of GER in endurance athletes remains unclear, but it is thought to be related to changes in blood flow and GI motor function that occur during exercise. Weight lifters also experience a significant rate of GER, presumed to be secondary to increased intra-abdominal pressure from lifting. In treating an athlete with GER, altering training methods and dietary habits alone may serve to alleviate symptoms.

Acute cardiac ischemic causes of chest pain should be suspected in an adult athlete who experiences classic symptoms in the setting of sustained aerobic exercise. Suspicion should escalate if the patient possesses multiple risk factors for ischemic heart disease, including a positive family history, hypertension, and elevated cholesterol. The situation is especially urgent if the presenting symptoms are associated with syncope. Any athlete in this situation requires a comprehensive diagnostic evaluation and treatment from a cardiologist, who will eventually determine activity limitations.

Traumatic Causes

It is important for the examining clinician to be aware of the traumatic causes of chest pain, which are potentially life threatening, in an athlete. The majority of injuries to the chest and thorax are mild and include chest wall contusion or muscle strain. The more severe injuries, including cardiac and pulmonary contusion and pneumothorax, have the potential to be catastrophic if unrecognized. Sports that possess the greatest risk for severe trauma to the chest include high-speed sports, such as skiing and cycling, and high-energy collision sports, such as football and hockey.

The severe chest wall traumatic injuries posing the greatest concern include rib fracture, sternal fracture, and sternoclavicular dislocation. With each of these entities, the importance of the injury lies not with the mechanical problem itself but with the associated potential injury to vital intrathoracic structures. Specifically, fractures to the first three ribs are often associated with severe injury to the vital nerves and blood vessels, whereas fractures to the 9th through the 12th ribs may be associated with injury to the abdominal organs. Cases of sternal (breastbone) fracture have traditionally led to a search for associated injury to the heart and great vessels. To date, sternal fractures have been found to have an associated incidence of myocardial contusion of 1% to 5%, with mortality significantly less than 1%. Though rare, sternoclavicular joint dislocation is most commonly seen in football players younger than 25 years. The clavicle is typically displaced in a posterior direction, with the resultant 30% incidence of injury frequently in the form of tracheal rupture or esophageal perforation.

Isolated pneumothorax, pulmonary contusion, and cardiac contusion can result from blunt injury to the thorax. Each may present as chest pain and shortness of breath, with no visible evidence of external trauma. The possible presence of these entities should be considered after reviewing the mechanism of injury in conjunction with presenting signs and symptoms. Each possesses significant risk for life-threatening complications potentially requiring surgical intervention and intensive care. The fracture/dislocation site must be stable and range of motion and breathing pain-free before return to play is possible. It is advisable to wear a protective flak jacket for 4 to 6 weeks postinjury.

Prevention of Injury

Some chest wall and chest injuries can be prevented by wearing sports-specific safety equipment. For instance, chest protectors and safety balls in baseball have been shown to decrease the incidence of commotio cordis (heart stops because of impact injury). An automated external defibrillator (AED) should be available at sporting venues.

General conditioning is important, particularly in the prevention of overuse injuries. Core strengthening will maximize protection in contact sports and minimize overuse injuries in noncontact sports. Ensuring proper sporting techniques can also prevent overuse injuries.

Return to Sports

Decisions regarding return to play on the field should be guided by the athlete's symptoms. Before being returned to play, an athlete should have pain resolution, normal vital signs, and no peritoneal signs. The athlete should also be able to exercise without exacerbating symptoms. Any suspicion of a significant injury should prompt transfer of the athlete to a trauma center.

Return to play following rib injuries should be made on a case-by-case basis. In general, return to play is typically possible within 4 to 8 weeks. Following a sternal fracture, an athlete can return to sports once he or she is pain-free with activity. The athlete should wear a flak jacket for protection if he or she participates in contact sports.

Cholinergic Urticaria

Cholinergic urticaria is the name given to hives that are precipitated by an increase in core body temperature. This is also referred to as *generalized heat urticaria*. One of the most common triggers is exercise. This entry discusses cholinergic urticaria, its triggers, how to diagnose and test for it, and how to treat and prevent it.

Epidemiology

Cholinergic urticaria is believed to account for 5% of all cases of chronic urticaria and about 30% of all physical urticaria. About 15% of the general population will experience an episode of cholinergic urticaria at least once in a lifetime. Onset is typically in the second or third decade of life. Familial cases have been reported but are rare, with all familial cases being male with father-son transmission. There may be a slight predominance in males.

Pathogenesis

The exact mechanism is not known at this time, but it is thought to be due to an abnormal cutaneous response that is triggered by increased temperatures. This results in the release of mediators that cause the urticarial response. Studies have shown that there are elevated levels of histamine in these patients.

Triggers

The most common triggers include exercise, strong emotions, and bathing in hot water. Essentially, anything that can cause a rise in core body temperature can be a trigger, including the ingestion of spicy foods. All these factors lead to increased sweat production, which has been postulated to have some bearing on the pathogenesis of the condition.

Diagnosis and Testing

Clinical Signs and Symptoms

The classic appearance is that of numerous punctuate wheals (1–3 millimeters) surrounded by a large erythematous flare ("fried-egg" appearance). As the response progresses, the flares may coalesce to form large areas of erythema. The wheals typically begin on the trunk and neck and spread distally to involve the face and extremities. Patients will often have sensations that can include itching, burning, or tingling. Rarely, this can progress to systemic symptoms such as hypotension, angioedema, and bronchospasm.

Testing

The presence of classic lesions in the setting of a typical trigger is enough to suggest a diagnosis, but diagnostic testing can be done for confirmation. A provocation test can be performed, which involves an intradermal injection of methacholine. A positive test produces hives around the injection site. This test, however, is only positive in about 33% of patients. Another type of provocation test is to have the patient mimic the activity that caused the hives (e.g., exercising, eating a certain food) in an attempt to produce a reaction. Last, the examiner can try to raise the patient's core body temperature by having the patient partially submerged in a hot water bath at 40 °C. The appearance of urticaria confirms the diagnosis.

Treatment and Prevention

Nonpharmacologic

Identification and avoidance of known triggers is the first step in controlling cholinergic urticaria. Avoiding strenuous exercise in hot weather and bathing in hot water may also reduce the chance of having a reaction. Athletes may be forced to change their training behavior and do more activities indoors in a temperature-controlled environment, and in extreme cases, an athlete may be forced to change his or her sport to avoid having an outbreak of urticaria.

Pharmacologic

Antihistamines are the treatment of choice; and of those, hydroxyzine is the agent of choice. A low dose should be started and then gradually increased until the urticaria is controlled.

Chondromalacia Patella

Chondromalacia patella is a condition in which the cartilage on the undersurface of the knee cap becomes softened or damaged. Classically, it refers to pathologic findings at the time of surgery. It differs from patellofemoral pain syndrome in that there are pathologic changes to the undersurface cartilage of the patella. It is often called "runner's knee." Chondromalacia patella is, generally, an overuse injury found in athletes with extrinsic anatomical abnormalities of the lower extremity. It can also be caused by an acute injury to the knee, such as in patellar dislocation or a direct blow to the knee. In the older population, it usually refers to osteoarthritis in the patellofemoral joint.

Anatomy

The knee joint consists of three bones: (1) the femur, (2) the tibia, and the (3) patella (kneecap). The bottom of the patella and the ends of the femur and tibia are covered with cartilage. The cartilage is what allows the bones to glide smoothly over each other. The knee joint is often considered to have three compartments. These are referred to as the medial, lateral, and patellofemoral compartments.

In addition, the patellar tendon extends from the quadriceps muscle over the patella and inserts into the tibial tuberosity. The medial and lateral extensions of this tendon form the medial and lateral retinaculum of the patella.

Causes

Chondromalacia patella can be considered as an advanced form of *patellofemoral pain syndrome.* With continued abnormal tracking of the patella over the femur, which is the cause of patellofemoral pain syndrome, the cartilage eventually begins to soften and then breaks down. The cartilage is often described as being fissured, fibrillated, or blistered. Conditions that can contribute to this abnormal tracking are femoral anteversion, external tibial torsion, genu varum or genu valgum, foot pronation, patella alta, increased Q angle (the angle measuring the relation of the femur and patella to the patella and tibia), and imbalance of the quadriceps muscles. A traumatic injury to the knee, such as a direct blow to the kneecap or recurrent subluxation/dislocation of the patella, can also cause chondromalacia patella.

Symptoms

The symptoms of chondromalacia patella often come on gradually. They are very similar to those of patellofemoral pain syndrome. Patients often complain of pain on the front of their knee that worsens after prolonged sitting, such as a long car drive or sitting in a theater. The constellation of these symptoms is often referred to as the "theater sign." Other symptoms that patients will complain of are a grinding sensation, pain with walking up or down stairs, or pain when going from sitting to standing. With prolonged sitting not only will they complain of knee pain but they will also describe a feeling of stiffness when they get up. It is also not uncommon for patients to present with bilateral knee pain. And last, with prolonged walking or activity, some patients may complain of knee swelling.

Diagnosis

Arthroscopy is needed to definitively make the diagnosis. Some clues, though, can be obtained from the history and physical exam as well as from imaging studies.

The symptoms described above in conjunction with the physical exam can help one diagnose chondromalacia patella. On exam, patients will usually have pain with compression and rocking of the patella. They can also be tender on the undersurface of the patella and over the medial and lateral retinaculum. Patellar tracking abnormalities can also be observed while having the patients flex and extend their knee. If the examiner places his or her hand over the kneecap during flexion and extension, he or she can oftentimes feel grinding, or crepitus.

X-rays looking particularly at the patellofemoral joint can show radiologic signs of arthritis that can suggest chondromalacia patella. For example, if joint space narrowing or osteophyte formation on the undersurface of the patella is present, it could be indicative of chondromalacia patella. Magnetic resonance imaging (MRI) can also show signs of fraying and cracking of the cartilage on the undersurface of the patella. Once the chondromalacia reaches Stage III to Stage IV, an MRI scan can reliably diagnose chondromalacia patella 89% of the time. Definitively, as stated above, the diagnosis is made at the time of surgery.

Once the diagnosis is made, it can typically be staged at that time. Stage I is present if there is swelling and softening of the cartilage. Stage II will have fissuring as well as softened areas. Stage III is when the fissuring extends just short of the subchondral bone, and Stage IV is when the cartilage is destroyed down to the subchondral bone.

Treatment

The approach to the management of chondromalacia patella almost always begins with nonoperative treatment. Surgery is reserved for those patients who continue to have symptoms despite maximal nonoperative management. Some newer treatments have shown benefit in providing relief for this disorder, but the mainstay of treatment continues to be conservative.

Nonsurgical Treatment

The conservative approach to chondromalacia patella focuses on physical therapy and activity modification. Simple measures such as icing, nonsteroidal anti-inflammatory drugs (NSAIDs), and reducing or modifying the activity that aggravates the symptoms can be instituted early in treatment. Next is to have the patient start with a good physical therapy program. The physical therapy program should focus on strengthening and balancing the quadriceps muscle. Often patients with chondromalacia patella have an underdeveloped vastus medialis oblique (VMO) that needs to be built up. In addition, stretching of the quadriceps, hamstrings, and iliotibial band can be helpful. Other modalities that can be employed by physical therapy include patellofemoral joint mobilization and patellar taping.

Bracing is often used by physicians for this disorder. Most of the studies on bracing have been for those with patellofemoral pain syndrome. The most common brace used is a patellar knee sleeve with passive patellar restraints plus or minus a patellar cutout. These have not been shown to reduce symptoms. Another type of brace is a patellar brace with rigid patellar restraints. This type of brace has been shown to be beneficial only if the patient is not compliant with physical therapy. For those with anatomic abnormalities, such as pes planus, orthotics can be considered.

Other nonsurgical options that can be instituted are injection therapies. There is not much evidence that supports these, but commonly, physicians will use a corticosteroid injection in the management of chondromalacia patella. In addition, viscosupplementation has been gaining popularity in the management of patellofemoral pain syndrome and chondromalacia patella.

Surgical Treatment

Surgery is saved for those who have persistent pain or dysfunction despite conservative management. It has been decreasing in popularity due to the success of conservative treatment. Arthroscopic surgery generally involves the surgeon smoothing out the irregular surface of the patellar cartilage. Any loose pieces or debris in the joint are then washed out. Some surgeons also then perform microfracture (tiny holes drilled into bone) to the undersurface of the patella for chondral defects. For those with excess lateral tilt or pressure, release of the lateral retinaculum is often performed. Distal patellar realignment procedures are sometimes done if there are patellar tracking abnormalities.

Prognosis

Most patients who are compliant with conservative treatment do well as long as the chondromalacia is not too advanced. For those who fail conservative treatment, surgery is successful in 60% to 90% of cases.

Circadian Rhythms and Exercise

Circadian rhythms are self-sustaining phenomena with a periodicity of approximately 24 hours (Latin: *circa* = about, *diem* = 1 day). For example, the human circadian rhythm of body temperature shows a cosine wave pattern, typically peaking in the early evening (5–7 p.m.) and reaching a nadir in the early morning (4–6 a.m.). This entry will review evidence that exercise can influence the circadian system and discuss implications for health and performance.

Every living organism displays circadian rhythms, which probably evolved to allow adaptation to the 24-hour rotation of the earth. The bilaterally coupled suprachiasmatic nuclei (SCN) of the hypothalamus are the predominant anatomic locus of the mammalian circadian pacemaker. Neural and humoral outputs from the SCN to other centers in the hypothalamus and endocrine system drive multiple behavioral and physiological rhythms.

In humans, direct measurement of SCN activity is essentially impossible, so measurement of the human circadian system involves assessment of the output markers, such as body temperature and melatonin excretion, which can be considered the "hands of the clock." The measurement of these rhythms can be partly confounded or "masked" by environmental and behavioral factors, such as energy intake, activity, temperature, and light. For example, the diurnal rhythm of body temperature observed under normal conditions is influenced partly by day-night fluctuations in physical activity and food intake.

However, by definition, these rhythms are endogenously produced, though their measurement is influenced by these masking factors. That is, the rhythms persist even when an organism is separated from time-of-day cues or from diurnal fluctuations in these masking factors. The earliest human studies demonstrated this point in cave experiments, where there was no fluctuation in temperature and light and participants were isolated from the environment. Modern laboratory techniques have been developed to "unmask" circadian rhythms from masking factors. These include the constant routine, forced desynchrony, and ultrashort sleep-wake cycle. In the 180-minute ultrashort sleep-wake schedule, participants are allowed 60 minutes for sleep in darkness (<1 lux), followed by 120 minutes of out-of-bed wakefulness in dim light (30 lux). This schedule is repeated round the clock for up to 10 days and distributes masking effects equally around the 24-hour day.

Circadian Malsynchronization

Under ideal conditions, the circadian system is synchronized precisely to the 24-hour rotation of the earth to promote adaptation to the environment. Synchronization occurs through exposure to daily time cues (*zeitgeber*s), including the light-dark cycle of day and night, physical activity, and ambient temperature. However, when circadian timing is out of synchrony with environmental demands, there are negative consequences, as reviewed below.

Shift Work

Shift workers, who constitute about one fourth of the U.S. work force, suffer an increased prevalence of cancer; cardiovascular, endocrine, mood, and gastrointestinal (GI) morbidity; and chronic sleep impairment. Moreover, the rate of automobile and work-related accidents increases precipitously at night, as exemplified by some notorious catastrophes, such as what occurred at Chernobyl, former USSR, and Bhopal, India. Shift workers suffer these symptoms chronically because their body clocks almost never fully adjust, for example, to the graveyard shift. This is because environmental zeitgebers tend to keep humans on a diurnal schedule and because shift workers usually revert to diurnal schedules when not working.

Jet Lag

Annually, more than 50 million U.S. travelers suffer from symptoms of jet lag, including mood disturbance, sleepiness during the day, insomnia at night, and GI disturbance. These symptoms persist until the circadian system is resynchronized to the new time zone; on average, this takes about 1 day per time zone crossed. Contributing to the feeling of jet lag is "internal desynchronization" between various physiological rhythms, which occurs as the rhythms resynchronize to the new schedule at different rates. Chronic air travel in airline crews has been associated with cardiovascular disease, cognitive deficits, and menstrual cycle dysfunction. In animals, chronic exposure to simulated jet lag increases mortality and cancer progression.

Delayed Sleep Phase

Delayed sleep phase (DSP) is characterized by inability to go to sleep at a normal time (before 2 a.m.) and extreme difficulty waking up before 10 a.m. These sleep patterns correspond with delays in multiple circadian markers, including body temperature and melatonin. DSP has a clear genetic link and is most prevalent in adolescents and young adults. If given the opportunity on weekends, or through special arrangements of work schedules, individuals with DSP will often sleep until 10 a.m. to 1 p.m. and will have normal sleep quantity and quality. However, most people with DSP go to bed late and must wake up at a normal time, resulting in chronic sleep deprivation and all its consequences.

Advanced Sleep Phase (ASP)

Advanced sleep phase (ASP) is characterized by sleep onset times (~6–9 p.m.) and wake times (~2–5 a.m.) that are ≥3 hours earlier than societal norms, as well as phase advances in other circadian markers. The prevalence of ASP increases with age. A genetic link with ASP has been well documented. Excessive late-afternoon sleepiness is common in ASP, and could contribute to decreased work productivity and increased risk for accidents. Adherences to very early bedtimes can lead to some strain in social relations, and many individuals with ASP would prefer to stay up later. Moreover, extremely early morning awakening is often a source of frustration and loneliness.

Synchronizing and Phase Shifting the Circadian System

There is growing evidence that robustness of circadian rhythms (e.g., amplitude, goodness of fit) and day-to-day stability in timing are associated with better health. Indeed, greater rhythm amplitude and stability has been associated with longevity in cancer patients, Alzheimer patients, and a large sample of older adults.

Considering the prevalence and consequences of circadian malsynchronization, shifting and resynchronizing the circadian system could have tremendous potential for reducing population morbidity.

Phase-Shifting Effects of Bright Light

Bright light is considered the most important zeitgeber, shifting circadian timing via a direct retinohypothalamic pathway to the SCN. The phase-shifting effects of light (and other zeitgebers) are characterized by phase-response curves (PRCs) describing the magnitude and direction of shift, depending on the circadian time of the zeitgeber. Bright light elicits delays when administered before the circadian temperature nadir and advances when administered thereafter, with smaller effects near the temperature peak. Thus, evening light can be used to correct advanced sleep phase and to resynchronize the circadian system following westward travel. Conversely, morning light can be used to correct delayed sleep phase and to adjust to eastward travel. Perhaps just as important as receiving bright light at appropriate times is to avoid bright light exposure at times in which light shifts the circadian system in a direction opposite to that desired. For example, graveyard shift workers desiring to delay their body clocks to match their work schedule are advised to avoid bright light (if possible) when they leave for work in the morning.

Although bright light is generally helpful, it is not effective for many (but not all) blind individuals, and it is not recommended for individuals with abnormally high sensitivity to light. Moreover, field studies demonstrate that bright light has less efficacy for shifting the circadian system than might be predicted from laboratory studies. Therefore, there is a need to explore alternative or adjuvant methods for shifting circadian timing.

Phase-Shifting Effects of Exercise

Rodent and human studies have established that physical activity can also have a significant circadian phase-shifting effect. Although it is generally assumed that the phase-shifting effect of exercise is far less potent than that associated with bright light, there is little empirical evidence supporting this assumption. In our human PRC study (n = 224), we found that 1 hour of vigorous exercise (65–75% heart rate reserve) elicited a PRC that was similar in shape but with an amplitude that was approximately one-third of the PRC associated with 3 hours of bright light (3,000 lux). This difference was comparable with the difference reported by comparing phase-shifting effects of 1 hour versus 3 hours of bright light. Moreover, other investigators found approximately equivalent phase-shifting effects of 2.5 hours of moderate exercise (average intensity 50% max) versus 3 hours of bright light (5,000 lux). Finally, our more recent within-subject counterbalanced study found that exercise (1 hour at 65–75% heart rate reserve) elicited a circadian phase shift that was approximately 80% of that observed following bright light (5,000 lux) of the same duration.

In a simulated shift work study, exercise elicited a significantly greater phase resynchronization than a sedentary control treatment. Phase shift was significantly correlated with a reduction in symptoms.

Phase-Shifting Interaction of Bright Light and Exercise

In hamsters, a fascinating interaction between the phase-shifting effects of light and physical activity has been established. Light and exercise antagonize each other's phase-shifting effects when administered within a few hours of each other, but they can have additive or synergistic effects when separated by more than 4 hours. Our recent human study also found additive phase-shifting effects produced by combining bright light with exercise. Furthermore, demonstration of this interaction in humans might have great practical utility for quickly re-entraining the circadian system.

In summary, circadian malsynchronization is a highly prevalent condition associated with multiple morbidities and possibly with mortality. Although bright light provides the best means of correcting circadian abnormalities, exercise also has a significant effect on the circadian system. Moreover, both animal and human studies suggest that the stimuli can have additive effects.

Circadian Rhythms, Jet Lag, and Athletic Performance

For many years, it has been assumed that there must be a circadian rhythm in athletic performance. Certainly, circadian rhythms have been established for numerous biological and behavioral functions that could influence athletic performance, including pulmonary function, body temperature, mood, reaction time, alertness, and cognitive function.

It has often been assumed that athletic performance is optimal in the evening, when body temperature peaks. Support for this idea stems in part from the observation that many world records have been set in the evening. However, this could be explained by more favorable weather or by the fact that major athletic events are scheduled more often in the evening than in the morning.

Numerous studies of time-of-day variations in athletic performance have found that optimal performance occurs in the evening for many types of performance (particularly those lasting <2 minutes). However, this pattern might be attributed to a number of environmental and behavioral factors independent of circadian regulation. For example, worse performance in the morning versus evening could be attributed to glycogen depletion following a 12- to 16-hour nighttime fast, joint stiffness following bed rest, sleep inertia (feeling groggy) on awakening, lower ambient temperature, less muscle "warm-up" associated with daily activity, expectancy, and the fact that many athletes are less accustomed to exercising in the morning versus evening. Other flaws of previous studies on this topic are that they have generally involved small numbers of unskilled performers completing novel experimental tasks of dubious generalizability to athletic competition (such as grip strength).

A recent study by Christopher Kline and colleagues in 2007 addressed these shortcomings. Twenty-five collegiate swimmers followed a 180-minute ultrashort sleep-wake cycle (1 hour sleep and 2 hours wake) for 50 to 55 hours. In this schedule, energy intake, light exposure, and sleep were equally distributed across the 24-hour day. Each swimmer swam six maximal-effort 200-meter (m) freestyle trials at times spread across the 24-hour cycle (a total of 150 trials). A clear circadian pattern was found. Performance peaked 5 to 7 hours before the body temperature peak (~11 p.m.) and was worse from 1 hour before to 1 hour after the body temperature nadir (~5 a.m.). Circadian range from peak to worst performance was 5.8 seconds.

The study by Kline and colleagues provides the first definitive demonstration of a circadian rhythm in athletic performance, independent of environmental and behavioral masking factors. The results could have considerable importance in athletic competition. For example, among women competing in the 200-m freestyle final at the 2008 Olympics in Beijing, the first and eighth places were separated by only 1.03 seconds.

Considering evidence that body cooling promotes endurance performance, it seems plausible that endurance performance might be optimal when performed near the temperature nadir in the early morning. This hypothesis should be tested with similar methods. Conceivably, athletes could shift their body clocks so that the peak of their performance rhythms coincides with the time of competition.

The results obtained by Kline and colleagues could be particularly relevant to performance after rapid transmeridian travel, depending on the time of day of competition, the direction traveled and number of time zones crossed, and the amount of time available before competition.

For the sake of illustration, we can consider the U.S. swimmers competing in the Olympic 200-m freestyle competition. It is standard practice for athletes to travel to the Olympics at least a week before the start of the games. For previous Olympics, in which the 200-m freestyle was scheduled in the evening (local time), such a practice seemed well justified from a chronobiological perspective. The swimmer would want sufficient time to allow his or her performance rhythm to shift such that the peak of this rhythm coincides with the time of competition.

However, an interesting situation occurred in the 2008 Beijing Olympics, in which the swimming events were scheduled in the morning (local time) to accommodate U.S. evening television programming. For the Beijing Olympics, U.S. swimmers might have performed even better had they arrived in Beijing immediately before the competition, exploiting the fact that their circadian peak in performance (evening in the United States) on arrival would have coincided with the time of competition.

There could be other advantages to arriving closer to the day of competition, including avoidance of a stressful environment, more freedom to train when desired, and less exposure to viruses. It is noteworthy that many horse trainers have concluded that horses perform best when they perform immediately after transmeridian travel as opposed to waiting for several days. This result makes some intuitive sense because the symptoms of jet lag are at the highest levels during the first few days in which an organism is adjusting to a new time zone.

Nonetheless, it is generally assumed that athletic performance is impaired following transmeridian travel. This impairment could be attributed to many aspects of jet lag, including mood disturbance, sleep loss, impaired reaction time and alertness, and alteration of the normal internal milieu between various biological rhythms.

Although anecdotally, some athletes report impaired performance after air travel, critical reviews of this topic have concluded that there is no consistent or compelling scientific evidence to show that either air travel across multiple time zones or jet lag symptoms cause a reduction in sports performance. Elite athletes who have honed their skills by performing tens of thousands of practice trials over years of training might rely especially on their ability to perform, and they might be resistant to the potential effects of jet lag. The limitations in this literature that prevent defensible scientific conclusions include assessment of nonathletes performing novel tasks of dubious generalizability to athletic competitions, lack of control groups, and failure to document performance preflight.

In summary, it is widely believed that jet lag adversely influences sport performance. Jet lag symptoms are unpleasant, and it is plausible that they could cause a reduction in performance. A circadian rhythm in performance could potentially result in either improvement or impairment of performance after travel. There is a need for methodologically sound research documenting whether athletic performance is influenced by rapid transmeridian travel.

Circuit Training

Circuit training is classified as a style of exercise that benefits muscular strength, muscular endurance, cardiovascular endurance, total body flexibility, and stability if necessary. This entry discusses what constitutes a circuit training program, the variables in circuit training, and why it is important to use circuit training in a periodized training regime.

Circuit training was devised in 1959 at Leeds University in England by Morgan and Adamson as a way to improve overall fitness. Since then, circuit training has been used by athletes in all sports at some point in their training. Circuit training routines are composed of a multitude of exercises from resistance training to cardiovascular exercise, and it may use a variety of tools, including medicine balls and Kettlebells, body weight, and resistance training machines.

Program Design

The program design of circuit training will significantly alter the performance outcome. The major variables of the program design are exercise type, the amount of rest between exercises, and the number of exercises in each circuit.

Exercise Type

In determining the type of exercises for the circuit training program, it is important to factor in the individual's level of fitness, existing injuries, and current phase of training. With novice exercisers, the program is usually designed with very basic exercises. Using a resistance training machine is often the exercise of choice with novice exercisers because of the ease of use of a single plane of motion. However, the use of body weight and multiplanar exercises are also excellent and necessary for the novice exerciser, primarily to increase proprioception and functional strength for daily activities.

Many fitness centers have resistance training machines set up in a circuit as a feature for people who are new to fitness centers. The circuits alternate between upper body and lower body exercises, allowing for one part of the body to recover while the other performs. A well-known example of this type of fitness center is Curves™, a women's-only fitness center. Although an excellent concept for novice exercisers and women who may be intimidated by the coed fitness centers, extended training with the same circuits or programs will not produce the same positive adaptations from training as it did in the first 6 to 8 weeks. As per the principle of Specific Adaptations to Imposed Demands (the SAID principle), it is prudent to subtly modify the circuit's exercise structure at least every 8 weeks. Modifications can be made by changing the intensity, volume, and tempo and, more important, the plane of motion of movement and demand for stability and application to an athlete or individual's weakest link. An individual's

Table 1 Sample Circuit Training Program for a Novice Exerciser/Athlete

No.	*Exercise*	*Sets*	*Repetitions*	*Intensity*	*Rest*
1	Push-up	2–3	12–15	30–50% of 1 RM	90 seconds[a]
2	Body weight squat	2–3	12–15	30–50% of 1 RM	90 seconds
3	Seated row machine	2–3	12–15	30–50% of 1 RM	90 seconds
4	Split squat	2–3	12–15	30–50% of 1 RM	90 seconds
5	Overhead press	2–3	12–15	30–50% of 1 RM	90 seconds
6	Leg press	2–3	12–15	30–50% of 1 RM	90 seconds
7	Cable upright row	2–3	12–15	30–50% of 1 RM	90 seconds
8	Seated leg curl	2–3	12–15	30–50% of 1 RM	90 seconds
9	Biceps curl	2–3	12–15	30–50% of 1 RM	90 seconds
10	Triceps extension	2–3	12–15	30–50% of 1 RM	90 seconds
11	Plank	2–3	30-second hold	30–50% of 1 RM	90 seconds
12	Floor bridge	2–3	30-second hold	30–50% of 1 RM	2 minutes[b]

Table 2 Sample Circuit Training Program for an Experienced Exerciser/Athlete

No.	*Exercise*	*Sets*	*Repetitions*	*Intensity*	*Rest*
1	Barbell front squat	3–5	12–15	40–60% of 1 RM	60 seconds[a]
2	Body weight pull–ups	3–5	12–15	40–60% of 1 RM	60 seconds
3	Single leg dead lift	3–5	12–15	40–60% of 1 RM	60 seconds
4	Physio ball DB chest press	3–5	12–15	40–60% of 1 RM	60 seconds
5	DB walking lunge	3–5	12–15	40–60% of 1 RM	60 seconds
6	Barbell bent over row	3–5	12–15	40–60% of 1 RM	60 seconds
7	Barbell step-up	3–5	12–15	40–60% of 1 RM	60 seconds
8	DB overhead press	3–5	12–15	40–60% of 1 RM	2 minutes[b]

Notes: RM = repetition maximum; DB = dumbbell. a. Rest prior to executing the next exercise. b. Rest prior to repeating the circuit.

functional weakest link is not his or her mobility or stability, rather it is his or her strength or cardiovascular endurance. Exercises in circuits providing improvement in functional mobility or stability for an individual are paramount in circuit training program design.

Rest Intervals

The durations of rest between circuit exercises and rest between repetitions of the entire circuit drastically change the ratios of the energy system's utilization. The three major energy systems used during exercise are the (1) phosphagen system, (2) glycolytic system, and (3) oxidative system. Depending primarily on the intensity of exercise, then secondarily on the duration of exercise and the rest between bouts of exercise in a circuit, one of the three aforementioned systems will be used more than the others. For example, if the work-to-rest ratios between exercises within a circuit is 4:1 (60 seconds of work and 15 seconds of rest), the primary energy system would be the glycolytic system (fast glycolysis and oxidative), which automatically becomes the primary energy system for any exercise lasting more than 10 seconds and less than 3 minutes.

When the intensity of a circuit is high to moderate (75–90% of maximum effort) and lasts less than 5 minutes, the system most stressed is the glycolytic system. However, if the circuit is of low to moderate intensity (30% or less of maximum effort) and lasts longer than 5 minutes, with little or no rest between exercises, the primary system stressed is the oxidative system. If the goal of a training phase is to increase the absolute maximal power, circuit training will not optimize power adaptations. However, improvements in functional power are seen per the need of an individual.

Number of Exercises

Circuit training traditionally involves 5 to 15 exercises in succession. Depending on the training needs and experience of the person performing the circuit, the number of exercises will vary. For a novice exerciser or beginner athlete, it is important to activate as many muscles as possible; therefore, the circuit should have more exercises—9 to 12 exercises are recommended. The duration of the training program should be at least 8 weeks but may last as long as 12 weeks, with subtle modifications to maintain consistent positive adaptations.

In the case of experienced athletes and exercisers, the number of exercises in the circuit can be fewer than nine, since the intensity and difficulty of the exercises will likely be greater than in the training program of a novice exerciser.

Tables 1 and 2 are examples of circuits for novice and experienced athletes or exercisers, respectively.

Conclusion

Circuit training is an excellent way to introduce the novice exerciser to a multitude of different exercises, as well as to allow the body to adapt to the stress of resistance and functional training. Experienced athletes and exercisers benefit greatly from circuit training as a foundational phase of their periodized training program. Muscular strength, hypertrophy, endurance, and power can all be improved with circuit training but will not reach peak levels with this form of training alone. For novice exercisers, it is perhaps the best form of training for their lifestyle and time constraints, and for the experienced athletes and exercisers, it is a fun and challenging way to transition out of the monotony of their regular training regimen.

Clavicle (Collarbone) Fracture

Clavicle fractures are common injuries, accounting for nearly 5% of all fractures seen by a doctor. The injuries are more common in young athletes, with over half of them occurring in children under 7 years of age. In the pediatric population, the fractures tend to heal quite well. In adult patients, a greater force is required to break the collarbone, and they do not heal as well or as quickly.

Anatomy

The *clavicle* is the S-shaped bone between the shoulder girdle and the trunk. It helps protect the subclavian blood vessels, the top of the lungs, and the brachial plexus (nerves). The medial end is the sternoclavicular (SC) joint. This is held together very tightly by ligaments. The sternocleidomastoid muscle attaches at the superior and proximal portions of the clavicle. The distal clavicle is the acromioclavicular (AC) joint. It is stabilized by the coracoclavicular and acromioclavicular ligaments. The middle portion is the thinnest and has no ligaments that help with stability, so it is the most commonly fractured site.

Causes

The three most common mechanisms for clavicle fracture are falling onto an outstretched hand, falling onto the shoulder, and direct trauma to the clavicle.

Clinical Evaluation

History

The patients will usually present after trauma and a consistent mechanism of injury. The pain is made worse by moving their arm, so they frequently hold their arm against their chest, as if they were wearing a sling. They may report a deformity and swelling.

It is important to ask about respiratory problems such as shortness of breath. Clavicle fractures can rarely cause a pneumothorax (puncture of the lung). It is also necessary to ask about function and sensation in the affected arm, as clavicle fractures rarely can damage the nerves and blood vessels leading to the arm.

Physical Exam

Patients will have bony tenderness over the fracture site. There is usually an obvious area of swelling and deformity at the fracture site, but this is not as common with distal clavicle fractures. They will have pain with motion of the affected arm.

It is important to assess pulse and blood supply in the affected arm to rule out vascular injury. The sensation and muscle function should also be checked to rule out nerve damage. Finally, listening to breath sounds can help rule out pneumothorax.

Diagnostic Imaging

Standard anteroposterior X-rays are usually sufficient to diagnose a clavicle fracture. The 45° cephalic tilt view can be helpful with diagnosis. Computed tomography (CT) may be needed for proximal and distal clavicle fractures, as they can be very difficult to diagnose.

Treatment

Most clavicle fractures can be treated without surgery. Eighty percent of the fractures occur in the middle third, 15% in the distal third, and 5% in the proximal third. Initial care should include evaluation to ensure that there is not a more serious injury as described earlier. Then, ice and pain medications can be used to help the athlete feel more comfortable.

Patients need to be examined by an orthopedic surgeon immediately if there is an open fracture (bone punctures the skin) or if there is neurovascular compromise. Often, fractures with multiple fragments (comminuted) can be treated without surgery.

There are adult athletes who may prefer to undergo surgery to potentially reduce their time away from sports. This is mainly because adults have a longer healing time and higher risk of nonunion.

Fractures of the Middle Third of the Clavicle

The goal of treatment is to stabilize the fracture site. This is best done with a sling or a figure-of-eight brace that restricts shoulder motion slightly. The sling or brace should be continued until there is no longer any tenderness at the fracture site. Within a few weeks, there should be a bump or callus present over the fracture site. This is the area of healing bone. In pediatric patients, this will usually remodel and disappear in time.

Any progress is usually documented by a healing callus, which can be seen on an X-ray, and a nontender fracture site with full shoulder range of motion on exam. In adults, this fracture should heal in 6 to 12 weeks. In children, it can take only 3 to 6 weeks.

However, the bone is still at high risk for refracture for 1 to 2 months following clinical healing. It is important for people to avoid jobs with significant physical exertion, sports with a high risk of falling, and contact sports during this time period after healing.

Nonunion is uncommon, and these patients should be seen by an orthopedist after 12 to 16 weeks of conservative treatment. Rarely, the bone will produce a large callus, which can compress the brachial plexus and cause ulnar or median neuropathy. These patients also should be seen by an orthopedist.

Fractures of the Distal Third of the Clavicle

These fractures are classified as Types I, II, and III. Type I fractures are the most common, and they have no ligament damage or displacement. Type II fractures can be difficult to diagnose with standard X-rays. These involve damage to the coracoclavicular ligaments and have upward displacement of the clavicle. Type III fractures are through the AC joint (intraarticular).

Patients with open fractures and neurovascular compromise need to be seen immediately by an orthopedist. Patients with Type II fractures tend to heal poorly without surgical stabilization.

Fractures of the medial third of the clavicle require treatment with immobilization followed by return to play. Fractures of the distal third may require a week or two more in the sling or brace than middle third fractures.

Fractures of the Proximal Third of the Clavicle

Patients with fractures of the proximal third of the clavicle tend to feel much more comfortable seated rather than lying down. It is also important to consider if there is any fracture of the sternum (breastbone) in athletes with these kinds of fractures.

Athletes who have posterior displacement of the clavicle need urgent surgical evaluation to prevent damage to the underlying nerves and blood vessels. Healing time and return to activity are consistent with fractures of the distal third of the clavicle.

Complications

Overall, clavicle fractures have an excellent prognosis in children and adults when they are compliant with their treatment. The most serious, but thankfully rare, complication is neurovascular compromise. This can cause damage to the subclavian, internal jugular, and axillary blood vessels. There can also be a pneumothorax.

More commonly, there is a residual bony prominence that can result in a poor cosmetic appearance but generally no functional limitations.

Hypertrophic (overgrown) callus formation can cause compression of the brachial plexus and resultant peripheral neuropathy. This can be treated by surgical reduction of the callus.

Nonunion is most common with fractures of the distal third of the clavicle but can happen with any clavicle fracture. In adults, fractures that are displaced are at increased risk for nonunion.

Arthritis can occur after clavicle fractures, most commonly Type III distal clavicle and proximal clavicle fractures.

Cold Injuries and Hypothermia

Cold injury encompasses a spectrum of pathophysiology from frostbite to hypothermia. Injury is caused by the body's inability to compensate for cold exposure. Activities and sports that are most commonly associated with cold injuries are those that take place in a winter or alpine environment (e.g., mountaineering, skiing), activities that involve water exposure or immersion (e.g., swimming, kayaking, triathlons, sporting events played during rain or snow), and those that are associated with prolonged endurance (e.g., ultraendurance events, marathons).

Physiology of Temperature Regulation

Humans function optimally in a narrow temperature range. The body has numerous mechanisms for producing heat when needed. With cold exposure, preshivering muscle tone increases and can double the body's baseline heat production. Because of fatigue and glycogen depletion, heat production lasts only a few hours. Increased output from the thyroid and adrenal glands also works to increase heat production. Shivering is another of the body's strategies for increasing heat production. Shivering thermogenesis increases the basal metabolic rate by two to five times.

Body temperature is influenced by four heat loss mechanisms: (1) conduction, (2) convection, (3) evaporation, and (4) radiation. Conduction is the transfer of heat by direct contact. Since the conductivity of water is approximately 25 times that of air, the body will rapidly lose heat when immersed in water. Convection is the transfer of heat associated with air movement. This form of heat loss is increased in windy conditions. Evaporative heat loss occurs when moisture on the skin converts to gas. It also occurs during respiration. Radiation heat loss occurs when heat is lost to the environment primarily from uncovered skin.

Peripheral Cold Injury

In a cold environment, the body's highest priority is to maintain its core temperature. One of the mechanisms used by the body is vasoconstriction of the circulatory system in the extremities, minimizing heat loss. This can cause the temperature of the tissues of the extremities and face to drop below the freezing point, resulting in injury. Likelihood of cold injury is also influenced by other factors such as duration of exposure, wind, humidity, altitude, clothing, medical conditions, behavior, personal variability, and hydration status.

Nonfreezing Cold Injuries

Chilblain (Pernio)

Chilblain is a reversible injury caused by skin exposed to damp, nonfreezing temperatures. It is characterized by localized erythema, edema, and cyanosis, which is often described as painful, pruritus (itching), or burning. The symptoms usually last for several days. The treatment includes rewarming, elevation, and gentle bandaging. Topical or oral steroid use has been shown to be useful. The affected areas are more prone to reinjury.

Trench Foot

Trench foot is a direct injury to soft tissues caused by prolonged exposure to cold and wet conditions. It was seen frequently among the soldiers of World War I, who spent long periods of time in water-filled trenches. Though it has most frequently been seen in military populations, it can also occur in civilian populations.

Trench foot occurs over hours to days. Initially, there is an uncomfortable tingling of the extremities. At this point, there is no permanent damage to the tissue. If allowed to continue, symptoms progress to numbness of the limb, and there is permanent damage to the tissue. The treatment is rewarming. As the extremity is rewarmed, it goes from pale, pulseless, numb, and immobile to painful and hyperemic (red) in the first few hours. Over the next 2 to 3 days, the extremity often swells and blisters form. The numbness will continue for weeks to months. In more severe cases, tissue damage can lead to gangrene and limb loss.

Freezing Cold Injuries

Frostbite

Frostbite occurs when the tissue temperature drops to less than 0 °C (32 °F). Ice crystals form in the extracellular space and pull fluid from the surrounding cells. This causes intracellular dehydration, electrolyte derangement, and protein and enzyme destruction, finally resulting in cell death. As the frostbitten tissues are rewarmed and some blood flow returns, injuries to the vascular structures cause vasoconstriction, in turn causing tissue ischemia, dry gangrene, and necrosis.

Clinical Features. Frostbite is classified by the extent of the initial tissue damage from first degree (partial skin freezing) to fourth degree (full-thickness skin, muscle, bone freezing). First-degree frostbite is associated with a stinging or burning sensation. The skin is erythematous and edematous without blisters. Second-degree frostbite is associated with the appearance of clear, fluid-filled blisters and numbness of the affected areas. In third-degree frostbite, blood-filled (hemorrhagic) blisters form. The tissue feels like a "block of wood" and has a blue-gray discoloration. Fourth-degree frostbite is characterized by a mottled or deep red hue that progresses to a dry, black appearance and possible joint pain.

Treatment. Treatment for frostbite centers on rewarming the affected tissues. Field management involves removal of wet and constrictive clothing, elevation of the affected area, and dry sterile dressing. To avoid further injury, it is often safest to initiate active rewarming in a controlled environment. Rewarming can be associated with significant pain, limiting ambulation, which can interfere with field evacuation. Rewarming should also be avoided if there is potential for interrupted or incomplete thawing since refreezing is associated with significantly worse outcomes. Once in a controlled environment, the injured tissue is rewarmed in a bath at 40 to 42 °C (104–107.6 °F). The patient should be instructed to actively move the injured area if possible. Appropriate analgesia should be administered. Care must be taken not to overheat the rewarming bath, which can cause further injuries. Dry heat such as campfires and heaters should be avoided since they tend to desiccate the injured tissues, worsening the damage. Treatments such as rubbing the affected areas with snow and friction massage are contraindicated and are associated with increased tissue damage. Except for minor cases, all patients should be hospitalized for 24 to 48 hours.

Postthaw care involves sterile debridement of clear blisters, tetanus prophylaxis, aloe vera cream, and prophylactic antibiotics (e.g., penicillin G).

The long-term effects of frostbite, especially cases involving the deep tissue, can be significant. Permanent cold sensitivity, tingling, burning electric shock sensations, and excessive sweating are all common. Thermal perception is often altered. Frostbite that involves joints and bones often results in arthritis. Discoloration of the skin can occur. In people with immature bones, growth plates can be damaged, causing abnormal growth, especially in the fingers and the forearms. Severe frostbite often results in amputation.

Central Cold Injury: Hypothermia

Hypothermia is defined as a core body temperature of less than 35 °C (95 °F). Exposure to profound cold is not necessary to produce hypothermia. Hypothermia can occur in temperate regions and during summer. Predisposing factors that increase the risk for hypothermia in the athlete population are trauma, exhaustion, hypoglycemia, immersion, exposure to cold with inadequate protection, and dehydration.

Clinical Features

Hypothermia can be divided into three stages based on core temperature. Mild hypothermia (32–35 °C/89.6–95 °F) is the excitation phase. During this stage, shivering thermogenesis is maximal. Cold-induced diuresis causes an increase in urination. There are increases in respiratory, heart, and metabolic rates, as well as blood pressure, as the body attempts to retain and generate heat. Ataxia, dysarthria (slurred speech), and apathy begin to occur in this temperature range. The body constricts the peripheral blood vessels to prevent further heat loss, causing cold extremities and increasing the risk for frostbite.

Moderate hypothermia (30–32 °C/86–89.6 °F) is the slowing phase, in which there is a slowdown of the body's functions. Shivering ceases. The metabolic rate slows down, causing a decrease in oxygen consumption, blood pressure, and pulse. Significant electroencephalogram (EEG) and electrocardiogram (EKG) changes are seen. Confusion, poor judgment, fatigue, and incoordination occur. Dehydration is a serious risk secondary to increased urination and lack of adequate mental faculty. Cardiac dysrhythmias become more likely in this stage.

Severe hypothermia (<30 °C/<86 °F) is associated with coma, dysrhythmia progressing to cardiac arrest, and respiratory failure. Hypothermic cardiac tissue becomes extremely unstable. Life-threatening dysrhythmias can occur if the patient is not handled gently. Severe hypothermia can easily be confused with death since there can be significant slowing of the body's functions. Death cannot be presumed until after full warming has taken place, which leads to the old emergency room adage: "You're not dead until you're warm and dead."

Diagnosis

Diagnosis can be difficult since many of the early clinical features are nonspecific. Also, most commonly used clinical thermometers are not adequate since they record only up to 34.4 °C (94 °F). If oral temperature is above 35 °C (95 °F), hypothermia can be excluded. Providers must have a high index of suspicion and a low threshold for obtaining temperatures on individuals exhibiting any clinical features of hypothermia. If an individual is suspected of having hypothermia, an accurate rectal core temperature must be obtained using a low-reading thermometer.

Treatment

There are three major approaches to the treatment of hypothermia: passive rewarming, active external rewarming, and active internal rewarming. Passive rewarming involves removing the individual from the cold environment and insulating, allowing the patient to rewarm on his or her own. This is most appropriate for the treatment of mild hypothermia, though many advocate using this approach for any patient with a stable cardiovascular status with even moderate hypothermia.

Active external rewarming augments the patient's own rewarming with external heat sources such as warm-water immersion, heating blankets, and warm objects (water bottles, etc.). This approach is often effective in raising the core temperature rapidly, though caution must be used especially with warm-water immersion, which can make monitoring and resuscitation difficult. Active external rewarming can be used for all stages of hypothermia.

Active internal rewarming is performed in a hospital setting. Rewarming takes place internally with techniques that include intravenous fluids, inhalation rewarming, gastrointestinal tract lavage, bladder lavage, and extracorporeal blood warming. This approach is used only in patients with cardiovascular instability and takes place in highly monitored settings such as intensive care units.

All patients with symptomatic hypothermia should be admitted to the hospital for monitoring.

Colles Fracture

A *Colles fracture* is a common fracture to one of the bones of the forearm near the wrist. These fractures are documented in athletes of all ages. Because of high-impact forces, including falls in sports such as football, snowboarding, and gymnastics, athletes who are otherwise healthy often experience these injuries. As participation in high school and junior high school sports increases, injuries such as Colles fractures are becoming more common in younger populations. This entry outlines the definition, symptoms, diagnosis, and treatment of Colles fractures in athletes.

The fracture is named after the Irish surgeon who first described it in 1814. Since that time, several classification systems have been devised to further describe this particular fracture. The Frykman classification system, for example, characterizes fractures based on the involvement of different joints at the wrist. Although it is helpful to be aware of these classification systems, the specifics are beyond the scope of this entry.

To understand the details of fractures and their management, it is necessary to have a basic understanding of the anatomy of the fracture site. The forearm contains two bones. The radius articulates, or connects, with the thumb side of the wrist. The ulna lies parallel to the radius, away from the thumb. A *Colles fracture* refers to a fracture of the radius near the wrist. The fractured portion of the radius moves dorsally, toward the back of the hand. These fractures commonly occur within 2 centimeters (cm) of the end of the radius. A *Smith fracture* is the name given to a fracture at the same site, when the fractured piece of bone tilts volarly, or downward to the palm side of the wrist.

The fracture may be isolated to the radius without joint involvement. But it is not uncommon for it to extend to the area where the radius meets the small bones of the wrist, or the joint between the radius and the ulna. There may also be an associated fracture of the ulna as well as ligament damage. The ulnar collateral ligament, which runs from the ulna to the small bones of the wrist, may experience stretching or rupture.

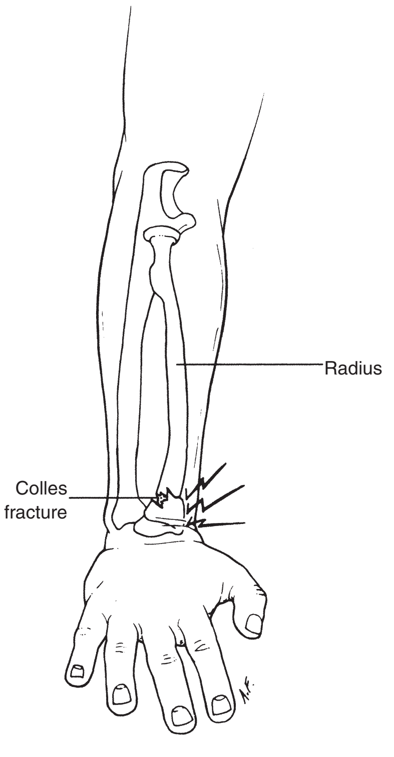

Figure 1 Colles Fracture Are Often Caused by a Fall Onto an Outstretched Arm

The appearance of the wrist following a Colles fracture is often described as an upside-down dinner fork. The fractured portion of the radius creates a bulge at the back of the wrist, similar to the curved portion of the back of a fork. The mechanism of injury accounts for the direction of the displacement of this fracture. A Colles fracture most often occurs following a fall onto an outstretched hand. This type of fall is extremely common in a variety of sports.

Snowboarding is a sport in which participants often use their hands to brace themselves when falling. Several studies have shown that the most common injury for snowboarders is one to the wrist. One Japanese study demonstrated that more experienced snowboarders were less likely to experience these fractures. Interestingly, expert snowboarders, though less likely to have fractures overall, experienced more severe fractures as a result of injuries sustained when performing jumps.

Although a fall on an outstretched hand is the most likely mechanism of injury for a Colles fracture, it is not the only one. A case report from the *British Journal of Sports Medicine* describes a unique instance of a Colles fracture. The athlete who sustained the injury was a 21-year-old weight lifter. While lifting weights at his club, he lost control and fell backward. His wrists were forced back by the weight and he landed on his elbow. The force of the weight caused a fracture to his distal radius.

Regardless of the sport involved, the signs of a Colles fracture remain the same. After the initial injury, the athlete will note pain and swelling as well as the dinner fork deformity. Bruising at the site is also common. Any motion of the wrist will increase the tenderness of the area, and the range of motion will often be compromised. In addition, athletes with this fracture will note extreme pain at the site of the injury during physical examination. It is important to evaluate the injured athlete's sensation over the wrist and hand as Colles fractures may be associated with nerve damage. Injuries may also involve arteries or ligaments, so pulses and hand motion should also be assessed.

Notably, there are fractures other than Colles fracture that present with similar symptoms. These fractures include a Smith fracture, mentioned above, as well as fractures to the smaller bones of the wrist, such as the scaphoid. Distinguishing these different entities during an on-field evaluation can be extremely difficult. To properly diagnose and treat a Colles fracture, it is essential to obtain plain X-rays of the injury. Films can demonstrate the type and severity of the fracture.

Generally, X-rays from three different views are taken to evaluate a suspected Colles fracture. These films will show the relationship of the fractured portion of bone to the rest of the radius and demonstrate the degree to which it is displaced from normal anatomy. The extent and severity of the fracture will often dictate the management; if there is any doubt as to the severity of the fracture on an X-ray, a computed tomography (CT) scan can be used for further assessment.

Treatment

The goal of treatment of a Colles fracture is to restore normal anatomy and function of the wrist. Failure to do so can compromise the athlete's motion at the wrist and thus interfere with activities such as throwing, shooting, or pushing off. Depending on the complexity of the fracture, Colles fractures may be managed by different means.

Simple fractures that are nondisplaced and do not involve the joint can be managed with immobilization alone. A double, sugar tong splint is the initial immobilization device of choice. Patients should be seen 3 to 5 days following the initial splint placement to allow resolution of the swelling before casting. At that time, the patient should be reexamined, and repeat X-rays should be taken to confirm the stability of the fracture. If the fracture remains stable, a short arm cast is applied. Follow-up X-rays as well as examinations are necessary, usually at 2-week intervals until healing is complete. These fractures generally take 6 to 8 weeks to heal.

As the fractures become more complex, however, so does the management. Displaced fractures will require manipulation of the bones back into proper alignment. Unstable fractures may require surgery to restore the radius to its normal anatomy. External or internal fixation devices can be used to anchor the fractured segments in place. Fractures that require reduction or surgical stabilization devices will require a longer period for healing.

Regardless of the method of treatment, patients should be aware of several red flags that require prompt evaluation by a physician: decreased sensation, tingling, or numbness of the fingers; discoloration of the nail beds; or worsening pain or swelling. Physical therapy is necessary after healing to strengthen the muscles of the hand and to increase its range of motion. It is important to note that return to unrestrained activities before a stable union of the fracture may result in serious complications that could compromise an athlete's ability to perform in the future. A rehabilitation program should be focused on protecting the fracture, restoring range of motion, and building strength in the affected area. A protective splint may be useful in the first month after the immobilization device has been removed.

Recognition and appropriate initial management of a Colles fracture are important for overall healing and return to play in athletes. These fractures are common injuries with the potential to impair long-term performance if treated improperly. A team approach to treatment and rehabilitation, combining the expertise of physicians, therapists, and trainers, will provide athletes with a safe, structured return to play.

Compartment Syndrome, Anterior

Compartment syndrome consists of a combination of pain, numbness, and/or weakness in an arm or leg due to muscle swelling or bleeding. Compartment syndrome can be an acute surgical emergency caused by broken bones or crushed limbs, but it can also occur in sports activities when the muscle grows too large because of its use during training or competition. The anterior compartment of the leg is the most common location of this syndrome. If it is not diagnosed and treated appropriately, compartment syndrome can cause loss of the ability to compete effectively as well as chronic pain, weakness, and numbness.

Anatomy

The portion of the leg between the knee and the ankle is divided into four compartments by a strong tissue called *fascia*. The anterior compartment of the leg is located just to the outside of the tibia and can easily be felt in an athlete. The muscles in the anterior compartment are responsible for bending the ankle and raising the foot away from the floor (dorsiflexion of the ankle). Dorsiflexion of the ankle is basically the opposite motion to putting pressure on the gas pedal of a car, which is called plantarflexion of the ankle. The muscles of the anterior compartment are also responsible for lifting the big toe and other toes away from the floor (extension of toes). The muscles that are contained in the anterior compartment of the leg include the tibialis anterior, which is the main dorsiflexor of the ankle; the extensor digitorum longus, the main extensor of the smaller toes; the extensor hallucis longus, the main extensor of the big toe; and the peroneus tertius. There are also nerves that pass through the anterior compartment, and the most important nerve is called the *deep peroneal nerve*. This nerve allows sensation to the space between the first two toes. There are also arteries, veins, and lymphatics in the anterior compartment. Finally, the tibia and fibula bones touch the anterior compartment and provide places for the muscles to attach.

The other three compartments of the leg are called the posterior deep, the posterior superficial, and the lateral. The gastrocnemius and soleus muscles and sural nerve are in the posterior superficial compartment. The posterior deep compartment contains the flexor hallucis longus, flexor digitorum longus, and posterior tibialis muscles and the tibial nerve. The lateral compartment contains the peroneus longus and brevis and the superficial peroneal nerve.

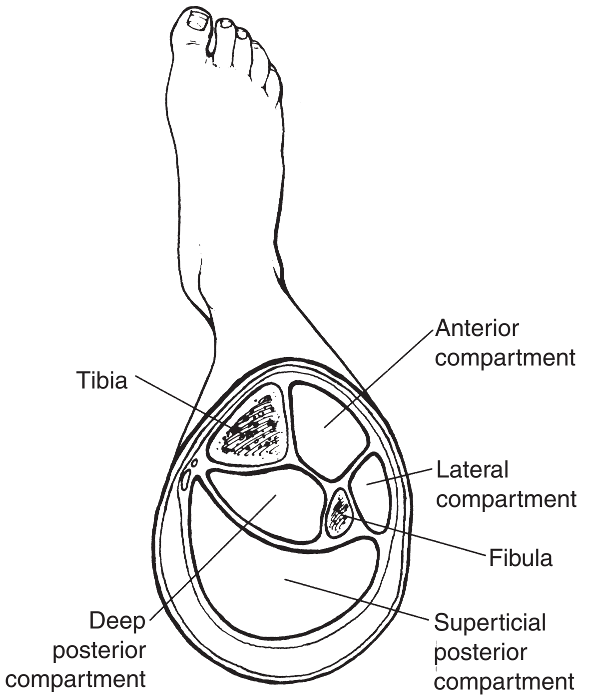

Figure 1 Anterior Compartment Syndrome

Notes: Excessive training can cause the muscles in the lower leg to grow too large for their surrounding heavy membranous walls, or compartments. At rest there is no problem, but during exercise, the muscles swell with blood, increasing pressure within compartment and producing the characteristic symptoms of compartment syndrome. The condition is most often seen in the anterior compartment.

Pathophysiology

The fascial bands surrounding the compartments of the leg are not elastic and do not stretch. If the muscles in a compartment become larger due to exercise, such as running, they can become too big for their compartment and start to become squeezed by the fascia. This is called exercise-induced, or chronic, or *exertional compartment syndrome*. The squeezing of the muscles is painful. The compression of the muscle allows less blood to get to the tissue, and the tissue that does not get enough blood becomes painful. The squeezing of the muscles causes the pressure of the compartment to increase, and that pressure can also squeeze the nerves and blood vessels. This squeezing can cause “pins and needles” or numbness and changes in the color of the leg due to changes in blood flow. This color change can be described as “mottling” of the leg. Mild forms of compartment syndrome allow the athlete to complete activity with various amounts of pain, but often compartment syndrome can become so painful that the athlete must stop the activity. The pain usually resolves with rest because the muscle at rest is smaller than the muscle in use; the muscle in use is full of blood to provide oxygen to the muscle cells. The smaller muscle fits better in the compartment and is not squeezed by the fascia.

Symptoms

The athlete will be asymptomatic at rest but will complain of pain during exertion. The pain usually begins at a predictable time during activity, such as a certain mileage or time of running. The pain is described as cramping or aching. The athlete may also notice something called *paresthesias*, which is the technical term for the “pins and needles” feeling when your arm or leg falls asleep. This should also resolve with rest. The athlete may notice weakness of the muscles of that compartment. Tightness or a sense of fullness of the leg is common during the symptomatic episodes.

Physical Exam

Much of the time, the athlete’s leg does not offer a clue to the diagnosis in the clinic because the leg looks normal. The abnormal findings are often only seen when the athlete is exercising. If the problem has been going on for a long time, there may be tenderness when the doctor presses on the leg, even at rest. It is helpful to note defects or holes in the fascia that can be felt through the skin. These will allow the doctor to feel whether the muscle is swollen because it can bulge or herniate through these holes.

If the athlete is symptomatic because of recent exercise, the physician may note a swollen or tight leg. The skin can become shiny if it is stretched over a swollen compartment. The physician will feel the compartment or leg and note any tenderness. Next, the physician will ask the patients to move their ankle up and down under their own power, and the physician will note any weakness compared with the other leg. Then the physician will move the ankle up and down and note any increase in pain. This is called passive stretch, and it is a sensitive test for compartment syndrome. There may be a change in the pulses of the foot, but this is rare. Finally, the doctor will test sensation and note if the athlete has any areas of decreased sensation. The deep peroneal nerve runs through the anterior compartment and supplies sensation to the first web space of the foot, also known as the space between the first two toes. The athlete may have changes in sensation in the first web space if he or she has anterior compartment syndrome.

The physician may measure the pressure inside the compartment with a special device that is attached to a needle inserted into the muscle. This procedure is done in a clinic and may be done before and after exercise so that the numbers can be compared. If the pressure in the compartment is normal at rest and does not fall enough after exercise, then the diagnosis is made. The diagnosis can also be made if the problem is so advanced that the pressure in the compartment is higher than normal even at rest.

Radiographs (X-rays) are usually normal in exercise-induced compartment syndrome. Magnetic resonance imaging (MRI) may show some muscle swelling but is most helpful for ruling out other causes of pain, such as stress fractures, tumors, and torn muscles.

Differential Diagnosis

Acute compartment syndrome is a surgical emergency, and the fascia must be released or the muscle and nerves can die. Exercise-induced compartment syndrome, on the other hand, is not a surgical emergency.

There are three other compartments in the leg, including the posterior superficial, posterior deep, and lateral. Each compartment has different physical findings. Many times, more than one compartment is involved.

Ruling out shin splints, or medial tibial stress syndrome, is sometimes difficult. Shin splints, like exercise-induced compartment syndrome, cause pain in athletes during exercise but usually not at rest. The athlete with shin splints will have pain on palpation of the medial, posterior aspect of the tibia. The bone in exercise-induced compartment syndrome is usually not painful on palpation.

Stress fractures can also cause pain in the leg and may not show up on an X-ray. An MRI scan can differentiate between shin splints and stress fractures.

Other problems that need to be considered include tears of muscles, contusions, blood clots, tumors, infections, and compression of blood vessels.

Treatment

Nonoperative

The most important part of nonoperative treatment is rest. Nonsteroidal anti-inflammatory drugs (NSAIDs), stretching, and ice may also help relieve the discomfort.

Operative

The physician may recommend surgery. Surgery consists of an incision over the anterior compartment, anterior to the fibula. The incision can be from a few centimeters (cm) to 15 cm long. After the skin is divided, the fascia is identified, and the surgeon opens the fascia carefully so that no tissue deep to the fascia is damaged. The skin is then closed with stitches, as long as the muscle is not too swollen.

Complementary Treatment

Complementary and alternative medicine (CAM) encompasses health care provided outside the realm of conventional Western medicine (medicine as practiced by medical doctors, doctors of osteopathy, and ancillary professionals, such as registered nurses and physical and occupational therapists). As more and more complementary treatments are studied and proven effective, they are being adopted by, and thus called, conventional therapy. With increasing public awareness, elements of CAM are being absorbed into conventional medicine and into the everyday lives of people. Surveys and studies are increasingly demonstrating the frequent use of CAM therapies by athletes at varying levels of play.

Among the other names by which CAM is known are complementary medicine, alternative medicine, and integrative medicine, each with a slightly different connotation. Complementary medicine refers to health care provided outside the realm of, yet as a complement to, conventional medicine. In contrast, alternative medicine describes health care provided outside the realm of and instead of conventional medicine. Integrative medicine, as its name implies, is a combination of studied and proven complementary and conventional medicine.

Throughout the ages, CAM has developed with different methods of application and focuses, of which there are several. Whole medical systems, such as ayurveda, homeopathy, and traditional Chinese medicine (TCM), provide complete systems of medical practice. Mind-body medicine works within the mind's capacity to affect bodily function and health and includes therapies such as meditation and prayer. Cognitive behavior therapy, now considered conventional treatment, was once considered mind-body medicine. Biologically based practices, such as aromatherapy, vitamin therapy, and herbal therapy, use naturally occurring substances in health and healing. Chiropractic manipulation and massage are classified as manipulative and body-based practices, under which passive movement of one or more body parts promotes health and healing. The last general focus is energy medicine, including Reiki therapy, which uses energy fields in health and healing. This entry provides an introduction to some of the more commonly used CAM-focused therapies, their history, philosophy, and uses.

Acupuncture

Philosophy and History of Acupuncture

Part of TCM, acupuncture is used to promote health and to maintain balance of yin (cold, slow, passive principle) and yang (hot, excited principle). Acupuncture is practiced using a variety of techniques to stimulate specific points on the body and unblock the flow of energy (*qi*) along the body's meridians and, thus, achieve balance.

Practitioners and Practice of Acupuncture

Although the stimulation of specific body points can be practiced in several different ways, the most common acupuncture technique involves the use of thin, solid, stainless steel needles of varying length and gauge, placed at specific body points along the meridians. These needles may be stimulated by movement or by electrical current. The needles themselves are regulated by the Food and Drug Administration (FDA) and are required to be sterile, nontoxic, single-use only, and used by a licensed practitioner. Another commonly used method of stimulating the body is acupressure, during which the specific body points receive manual manipulation with the therapist's hands and fingers instead of with needles.

Although acupuncture practitioners can come from any of several different professional bases, most states require a license of some kind, although the requirements for attainment of that license (i.e., specific training) may vary. Although it may seem harmless, potentially dangerous side effects of acupuncture, if performed by an unskilled practitioner, include infection and punctured organs. Licensed acupuncturists are those who have studied for 3 years or more in an Oriental college of medicine. Chiropractors can practice acupuncture provided that they have received additional training in acupuncture. Physicians and dentists can also add acupuncture to their practices if they obtain additional training in acupuncture, although the length of training required varies by state from none to up to 300 hours. Physicians may also become board certified in acupuncture by the American Board of Medical Acupuncture.

Similar to other health care visits, acupuncture visits will follow a certain format. Typical acupuncture sessions include a discussion of the individual's medical history (e.g., medical conditions, menstrual cycle, eating and sleeping habits) as well as an examination of the patient's posture and mental state (e.g., tone of voice, emotional stress). Sessions can vary in length, although, once the needles are in, they usually last from 20 to 30 minutes. Though acupuncture can be used alone, sessions are often accompanied by the use of Chinese herbs. Sessions usually conclude with recommendations for certain lifestyle changes (e.g., diet, physical activity).

Uses of Acupuncture

Acupuncture has a variety of treatment uses, ranging from mental conditions and headaches to immune disorders and asthma. Acupuncture also has been found successful in treating addiction to illicit substances. With other mental health conditions, acupuncture helps decrease the length of stay in hospitals, as well as improves social interactions, mood, and sleep. Acupuncture research has also shown better control of allergic symptoms in patients using acupuncture in conjunction with herbs. Acupuncture has also found its way into the operating room. Acupuncture analgesia is one of the main methods of providing operative analgesia in Beijing and has been found to be beneficial in neurosurgery, thyroid surgery, tonsillectomies, and some open chest surgeries. Acupuncture research has also demonstrated a need for less traditional pain medications and a decrease of brain activities associated with pain on magnetic resonance imaging (MRI). Although further research is needed, some studies have demonstrated a decrease of symptoms from exercise-induced asthma when acupuncture was provided before the activity. Studies of acupuncture and acupressure have demonstrated a decrease in nausea and vomiting in patients who have undergone surgery and are undergoing chemotherapy. The relief and prevention of headaches is another of the studied benefits of acupuncture. Acupuncture has also been noted to promote fertility by improving fertility-related functions, such as an improvement in sperm number as well as improved follicular health and ovulation and increased vaginal lubrication.

Acupuncture is extensively used in the sporting arena. Athletes have found acupuncture an effective method for pain control. Acupuncture has also been used to treat musculoskeletal injuries and to improve performance and prevent injuries. In addition to appropriate training, acupuncture promotes muscle building and glycogen storage, stimulates substrate usage at the time of performance, and treats injuries or other chronic conditions that might affect performance.

Research and Future Directions for Acupuncture

As with many practices of complementary medicine, acupuncture research designs of the past have been difficult to interpret. Currently, the National Institutes of Health (NIH) is conducting several studies on acupuncture that are related to the treatment of low back pain, how acupuncture works, and meridians and *qi* flow. Along with growing research in acupuncture, practitioners believe that it will increasingly complement and integrate with conventional medicine. Currently, one third of the conventional medical schools have included acupuncture content in their curricula.

Aromatherapy

Philosophy and History of Aromatherapy

Aromatherapy is a type of herbal medicine that uses the essential oils of a plant in the promotion of health and healing. Practitioners believe that the wide-ranging pharmacologic properties of essential oils can aid in healing infection, promoting healthy bodily functions, and detoxifying the organ systems. Although aromatherapy has been used for healing since ancient times in China, Egypt, India, and Italy, the term *aromatherapy* was first used in 1937 by the French chemist Rene-Maurice Gattefosse, who used lavender oil to help heal his burned hand. Apart from its use in treating disease, aromatherapy has also been used to prevent diseases throughout the years. During the plague epidemic in Europe, incense was burned in sick rooms and common areas in an effort to prevent the spread of the disease.

Practitioners and Practice of Aromatherapy

Aromatherapy can be practiced using several methods, each with a variety of subpractices: (a) inhalation, which is particularly useful for respiratory conditions; (b) external application, especially helpful in the treatment of skin conditions; and (c) internal administration. Inhalation of essential oils can be accomplished with diffusers, in which small particles of the oil are dispersed into the air. Diffusion has been used for general mood improvement, in addition to improving respiratory conditions. Another inhalation method useful for relieving respiratory conditions, such as colds and flu, is the use of steam tents, under which patients inhale concentrated, oil-scented steam. Nose cones, which involve the use of concentrated oil drops on tissue papers, can also improve certain respiratory conditions, excluding asthma. With the instillation of essential oil drops into water, these “floral waters” can be sprayed onto the skin or into the air (e.g., as a room disinfectant).

With external application, essential oils are easily absorbed by the skin. There are several pleasant methods of applying the oils to the skin. Baths are easy, inexpensive, and available to many. They can encompass the entire body or a body part (e.g., foot baths, sitz baths). The heat of the bath promotes relaxation and oil absorption and also stimulates the skin and, under certain circumstances, energizes the body. Essential oil baths can help rid the body of toxins, if sweating occurs after the bath. Massage, another pleasurable method of applying oils to the skin, uses direct rubbing of essential oils onto the skin and can foster relaxation or stimulation depending on the oils and massage techniques used. Massage should not be applied to areas with infection or cancer. The application of compresses (hot or cold) can help calm minor complaints and decrease swelling.

Internal administration of essential oils should only be done under medical supervision. Administration can be by mouth or by suppository, using small amounts of oil mixed with a carrier, such as honey.

As the use of essential oils is amenable to home use and requires minimal education, the average individual can be a practitioner. A few adverse side effects have been reported, mostly involving allergic reactions and the excessive use of irritating oil. As implied earlier, precaution should be taken when considering ingesting any essential oils.

Uses of Aromatherapy

With its variety of application methods, the uses of aromatherapy are many. Essential oils can be used to treat bacterial and viral infections, such as the herpes simplex and zoster viruses. Skin conditions, such as acne and the effects of aging, also respond to aromatherapy. Muscle spasm, arthritis, and other musculoskeletal disorders benefit from treatment with oils. Aromatherapy has also been useful for the treatment of nervous system disorders, including anxiety, depression, and headaches. Other general home uses for aromatherapy include its use for daily hygiene, digestive cramping and nausea, bruises, insect bites, burns, low energy, and relaxation.

Research and Future Directions for Aromatherapy

Research and future directions for aromatherapy are continuously evolving. With research ongoing, some studies have looked at the effects of essential oils on brain waves. Practitioners anticipate an increase in the demand for and growth of aromatherapy in healing in the United States.

Ayurvedic Medicine

Philosophy and History of Ayurvedic Medicine

The term *ayurveda* comes from the Sanskrit words for life (*ayur*) and science (*veda*). Based on ideas from Hinduism and practiced in India for thousands of years, it describes an ancient, whole medical system designed to promote balance of the body, mind, and spirit and to achieve and maintain health and wellness. Over 2,000 years ago, the first Sanskrit texts on ayurveda discussed multiple health-related topics, including the cause of illness, its diagnosis, its treatment, surgery (not used in ayurveda at present), caring for children, lifestyle, advice for practitioners (including discussion of ethics), and philosophy. Ayurveda incorporates other CAM therapies, including yoga and herbs, within its practice. Widely practiced in India, Nepal, Pakistan, Sri Lanka, Bangladesh, and Tibet, yoga is becoming increasingly popular in the United States.

The basis of ayurveda includes two major beliefs: interconnectedness and constitution. Interconnectedness means that all things in the universe are connected. Disease occurs when an imbalance occurs between a person and the universe. Constitution (i.e., general health) and *doshas* comprise the second major ayurvedic philosophy. The three doshas, which comprise the basic characteristics that affect the constitution, each contain two of the five basic elements (space, air, fire, water, earth). The five basic elements are present in each person in varying degrees, affecting physical, emotional, and mental health. An imbalance, due to diet or lifestyle, can lead to disease and poor health.

Practice and Practitioners of Ayurvedic Medicine

A typical ayurveda session will include an evaluation of the individual's dosha by focusing on the patient's diet, lifestyle, and current health concerns, as well as a physical exam of the patient's overall appearance, skin, nails, teeth, weight, heart rate, digestive system, and elimination (evacuation of the bowels). The treatment prescribed often serves as a diagnostic method as well. If the patient improves, this suggests further treatments to improve the balance of the dosha to which the original treatment was directed.

Those who practice ayurveda include the therapist and the patient as well. Practitioners of ayurveda rely heavily on their patients, as many treatments also involve changes in the lifestyle and behavior of patients. As with other forms of CAM, there is no licensure or certification approved in the United States. Despite this lack of regulation, practitioners, who may also have a background in Western medicine, may train at an ayurvedic school in the United States or in India. Indian ayurveda training requires 5 years of study; practitioners can receive a degree (bachelor or doctoral) on completion of their courses.

Uses for Ayurvedic Medicine

Ayurvedic uses and methods relate strongly to the treatment goals. Using a variety of methodologies, such as diet and fasting, enemas, exercise, herbs, inhalations, meditation, medicinal oils, metals, minerals, and yoga, ayurveda helps eliminate impurities, reduce the symptoms of a disease, reduce worry and increase harmony, and eliminate physical and psychological problems. One caveat is a concern for toxicity if herbs, metals, and minerals are used, particularly if they are ingested.

Research and Future Directions for Ayurvedic Medicine

Although the interpretation of past studies has been difficult, due mainly to study design flaws, research in ayurveda continues. Current research focuses on the effects of botanicals on inflammation and asthma and the effects of other compounds on Parkinson disease. Practitioners are optimistic about the increased recognition of ayurveda and its use as a modern medical system.

Biofeedback

Philosophy and History of Biofeedback

Biofeedback is the process of using feedback mechanisms to gain improved control over one's body and body processes, some of which may be under more unconscious control. Its philosophy is one of self-regulation and control over one's body and life. First used in 1938 by O. Hobart Mowrer to detect urination with an alarm for bed-wetting, it was not formally studied until the 1960s' research on the altered state and electroencephalogram (EEG) patterns of yogis.

Practice and Practitioners of Biofeedback

Biofeedback sessions involve the use of electrical instruments to monitor body processes and provide immediate and understandable feedback to the individual. Usually, the participant begins with focusing on a small area or function, such as muscle control. As the individual becomes more aware of his or her body, he or she can increase the focus area to include general physical and mental health and well-being. Although someone will be providing the monitoring equipment and the initial instruction on focusing, the principally involved person in biofeedback is the individual undergoing the therapy.

Uses for Biofeedback

Biofeedback has been particularly helpful in the treatment of disorders affected by stress. These include mental health disorders, such as insomnia, anorexia, and bulimia, as well as pain disorders, including migraines and temporomandibular joint (TMJ) syndrome. Hypertension, incontinence, and asthma have also been improved with biofeedback.

Research and Future Directions for Biofeedback

Current research supports the use of biofeedback to help control many different conditions, including anxiety, hypertension, depression, and seizures. Biofeedback scientists envision a future in which biofeedback can be used to monitor the moment-to-moment levels of various chemicals (e.g., hormones) within the bloodstream.

Chiropractic Therapy

Philosophy and History of Chiropractic Therapy

The term *chiropractic* comes from the Greek words for hand (*cheir*) and action (*praxis*)—in other words, hands-on therapy. Chiropractic, a medical system centered on the body's structure (especially spine) and how it affects the body's function, was founded (in modern times) by Daniel David Palmer in 1895, who believed that realigning the spine could help improve the flow of energy in the body and promote health and healing. Chiropractic therapy operates on three basic principles: (1) the body has healing properties; (2) a relationship exists between body structure and body function; and (3) therapy improves that relationship, helping the body to heal itself. Currently, chiropractic therapy ranks among the 10 most used complementary therapies worldwide.

Practice and Practitioners of Chiropractic Therapy

An initial chiropractic visit mirrors other initial conventional and complementary medical visits. Practitioners obtain a health history and perform a medical exam, although the exam focuses mainly on the spine. Unlike many other CAM therapies, chiropractors will often obtain X-rays when necessary. The initial visit may also include preparations for an adjustment if warranted. Follow-up visits may include a variety of adjustments, designed to improve the range and quality of motion of an area and promote health, including manipulation (i.e., passively moving a joint outside its regular range of motion) and mobilization (i.e., passively moving a joint within its regular range of motion). Follow-up visits may also include additional treatment modalities, such as heat and ice, electrical stimulation, rest, rehabilitative exercises, counseling on diet and exercise and other behavior modifications, and dietary supplements.

Practitioners of chiropractic therapy must have a Doctor of Chiropractic degree from a 4-year academic program accredited by the Council of Chiropractic Education. Acceptance into such a program usually requires at least 3 years of regular undergraduate education. Some chiropractors will augment their education with a 2- to 3-year residency, training in a special field. Practitioners must also be licensed in the state in which they practice and maintain continuing education credits. Many, if not all, chiropractic services are covered by insurance, state workman's compensation, and Medicaid.

Uses of Chiropractic Therapy

Over half of the chiropractic patients use it to complement conventional medicine. Commonly used indications for chiropractic therapy include low back and neck pain and headaches. Side effects are commonly related to the type of therapy provided. Temporary headaches or body pains may follow an adjustment. Occasionally, dietary supplements may interact with other medications.

Research and Future Directions for Chiropractic Therapy

Research continues in chiropractic therapy. Ongoing studies are looking at the effects of the different therapies and the physiologic basis for them, as well as at the different diseases and conditions that are best treated with chiropractic therapies. Additional research focuses on the treatment success of specific conditions, such as back pain, neck pain, and headaches, as well as on the placebo effect of the treatment. Practitioners support the continued use of chiropractic therapy as a complement to conventional medicine.

Energy Medicine

Philosophy and History of Energy Medicine

Energy medicine is a complementary medicine involving the energy fields (i.e., vital force, life force) of the body. This energy, or life force, has been used in other long-standing forms of complementary medicine, including TCM (discussed later) and ayurveda (discussed earlier). It is also described by the Greek philosopher Pythagoras as "pneuma"; by the founder of Western medicine, Hippocrates, as "life force energy"; and in the Judeo-Christian tradition as "spirit." This energy is composed of veritable energy, which has been measured, and putative energy, which has not yet been measured. With veritable energy, mechanical vibrations and electromagnetic forces at specific, measurable frequencies and wavelengths of energy (e.g., sound, magnets, lasers) are used to treat patients. Putative energy, also known as biofields, is a more subtle form of energy that is believed to infuse the entire human body. Therapists manipulate putative energy with a variety of processes, including Reiki (discussed later) and healing touch therapy. Practitioners of energy medicine believe that disease comes from imbalances in the subtle energy field of the body.

Practice and Practitioners of Energy Medicine

There are several different methods of receiving energy therapy. Veritable energy therapies include magnet therapy, millimeter wave therapy, and sound and light therapies. Magnet therapy can be static, used for the relief of pain and to help relieve edema and ischemia. In fact, recent research has noted an effect on the microvasculature of skeletal muscle. Magnet therapy can also be pulsatile, which has been proven effective in the treatment of fracture nonunion. Inconclusive data exist for the use of pulsatile magnet therapy for multiple sclerosis, osteoarthritis, migraines, and sleep disturbances. Millimeter wave therapy, practiced in Russia and other Eastern European countries for decades, uses irradiation to treat skin conditions, cancers, and intestinal conditions. Despite ongoing research, its mechanism of action is still unknown. Sound therapy, also known as vibration or frequency therapy, posits that certain sound frequencies resonate with certain organ systems in the body. Types of sound therapy include music, wind chimes, and tuning forks and have been used to treat pain and various mood states, as well as to affect certain biochemicals (e.g., beta endorphins). Light therapy, the last of the veritable therapies, uses varying frequencies of light to treat disorders, such as seasonal affective disorder, sleep disorders, and depression. Ongoing research, supporting the use of low-level laser therapy in pain treatment and wound healing, continues.

As putative energy is less measurable, so are its methods. Acupuncture promotes the balanced flow of *qi* (i.e., energy) along meridians in the body (discussed earlier). Case studies of Qigong, another form of putative energy medicine, support its use for the treatment of blood pressure disorders and asthma. Homeopathy involves the use of dilutions of herbs to help the body's life force (i.e., energy) support health and promote and direct healing throughout the body. Few research studies of adequate quality exist for Qigong. Therapeutic touch, in which the application of the therapist's hands helps balance the patient's energy fields, has been demonstrated to be useful in the treatment of anxiety, headaches, wound healing, and pain.

Future Directions in Energy Medicine

Practitioners aspire to a change of focus from conventional, chemical medicine and treatment to energy medicine and disease prevention.

Massage Therapy

Philosophy and History of Massage Therapy

An ancient therapy, thousands of years old, massage therapy involves the manipulation of the muscles and soft tissues of the body to promote health and healing, via promotion of increased blood flow, decreased pain, and relaxation of muscles. Massage therapy first became popular in the United States in the mid-1800s; however, a significant increase in its use came in the 1970s, mainly in the athletic arena. Although still considered complementary for some conditions, massage is sometimes considered part of conventional medicine.

Practice and Practitioners

With its long history, massage therapy exists as more than 80 different therapies. Commonly used massage treatments include the Swedish massage, which uses long strokes, kneading, and friction; deep tissue massage, which uses long strokes and the fingers for deep pressure; trigger point massage, which incorporates a variety of deep strokes with a focus on muscle tightness; and shiatsu massage, which uses varying, rhythmic finger strokes to stimulate energy points in the body.

Massage sessions typically follow the same pattern as other forms of CAM. Conducted in a calm and soothing environment within an office, health club, or an individual home, a session usually begins with the practitioner taking a medical history and obtaining the patient's goals for the session, followed by a visual and light touch exam and then the massage. Although session times can range from 15 minutes to 2 hours, sessions generally last from 30 to 60 minutes.

An increasing number of U.S. states (33) require appropriate training for massage practitioners at an accredited school, as well as certification and licensure. Currently, massage practitioners can attain several different levels of training, licensure, and certification. Listed in ascending order, they include Licensed Massage Therapist (LMT), Licensed Massage Practitioner (LMP), Certified Massage Therapist (CMT), and National Certification Board for Therapeutic Massage and Bodywork (NCBTMB, NCBTM).

Uses of Massage Therapy

Massage therapy is used to improve pain and rehabilitation; to promote stress relief, relaxation, and a decrease in anxiety and depression; and to maintain general health. As with other conventional and CAM therapies, massage has its contraindications and precautions, including its use in patients with a tendency to bleed or clot, an active infection or inflammatory condition, cancer, nerve damage, or pregnancy.

Research and Future Directions for Massage Therapy

Current research on massage therapy is focused on how massage exerts its effect. Studies have proven that it not only decreases pain by taking the focus off the area of pain but also promotes muscle relaxation and decreases stress. Theory in massage research suggests that it might stimulate the parasympathetic nervous system, increasing relaxation; enhance the release of biochemicals, such as serotonin; improve soft tissue healing, such as decreased scarring and lymphatic drainage; augment sleep, which improves relaxation; and have a direct therapeutic effect from the interaction of the therapist with the patient. Future directions in massage therapy involve NIH research on the use of different types of massage on healthy people, for neck pain, and for improved quality of life in end-of-life care.

Meditation

Philosophy and History of Meditation

Meditation involves the suspension of the streaming thoughts of the mind. It is a form of mind-body medicine based on Eastern spiritual traditions.

Practice and Practitioners

Although many different methods of meditation exist, they all contain four key components. One must find a quiet place, free from distraction, and select a specific (based on the style of meditation) but comfortable posture. The third element involves the focus of one's attention, usually on a word (i.e., mantra), the breath, or an object. The last component is openness, the ability to acknowledge the thoughts and let them pass without losing focus. Mindfulness meditation has as its key component the focusing on and being aware of "the now" without being affected by it. Transcendental meditation involves use of a mantra, or repeated phrase, to help the mind avoid distraction. Meditation can be practiced alone or with the aid of an instructor and is often used within other CAM therapies, such as yoga (discussed later), Qigong, and Tai Chi.

Uses of Meditation

Meditation is often used to treat disorders affecting the psyche. Psychological disorders, such as anxiety, depression, lack of self-esteem, insomnia, and stress, especially benefit from meditation. Patients also experience less pain and are better able to deal with the symptoms of chronic diseases when meditation is part of their treatment. Meditation is not just for the infirm; it can be used for overall general health promotion and for motivation and performance enhancement in the athlete as well.

Research and Future Directions for Meditation

Although a mechanism of action of meditation has been proposed—a decrease in the stress response (i.e., sympathetic nervous system) and an increase in the resting response (i.e., parasympathetic nervous system)—the search for additional answers continues. What occurs in the body and mind during meditation? What conditions—such as heart disease, rheumatoid arthritis, and low back pain—might be treated with meditation?

Some practitioners envision the increasing future use of meditation in the treatment and prevention of disease.

Reiki Therapy

Philosophy and History of Reiki Therapy

Developed officially in Japan in the mid-1800s by Dr. Mikao Usui, Reiki therapy acquired its name from the Japanese words for universal spirit (*rei*) and life force energy (*ki;* analogous to the Chinese word *qi*). Dr. Usui not only defined the practice of Reiki therapy, he also created an organization for its teaching and dispersion. Dr. Usui defined Reiki therapy as a form of energy medicine in which the therapist affects and improves the flow of *ki* within and around the patient's body to achieve balance.

Practice and Practitioners

Reiki sessions are conducted with the patient fully clothed and either sitting or lying supine. The practitioner places his or her hands in 12 to 15 different positions immediately above or on specific body locations for a period of 2 to 5 minutes until the flow of *ki* stops. Reiki that is performed at great distances is termed *distance healing*.

As with other forms of CAM, no certification or licensure is required for Reiki therapy. Reiki practitioners are trained under a Reiki master, who has achieved the four levels of expertise in at least one school of Reiki therapy. As one state, Florida, classifies Reiki therapy as "massage," its therapists are required to be certified massage therapists.

Uses for Reiki Therapy

Reiki therapy has several common uses. In the area of mental health, Reiki therapy helps alleviate the effects of stress, promote mental well-being and clarity, and aid patients in dealing with the diagnosis of a terminal illness. It also can help ameliorate the side effects of cancer treatments and general pain and has, thus, been useful in postoperative recovery.

Research and Future Directions for Reiki Therapy

Currently, comparatively little is known about Reiki therapy. Research continues, attempting to determine how Reiki works and specific diseases for which it might be useful (fibromyalgia, improved quality of life for AIDS patients, disease progression in prostate cancer and associated anxiety, blood sugar control). As with other forms of energy medicine, Reiki practitioners hope for a change of focus from chemical medicine and treatment to energy medicine and prevention.

Traditional Chinese Medicine

Philosophy and History of TCM

TCM is a whole medical system used to promote health and to maintain the balance of *yin* (cold, slow, passive principle) and *yang* (hot, excited principle) and the flow of *qi* (energy, life force) along meridians (pathways) in the body and through the organs. The term *yin* is often used to describe organ or tissue, while *yang* is often used to describe the activity of the organ or tissue. Organs themselves are also defined according to either yin or yang, as well as according to the five phases (fire, earth, metal, water, and wood). As fire can burn wood and water can destroy fire, all of the phases and, thus, the organs, promote or inhibit the actions of another, creating synergy and harmony within the body.

TCM, practiced for more than 5,000 years, is one of the world's most widely accepted and used forms of medical health care. Practitioners aim to treat the patient and not the disease and consider prevention the key. Early discussions of lifestyle (e.g., diet, exercise, stress management and relaxation, rest) reflect their focus on preventing illness and promoting health.

Practice and Practitioners of TCM

As with many other forms of medical therapy, conventional and CAM, a typical session of TCM begins with an examination of the history of the patient's present concerns (symptoms), the patient's medical history, his or her current behavior (e.g., diet, lifestyle, sexual activity), and any previous treatments used to treat this concern. This history taking is followed by an examination of the patient's general demeanor (body language, tone of voice), pulse, body odor (e.g., sweat, breath), abdomen, and the meridians.

Over its long-standing history, TCM has evolved a variety of treatment types, including the use of herbs, diet therapy, acupuncture, massage, and energy healing.

Herbs are a common part of TCM. Coming from plants, animals, and minerals, the herbs can be taken in many forms, including as decoctions, pills, tinctures, suppositories, soaks, and poultices. Herbal therapy has been proven to strengthen specific and nonspecific immunity, as well as to relieve some of the effects of chemotherapy medications. Those who practice diet therapy believe that foods have healing properties, helping to balance *qi* that is out of sync. Ginger, for example, has been used to aid digestion and to fight infections, such as colds. Acupuncture, discussed earlier, involves the stimulation of certain points along the body's meridians to improve the flow of *qi*. Massage therapy and manipulation can balance the flow of *qi* and are often used in combination with other therapies. Energy healing therapies, including Qigong and Tai Chi, can be used for chronic medical conditions. Qigong has been used to ameliorate hypertension, respiratory disease, and cancer.

Uses of TCM

In addition to the indications for TCM listed above, TCM also may be used to treat asthma and allergic conditions; headaches; systemic diseases, such as diabetes, lupus, and infections; and organ system diseases, such as gallbladder diseases and gynecologic disorders. Athletes find the herbs used in TCM particularly useful, including Siberian ginseng, a gentle herb that affects the adrenal glands, helping the body better adapt to stresses, such as the physical stress of athletic performance; Cordyceps, a tonic use to decrease lung inflammation, which can be helpful for exercise-induced asthma; and ginseng, a herb that affects a variety of organ-system functions, with the effect of improving energy levels and maintaining alertness.

Research and Future Directions for TCM

Current research supports the use of TCM as a complement to Western medicine in acute and chronic conditions. Practitioners anticipate that TCM may begin to incorporate other aspects of medicine (e.g., electro-acupuncture, biofeedback testing, modern homeopathy) to become "integral Chinese medicine" in the future.

Yoga

Philosophy and History of Yoga

Yoga is an area of mind-body medicine that uses certain body postures, breathing, meditation, and relaxation to promote health and healing. Initially, yoga originated in India as a way to direct one's attitude and behavior and to achieve spiritual enlightenment. With the writing of *The Yoga Sutras,* the first text of yoga, 2,000 years ago, eight factors were clearly described in the promotion of physical and mental well-being: (1) moral behavior, (2) healthy habits, (3) physical postures, (4) breathing exercises, (5) sense withdrawal, (6) concentration, (7) contemplation, and (8) higher consciousness.

Practice and Practitioners of Yoga

With its ancient history, yoga has developed into a variety of different styles of practice, all of which focus on different combinations of the eight sutras. Hatha yoga, the most commonly practiced yoga in the United States, uses two of the eight sutras, physical postures and breathing exercises.

Although no definitive certification or licensure to teach yoga is required in the United States, many organizations provide formalized training and certification. The specific training required for certification depends on the style of yoga.

Uses of Yoga

Yoga has been used to treat a variety of diseases, including psychological disorders such as high stress, anxiety, and depression. It also benefits patients with heart and respiratory conditions, such as high blood pressure and asthma, respectively. Yoga can also be used for the promotion of physical fitness and overall health and well-being. As with other therapies, yoga has its contraindications as well, which include bone or disk disease of the spine, extremely high or low blood pressure, glaucoma, ear problems, severe osteoporosis, and blood clots in individuals who are at risk for such clots. Yoga can also be used to promote general musculoskeletal health, affecting posture, balance, and gait. As such, athletes can find it a useful adjunct to their overall training.

Research and Future Directions for Yoga

Research in yoga continues. Several studies support the use of yoga for the treatment of mental health conditions such as anxiety, depression, overall mood, insomnia, and stress. Additional research points toward yoga fostering better cardiorespiratory fitness, with improved lung capacity and decreased blood pressure. Musculoskeletal conditions have also been proven to benefit from yoga, resulting in improved flexibility and strength and muscle relaxation. Ongoing research on yoga's effects centers on blood pressure, chronic back pain, arthritis, immune function, and smoking cessation.

Conclusion

Although the definition of CAM encompasses health care provided outside the realm of conventional, Western medicine, better understanding and improved research are gradually making its use more mainstream. With its inclusion of whole medical systems, mind-body medicine, biologically based practices, and energy medicine, CAM focuses on the whole patient in the promotion of health, well-being, and athletic performance and in the treatment of disease and disability.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is a puzzling chronic pain syndrome with underlying dysfunction of the central and/or peripheral nervous system. Usually involving an arm or leg, CRPS causes continuous, intense pain out of proportion to the severity of injury. This uncommon disorder can affect athletes with limb injuries. This entry provides a discussion of CRPS, with an emphasis on diagnosis and treatment.

Prevalence

The prevalence of CRPS is uncertain. Both men and women are affected, and a person can develop CRPS at any age. CRPS tends to be more common in young women. Depending on how CRPS is defined, the incidence varies from common to nonexistent. Equally mysterious is the underlying cause of CRPS.

Pathophysiology

Generally, two types of CRPS have been identified. In CRPS Type I, known historically as *reflex sympathetic dystrophy,* nerve damage cannot be found. In CRPS Type II, or *causalgia,* nerve damage can be detected, but the pain mysteriously extends beyond the injured nerve. The pathophysiology of CRPS is a matter of significant debate. Pain receptors may become more responsive to nervous system messengers known as *catecholamines* after nerve damage. Another theory is that the underlying injury triggers an immune response. CRPS is quite likely multifactorial, with no single underlying cause. Research is enhancing our understanding of CRPS, but there are still many unanswered questions.

Physical Examination

CRPS is difficult to diagnose. In patients with severe, advanced CRPS, recognizable features are present, including limb pain, heightened skin sensitivity, a smooth shiny skin with abnormal skin color and temperature, joint stiffness, and diffuse swelling. However, early in the disorder, CRPS symptoms and signs may be mild. Research has revealed that no psychological or personality traits appear to predispose individuals to CRPS. Additionally, fracture type and severity of injury are not significantly different from those in patients who recover normally. Any athlete could therefore be affected by CRPS regardless of the degree of injury.

Symptoms

CRPS can cause a wide variety of symptoms. A key component of CRPS is continuous, intense pain out of proportion to the severity of injury. The pain is usually described as "burning" or "stinging." Other symptoms include increased skin sensitivity (i.e., clothing resting on the affected body part causes pain) and increased sensitivity to temperature differences (in the environment and while bathing).

Signs

Commonly observed signs include changes in skin temperature (warm or cold), color (blotchy, pale, red), and texture (shiny, sweaty) compared with the unaffected body parts. Nails become brittle, and hair stops growing. Swelling, decreased range of motion, and weakness are reported.

Stages

Some experts think that CRPS exists in three symptomatic stages and that patients progress from one stage to the next. Stage I lasts from 1 to 3 months and includes severe pain, color and temperature changes, muscle spasm, and joint stiffness. Stage II lasts from 3 to 6 months and includes increasing amounts of pain, swelling, decreased hair growth, brittle nails, stiff joints, and weakened muscles. Stage III is the final stage and is manifested by disuse of the body part due to pain, muscle loss, and joint stiffness, with resultant contractures and, occasionally, contorted limbs.

Diagnosis

Diagnostic Criteria

Diagnostic criteria for CRPS exist, although there is no consensus as to the best method of diagnosis. No one test identifies all patients with CRPS. Additionally, CRPS presents differently from one person to the next, and symptoms vary over time. The key to diagnosis is to remain alert for this disorder based on clinical symptoms and signs.

Other Disorders

When diagnosing CRPS, other disorders need to be ruled out. The differential diagnosis for limb pain in an athlete is quite broad and includes orthopedic, vascular, autoimmune, infectious, and neurologic conditions. Useful studies to include in the evaluation of an athlete with possible CRPS include laboratory tests (complete blood count, inflammatory markers), nerve conduction studies, X-ray, and possibly advanced imaging (bone scan, magnetic resonance imaging [MRI]). A multidisciplinary approach may be needed to make an accurate diagnosis.

Studies Specific for CRPS

Various laboratory tests and imaging procedures have been applied to CRPS. The majority have not been evaluated with regard to their sensitivity (i.e., the probability that a patient with CRPS will have a positive result) or specificity (i.e., the probability that a patient without CRPS will have a negative result). Diagnostic instruments have been plagued by difficulties in objective measurement of clinically apparent signs such as hand volumetry to measure swelling, thermometry to measure skin temperature, and resting sweat output to measure sweating. Unfortunately, many variables can affect these instruments, such as time of day, environmental and body temperatures, and correct placement of the device, decreasing their usefulness. Radiological studies such as X-rays and bone scans appear to add little compared with clinical assessment. Sympathetic nerve blocks have demonstrated poor sensitivity and specificity for diagnosis.

Treatment

Treatment of CRPS is largely based on expert opinion and is in need of more study. Although no clear guidelines exist at present, research has shown that a multidisciplinary approach appears to work best. The goal of treatment is functional restoration. Functional restoration includes normalizing range of motion and flexibility, minimizing swelling, and increasing functional use in activities of daily living, leisure activity, and work. For athletes, return to safe and successful play is paramount and is an added goal.

Therapy

Treatments for CRPS should include those least likely to do harm. The cornerstone of rehabilitation appears to be early physical, occupational, recreational, and vocational therapy. Slow, steady progression is critical as aggressive therapy can trigger pain, swelling, distress, and fatigue and may exacerbate inflammation and therefore symptoms of CRPS. Patients begin with very gentle range of motion of the affected limb, with a steady progression to incorporate load bearing. Additionally, normalizing sensation is critical, so that patients no longer experience pain out of proportion to normally nonpainful stimuli. This may include specific therapy with fabrics and contrast baths.

Psychologic Therapy

CRPS is a biopsychosocial disorder, and the psychological aspects of treatment are also important. Psychologic therapy focuses on educational goals such as teaching the patient that pain does not indicate tissue damage and that therapy is crucial to begin regular use of the affected body part. The negative effects of disuse are emphasized. Immobilization, disuse, and fear of movement can lead to significant phobias. Often, the fear of movement is more disabling than the pain of CRPS itself. Relaxation training with biofeedback, training in pain coping skills, and behavioral interventions that address disuse and activity avoidance are frequently used. Correction of misinformation and reframing the involvement of the patient (as an active, not passive participant in therapy) are key aspects of cognitive behavior therapy and can be helpful. Those with CRPS frequently have coexistent depression, anxiety, and posttraumatic stress disorder. These associated conditions also need to be addressed as they can heighten the pain from CRPS and make treatment more difficult.

Medical Management

If a patient is not progressing in a reasonable amount of time, other agents can be employed. Pain management is the focus of these additional treatments. A wide variety of medications can be used to treat the pain from injured nerves, skin, and muscle and include topical analgesic drugs, which act locally on the affected body part, antiseizure drugs, antidepressants, corticosteroids, and opioids. Unfortunately, no medication has proven to provide consistent results. If pain persists, interventional therapies take on a larger role and can include sympathetic nerve blocks (placing an anesthetic adjacent to a nerve), spinal cord stimulation (placing electrodes next to the spinal cord), implantable spinal medication pumps, and sympathectomy (destroying the nerve either temporarily or permanently). Multiple specialists are involved in the care of a patient with persistent symptoms.

Pediatric Patients

Pediatric patients tend to have greater lower limb involvement. The primary focus of treatment in pediatrics is similar to treatment for adults, beginning with therapy. Children tend to have a milder course, which is felt to be secondary to better participation of children in therapy. Recurrence is higher in children, but they respond well to additional treatment. Medications and invasive procedures are used cautiously in children.

Prognosis

The prognosis for patients with CRPS is variable. Some cases resolve spontaneously, while others have a severe, unremitting course. In both adults and children, athlete-specific guidelines are nonexistent. Return to play should be decided individually. Return to normal life is key as CRPS can be debilitating.

Concussion

Each year in sports, it is estimated that nearly 300,000 concussions occur at all levels of competition. Concussions are likely underreported as athletes may withhold their symptoms from coaches, teammates, parents, athletic trainers, and physicians for fear of being kept out of competition.

Definition

In 2001, a new definition of sports-related concussion was proposed. *Sports-related concussion* is defined as a complex pathophysiologic process induced by biomechanical forces that affects the brain. Major features of a sports-related concussion include the following:

- Caused by a direct blow to the face, head, neck, or other area of the body, which results in an impulsive force to the head

- Short-term impairments to neurologic function that resolve on their own
- Typically a functional rather than a structural impairment
- May or may not involve loss of consciousness
- Typically associated with normal computed tomography (CT) and magnetic resonance imaging (MRI) studies

Pathophysiology

Currently, there is no human experimental model for the pathophysiology of concussions. Animal models have suggested abnormalities of brain metabolism affecting glucose. It is unclear if this model can be applied to the human sport concussion.

Signs and Symptoms

There are many signs and symptoms that an athlete may present with after sustaining a concussion. An athlete may present with a sign or symptom in isolation or in combination. Signs and symptoms may include headache, vomiting, nausea, sensitivity to light or sound, ringing in the ears, difficulty concentrating, memory loss of events both before and after the concussion, unsteady balance, slurred speech, "glassy-eyed" staring, loss of consciousness, feeling foggy or slow, emotional changes, and visual changes such as blurry vision, "seeing stars," or double vision.

Physical Examination and Evaluation

On-Field Assessment

In the acute setting for athletes who are evaluated on the field, the initial evaluation should be for consciousness, as the unconscious athlete must be assumed to have a cervical spine injury and appropriate management must be initiated. If an athlete is conscious, assessment of his or her cognition, including details of the current game, amnesia before or after the injury, and confusion must be assessed. The athlete should be asked about the symptoms related to his or her concussion.

The physical exam should be focused on neurologic assessment, including evaluations of short-term memory and observation of balance ability, changes in personality, ability to follow instructions or answer questions, vomiting, or emotions inappropriate to the situation or the athlete, such as laughing or crying.

A useful sideline assessment tool is the Sport Concussion Assessment Tool (SCAT), which was developed during the 2004 Second International Conference on Concussion in Sport. The SCAT is a combination of various previous sideline evaluation tools, which used the most evidence-based assessments of each of these tools.

In-Office Assessment

If the first assessment is in an office-based setting, history of the concussion and any prior concussions must be obtained. A thorough neurological assessment should be undertaken, as well as evaluation of cognitive function. A postconcussion symptom checklist with grading of the common symptoms related to concussions can be useful to assess the present condition of the athlete and to follow up his or her improvement over time.

Neuroimaging

In the vast majority of sports-related concussions, results of neuroimaging studies such as CT and MRI scans are normal. Indications for considering further neuroimaging would include worsening neurological status, recurrent vomiting, focal neurologic findings on physical exam, and loss of consciousness. Further imaging may also be warranted in a person with symptoms that are not improving over a 10-day period, as most concussions will see improvement of symptoms over that time. There is no consensus as to how long an athlete should have been unconscious to require neuroimaging. Various sources suggest loss of consciousness for at least 30 to 60 seconds before one may consider further neuroimaging.

Current research is focused on functional MRI scanning as a potential neuroimaging study to evaluate concussions.

Neuropsychological Testing

The use of neuropsychological testing, both in computerized and in pencil-and-paper forms, is becoming more commonplace in the evaluation of an athlete following a concussion. It is one tool in the comprehensive evaluation of an athlete with a concussion. Current recommendations are to consider evaluating an athlete with a neuropsychological test following resolution of symptoms, as a symptomatic athlete will not be returned to play. Comparing a test's results with a previously obtained baseline for that athlete is helpful but not required.

Concussion Management

Symptomatic athletes should be rested both from physical and cognitive activities. That may mean accommodations for the athlete in school with reduced school load, prolonged times for testing, and even staying home from school. Athletes should not be returned to physical activity until their symptoms have resolved.

Return to Sports

In recent years, there has been a dramatic shift from the use of various grading scales to determine the appropriate time to return an athlete to play following a concussion to a symptom-based approach to return to play. It is currently recommended that no athlete be returned to play while still suffering from any symptoms of the concussion. No longer is it recommended that an athlete return to play the same day of his or her concussion.

Once symptoms have resolved, it is recommended that the athlete follow a stepwise return-to-play protocol over a 5-day period. If athletes do not have return of their symptoms following each step, they can progress to the next step. If they have a return of their symptoms, they should wait an additional 24 hours and repeat that same step.

The first step would include light aerobic exercise such as light jogging or easy activity on an exercise bike. The second step involves more sport-specific training, which may include running sprints or skating on the ice. The third step involves participating in noncontact training drills. The fourth step allows full contact practice after being medically cleared. In the final step, the athlete is allowed to return to game play. Each step should take a minimum of 1 day to proceed to the next step, but if there is any return of symptoms, it may take an athlete longer than the minimum 5-day plan to return to competition.

Postconcussive Syndrome

Some athletes have a more prolonged course of symptoms following a concussion. Symptoms that persist beyond 3 to 4 weeks define the postconcussive syndrome. Symptoms include recurrent headaches, impaired memory, alcohol intolerance, depression, ringing in the ears, anxiety, loss of libido, sensitivity to light, dizziness, and difficulty in concentrating and balancing. Development of postconcussive syndrome has not been demonstrated to be related to the severity of the concussion. Athletes with postconcussive syndrome may need to be treated with medication to control their symptoms and may benefit from formal neuropsychological assessment.

Second-Impact Syndrome

Second-impact syndrome is a rare condition that has been defined as an event in which diffuse cerebral swelling, and potentially death, occurs when an athlete sustains a second hit, or concussion, when not fully recovered from the first one. There has been debate as to whether this syndrome, as described, actually exists. There have been published reports in both medical journals and the lay press of athletes, typically those below age 20, who have had diffuse cerebral swelling on autopsy. The difficulty lies in determining whether these athletes had the cerebral swelling from a solitary hit or multiple hits.

Prevention

Ideally, preventive measures can be developed to continue to reduce the likelihood of concussions. These may include modifications to equipment, such as changing helmet designs, better rule enforcement or development of new rules, and education of players, coaches, officials, and families about concussions.

Conditioning

Conditioning is a learning process in which an organism's behavior becomes dependent on the occurrence of a stimulus in its environment. In physiology, it is a behavioral process whereby a response becomes more frequent or more predictable in a given environment as a result of reinforcement, with reinforcement typically being a stimulus or reward for a desired response.

Conditioning for sports is a physical or psychological training that prepares the athlete for a specific sport. It is usually defined as a systemic process of repetitive, progressive exercise or work, involving the learning process and acclimatization. Through the use of systemic work increments, improved voluntary responses by the organs are attained. Through constant repetition, the conscious movements become more reflexive, requiring less concentration by the higher nerve centers, and this reduces the amount of energy expended by eliminating unnecessary movement for the performance of the desired task.

Conditioning for sports participation prepares the athlete for high-level performance and reduces the likelihood of injury. A considerable number of injury etiologies are directly attributable to insufficient or improper conditioning. Some of these causes include inadequate cardiovascular or muscular endurance; inadequate muscle, tendinous, or ligamentous strength; inflexibility; poor body composition; faulty neuromuscular coordination; and muscular imbalance. Modern sports programs often require elaborate conditioning facilities and equipment for injury prevention.

Principles of Conditioning

The following principles should be applied in all programs of training and conditioning to minimize the likelihood of injury: warm-up/cooldown, motivation, overload, consistency, progression, intensity, specificity, individuality, minimization of stress, and safety.

Warm-Up/Cooldown

The main purposes of warming up are to raise the general body and the deep muscle temperatures and to stretch collagenous tissues to permit greater flexibility. This reduces the possibility of muscle tears and ligamentous sprains and helps prevent muscle soreness. It takes at least 15 to 30 minutes of gradual warm-up to bring the body to a state of readiness. The time needed for satisfactory warm-up varies with the individual and tends to increase with age.

Cooling down is the gradual diminishing of work intensity, which permits the return of both circulation and various other body functions to pre-exercise levels. Gradual cooldown is recommended because it decreases blood and muscle lactic acid levels more rapidly than just allowing passive recovery. Cooling down also keeps the heart pump and muscle pumps active, preventing blood from pooling in the extremities. When cooling down, it is recommended to allow 30 seconds to 1 minute for jogging, followed by 5 minutes of walking to permit the body to adjust to the nonexercise mode.

Motivation

Athletes who are highly motivated tend to be very self-confident about their abilities. Thoughts that come into an athlete's mind during competition can be either positive or negative. The athlete must learn to control his or her thoughts and to structure them to his or her advantage. By varying the training program and incorporating different aspects of conditioning, the program can remain enjoyable rather than becoming routine and boring. An athlete's motivation to improve may come from within or may be the result of coaching demands.

Overload

The principle of overload states that a greater than normal stress or load on the body is required for training adaptation to take place. The body will adapt to this stimulus. Once the body has adapted, then a different stimulus is required to continue the change. For a muscle (including the heart) to increase its strength, it must be gradually stressed by working against a load greater than it is accustomed to. To increase endurance, muscles must work for a longer period of time than they are accustomed to. If this stress is removed or decreased, there will be a decrease in that particular component of fitness. Keeping a workout stimulus status quo will maintain the current fitness but not improve it.

Consistency

Conditioning for sports must be programmed on a consistent basis to be effective.

Progression

The principle of *progression* implies that there is an optimal level of overload that should be achieved and an optimal time frame for this overload to occur. Overload should not be increased too slowly or improvement is unlikely. Overload that is increased too rapidly will result in injury or muscle damage. Exercising above the target zone is counterproductive and can be dangerous.

Intensity

Intensity refers to how hard one exercises. Intensity can also describe the amount of energy needed to perform a particular exercise or activity. For cardiorespiratory training purposes, intensity is expressed as a percentage of maximal heart rate or heart rate reserve and is displayed in heart beats per minute. For resistance training, intensity usually refers to a percentage of the person's repetition maximum. For purposes of flexibility training, intensity usually refers to the degree of stretch or "stretching sensation."

Specificity

The *specificity principle* simply states that training must go from highly general training to highly specific training. The principle of specificity also implies that to become better at a particular exercise or skill, you must perform that exercise or skill. The program must be designed to address specific components of fitness relative to the sport in which the athlete is competing.

Individuality

Because every athlete is different, each person's response to exercise will vary. A proper training program should be modified to take individual differences into account. The coach or athletic trainer must recognize these individual differences and adjust the conditioning program to the individual athlete.

Minimize Stress

Coaches and athletic trainers must consider stressful aspects of the athlete's life. For example, student athletes have two extremely time-consuming jobs: school and sports. Success in either hinges on how well a student athlete handles stress and pressure on and off the field. The probability of performing consistently well in both can be greatly enhanced by learning and implementing key principles from sport psychology.

Safety

The training environment must be as safe as possible. Exercise programs are devised with the goal of improving one's health and fitness levels. Yet any training regimen can prove inherently dangerous if certain guidelines are ignored. If an individual consistently ignores some parts of the activity program and overemphasizes others, he or she risks injury. In addition, he or she jeopardizes his or her chance of achieving the desired goals. Examples of safety measures include lifting weights with a partner and cleaning of equipment between uses to prevent spread of infections.

Conditioning Seasons

Sports conditioning often falls into four seasons: (1) postseason, (2) off-season, (3) preseason, and (4) in-season.

Postseason

Conditioning during this season is commonly dedicated to physical restoration. This period is particularly appropriate when the athlete has been injured during the season. This is a time when postsurgical rehabilitation takes place and detailed medical evaluations can be obtained.

Off-Season

During this season, athletes are not required to continue an intensive conditioning program.

However, it is recommended that they participate in sports activities sufficiently demanding to require a good level of fitness to participate effectively. If it is not feasible for the athlete to participate in an off-season sport, a detraining program should be planned. This program will allow a gradual decrease in the usual workload and allows the athlete to exercise less frequently and less intensively. Usually, a weekly workout of moderate to heavy intensity is all that is required. It must be kept in mind, however, that caloric intake must be decreased accordingly when the exercise load is decreased, since not as much energy is burned.

Preseason

If the athlete kept a reasonably high level of physical fitness during the off-season, the preseason will be more rewarding, with less potential for injuries. During the preseason, flexibility, endurance, and strength should be emphasized in a carefully graded developmental program. No difficulty with reaching a state of athletic fitness suitable for competition within 6 to 8 weeks should then be experienced.

In-Season

Athletes need to undergo maintenance conditioning during the competitive season. If not, they may lose their base level of physiological fitness earned during the preseason. The sport itself is not enough to maintain this level.

Major Components of a Good Conditioning Program

Preconditioning

Preconditioning gives the body time to adjust and provides a safe, gradual response to exercise to avoid injury, rather than too much exercise too soon. It is less demanding on the cardiovascular and muscular systems. An example is the use of low-gear biking on level ground before adjusting to high-gear cycling on the hills.

Warm-Up

The two components of any warm-up program are low-intensity activity and stretching. The purpose of warm-up is to gradually increase the heart rate, reduce muscle stiffness, increase the blood flow to major muscle groups, facilitate enzymatic activity, and ready the body for more strenuous effort. Warm-up should begin with 5 minutes of low-intensity activity. This should be followed by approximately 5 minutes of slow, gentle stretching of the major muscle groups, particularly those most used during the exercise.

Exercise Period

The mode of exercise used during this period should be the mode used in the performance of the sports skill. However, the training effects induced by running, although specific, do appear to have beneficial cross-over effects for other groups. The purpose of this period is to cause specific and efficient biological adaptation to improve performance in specific events. Therefore, the muscle groups used for these events must be trained.

Cooldown

Like the warm-up period, this period has two components: low-intensity activity and some light stretching. The cooldown allows for proper recovery from exercise. This part of the conditioning allows the body to accommodate and adjust to the nonexercise mode. It allows the muscles to rid themselves of excess lactate buildup during the exercise period.

Progression

If an increase is contemplated in an exercise program, it should be accomplished slowly over a period. There should be no pain or history of recent injury before an increase is undertaken. Also, frequency, intensity, duration, and mode of activity should be increased one at a time and not at the same time. The 10% rule states that none of these should be increased by more than 10% per week.

Return From Injury

Patient compliance is easier to achieve, and there is less muscle atrophy and detraining if there is relative rest instead of absolute rest. Relative rest is when there is a decrease in the training regimen, but it still allows the athlete to train at a lower level without further damaging the injured area. Also, an alternative activity is a good option for some patients. For example, an athlete with a stress fracture, who cannot run without pain, can swim if possible.

Light-Intensity Training Program

This program allows an orderly stepwise return to a previous training regimen and incorporates the cooperation and help of the patient.

The three options to be considered are as follows:

1. If pain and/or swelling develops during the activity, stop all activity immediately, and decrease activity the following day by 25%.
2. If pain and/or swelling develops after the exercise is completed, continue the following day at the same level, but do not increase the level of activity.
3. If pain and/or swelling is not present during or after activity, increase the activity slightly.

Main Effects of Conditioning on the Human Body

Effects on the Heart

As the body begins to exercise, the muscles use oxygen at a higher rate, and the heart must pump more oxygenated blood to meet this increased demand. The heart is capable of adapting to this increased demand through several mechanisms. The heart rate shows a gradual adaptation to an increased workload by increasing proportionally to the intensity of the exercise and will plateau at a given level after about two to three times.

A second mechanism by which the heart is able to adapt to increased demands during exercise is increasing the stroke volume. Stroke volume is the volume of blood being pumped with each heartbeat. Stroke volume can continue to increase only to the point at which there is simply not enough time between beats for the heart to fill up.

Stroke volume and heart rate together determine the volume of blood being pumped through the heart in a given unit of time. This is known as cardiac output. After adequate conditioning, the heart becomes more efficient. This is because the heart will be capable of pumping more blood with each stroke. The stroke volume increases, while exercise heart rate is reduced at a given standard exercise load. Because the heart is a muscle, it will hypertrophy.

Effects on the Ability to Resist Fatigue

Fatigue is closely related to the percentage of maximum aerobic capacity that a particular workload demands. If aerobic capacity is impaired, fatigue will occur earlier. Exercise conditioning improves aerobic capacity. If an exercise program is too rigorous, the athlete can experience overtraining syndrome.

Effects on Muscular Endurance

Muscular endurance is the ability to perform repetitive muscular contractions against some resistance for an extended period of time. As muscular strength increases, there tends to be a corresponding increase in endurance. Muscle strength is a function of the number and diameter of muscle fibers composing a given muscle. Adequate muscle conditioning will increase the muscle strength and muscle endurance needed for different sports activities.

Effects on Flexibility

Flexibility is the ability to move a joint or series of joints smoothly and easily throughout a full range of motion. Some sports activities, such as gymnastics, ballet, diving, and karate, require increased flexibility for superior performance. An individual who performs stretching exercises to improve flexibility about a particular joint is attempting to take advantage of the highly elastic properties of a muscle. Over time, it is possible to increase the elasticity of a given muscle—the length it can be stretched.

Effects on Proprioception

Proprioception is a specialized variation of the sensory modality of touch that encompasses the sensation of joint movement and joint position. The ability to sense body position is mediated by cutaneous, muscle, and joint mechanoreceptors. A mechanoreceptor is a sensory receptor that responds to mechanical pressure or distortion. Injury and subsequent immobilization can affect the proprioceptors in the skeletal muscles, tendons, and joints. The proprioceptors are sensors that provide information about joint angle, muscle length, and tension, which is integrated to give information about the position of the limb in space. Some of the exercises used in conditioning stimulate and re-educate the proprioceptors.

Effects on Coordination and Balance

Coordination refers to the body's ability to execute smooth, fluid, accurate, and controlled movements. Coordination and proprioception are directly linked. Some conditioning techniques include activities that improve coordination. Some of these activities include constant repetition of motor activities or increasing the speed of the activity.

Balance is the ability to maintain the center of gravity of a body within the base of support with minimal postural sway. Poor balance has been significantly associated with an increased risk for musculoskeletal injury. Balance training as a part of the conditioning program appears to decrease the risk for musculoskeletal injury.

Congenital Heart Disease

A prime objective of preparticipation screening for athletics is to identify cardiovascular abnormalities that can cause sudden death. Congenital heart defects most commonly associated with sudden death include hypertrophic cardiomyopathy, coronary artery anomalies, Marfan syndrome, and aortic valve disease. Findings during preparticipation screening may raise clinical suspicion for cardiovascular disorders. The presence of a heart murmur or cardiac symptoms with exertion, such as chest pain, unusual shortness of breath, and change in level of consciousness, all may be of clinical significance. Also important is a family history of heart disease or sudden, unexpected cardiac death.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is the most common cause of sudden cardiac death in athletes younger than age 30. It is a genetic disorder causing mutations in an estimated 12 different genes. These gene mutations create abnormalities in the left ventricle muscle. Asymmetric thickening of the ventricular walls greater than 15 millimeters (mm) with no dilation or enlargement of the ventricle develops, causing possible obstruction of outflow from the ventricle with exercise. Changes in the ventricular muscle cells may also generate abnormal heart rhythms. Often a thickness of 13 to 14 mm is identified, placing the patient in a "gray zone," making precise diagnosis more difficult and requiring additional testing. Many hypertrophic cardiomyopathy patients are asymptomatic.

Symptoms such as syncope, chest pain, and shortness of breath may be noted. A murmur on exam and a family history of sudden cardiac death at age <50 also raises suspicion. Any athlete with symptoms, a suspicious murmur, or a family history of sudden death should undergo further evaluation. An echocardiogram (ECG) along with an electrocardiogram (EKG) is typically performed to assess for hypertrophic cardiomyopathy.

As the technology of genetic testing improves and becomes more readily available, it may be possible to identify athletes who are potentially at risk via genetic testing before clinical evidence appears. Athletes with a probable or definitive diagnosis of hypertrophic cardiomyopathy should be restricted from competitive sports.

Coronary Artery Anomalies

Congenital coronary artery anomalies are the second most common cause of sudden death in young athletes. The coronary arteries supply blood to the heart muscle tissue. In the normal heart, the left main coronary artery originates from the left side of the aorta and passes behind the pulmonary artery. From there, it leads to the heart muscle on the front and side of the heart, branching off into smaller arteries. The right coronary artery originates on the right side of the aorta and passes down the front side of the left ventricle, branching off to the back side of the heart.

Several types of anomalies have been identified. The most common malformation is anomalous origin of the left main coronary artery from the right side of the aorta, with a sharp-angled bend passing between the pulmonary artery and the aorta. This abnormal path may result in myocardial ischemia (lack of blood supply to the heart muscle) due to inadequate blood flow in the coronary artery or compression from the sharp-angled path between the two large blood vessels. Less common malformations involve anomalous origin of the right coronary artery from the left side of the aorta, coronary artery hypoplasia (incomplete formation), or anomalous origin of the left main coronary artery from the pulmonary artery, which carries poorly oxygenated blood.

Identifying these anomalies can be quite difficult, since patients often have no symptoms and EKGs at rest or with exercise are usually normal. Any athlete with symptoms of syncope or abnormal heart rhythm should be evaluated. Studies may include an ECG, a cardiac magnetic resonance imaging (MRI) scan, or a computed tomography (CT) scan, and possibly cardiac catheterization. Athletes diagnosed with anomalous coronary arteries should be excluded from competitive sports. Surgical repair should be considered, and if successful, showing no myocardial ischemia, the athlete may be allowed to return to sports.

Marfan Syndrome

Marfan syndrome is an inherited connective tissue disorder caused by more than 400 gene mutations. It occurs in 1:5,000 to 1:10,000 individuals in the general population. Abnormalities of the connective tissues can cause changes in the tissues of the skeleton, eye, aorta, and skin. Skeletal changes often generate suspicion of the diagnosis and include tall stature, arm span greater than height, scoliosis, and chest wall abnormalities.

The cardiovascular changes include weakening of the walls of the aorta, which places the athlete at risk of developing dilation and potential rupture of the aorta. Abnormalities of the heart valves may also develop. Complete evaluation, including EKG, ECG, and DNA testing, should be performed in any athlete suspected of Marfan syndrome. Those diagnosed with Marfan syndrome should not participate in vigorous dynamic or contact activities. Athletes should have repeat exams of the aorta every 6 months for close surveillance. They may participate in low-intensity exercise, such as golf or bowling.

Other Congenital Heart Defects

Many additional heart lesions can occur, including those of the heart valves, and are discussed elsewhere. Defects of the septum (the muscle tissue dividing the heart) can occur between the upper chambers (atria) or lower chambers (ventricles). Athletes with septal defects may be able to participate in sports after evaluation shows normal cardiac function. Coarctation of the aorta is a narrowing or obstruction of the aorta, which can lead to abnormal blood flow or high blood pressure. Most patients will undergo dilation or surgical correction for treatment. If repeat evaluation shows normal blood flow and blood pressure with exercise, the patient may be allowed to return to sports.

Numerous congenital defects can occur that pose a life-threatening risk in the newborn period. These lesions involve abnormal placement of major blood vessels or malformed atria or ventricles. Surgical correction is necessary to improve survival and ability to perform even normal activities of daily living. It is possible that some patients may be able to participate in some level of physical activity. The clinician must carefully assess the type of defect and the risk for sudden death with exercise. Also, the ability of the heart to perform under the demands of exercise without causing deterioration in function is central to determining eligibility for sports. Ongoing reevaluation of these patients annually allows for assessment of continued eligibility.

Contusions (Bruises)

One of the most common sports injuries is a *contusion,* which results from blunt force trauma resulting in the accumulation of blood in tissue due to disrupted capillaries.

The contusion is noticeably different from *ecchymosis,* which is a bruise with significant discoloration but lacking swelling (edema). At the other end of the spectrum is the *hematoma,* which is a contusion with significant swelling due to accumulation of blood and serous fluid from the disrupted capillaries and tissues.

Mechanism and Symptoms

The contusion can vary in severity due to its size and location, especially in areas with richer blood supply. Most contusions result in some level of pain and discomfort, a result of the release of histamine and other anti-inflammatory chemicals into the spaces between the cells. Generally, the larger the contusion, the more blood is leaked into the intercellular space and the more discomfort is associated with it. Most contusions are self-limiting injuries and respond favorably to *r*est, *i*ce, *c*ompression, and *e*levation modalities (RICE) immediately after injury.

The spectrum of color changes associated with contusions follow the body's ability to remove the displaced elements of blood from the leaking capillaries. Initially, there is a reddish-blue color from hemoglobin concentrations, which advances to more blue-green hues from the breakdown of hemoglobin to bilirubin in the next week or so. From this, it tends to fade into a golden-brown color with the hemosiderin deposition from iron deposits in the intracellular tissue, finally resuming normal flesh tones.

Minor contusions may take a week or two to resolve, while more serious contusions can take longer. However, there are various contusions that will require more elaborate investigation and management as they can be found in critical tissue areas, such as organs, and can result in permanent disfigurement and dysfunction and sometimes death.

The following is a partial list of organ- and site-specific areas that can present with varied complications and consequences: the retina, ear (wrestler's ear), face, heart, lung, abdomen (liver, spleen, pancreas, intestines), vulva, testicle, bone, rotator cuff, and large muscles, such as the quadriceps, among many others. Several of these will be reviewed here.

Bone Bruises

A bone bruise is the result of blunt force trauma sufficient to disrupt the matrix of the bone just underneath its surface but not sufficient to fracture the entire bone. These injuries are typically associated with increased pain and injuries to adjacent ligaments or tendons. Imaging beyond radiographs, such as computed tomography (CT) and magnetic resonance imaging (MRI), is necessary to confirm bone bruises and also help identify associated injuries to adjacent ligaments or tendons. The natural history of a bone bruise suggests that it is a precursor to early degenerative changes (early arthritis). As such, it is important to delay return to full weight-bearing status in order to prevent further collapse of bone just beneath the surface (subchondral bone) and further aggravation of the lining of the joint spaces (articular cartilage).

Contusions to Large Muscles

Contusions to large muscles such as the quadriceps can result in significant disruption of the muscle belly and, due to its large size, can bleed extensively. One potential adverse complication of a quadriceps contusion is the development of myositis ossificans (heterotopic bone, bone that does not belong there) within the contusion, which can result in prolonged rehabilitation and muscle dysfunction and occasionally requires surgical intervention. The recommendation for this particular injury differs from others in that the knee is immediately placed into a flexed position of 120° and maintained in that position for 24 hours. It is felt that keeping the muscle stretched helps in reducing blood accumulation and also in decreasing contracture. Diagnostic ultrasound investigation of the size and type of echogenicity of the lesion is valuable in predicting the severity of the trauma, with anechoic and low-echogenic lesions taking longer to heal.

There have been isolated reports of delayed compartment syndrome (swelling that entraps the local blood vessels and nerves) following contusion to the thigh as well as other areas of the limbs, so serial monitoring of the size of the hematoma is prudent. Compartment syndromes can occur in any closed fascial space, such as an arm or a leg. A large contusion can create sufficient compressive forces, resulting in symptomatic pain, pallor, pulselessness, paralysis, and paresthesias that represent a suffocating limb. Urgent surgical fasciotomies are required to release the pressure.

Pulmonary Contusions

Pulmonary (lung) contusions are frequently associated with major chest trauma and may impair ventilation (breathing) due to derangements in the flow of air and/or blood. The forces associated with blunt thoracic trauma can be transmitted to the lung tissue. Athletes may complain of shortness of breath, rapid breathing, and chest pain, with blood-tinged sputum and low oxygen concentrations. Radiographs (X-rays) may show areas of small or diffuse patterns of congestion that do not fit the typical segmental patterns of pneumonia, and these are not evident until 4 to 6 hours after injury and may take up to 48 hours to appear. A CT scan of the chest can demonstrate these injuries immediately. Treatment consists of pain control, breathing exercises, and supplemental oxygen if there is low oxygen concentration in the blood. Larger contusions that interfere with oxygenation, leading to hypoxia and hypercardia, may require intensive medical care that may include being placed on a mechanical ventilator. The extent of low oxygenation typically parallels the degree of lung tissue involvement and contused lung volume seen on initial imaging studies.

Other Types of Contusions

Contusions to the heart muscle following blunt chest injury through violent contact in collision sports are rare but can have disastrous consequences such as cardiogenic shock (the heart failing to pump properly) if not evaluated thoroughly. Continuous EKG monitoring along with serial cardiac enzymes (blood tests of the leaking heart muscle) and echocardiography (sound waves showing heart motion) are necessary to assess clinical suspicion for this potential problem.

Blunt injury to the shoulders can result in contusions to the rotator cuff muscles. Most injuries will require conservative treatment, with a minority progressing to more severe injuries such as rotator cuff tears. An MRI scan can grade the severity and extent of injury, providing more useful information of the tendon's integrity to determine the prognosis.

Other contusions to organs are considered serious and need to be monitored medically. A contusion to the eye, kidney, liver, spleen, or testicle especially will require evaluation by a trained medical professional to ensure the best outcomes as there may be permanent loss of the organ if the injury is not monitored carefully and treated appropriately.

Core Strength

Critical for both stability and movement, the core includes muscles of the spine, abdomen, hip, and shoulder. Over the past 20 years, there has been growing interest in the area of core stabilization for the prevention and rehabilitation of back injuries as well as for the enhancement of athletic abilities. For example, it is now known that weakness of the pelvic muscles is a predictor of back pain in the college athlete. It has also been shown that sports performance is related to the strength of pelvic musculature and proper activation of the abdominal and back muscles.

However, debate continues over the exact definition of the core and the most effective methods of stabilization. Some authors have divided the core into the upper quadrant core and the lower quadrant core. The upper quadrant core refers to the shoulder girdle, including the glenohumeral joint (the shoulder joint) and the scapulothoracic articulation (the area of contact between the shoulder blade and the upper back). The lower quadrant core muscles include those of the spine, abdomen, and hip.

Power for many athletic movements is generated in these core muscles. Adequate power must be created and transferred efficiently from the core to the limbs for the system to work at maximal capacity. In the overhead throwing athlete, the transfer of force from the lower quadrant core to the upper quadrant core is essential for effective throwing.

These muscles must be both strong and well coordinated to provide stability and allow the athlete to adapt rapidly to changing conditions on the field of play. Therefore, they are a crucial aspect of training and rehabilitation programs. A large variety of exercises are classified under the category of "core stabilization," and the importance of specific components of core stabilization is an area of ongoing study. Combinations of muscles are used for different tasks, and in general, it is recommended that athletes not focus solely on individual muscles but instead address muscle groups and functional motor patterns.

Anatomy

Lower Quadrant Functional Anatomy

The lower quadrant core muscles include spinal, abdominal, and hip muscles that help support and position the spine. The spinal muscles include the erector spinae, multifidus, and quadratus lumborum and a variety of other muscles. The erector spinae work to bend the trunk backward (extend the spine). These muscles are located at the back. They originate at the level of the tailbone (sacrum) and divide into three bands on each side of the spine. They attach at different spinal levels and the back of the skull.

The multifidus muscle and the quadratus lumborum also extend the back when activated on both sides of the spine. When activated unilaterally, they bend the trunk to one side. The multifidus are shorter muscles that come in pairs on each side of the spine, located along the entire length of the spine. Each multifidus spans only two to three vertebral levels and, therefore, works to compress and carefully control the small, segmental motion of the spine. Conversely, the quadratus laborum originates at the back of the pelvic bone at the iliac crest and attaches to the 12th rib and the first four lumbar vertebrae (L1-L4). This provides a longer lever arm of extension but with less control over individual segments.

The abdominal muscles work together to flex the spine and assist in rotation. These muscles include the rectus abdominus and the three layers of the abdominal wall with the internal and external obliques and the transversus abdominus. The rectus abdominus is one of the main muscles involved in bending the body forward. One of the first muscles activated with power motions is the transversus abdominus, which attaches directly to the thoracolumbar fascia in the back. The coactivated abdominal, oblique, and back muscles work together to stabilize the spine.

The internal and external obliques flex the body forward when they are fired on both sides of the body. When fired unilaterally, they cause the body to bend to one side and rotate. Because the oblique muscles are connected to the torso and the pelvis, they are important in the rotation of the body, especially during sports participation.

The hip muscles are important in pelvic stability and for rotating the hips and legs. The piriformis, the obturator internus and externus, and the superior and inferior gemellus act to turn the hip outward. The gluteus maximus extends the leg back and rotates the upper leg outward. The gluteus medius and minimus rotate the upper leg inward. The gluteus medius acts primarily to abduct the hip, moving it away from the body.

Upper Quadrant Core

The upper quadrant core is important for transfer of forces to the upper extremities. For the glenohumeral (shoulder) joint to function properly, the scapula (shoulder blade) must be in proper position. The serratus anterior and trapezius rotate the scapula. The serratus anterior originates on the side of the ribs and attaches to the scapula. The trapezius originates from the back of the skull, the cervical vertebra, and the thoracic vertebra and attaches to the clavicle and scapula.

It has been suggested that there are several muscle "slings" that coordinate and stabilize the motion of the upper and lower core quadrants. These slings cross from one side of the body to the other and transfer forces from the lower to the upper extremity via the core stability system. The posterior oblique sling is composed of the latissimus dorsi on one side of the body and the gluteus maximus on the opposite side through the thoracolumbar fascia. The anterior oblique sling is made from the connection of the external oblique on one side of the body and the internal oblique on the opposite side, through the abdominal fascia.

Evaluation and Rehabilitation

Strong and balanced core muscles support the spine and reduce any stress that can lead to injury. Weakness in any part often leads to compensation, resulting in a less efficient movement and an increased risk for injury. Weakness in the core or poor energy transfer can lead the peripheral muscles to be overtaxed in their effort to generate adequate power. The entire chain of sport-specific movement should be evaluated and any deficit addressed.

The evaluation is ideally done preseason according to a standard protocol to assess each of the core components. To begin, the standing posture can be informative. For example, deep lumbar lordosis with a forward tilted pelvis (also called sway back) may indicate weak abdominals. A single leg squat can evaluate pelvic strength: With the hands on the hips, the athlete is instructed to keep the hips level and shoulders upright. If the hips tilt to one side while squatting, the hip abductors (gluteus medius) are weak. If the athlete leans forward, the hip extensors (gluteus maximus) are weak. A jump drop test is also very helpful for evaluation of these muscles: The athlete is asked to jump up off a box and onto the floor. If the knees collapse inward during the landing, the hip abductors are weak. Abdominal strength may be assessed with an abdominal brace test: Lying on the back with the knees bent 90° and the feet held flat by the examiner, the athlete is asked to hold a sit-up in 60° of flexion until fatigued.

Flexibility, important for fluid motion of the pelvis in synchronization with the lumbar spine, should also be assessed. Key muscles for evaluation include the hip flexors and the hamstrings.

When an athlete suffers an injury, the core should be assessed along the entire kinetic chain. Rehabilitation follows a specific sequence from the acute phase of rest and gentle range of motion, to the longer rehabilitation phase of strengthening and conditioning, and finally to the sport-specific phase. In the strengthening phase, the areas of known weaknesses are addressed first in a more isolated manner and then as part of coordinated motions. The final, critical phase of sport-specific movement gradually reintroduces the athlete to those activities necessary for full return to play.

Good neuromuscular control is also necessary to coordinate movement. Proprioception (the body's awareness of spatial positioning) is an important part of this neuromuscular control. The balance ball is one tool used in proprioceptive training. This type of training should be initiated early and continued throughout the rehabilitation process.

Corns

A *corn* is a buildup of skin located on the top, side, or end of the toe or between two toes. Corns are caused by constant friction against the shoe or between two toes. They are actually a normal and natural way for the body to protect itself, by thickening of the skin in response to increased pressure. They may be soft or hard, depending on their location. Most corns on the top of the toes are hard, while those in between toes are soft. Other names for corns are hyperkeratosis, clavus, and heloma.

Diagnosis

History

A patient will usually present with a corn when it becomes painful due to the buildup of excess skin and increased pressure. Increased pressure can result from shoes that are too tight, toe deformities such as hammertoes, bony prominences on the toes, or biomechanical or gait abnormalities that cause the toes to flex, or bend, while walking.

Common sports and dance activities may predispose an individual to the development of corns. Ballet dancers have an increased tendency to develop corns due to the tightness of the pointed shoes they wear.

As there is a whole range of causes for corns, it is important to note that corns are merely the symptom of an underlying condition.

Physical Examination

Corns can be recognized on visual examination of the foot. The doctor will likely evaluate the underlying cause of the corn, such as a bony deformity. A gait analysis and inspection of footwear may be performed to evaluate for any contributing factors of increased pressure.

Occasionally, fluid may develop underneath a corn, causing a painful condition. Drainage of this fluid usually decreases the painful symptoms. Additionally, the fluid can be located deeper, underneath the skin. *Bursitis,* a painful, inflamed, fluid-filled sac, can develop deep beneath a corn.

Imaging Studies

Radiographs (X-ray films) of the foot may be taken to evaluate the presence of any bony deformities. This will assist in the diagnosis and help direct appropriate treatment of the corn.

Treatment

Initial treatment will likely involve scraping the excess skin from the corn to reduce the pressure and decrease the pain symptoms. Additionally, any fluid causing pain can be drained. The doctor may also recommend methods of trimming the corns at home with a pumice stone to prevent recurrence.

Padding of the corns with over-the-counter pads may decrease irritation of the skin. Generally, the medicated type of pads should be avoided, as they may cause acid burns to the skin.

When conservative treatment fails to resolve the pain symptoms, addressing the underlying deformity may be necessary. This may involve surgical correction of the hammertoe or removal of the bony prominence.

Prevention

Corns and calluses can usually be prevented by avoiding friction-causing activities and wearing shoes that fit properly, are activity appropriate, and are kept in good condition. Soles and heels that wear unevenly may indicate a need for corrective footwear or orthotics.

Return to Sports

An athlete may return to sports once the pain symptoms resolve. Depending on the underlying cause, supportive foot devices called orthotics or special padding may be ordered to prevent recurrence of the corn.

Costosternal Syndrome (Costochondritis)

Chest pain can result from a broad range of causes, including both musculoskeletal and nonmusculoskeletal etiologies. Pain due to musculoskeletal causes can arise from the cartilage, bones, muscles, nerves, or joints that make up the chest wall. *Costochondritis* is one of the most common causes of chest wall pain and refers to inflammation in the costochondral or costosternal junction; it is also known as *costosternal syndrome.* Up to 30% of cases of chest pain that present to the hospital emergency room may be explained by costochondritis. However, it is a much more benign diagnosis than many of the causes of chest pain diagnosed in emergency facilities.

Costochondritis is slightly more common in females than in males, but it occurs in both. It is not isolated to the athletic community. It can occur in both children and adults, although it is more commonly seen in individuals 40 years and older. It can result from repetitive trauma, or it can be due to a particular incident that places strain on the costochondral region. The level of physical activity in affected individuals can range from very active to very sedentary. In various instances, it has been known to result from repetitive coughing. It most commonly occurs between the second and fifth ribs and can involve one or more ribs at the same time. Recognizing costochondritis is important because it is benign and should be distinguished from more serious causes of chest pain, which would be more worrisome.

Anatomy

The chest wall is made up of 12 ribs. Ribs 1 through 7 are referred to as true ribs, and they are attached to the sternum (the breastbone) via a cartilaginous tissue known as *costochondral cartilage* (also known as costocartilage). The joint between the sternum and the costochondral cartilage is known as the *costosternal joint*. The joint between the ribs and the costochondral cartilage is known as the *costochondral joint*. Ribs 8 through 10 are called false ribs because they are indirectly attached to the sternum via the costochondral cartilage of the ribs above them. Finally, Ribs 11 and 12 are called the floating ribs because they are not attached to the sternum at all. In the back, or posterior side, the ribs are attached to the spine. The *intercostal muscles* are the muscles located between the ribs; they help support the rib cage and participate in the chest wall movement that facilitates breathing. The intercostal nerves and vessels are located under the ribs. Various other muscles attach to the ribs from other angles and help support and move the adjacent structures, including the neck, arms, back, and chest. Therefore, repetitive upper body activity can lead to pain and overuse injuries affecting these various structures that make up the chest wall (see Figure 1).

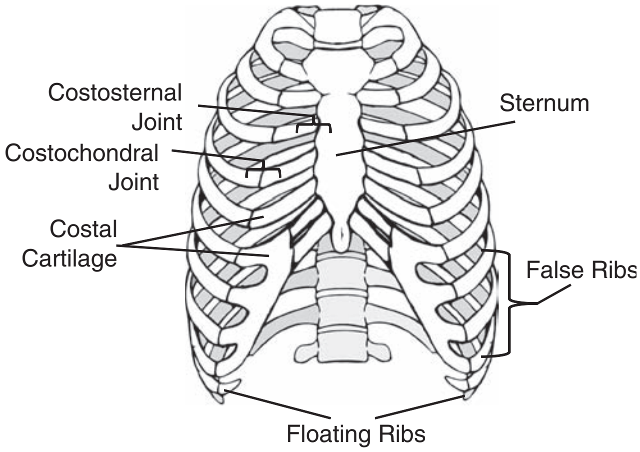

Figure 1 Anatomy of the Rib Cage

Diagnosis

Costochondritis is associated with sharp chest wall pain, often worsened by taking in a deep breath, coughing, and various movements affecting the rib cage, such as moving the arm around. One or more costochondral or costosternal joints can be involved, and the primary source of pain will arise from these structures. Placing direct pressure on the affected costochondral or costosternal joint will exacerbate, or bring out, the pain that the individual is having, although sometimes this is difficult to identify during the examination. There is no swelling or fever or deformation associated with this condition. The skin overlying the affected region should be normal in appearance and not associated with heat.

The diagnosis is made clinically—that is, by physical exam and history alone. No studies are needed unless an alternative diagnosis is being considered or if there is suspicion of something more serious. X-ray findings will be negative, but they may be ordered in select circumstances when other etiologies are being considered.

Costochondritis is a benign condition that does not predispose one or more serious issues. Thus, if the pain worsens, if it is related to difficulty breathing or feeling lightheaded, or if the pain is really severe, then a physician's attention should be sought urgently to exclude more serious causes.

Treatment

Costochondritis is a self-limiting diagnosis. It usually resolves within several weeks to months. Management includes taking analgesics to treat the pain, especially anti-inflammatory medication such as naproxen or ibuprofen, and minimizing activities or repetitive motions that worsen the pain. Acetaminophen can be used if the individual cannot take anti-inflammatories. Sometimes, placing a heating pad on the affected area may be helpful.

Other Causes of Chest Wall Pain That Can Mimic Costochondritis

A number of etiologies can cause chest wall pain apart from costochondritis and may need to be considered or ruled out to make an appropriate diagnosis. These are discussed below.

Tietze syndrome is the most common alternative diagnosis that can be confused with costochondritis. It occurs in any of the cartilaginous joints of the chest wall but most commonly is located at Rib 2 or 3. The sternoclavicular joint can be affected as well. Unlike costochondritis, there will be obvious swelling in the affected region. The pain will often radiate down the arm or shoulder and can last for several weeks. In severe cases, aspiration (placing a needle into the pocket of inflammation to take a sample) or a biopsy may be needed to exclude infectious causes. X-rays will often be normal, but the involved area will light up on bone scan imaging. The condition occurs most often in young people and is self-limiting and benign. It is treated with analgesics and anti-inflammatories and resolves on its own. Severe cases may require a local injection of corticosteroid.

The *intercostal muscles* can be injured as a result of sport activity if the rib cage is moved in an awkward position or if too much strain is placed on the muscles. This will be characterized by tenderness located on the muscles between the ribs as opposed to the costochondral joint. This entity is more common in sports that involve repetitive overhead activity, such as rowing. The pain can worsen with deep breathing, coughing, and overhead motions and can be treated with analgesics.

Precordial catch syndrome occurs mostly in teenagers and young adults below 35 years of age. It refers to sudden, sharp, stabbing pain that lasts several seconds and is most often located in the left upper chest wall region. It often occurs at rest or with change in activity. The pain is often relieved by stretching or changing one's posture. It can occur multiple times a day and can worsen with deep breathing. It is benign, and there is no known treatment.

Pleurodynia, also known as *epidemic myalgia, Bornholm disease,* and "*devil's grip,*" is caused by a viral infection. It presents as a sudden, sharp, severe pain in the lower chest or upper abdomen. The pain often worsens with coughing or deep breathing. However, unlike costochondritis, it is associated with fatigue, fever, headache, and other signs of a viral illness. It is self-limiting and should resolve within several days to a week. Although it is most often due to the Coxsackie virus, it can result from a variety of viral syndromes. For pain relief, anti-inflammatories or a heating pad can be used.

Stress fracture refers to a microtear in bone that has sustained repetitive trauma. It can occur in any bone, especially in athletes. This diagnosis should be considered in any athlete with severe rib pain, especially in athletes participating in sports involving frequent overhead activity, such as rowing, golf, tennis, swimming, javelin throwing, or weight lifting. X-rays may be normal early on in the disease, so a bone scan is often required to identify the affected location, which will light up. The athlete will need to stop sports activity for the injury to heal, and this can take up to 6 to 8 weeks. The pain associated with a stress fracture is often much more severe than in costochondritis and usually results in a noticeable limitation of movement in the affected individual.

Slipping rib syndrome is known by multiple other names, including painful rib syndrome and rib tip syndrome. It begins with a sharp stabbing pain that lasts only several minutes, followed by several days of a dull ache. The pain is specifically located under the rib cage. It can be associated with a sensation that the rib is slipping or popping out as a result of moving in various positions. Sometimes a "clicking" sound can be heard. Often palpation of the costal margin will bring out the pain. Slipping rib syndrome will not be visible on any type of imaging. It is believed to result from hypermobility of the floating ribs, which are believed to be slipping underneath the rib located above. It is benign and usually resolves within 4 to 6 weeks. Sometimes taping the area can be helpful.

Rarely, chest wall pain can result from a *costal cartilage fracture.* This is characterized by the sudden onset of sharp pain during sports activity, and tenderness is localized to the costal cartilage itself. Occasionally, it is associated with a painful "click." Most imaging will be unrevealing, but a computed tomography (CT) scan can be helpful in making the diagnosis. Surgery may be required for treatment.

Herpes zoster is a virus that can invade the nerves in a specific distribution (known as a dermatome) and causes painful skin rash associated with a burning sharp pain. Unlike costochondritis, it is associated with a characteristic rash, but during its early stages, the rash may not be evident, and it may be confused with musculoskeletal causes of chest wall pain.

Nonmusculoskeletal causes of chest pain can be more serious than costochondritis and, therefore, should be ruled out in the appropriate setting, especially in older adults. Chest pain can result from various thoracic organs that include, but are not limited to, the heart, lungs, aorta, and esophagus and from the pleural lining of the lung.

Cramping

Cramping in athletes is frequently referred to as *exercise-associated muscle cramps* (EAMC) and is the term used to describe the painful, involuntary contraction of skeletal muscle. EAMC are a common complaint among endurance athletes and those who compete outdoors in hot, humid environments. While the exact cause is unknown, many factors are believed to contribute to EAMC, including dehydration, electrolyte depletion, and muscle fatigue. Cramping has been reported in athletes of every sport and can occur in athletes of any age, race, or gender. Contractions can be visible and palpable and can affect a single muscle or an entire muscle group. Cramping may occur during or immediately after exercise. After cramping, it is common to have muscle soreness for 2 to 3 days.

The diagnosis of EAMC is made clinically, and the most effective immediate management of EAMC is rest and passive stretching. The key to the prevention of EAMC is to reduce the risk of developing premature muscle fatigue, dehydration, and electrolyte depletion. Skeletal muscle cramping is one of the most common conditions that require medical attention during sporting events.

Etiology

There are many theories as to the cause of EAMC, but none has been universally accepted. Some of the more common theories include electrolyte depletion, dehydration, and muscle fatigue. Because electrolytes, such as sodium, potassium, and magnesium, play vital roles in the physiology of muscle contraction, depletion of any of these elements through increased sweating or urination could inhibit proper contraction of the muscle. Dehydration could also play an important role in skeletal muscle cramping, because water has many important functions in muscle physiology and is an important method of thermoregulation in the body. A third hypothesis for the etiology of EAMC is muscle fatigue, which leads to altered neuromuscular control. The increased excitation of muscle spindles and the reduced inhibitory response of Golgi tendon organ activity could lead to abnormal neuromuscular excitability, which could cause the muscle to cramp. Muscle fatigue could also be caused simply by exercising at a level of higher intensity or duration than is standard for the athlete. There is literature to support all three of these hypotheses.

From a historical perspective, stokers on ships mixed seawater with drinking water to fend off cramps. Heat cramping and exhaustion were reduced when a saline drink was given to industrial stokers and coal miners in England. It has also been shown that the sweat sodium levels of athletes who cramp are significantly higher than in those who do not cramp. The exact mechanism for cramping from sodium loss is not clear. What is known is that sodium loss reduces extracellular fluid space and may alter ion channels to make neuromuscular junctions or muscle units hyperexcitable, causing involuntary and sustained contractions, or EAMC.

It is also important to recognize that skeletal muscle cramps can be associated with numerous congenital and acquired conditions, including hereditary disorders of carbohydrate and lipid metabolism, neuromuscular and endocrine diseases, medicines, and toxins. There are several risk factors that may be associated with the development of EAMC. However, the most important intrinsic risk factors for EAMC are a previous history of EAMC, current hydration status and electrolytic balance, and performing exercise at a higher intensity or for a longer duration than normal training. Participating in hot and humid environmental conditions is the most important extrinsic risk factor.

Diagnosis and Treatment

Muscle cramping in athletes has a classical presentation, and the diagnosis is made based on history and clinical examination. Special tests are usually not indicated. EAMC typically occur in athletes earlier in the season, when they have just begun their training; toward the end of a strenuous workout; and when athletes are unacclimatized to exercising in hot, humid conditions. Cramping is usually preceded by a noticeable twitching of the muscle, which develops into spasmodic contractions and then frank muscle cramping. This is usually associated with pain and continues until the activity is stopped and the muscle is stretched. Typically, muscle cramping is confined to muscle groups that are used during exercise, such as the calf muscles, hamstring muscles, and quadriceps muscles.

EAMC can be treated initially by stopping exercise and passively stretching the muscle. This stretching increases the tension in the muscle, thereby increasing the inhibitory activity of the Golgi tendon organ. Passive stretching is the most effective treatment for a cramping muscle and should be maintained until cramping of the muscle or muscle group ceases. Massage of the cramping muscle is sometimes useful as well. It is important for the athlete to rest for a short period of time before returning to exercise. Other common treatments include ice massage and intravenous or oral fluids containing electrolytes. Ice massage cools the muscle, while the massage component that can be beneficial as well. EAMC can often be reversed fairly quickly with 2 to 3 liters (L) of intravenous normal saline.

After acutely evaluating the athlete, a thorough physical exam should follow. The examiner should visually inspect the involved muscles, which includes looking for a hard contracted muscle or visible fasciculation. Usually, there is no other abnormality seen on physical exam. In patients with chronic cramping problems, a full musculoskeletal and neurological evaluation should be performed. It will be important to rule out other causes of cramping by obtaining a complete family and personal history, including a history of diabetes, metabolic disease, cramping, and prescription and over-the-counter medicines.

Prevention

The exact causes of EAMC are still being debated, and there is no treatment that will work for every patient, every time. However, in patients with chronic cramping problems, a thorough evaluation of exercise warm-up, training, and cooldown habits; diet; and game-day routine will be important to identify any possible conditions that may lead to cramping. Ensuring a normal training and game-day routine will be an important part of knowing what to change in order to help athletes overcome the cramping problem. Assessing the athlete's diet will also be a vital part of treating and preventing cramping; proper hydration, carbohydrate and electrolyte supplementation, and a balanced diet should be encouraged as well. There is some literature that suggests that supplements such as creatine may increase the risk of cramping because of the small amount of fluid retention in the muscle caused by the supplement.

Another important consideration for teams who experience problems with cramping will be to alter the time or environment in which they practice and play. Practices should be scheduled during early-morning or early-evening hours, avoiding the middle of the day, when temperature and humidity are at their highest. Having plenty of rest periods, and times and methods of cooling players off, will also be helpful. Also, it takes time to become acclimatized to the heat and humidity, so by gradually increasing the workout intensity, athletes should experience fewer episodes of cramping. The key to the prevention of acute EAMC is to protect the muscle from developing premature fatigue during exercise by maintaining a balance of electrolytes and proper hydration.

Conclusion

There is a high lifetime prevalence of EAMC in athletes, specifically in endurance athletes. While the exact cause is unknown, there are many factors that are believed to contribute to EAMC, including dehydration, electrolyte depletion, and muscle fatigue. The most important intrinsic risk factors for EAMC in athletes are a previous history of EAMC and performing exercise at a higher relative intensity or for a longer duration than in normal training. The most important extrinsic risk factor is participating in hot and humid environmental conditions. The diagnosis of EAMC is made clinically, and the most effective immediate management of EAMC is rest and passive stretching. Athletes presenting with recurrent episodes of EAMC require a comprehensive examination. The underlying medical causes of cramping must be excluded in these athletes. The key to the prevention of EAMC is to reduce the risk of developing premature muscle fatigue by maintaining proper electrolyte balance and hydration.

Craniofacial Injuries

The prevalence of sports-related facial injuries has increased over the past several years, accounting for up to one third of all facial injuries encountered by maxillofacial specialists according to recent studies. Thus, the ability to care for an athlete suffering facial trauma has become an important part of sideline coverage. In this entry, we will discuss key components of the evaluation and management of the most common facial injuries.

The proportion of sports accounting for facial fractures varies according to the regions of the world and the popularity of sports with high contact and lack of protective facial equipment. Baseball, basketball, and racquet sports account for the majority of injuries in the United States, while soccer is overwhelmingly the leading cause in most of Europe. Rugby and cricket are the most common causes in the United Kingdom, Australia, and New Zealand.

The most common sites of injuries vary according to studies, with some showing that nasal and zygomatic fractures are most common while others show that mandibular and orbital fractures are more prevalent.

Acute assessment of an athlete suffering from facial trauma should start with the ABCs of basic life support. The airway should be kept patent from bleeding, and hemodynamic status should be assessed. A rapid neurologic assessment should be done as well to rule out concomitant head and neck injury.

Nasal Injuries

Nasal fractures are among the most common facial fractures, accounting for up to 40% of the cases of facial trauma. Fights, sports, and motor vehicle accidents are the most common causes. Bony anatomy of the nose includes the paired, wedge-shaped nasal bones; the nasal processes of the frontal bone; and the maxilla. The lower half of the nose is supported by lateral cartilaginous tissues and the midline nasal septum. The septum becomes increasingly thin and requires less force to fracture than any other facial bone. However, fractures of the base of the nose require more force and are often associated with other facial fractures.

Direct frontal blows cause depression and telescoping of the fractured bones posteriorly. Lateral blows can cause ipsilateral depression and contralateral protrusion of the fractured bone. As stated earlier, cervical spine injuries and airway compromise can result from facial trauma and should be evaluated. Significant bleeding can also occur from nasal fractures, with the anterior ethmoid artery causing anterior bleeding and the sphenopalatine artery causing posterior bleeding. Red flags in the evaluation of nasal fractures are cerebrospinal fluid (CSF) rhinorrhea, subcutaneous emphysema, malocclusion, limited extraocular movements, and mental status changes, any of which should prompt transfer to the emergency department. It is important that the examiner on the field be alert for nasal discharge of any clear fluid after facial trauma, which could suggest a CSF leak.

Once the initial assessment has been done and ABCs, neurologic status, and concomitant facial fractures have been evaluated, the focus can be turned to addressing the nose itself. Examination of external soft tissues and internal structures may be impeded by soft tissue swelling, ecchymoses, and blood. Fortunately, uncomplicated nasal fractures can be reduced in 3 to 5 days once swelling has subsided. However, examination of the nasal septum should be done at the time of injury to rule out septal hematomas. Septal hematomas are blood-filled cavities between the cartilage and supporting perichondrium. If left untreated, they can become infected and lead to necrosis and perforation of the septal cartilage, possibly leading to a permanent saddle nose deformity.

Internal inspection will require adequate lighting, suction, topical anesthesia such as lidocaine, and vasoconstrictors such as oxymetazoline (Afrin). If visualized, the hematoma should be aspirated or incised, and then a sterile gauze and splint or nasal packing should be used to prevent reaccumulation. Once stabilized, a final exam should be done, and the patient should be referred for otolaryngology or plastic surgery follow-up in 3 to 5 days.

Orbital Fracture

One third of orbital fractures are caused by sports activity, which trails only assault as the leading cause. In the United States, baseball is the leading cause, while in the United Kingdom and Australia, soccer and rugby are the major culprits. The major mechanism of injury is blunt trauma from either a projectile or an opponent's body part.

Orbital fractures may involve the orbital floor alone or a larger portion of the orbital rim. Damage to the orbital rim often requires a direct blow to the bony orbit, while an isolated orbital floor fracture results from direct trauma to the globe, with subsequent buckling of the orbital floor due to increased intraorbital pressure. The latter injury is often referred to as an orbital blowout fracture and affects the thinnest portion of the orbital floor, the posteromedial portion.

Evaluation of the athlete should include assessment of the bony orbit, globe, extraocular movements, and visual acuity, as well as a fundoscopic exam. A grossly ruptured globe should be protected from any pressure or direct contact by using a rigid shield, and the patient should be immediately transported to the emergency room. Foreign bodies should be left undisturbed, and an eye patch should not be used. Loss of vision and severe eye pain precluding examination should also prompt emergency ophthalmologic evaluation.

Diplopia and deficits in upward gaze may be a sign of an orbital blowout fracture in which the inferior rectus or oblique muscle have become entrapped in the orbital floor defect. Medial wall fractures may cause entrapment of the medial rectus, limiting lateral gaze. The orbital rim should be palpated to assess for gross deformity or crepitus; the latter may indicate subcutaneous emphysema from a sinus fracture. Numbness of the cheek and lateral nose may indicate injury to the infraorbital nerve.

The imaging study of choice for orbital injuries is a computed tomography (CT) scan of the face and orbits. Orbital plain films are not recommended, as some studies have shown a false-negative rate as high as 50%. Once ocular emergencies have been ruled out by careful examination and a CT scan, treatment of isolated orbital floor fracture may consist of early surgical repair or conservative management. Indications for early surgical repair are deficits in gaze, fractures involving greater than 50% of the orbital floor, globe malposition, and enophthalmos (backward displacement of the globe into the orbit) of greater than 2 millimeters (mm). Conservative management should include regular follow-up and may include prophylactic antibiotics and oral corticosteroids to help limit infection and fibrosis, respectively. Return to play following surgery is usually within 6 weeks with protective eyewear. The most common chronic complication of orbital fractures is diplopia.

Maxillary and Mandibular Fractures

Maxillary and mandibular fractures are primarily caused by motor vehicle accidents and assault, with sports accounting for 2% to 8% of these fractures. Maxillary fractures are classified by the Le Fort classification system. Le Fort I fractures are transmaxillary, with complete separation of the maxilla from the rest of the facial bones. Le Fort II fractures are through the nasoorbitolethmoid complex and are also referred to as pyramid fractures because on exam the maxilla and nose move together as a pyramid-shaped complex. Le Fort III fractures are complete craniofacial separations. The most common sports-related maxillary fracture is a non–Le Fort fracture called a tripod fracture. It is a zygomaticomaxillary complex fracture (ZMC), resulting in complete separation of the zygoma from the rest of the face.

Examination of maxillary fractures may reveal a flattened face, a lengthened face, ecchymosis, paresthesias, crepitus, and often malocclusion. Examination may also reveal limited gaze due to entrapped extraocular muscles, decreased visual acuity due to propagation of the fractured fragment into the orbital canal, or restricted mandibular motion from an inferiorly displaced fragment. Special care must be taken in Le Fort III fractures of airway compromise from posteriorly displaced tissues. Evaluation is done with a facial bone CT, and treatment is often with maxilla-mandibular fixation to reestablish dental occlusion, followed by midface restoration.

Mandibular fractures can be classified as single, multiple, fragmented, or avulsive. The most common locations are at the condyle and angle of the mandible. Examination should include the skin, oral mucosa, dentition, and palpation of the mandible for step-off or mobility of specific segments. Examination may reveal trismus, crepitus, malocclusion, lip and chin paresthesias, and inferior facial asymmetry. Acute management should involve use of a Barton bandage to immobilize the lower jaw for transport. Treatment is by surgical fixation.

Conclusion

Facial trauma is becoming increasingly common in sports. Initial assessment should focus on the ABCs and neurologic exam. Care should be taken to evacuate nasal septal hematomas as early as possible. Orbital trauma, extreme pain, deficits in gaze, and diminished visual acuity should prompt immediate ophthalmologic evaluation. Most athletes will require transport to the emergency room and imaging in the form of a facial CT scan. Return to play will be based on the level of trauma and specific surgical intervention.

Creatine

Creatine is a popular, legal, over-the-counter dietary supplement that athletes use in preparation for sports and during training. It is not a steroid or stimulant but has been known since the early 1900s to have ergogenic properties. It became widely available and popular in 1993. Creatine is typically used to gain weight and muscle mass and to enhance strength training. It appears to be helpful by improving performance in short bursts of intense exercise, such as bench press or sprint cycling. It has no benefit on endurance in aerobic exercise. There is speculation suggesting that creatine supplementation may even help in improving mental performance, but this is still under debate.

The exact mechanism by which creatine supplementation improves athletic performance is not exactly clear, although there are several theories. Creatine seems to help athletes recover from vigorous exercise. The body uses creatine to make phosphocreatine, which acts as a buffer to keep up the production of ATP (adenosine triphosphate). ATP is the fuel used by the muscle during exercise, and the by-product is ADP (adenosine diphosphate). Creatine, among other things, essentially helps regenerate ADP back to ATP, thus replenishing the muscle's energy stores. There can also be weight gain and increased muscle mass with creatine use, up to 2.5 pounds (lb)/week (1.13 kilograms [kg]/week). Some proportion of this is likely due to water retention.

Creatine, in the monohydrate form or ethyl ester (CEE), is available as a sports drink powder or in a capsule form. The average daily intake of creatine from nutritional sources is about 1 gram (g)/day. It is found naturally in meat and fish. Creatine content in beef is approximately 4.5 g/kg. Tuna has about 4 g/kg, and herring has about 6 to 9 g/kg.

There are no universally agreed-on dosing or duration schedules, but there are some general recommendations. Most agree that the previously suggested "loading doses" of 20 to 30 g/day of creatine supplementation over a period of a week are not needed. They seem to increase potential side effects without giving significant benefits. In general, a maintenance dose of 3 to 5 g/day (or 0.03 g of creatine/kg of body weight), with no loading dose, is suggested. Many athletes cycle creatine use, using it for 3 months at a time followed by 1 month without creatine use. The optimal time to take creatine is immediately after a workout, combined with a drink with a high glycemic index (e.g., a commercial sports drink).

Short-term use of creatine is considered safe but can still have potential side effects. The most common side effects are bloating, diarrhea, and possibly muscle cramping. These effects can be minimized by forgoing the loading dose and staying well hydrated. Creatine does not seem to adversely affect kidney function but is not recommended for athletes with preexisting kidney disease. Because there is a lack of research in the pediatric population, creatine is not recommended by the American College of Sports Medicine (ACSM) for athletes under 18 years.

Credentialing for Team Physicians

Medical education in a medical school, residency, and fellowship provides a physician with the scaffolding to provide appropriate care for athletes. Continuing medical education and years of experience are essential for a team physician to establish credibility in treating active individuals.

Becoming a Physician

A physician is an individual who holds an unrestricted medical license and the degree of Medical

Doctor (MD) or Doctor of Osteopathic Medicine (DO). To become a physician, one typically completes an undergraduate degree before attending 4 years of medical school. Classroom didactics constitute the first 2 years of medical education, and the final 2 years include both required and elective medical rotations. On medical school graduation, a person is considered a physician but cannot practice unrestricted medicine. The physician must pursue a residency in a medical specialty. The first year of residency training is called the internship year. Residency training lasts from 3 to 6 years depending on the specialty. After successful residency graduation, the physician may become "board eligible," and after completion of a certification examination and specialty requirements he or she may become "board certified." Board certification signifies to the lay public that the physician is a recognized specialist in that field.

One may pursue an additional 1- to 2-year specialty education titled fellowship training. This training further refines the physician as an expert in a more specialized field of medical expertise.

The Team Physician

A team physician is primarily responsible for the health and welfare of the individual athletes or athletic teams. The team physician coordinates care with the remainder of the health care team, including athletic trainers, physical therapists, sport psychologists, nutritionists, and other allied health professionals. The responsibilities of a team physician include coordinating preparticipation screening, evaluating injuries and illness, managing injuries on the field of play, developing rehabilitation protocols, establishing return-to-play guidelines, and referring to appropriate specialists outside the team physicians' scope of practice.

Team physicians usually come from two main areas of medical expertise: primary care and orthopedic surgery.

Primary Care Sports Medicine Team Physicians

The American Medical Society for Sports Medicine (AMSSM), founded in 1991, and the American Osteopathic Academy of Sports Medicine (AOASM), founded in 1984, are primary care–based multidisciplinary organizations with the mission to care for the medical and nonsurgical musculoskeletal needs of active individuals.

Many primary care team physicians have completed fellowship training to learn the art and science of sports medicine. Prior to 1999, primary care team physicians who had completed a residency program could sit for the Certificate of Added Qualifications in Sports Medicine exam. Today, a physician must be board certified in family medicine, internal medicine, pediatrics, emergency medicine, or physical medicine and rehabilitation and should have completed a 12- to 24-month accredited primary care sports medicine fellowship to take the certification examination. On successful passing of the examination, one is considered a "sports medicine specialist." Recertification is required both in the primary medical specialty and for the Certificate of Added Qualifications in Sports Medicine on a 7- to 10-year basis. There are two organizations that certify the physicians. They are the American Board of Medical Specialties (ABMS) and the American Osteopathic Association (AOA) Bureau of Osteopathic Specialists. A claim of "board certification" or "certificate of added qualifications" must be accredited by one of these two organizations.

In addition to maintaining specialty certification, the primary care physician must show continuing medical education in sports medicine. Physicians are strongly encouraged to be trained in cardiopulmonary resuscitation (CPR) and advanced cardiac life support and participate in a sports medicine society.

Primary care practitioners who have *not* completed a sports medicine fellowship or who do not have a Certificate of Added Qualifications in Sports Medicine may be qualified to treat athletes depending on their level of experience.

Orthopedic Surgeon Team Physician

The American Board of Physician Specialties certifies candidates who wish to present themselves to the public as qualified orthopedic surgery medical specialists. Board certification includes a written, oral, and clinical (on-site) exam. One must first successfully pass the written portion of the examination before proceeding to the oral exam at the next testing cycle. Trained board-certified examiners, who ask the candidates to present their approach to managing three to five case presentations, conduct the oral examination. After passing the oral exam, two board-certified orthopedic surgeons conduct a clinical (on-site) exam by observing the candidates perform two major orthopedic surgery procedures. They also conduct a medical chart review.

Physicians must recertify on a 7- to 10-year basis. This includes continuing medical education, self-assessment, passing Continuing Medical Education examinations, and passing a 100-question written or computer-based examination. In addition, diplomates must maintain a full and unrestricted medical license.

Orthopedic Sports Medicine Certification

In 2003, the ABMS approved the American Board of Orthopedic Surgery (ABOS) application for subspecialty certification in orthopedic sports medicine. Of the 95 orthopedic sports medicine fellowship programs, 55 are accredited by the Accreditation Council for Graduate Medicine Education. Approximately 200 fellows are trained per year in orthopedic sports medicine. The year 2007 was the first year the sports medicine certification test was offered. After 5 years, one will not be able to sit for the exam unless he or she has completed a certified fellowship.

It is accepted that the training for a general orthopedist plus board certification constitutes more than adequate training. The subspecialty certification was designed to rein in and control the quality of sports medicine fellowships and not preclude anyone from caring for athletes. Any orthopedist may consider himself or herself a sports medicine specialist.

Cricket, Injuries in

The game of cricket, which originated in England, is played on a grass oval field by two teams. Cricket injuries are documented as far back as 1751, when a prince in England was killed by a cricket ball striking his head.

Game Description

Each team (with 11 players) takes a turn "at bat," during which time two of its players attempt to protect wooden "wickets" placed at the end of the batsman's crease located in the field center. The batsmen are supplied with broad cricket bats made of willow, considerably wider than a baseball bat, with which they attempt to score runs (points) and defend their wicket. Runs are scored by hitting a ball "bowled"

A cricket batsman in action. Ball contact injuries are common while batting, and hand injuries are common while catching the ball.

Source: Can Stock Photo.

toward them using a technique involving a run-up, then projection of the ball with the arm in full elbow extension following an arc that begins with the shoulder in extension and the hand at the side and ends 180° later with the hand at the crest of the arc and the shoulder fully elevated.

The team "in the field" positions its players around the batsmen and attempts to catch balls that are hit toward them. If the ball is successfully hit past the fielders, the batsmen can score runs by running between the two wickets (in effect, the wickets are similar to bases). If the ball is hit hard enough, four runs are scored if the ball leaves the field and six runs if it does so without bouncing. Some of the ways in which the batsmen can be defeated (got "out") are (a) by bowling the ball past them to hit the wickets, (b) catching the ball after it is hit, or (c) throwing the ball back to the wickets while the batsmen are in transit between them after the ball was hit (a "run out"). The ball is made of a core of cork, which is layered with tightly wound string and covered by a leather case with a slightly raised sewn seam, usually red or white; the ball must be caught by the fielder without the use of gloves (except for the wicketkeeper).

Games vary in length, from a "one-day" to a "five-day" series (Test cricket). Cricket is played worldwide, particularly in the countries of the British Commonwealth. The Cricket World Cup conducted by the International Cricket Council is contested every 4 years.

Injuries and Epidemiology

A 2005 consensus recommended that a cricket injury (or "significant" injury for surveillance purposes) is defined as any injury or other medical condition that either (a) prevents a player from being fully available for selection for a major match or (b) during a major match, causes a player to be unable to bat, bowl, or keep wicket when required by either the rules or the team's captain.

Injuries are reported in several contexts. There is little player-to-player contact; however, ball contact injuries are common while batting, and hand injuries are common while catching the ball. Injuries resulting from such impacts are more common during low-level competition or informal participation.

Overuse and improper bowling techniques are thought to be responsible for the high incidence of lumbar spine stress injury, such as spondylolysis. Surveillance of cricket injuries has consistently identified fast bowlers to be the players at greatest risk for such an injury. Such injuries develop gradually and are associated with the cumulative effects of microtrauma to the musculoskeletal system. Fast bowling repetitive microtrauma may be related to a combination of poor technique, poor physical preparation, and biomechanical overload. Studies of fast bowling techniques have reported lower back injuries to be more common with a mixed bowling technique than with a front-on or side-on technique.

Studies of cricket injuries show incidences varying from 0.3 to 33.3 per 1,000 player-hours, with 28% to 72% of cricketers sustaining 1.6 to 1.9 injuries per season. Injuries to the lower limbs vary from 23% to 50% of all injuries. Upper limb injuries account for 20% to 34%, with the site most often injured being the fingers. Back and trunk injuries account for about 18% to 33%; injuries to the head, neck, and face vary from 5% to 25%. An acute injury rate of 57.4 per 1,000 days of cricket played was found in one study in England, with the regional distribution to the head and neck, upper limbs, trunk, and lower limbs being 6%, 29%, 20%, and 45%, respectively. Studies have also found a relatively high incidence of facial injuries in cricket, in comparison with other sports, with the ball's trajectory and bounce off the field during fast bowling to be the major cause of the majority of these injuries.

Among children, cricket injuries comprise 4% of all sports-related injuries, ranking the game as the eighth largest cause of sports-related injuries leading to pediatric emergency department presentations in Australia.

Prevention

Strategies for prevention of injury include mandatory use of helmets for batsmen in youth cricket. Because of the potential severity of the impacts associated with the hard ball, a range of protective equipment has become a common feature of standard cricket equipment.

General strategies that can be used to prevent a wide range of injuries from occurring include good stretching programs before and after play, as well as comprehensive conditioning and technique programs before and during the season.

Cricket is generally a summer sport; thus, with exposure to the sun and high temperatures comes an increased risk of skin cancer, dehydration, heat exhaustion, and heat stroke. For Test cricket, cricketers are required to wear white shirts and pants ("trousers"), while a hat is optional. The white color reflects heat to a greater extent than darker-colored clothes. The eyes and skin are also given additional protection from the sun. Sun block gives additional protection to the exposed body parts. More often now, professional cricket is played at night under floodlights.

Cross-Training

Athletes spend endless hours participating in their sport of choice. But at times, they may choose to cross-train. By definition, *cross-training* means an athlete participates in a different form of exercise than his or her usual sport. Therefore, it is a form of exercise that is not necessarily sport specific. It has been classically used to refer to aerobic forms of exercise only. This entry provides an overview of the basic concepts and discusses the potential benefits of cross-training for athletes.

Common forms of exercise that improve cardiovascular function include running, biking (stationary or road), using the elliptical trainer, swimming, and deepwater running. The main concept behind cross-training is to pick a form of exercise that stresses a body part that is different from the athlete's primary sport of choice. Therefore, if an athlete is involved in a predominantly weight-bearing sport such as running, he or she would likely cross-train on a bike or in a pool. Athletes involved in sports that emphasize overhead activity, such as tennis, volleyball, baseball, and softball, may benefit from choosing a form of cross-training that emphasizes lower body fitness. This would include all the above forms with the exception of swimming. These concepts can be applied for basic fitness training as well as for rehabilitating an athlete who is recovering from either an acute or a chronic injury.

Athletes may choose to cross-train for a variety of reasons. One of the most common reasons is to decrease boredom. Individuals frequently get bored participating in the same form of exercise day in and day out. By mixing up the routine with a different form of exercise, they may be more compliant with their workout regimen. The variety can help keep athletes motivated and engaged in their program, which may eventually lead to improved fitness.

Another common reason for cross-training is injury prevention. When athletes are involved in training on a regular basis, they are at increased risk of suffering an overuse injury. For instance, runners are at high risk of suffering stress fractures in the weight-bearing bones, such as the metatarsals, tibia, and femur. Similarly, athletes who perform repetitive overhead activity, such as swimmers, may develop chronic shoulder pain. These injuries can limit an individual's ability to participate in sport-specific training. Cross-training can be substituted for sport-specific training before an injury happens. This may help limit the athletes' risk of overuse injury, simply by decreasing their time spent training in their primary sport. Therefore, some people view cross-training as a possible preventive training technique.

Cross-training is most commonly relied on as a way of conditioning individuals when they are unable to train in their usual sport of choice. This situation typically arises when an individual is injured. For instance, if a runner has suffered a lower extremity stress fracture and is unable to run, it may be safe for him or her to swim or even run in deepwater, helping to minimize the impact. Likewise, an athlete who is recovering from an acute injury, such as a football player with a dislocated shoulder, may be unable to return to the football field, but he or she can likely ride a stationary bike and even progress to running when he or she is more comfortable. This allows the athletes the ability to maintain their cardiovascular fitness while they are unable to participate in sport-specific forms of training. Cross-training also allows injured athletes to remain actively involved in their rehabilitation process. Athletes who are able to stay active through cross-training may have less anxiety about their injury, feel less depressed about missing time away from their sports, and feel better prepared to return to competition when they are physically able to.

The actual training benefits of cross-training are variable. For individuals who are unfit or moderately fit, cross-training can help improve their cardiovascular base. It can also help these athletes diversify their sports skills and gain skills that they may not have gained in their primary sport of choice. For elite athletes, there is very little cardiovascular gain that can occur from cross-training. These individuals typically are already maximally conditioned, and cross-training will not improve their fitness. Some researchers believe that the time away from his or her primary sport may even harm an elite athlete's ability to perform sport-specific skills.

Overall, sport-specific training appears to provide greater gains in both cardiovascular fitness and sport-specific skills for athletes. Still, cross-training can play an important role for athletes, particularly for unfit individuals or those who are rehabilitating from an injury.

Crutches, How to Use

Crutches have long been used as a support device for individuals with lower extremity injury. They serve a vital function for the athlete seeking to maintain mobility and fitness while not bearing weight. Proper and efficient use of crutches depends on careful fit and comprehensive instruction in appropriate gait sequence.

Function

Crutches are within the class of medical tools called *orthotics* (or orthoses). They are commonly prescribed after an acute orthopedic injury to the lower extremity. Often with such injury, the patient is either unable or specifically instructed not to bear weight. Crutches serve as a support onto which weight is shifted, thus helping relieve discomfort and reduce recovery time from injury. Crutches are most essential as an assistive device for mobility purposes, also referred to as an ambulatory aid.

The primary function of the crutch is to reduce weight load on the injured leg while also enabling adequate balance and stability during ambulation. Serving as a broad-based extension of the upper extremities, crutches shift the force of upright movement from the legs to the upper body. Proper use of crutches as an ambulatory aid requires sufficient upper limb strength, coordination, and hand function.

Types

There are primarily two types of crutches currently in use. The underarm (or axillary) crutch, the type most commonly prescribed in the United States, is used most often by patients with acute injury or temporary disability. The forearm (or nonaxillary) crutch is used in the United States almost exclusively by patients with permanent lower extremity disability.

The underarm crutch has the primary advantage of allowing transfer of 80% of the user's body weight. By providing support from the axilla to the floor, underarm crutches allow for better trunk control. In contrast, forearm crutches allow transfer of only 40% to 50% of the user's body weight and require good trunk control to operate safely.

Proper Fit

The standard underarm crutch is adjustable for length. There are several key components of an underarm crutch, designed to enhance safety and comfort. The crutch tips, in contact with the floor, must be made of rubber and be at least 1.5 inches (in.) (3.81 centimeters [cm]) in diameter. The crutch tip can be fitted with a retractable metal spike for use on ice. The handgrips are ideally thickly padded with sponge rubber to reduce friction and blunt the pressure on the palms. The underarm component is typically fitted with a sponge rubber pad, but it must be stressed that the axillary crutch is not designed to be tucked into the underarm and rested on for body support. This action increases risk of injury to the axillary nerves and blood vessels.

To optimize dynamic function while simultaneously minimizing risk for complication, crutches must be properly fitted via a measurement prescription. For underarm crutches, measurement should proceed as follows: With the patient standing, determine the crutch length by measuring the distance from a point 3 in. (7.62 cm) below the armpit to a point 6 in. (15.24 cm) lateral to the fifth toe. With the crutch now set at proper length, place the tip 3 in. (7.62 cm) lateral to the foot to determine the optimal hand piece location. The hand should rest at a level that allows for 30° of elbow flexion while the wrist is in maximal extension and the fingers are flexed into a fist. To confirm proper fit, the patient should be able to raise his or her body 1 to 2 in. (2.54–5.08 cm) with complete elbow extension. If the patient is in a supine position, the measurements will not be accurate.

Gait Sequences

There are different gait sequences available to the patient requiring crutches. The appropriate sequence is determined in large part by the nature of the injury or disability in conjunction with the patient's capabilities. Some gait sequences require considerable upper body strength and energy expenditure, whereas others require exceptional balance and coordination. In the case of an athlete with acute injury to the lower extremity, two gait sequences are commonly employed. The "three-point" or non–weight-bearing gait entails a first step of putting forward both crutches and the injured lower limb (the three points), then a second step of bringing the unaffected limb up to and even with the crutches. The more difficult "swing-through" gait entails a first step of planting both crutches forward, followed by a second step of swinging both lower limbs through and past the crutches. This technique allows the patient to move faster than with a normal walking gait. To perform this sequence safely and effectively requires strong, functional abdominal and upper limb musculature and good trunk balance.

How to Use

These gait sequences are ideally taught by an experienced physical therapist prior to hospital discharge. The majority of patients, however, are instructed in the non–weight-bearing gait in an office setting. The basic principles for safe and effective performance of this sequence are as follows: To begin walking, lean forward slightly, and place the crutches about 1 foot (0.3048 meters) in front. Shift your weight to arms/crutches, and sway forward. Swing the good leg forward between the crutches, and plant it on the ground. Shift the weight to the good leg, and repeat the sequence. Remember to keep your eyes focused on where you are walking and not on your feet. Keep your steps small, and never support yourself on your armpits.

To safely sit with crutches, the following is recommended: Back up to the seat. With both crutches in one hand, place the other hand on the seat, and lower yourself down. To stand from a seated position, first move to the front edge of the seat. Hold both crutches in the hand on the injured leg side, put your weight on the good leg, and push with your arms to stand. Crutch use on stairs is best avoided whenever possible given the inherent risk of falling, particularly on descent.

Complications

Underarm crutches set at too long a length or used incorrectly can lead to significant medical complications. It has been determined that excessive weight bearing on the axillary bar can lead to a seven-fold increase in force on the axilla. Complications that may result include compressive injury to the nerve complex (the brachial plexus) located in the underarm, otherwise known as *crutch palsy*. The affected individual typically presents with grossly evident muscle weakness in both arms. With proper treatment, most patients with crutch palsy fully recover in 8 to 12 weeks. A less common complication is crutch-induced axillary artery injury. With this entity, blood vessel injury leads to decreased blood flow to the arm. These complications are largely preventable by ensuring correct length and proper use of underarm crutches. The advent of spring-loaded axillary crutches, which may alter the way loads are transmitted to the body during crutch gait, may reduce the potential for complications.

Cryotherapy

Immediate application of cryotherapy is one of the essential modalities in the treatment of an acute injury. *Cryotherapy* is the therapeutic use of cold to control inflammation and edema, decrease pain, reduce spasticity, and facilitate movement. Tissue cooling is achieved through the application of cold through the skin. The application of cold produces a sensation of intense cold followed by burning, aching, decreased pain, and numbness.

Indications for cryotherapy include acute injury or inflammation, acute or chronic pain due to muscle spasm, edema/swelling, spasticity accompanying a central nervous system disorder, painful limitation of motion secondary to immobilization, and first-degree burns.

Contraindications include cold hypersensitivity, circulatory compromise, history of frostbite, leukemia, and/or systemic lupus. Precautions must be taken in the case of open wounds, hypertension, poor sensation, aversion to cold, poor mentation, prolonged application over a superficial nerve, and patients who are very young or very old.

Adverse reactions can include tissue death, frostbite, nerve damage, and unwanted opening of the blood vessels (yielding increasing blood flow).

Cold Packs

A cold pack is a superficial physical agent that reduces tissue temperature by means of conduction. Cold packs are typically composed of an outer vinyl pouch filled with a silica gel mixture that is kept between 0 °C and 5 °C. This method is used to achieve constriction of the blood vessels, decrease tissue metabolism, decrease pain threshold, reduce muscle spasm, temporarily decrease spasticity, and decrease tissue elasticity.

A protective layer should be placed between the cold pack and the skin. The layer can be either dry or damp. Place the pack on the area to be treated, and secure it well. The skin should be checked after 10 to 15 minutes for any signs of adverse effects, such as a rash or bluish/whitish coloring of the skin. Following 20 minutes of cold, the skin may be red or dark pink. Application of the cold pack may be repeated every 1 to 2 hours to control pain and inflammation.

Ice Massage

Ice massage is a convenient and easy example of cryotherapy. An ice cup (a paper cup filled with water that has been frozen) is used for the massage. Move the ice over the area to be massaged in small, overlapping circles. Ice massage can be done for 3 to 5 minutes or until numbness is experienced. The treatment area should be inspected for any signs of adverse reactions.

Contrast Bath

A contrast bath is a method applied by alternately immersing an area in warm or hot water, followed by cool or cold water. This method is used to increase superficial circulation, decrease pain, reduce muscle spasm, relieve joint pain and stiffness, decrease swelling, and increase tissue metabolism. Due to the circulatory effect of alternating opening and closing of the blood vessels, a pumping effect is achieved. Contrast bath is often used for edema and inflammation control. Indications for contrast bath are sprains, strains, tendinitis, and hypersensitivity. Contraindications are recent skin grafts, infection, bleeding, or decreased thermal sensation.

Two containers of water are placed adjacent to each other, one filled with warm water (38–44 °C) and the other filled with cool water (10–18 °C). The area to be treated is placed in the warm water first for 3 to 4 minutes. Then the area is immediately placed into the cool water for 1 minute. This sequence is repeated for up to 30 minutes. Recommendations for ending with cold or hot may be found equally in the literature, but there is no conclusive evidence to support either hot or cold as having superior effectiveness.

Cyst, Baker

A *Baker cyst,* synonymous with a popliteal or synovial cyst, is an outpouching of fluid located at the back of the knee. Each of the three terms illustrates a different aspect of this condition or refers to its history. Dr. William M. Baker was one of the first physicians to describe this cystic structure. His publication on the formation of synovial cysts dates back to 1877. The term *synovial cyst* is used because the cystic structure often fills with synovial or joint fluid to produce its characteristic bulge. The term popliteal refers, in anatomy, to the area at the back of the knee where this cyst is found. For consistency, the term *Baker cyst* will be used for the remainder of this entry, but it is important to consider these other terms when conducting further research or communicating with health care providers. This entry will outline the symptoms, diagnosis, complications, and treatment of Baker cysts.

Symptoms

Although a Baker cyst is generally not a dangerous condition, it can impair an athlete's ability to train. This cyst, characterized by excess swelling in the back of the knee, presents as a smooth, compressible bulge and has the feeling of a fluid-filled sac. The cyst will be more prominent with the extension of the knee. Cysts will frequently soften with flexion of the knee to 45° and may sometimes disappear. The area of swelling can be quite painful, especially if the cyst ruptures. In addition, larger, painful cysts can limit the range of motion of the knee, thus limiting the athlete's ability to participate in training. Although the medical community generally views this condition as benign, it can be debilitating to active individuals.

Baker cysts are found in both children and adults; however, their prevalence tends to increase with age. There are two peaks in incidence, one occurring between ages 4 and 7, the second between ages 35 and 70. Interestingly, younger patients rarely have any associated joint problems, while older patients often have a variety of conditions affecting the knee. The presence of a Baker cyst may actually be an indication that there are other mechanical or inflammatory problems with the knee. Meniscal tears, arthritis, and ligament damage are all conditions that have been associated with Baker cysts in adults. Athletes who develop a cyst after trauma to the knee should be wary of possible soft tissue damage within the joint.

While there are several injuries that can lead to the development of a Baker cyst, there are also separate conditions that may imitate it, such as deep vein thrombosis (blood clots), aneurysms, muscle strains, and soft tissue tumors. Some of these conditions, especially blood clots, are more serious and may require prompt evaluation by a physician.

Anatomy and Pathophysiology

To understand how a Baker cyst is formed, it is important to understand the anatomy of the knee. The knee is a compound joint involving three bones: the tibia, the femur, and the patella, otherwise known as the kneecap. The medial and lateral menisci are structures composed of cartilage that cushion the impact between the two heads of the femur and the tibia. As noted earlier, injuries of the menisci can be related to the development of a Baker cyst.

Generally, the back of an extended knee, commonly referred to as the popliteal fossa, is soft and flat. The popliteal fossa is bordered by several muscle tendons, including the hamstrings and the gastrocnemius, commonly referred to as the calf. Important structures such as the popliteal artery and vein, as well as the tibial nerve, run through this space.

The actual knee joint is in front of the popliteal fossa. The joint is completely enclosed in a fibrous material referred to as the joint capsule, which contains the synovial fluid of the knee. Synovial, or joint, fluid is secreted by the cells within the capsule and is essential for lubrication of the knee, which decreases friction at the joint. The leaking of this fluid is one mechanism by which a Baker cyst is formed.

The most widely discussed mechanism for the formation of a Baker cyst is the swelling of a bursa, which results from the connection of the bursa with the joint space. Bursae are fluid-filled sacs that cushion areas of increased friction in the body. There are several primary bursae located around the popliteal fossa. Although any of the bursae in this area may swell, the gastrocnemius-semimembranosus bursa is most commonly related to the development of a Baker cyst. This bursa is located on the medial, or inner, portion of the back of the knee.

When an athlete experiences trauma to the knee, resulting in damage to one of the inner structures, an effusion often forms. As the amount of fluid increases, so does the pressure inside the joint capsule. Under normal circumstances, there is no passage of fluid from the knee joint to the bursa. As the fluid in the knee builds, however, it can sometimes leak into the adjacent bursa and create a cyst. Notably, there are instances when athletes develop Baker cysts and underlying problems with the knee are never detected. There have also been cases of Baker cysts that form as a result of swelling of the bursa, with no communication to the joint. Occasionally, the joint capsule itself can swell to the point where it is responsible for the formation of a Baker cyst.

Diagnosis

Although these cysts can be diagnosed by physical examination alone, imaging may help distinguish them from other, more serious problems. Several techniques, including ultrasound and magnetic resonance imaging (MRI), have been used for examination. Ultrasound is extremely useful as it allows the physician not only to visualize the cyst but also to distinguish it from a deep vein thrombosis or an aneurysm. An MRI scan is generally not necessary for diagnosis; it can be extremely useful though in visualizing damaged soft tissue, such as meniscal tears or ligamentous injuries. Although plain X-rays cannot clearly visualize the cyst, they may be useful in identifying underlying arthritis.

Complications

Rupture is the major complication of a Baker cyst and can sometimes be the presenting sign. Rupture can be very painful and lead to additional swelling of the back of the calf. Because of the additional swelling, ruptures mimic the signs of a blood clot more closely than an intact cyst. The *British Medical Journal* reported just such a case in a 25-year-old rugby player. The man, a healthy athlete who did not report any previous knee injury, was admitted to the hospital 3 hours after playing in a rugby game. During the second half of the game, he experienced pain in the back of his left calf. On evaluation, his knee and the back of his calf were swollen, and the back of his knee was very tender. An imaging study demonstrated that he had a ruptured Baker cyst. The patient rested for 48 hours and then resumed normal activities but did not return to athletics until 2 months later. Generally, ruptured cysts may be treated with analgesics, rest, and elevation.

Treatment

Treatment of a Baker cyst varies with the degree of impairment an athlete experiences. Asymptomatic cysts require no treatment. There are several reports of improvement of Baker cysts after steroid injections into the knee joint. The injected steroid limits inflammation at the joint. Notably, these injections are not generally successful if the cyst does not communicate with the joint space. If underlying joint or soft tissue disease is identified, treatment of these conditions may result in resolution of the cyst. Although surgical excision is not a definitive cure, patients with bothersome cysts refractory to conservative management may consult a surgeon regarding cyst excision.

Baker cysts are common findings in athletes, particularly those with associated knee injuries. Although these cysts are benign, they can mimic other, more serious conditions, and for this reason, they require evaluation. Athletes whose performance is impaired by a Baker cyst can often achieve alleviation of symptoms with conservative management, which has few complications.

Cyst, Ganglion

A *ganglion cyst* is a small, fluid-filled sac (usually less than 2 centimeters) that is located near a joint capsule or tendon sheath (the covering surrounding a tendon). It is thought to arise from a herniation of synovial (joint) tissue from the joint or tendon sheath. Experts do not know the exact cause of ganglions but believe that they may be associated with some type of trauma or tissue irritation. Overuse or repetitive motion may predispose a person to the formation of a ganglion cyst. Ganglion cysts are often found on the back of the wrist and appear as firm, pea-sized nodules (see Figure 1).

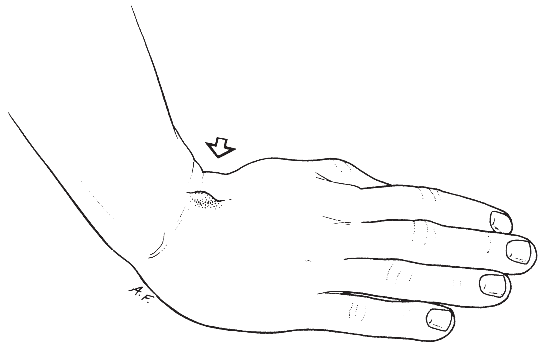

Figure 1 Common Location for a Ganglion Cyst

Ganglion cysts account for approximately 60% of the soft tissue tumors affecting the hand and wrist. When found at the fingertip, just below the cuticle, they are called *mucoid cysts*. The cyst is composed of a thick, jelly-like material. They are not cancerous. Ganglions affect people of all ages. They are common in adults between the ages of 15 and 40 and occur in women three times as often as in men. Ganglion cysts may occur in children as well (see image, page 345). Treatment consists of both nonsurgical and surgical options.

Anatomy

Since ganglia most commonly affect the hand and wrist, this anatomic review will focus on that region. The hand is composed of 14 bones, and the wrist is composed of eight bones. Special hinges called *joints* separate the bones. These joints contain fluid that lubricates them, allowing for smooth motion. Muscle contraction creates the movement of the bones. The muscles are attached to the bones by tendons. When the muscles in the forearm contract, the tendon is pulled, and the finger bends. A special tube containing lubricating fluid covers some of the tendons. The lubricating fluid allows for smooth and painless movement. The tendons and their special tubing are held in place by a specialized covering called a *sheath*. The joints and tendons are common areas where ganglia can develop.

Source: Photo courtesy of the authors.

Symptoms

Usually, ganglions are small, painless masses that may change in size. Some ganglia, however, may cause pain because they put pressure on the surrounding nerves. This pressure may also cause a tingling sensation in the hand. The pain is usually described as an ache and is made worse by repetitive activity. Larger ganglia may cause limitations in the range of motion. When the cyst is connected to a tendon in the hand, a sense of weakness may occur. Some ganglions may be cosmetically unappealing.

Diagnosis

A ganglion can usually be diagnosed by its appearance and location. An experienced health care professional will ask questions relating to the duration of the mass, whether it is painful, and whether it has changed in size, to aid in making the diagnosis. He or she may examine the mass and shine a light beside it. If the light shines through it, it is likely a ganglion. This process is called *transillumination*. An ultrasound can be helpful if the diagnosis is uncertain or if there is concern that the mass is caused by another tumor or a blood vessel. In some cases, ganglions may be small and undetectable on examination (occult), but they can still cause pain. In these cases, magnetic resonance imaging (MRI) can help identify the cyst and differentiate other types of masses.

Treatment

A traditional treatment for a ganglion cyst was to hit it with a large book, such as a bible, since the cyst can burst when struck. This form of treatment is no longer recommended due to the possibility of causing other damage to the hand or wrist. Today, there are alternative options for treatment, both surgical and nonsurgical.

Nonsurgical Treatment

If the cyst is not painful, treatment may consist of nothing more than watching and waiting, as the ganglion may resolve on its own. Avoiding repetitive motion may help reduce the symptoms. This may be accomplished by wearing a brace or splint to immobilize the wrist. Massaging may reduce the fluid within the ganglion. If the cyst is large or painful, the fluid may be drained with a needle and syringe. This is called *aspiration*. Unfortunately, the cyst wall and the stalk are still present and can refill with fluid. The recurrence rate of ganglion cysts after aspiration is as high as 30% to 60%. Sometimes, an injection of a corticosteroid may follow aspiration in an effort to avoid recurrence of the cyst. However, the efficacy of the corticosteroid injection is questionable. It is not found to offer any additional benefit over aspiration alone and can cause skin discoloration as well as thinning of the skin and underlying tissue.

Surgical Treatment

Surgery may be recommended if the other treatments fail and the cyst is painful, limiting normal function, or causing numbness and tingling. The recurrence rate for ganglion cysts after surgery is 5% to 15%. This surgery is usually performed as an outpatient operation, and the patient goes home on the same day of the surgery. The operation is done through a small skin incision after the area is anesthetized. The surgery includes the removal of the cyst, along with a small amount of surrounding tissue. Normal activity can usually resume within a few weeks after surgery.

D

Dance Injuries and Dance Medicine

Dance medicine is the much younger and less well-endowed stepsister of sports medicine. As a clinical specialty, its origins can be traced back to the early 1980s, when a few pioneering orthopedic surgeons became associated with major ballet companies, mainly in the English-speaking world. More widespread interaction has developed steadily but slowly, restricted by a number of factors. Relative to athletes, for example, dancers are a small and, for the most part, impecunious population; hence, there is little incentive for doctors to seek them out as patients. From the dancer's point of view, doctors have traditionally been seen to be ill informed where the demands of their discipline are concerned, all too ready to require of them untenable lapses of time away from dance and prohibitively expensive. At least, until recently dancers have tended to seek out instead what they consider to be the quick-fix services of adjunctive medicine practitioners, such as chiropractors.

Several developments have begun to alter this situation. For one, various forms of health insurance—including, but by no means limited to, workers' compensation—have become available to an ever-increasing number of dancers at all levels of the field. Perhaps more important is the role of physical therapists, broadly defined as liaisons for dancers with the world of medicine. Because these people tend to be readily available and use therapeutic modalities that are particularly germane to the treatment and rehabilitation of dance injuries, they have been especially effective in making standard medical care more acceptable and available to dancers.

The other part of the foundation on which dance medicine rests—scholarly research—was also laid down in the 1980s. Indeed, although there had been what might be described as a smattering of articles previously distributed through the periodical literature, one publishing event can reasonably be identified as having set the whole enterprise in motion. In conjunction with the summer Olympic Games of 1984, a "Scientific Congress" was held in Eugene, Oregon, one aspect of which was devoted to dance medicine. This gave rise to the book *The Dancer as Athlete,* edited by Caroline G. Shell, which was essentially a compilation of the papers presented at the Congress. In short order, this was followed by three other edited books of the same nature—that is, collections of articles intended cumulatively to provide an overview of the major concerns of the field—*Dance Medicine: A Comprehensive Guide* (Allan J. Ryan and Robert E. Stevens, 1987), *Dancing Longer, Dancing Stronger* (Andrew Watkins and Priscilla Clarkson, 1990), and *Preventing Dance Injuries* (Ruth L. Solomon, John L. Solomon, and Sandra C. Minton, 1990, 2005). These remain the classic dance medicine texts.

There is now a *Dance Medicine and Science Bibliography* that, in its fourth edition (2007), lists 2,927 entries indexed under 600 subject headings, with an author index as a comprehensive guide to the 3,600 authors whose names appear in the

Bibliography. There is also the *Journal of Dance Medicine and Science,* a quarterly devoted to publishing the most current and germane research in the field. These publications are distributed under the auspices of an organization, the International Association for Dance Medicine and Science (IADMS), that, since it was founded in 1990, has played a crucial role in organizing and promoting the interests of the field worldwide. IADMS was created by an international group of dance medicine practitioners, dance educators, dance scientists, and dancers. Membership is drawn equally from the medical and dance professions and has grown from an initial 48 members in 1991 to more than 900 at present, representing 35 countries.

As should be apparent from the linking of "medicine" and "science" in so much of what has already been said, it is virtually impossible to separate these two aspects of the subject at hand. Dance medicine and science is thoroughly interdisciplinary in nature, and what the science component brings to the table is a sweeping panorama of perspectives that qualify and enhance the medical focus in innumerable ways. Among the most notable contributing disciplines are the following: anatomy/physiology, kinesiology, biomechanics, movement analysis, psychology, nutrition/diet, somatics, body therapies, physical therapy, dance therapy, and dance education.

Dance Injuries

Not surprisingly for such a young field, the early history of dance medicine, especially as it pertains to the injuries that most specifically distinguish dancers as a medical population, is marked by fits and starts, hits and misses. The epidemiology of dance injuries is an excellent case in point. Early researchers were quick to tackle this issue, but with no history and few lines of communication to draw on, they tended to go their separate ways. Basic questions such as how to define "injury," how most accurately to gather injury-related information, and how best to correlate injuries with other variables remain somewhat in doubt even to this day. Hence, it is generally no easy matter to compare the results of one study with the results of any another, and the deviations between studies are often alarmingly large. Nonetheless, certain basic facts are by now well established.

First, there is no doubt that the vast majority of dance injuries occur below the waist. Although percentages of the whole will vary from study to study, or in the anecdotal observations of clinicians drawn from their practices, the most common sites of dance injuries are the foot/ankle, lower back, hip, and knee, almost unequivocally in that order. Second, granted that strains/sprains (especially of the back and ankle) are very common occurrences, most dance injuries that result in significant time away from dance are microtraumatic rather than traumatic in their etiology. This relates directly to the concept of "overuse," which is very commonly used in the field, especially when discussing the "risk factors" that are said to perpetuate dance injuries.

It is well understood that dancers are exposed, in pursuing their daily regimen, to certain potentially injurious factors. The most obvious of these are said to be "external," or "environmental," in nature. This refers to matters such as practicing and performing on hard or uneven floors, sometimes in venues that are insufficiently heated, and in footwear that provides less than adequate protection. There are also the problems that dancers impose on themselves by failing to warm-up or cooldown appropriately or that result from faulty conditioning or diet. More subtle, but also on balance more important, are the so-called internal risk factors. These all relate to one basic idea—namely, that any asymmetry or anomaly in the dancer's anatomy is a potential source of injury when it comes into conflict with the demands of the discipline. This is, again, the concept of "overuse"—that is, at the point where the dancer's anatomic weakness is exploited day after day by the need to perform the same movements endlessly, the body is likely to break down.

That these principles are indeed at work in dance is clearly illustrated by the nature of the injuries that dance medicine practitioners most often encounter. This could be demonstrated with reference to any of the common sites of dance injuries previously enumerated, but space allows for just one example. A recent article by John J. Kennedy and Christopher W. Hodgkins, titled "Foot and Ankle Injuries in Dancers," begins with the following statement: "Much of a dancer's ability is reliant on favorable anatomy, strength and flexibility. Their foot mechanics, training and performing techniques are unique and thus they present with particular injury patterns." The article goes on to discuss the following conditions: bunions, hallux rigidus, sesamoiditis, sesamoid bursitis, Joplin neuroma, nerve entrapment, metatarsal-phalangeal instability, Freiberg infraction, fifth metatarsal fractures, ankle sprains, posterior impingement syndrome, os trigonum, flexor hallucis longus tendinitis, Achilles tendinitis, heel spurs, plantar fasciitis, plantar calcaneal bursitis, and Baxter nerve neuropraxia. This list is noteworthy both for its inclusiveness (dancers obviously are vulnerable to many different foot and ankle injuries) and its homogeneity; almost without exception, these are injuries that result from repetitive microtrauma.

Conclusion

As it progresses well into its third decade as a recognizable discipline, dance medicine and science is positively influencing the dance community in general and, most specifically, the daily lives of dancers in numerous ways. Its greatest achievement may well lie in the rapprochement it has begun to effect between dancers and the medical personnel who are equipped to deal with their injuries. This has much to do with an increased willingness on the part of dancers to accept the fact that they are, albeit in a very special sense, athletes. Movement in that direction has the potential of opening to them all the established resources of sports medicine. Such an alliance between these two siblings should over time work very much to the advantage of dance medicine and science.

Deep Heat: Ultrasound, Diathermy

Deep heat is provided by therapeutic modalities that are capable of increasing the temperature of the deeper tissues and structures. Physical therapists traditionally use these modalities as a component of a comprehensive treatment program to improve impairments and functional limitations that may be caused by an injury.

The physiological and clinical effects of deep heating agents are generally the same as those produced by superficial heating agents—that is, they control pain, decrease joint stiffness, increase circulation, and promote healing.

Ultrasound

Therapeutic ultrasound (US) is produced by a transducer that converts electrical energy into sound energy. On the electromagnetic spectrum, US waves occupy frequencies greater than 20,000 hertz (Hz)—for therapeutic US, usually 0.7 to 3.3 MHz. (Humans hear sound with frequencies of 16–20,000 Hz.) Sound waves can be produced as a continuous wave or as a pulsed wave. These waves can penetrate deep into tissues, perhaps as far as 5 centimeters. Clinically, the effects resulting from the interaction of US with tissue can be grouped into two categories: (1) thermal US elevates tissue temperature—in subacute and chronic conditions, thermal US can be used to treat muscle spasms, joint stiffness, and pain—and (2) nonthermal US changes the cellular processes that enhance tissue healing—in acute cases, nonthermal US can be used to decrease swelling and pain in conditions such as bursitis or tendinitis. There is some preliminary research to indicate that low-intensity pulsed US may be helpful in promoting the healing of fractures. Standard contraindications/precautions for the use of US include malignancy, pregnancy, cardiac pacemaker, thrombophlebitis, acute inflammation, open growth plates in children, and fractures (for high-intensity US). Therapeutic US should not be confused with diagnostic US, which is used, for example, over the uterus in pregnancy.

Shortwave Diathermy

Shortwave diathermy (SWD), a modality used less commonly today than in the past, uses electromagnetic energy to generate heat that can affect a larger area of the body and penetrate deeper into tissues (continuous SWD with high pulse frequencies). It also produces nonthermal effects in the treatment of acute and chronic infections to decrease pain and edema (pulsed SWD with low pulse frequencies). SWD may cause soft tissue burns if not used at correct doses. It has been suggested that the therapist delivering the treatment may be susceptible to an electromagnetic field and be exposed to radiation. For these reasons, other modalities are preferred by therapists and athletes. Standard contraindications/precautions for the use of thermal SWD include metal implants, malignancy, pregnancy, open growth plates in children, and obesity. Those for the use of nonthermal SWD include pregnancy, metal implants, open growth plates, pacemakers, and the treatment of deep tissues (internal organs).

Dehydration

Dehydration means an abnormal depletion of body fluids, which occurs when fluid intake does not match body fluid loss, giving rise to imbalances. Dehydration may occur frequently during exercise, impairing performance and exposing athletes to risks that could be serious. The term *euhydration* refers to normal body water content, and the terms *hypohydration* and *hyperhydration* are related to deficits and excesses in body water content, respectively. This entry focuses on the following topics: (a) fluid intake and fluid loss mechanisms, (b) dehydration symptoms, (c) the relationship between dehydration and heat illnesses, (d) dehydration-influencing factors, and (e) prevention measures against dehydration in sports.

Fluid Intake and Fluid Loss

Fluid intake occurs principally during drinking (about 60%) and eating (about 30%); 10% of the fluid intake results from the metabolic processes within the body.

Fluid loss occurs through excretion from the kidneys (which in resting conditions amounts to approximately 60% of the total fluid loss), excretion from the large intestine (approximately 5%), evaporation of water from the respiratory tract, and sweat secretion (about 35%).

Sweat components are principally water and electrolytes; these help in regulating nerve and muscle function and in maintaining acid-base balance and fluid balance.

Fluid loss rates can vary greatly depending on many factors. These include environmental factors (e.g., radiant heat from surfaces such as black asphalt), climatic conditions (e.g., temperature, humidity, solar load, and wind velocity), and other factors concerning the specific characteristics of each individual (e.g., gender, age, health status, training status, psychological features, clothing and equipment, intensity of physical activity, degree of heat acclimatization, and exercise-induced metabolic body heat production). Moreover, all these factors may interact synergistically, stressing the physiological systems even more. However, even in cool conditions, sweat loss can be considerable: The highest sweat rate reported in the literature, measured in an athlete during his preparation for a marathon, is 3.7 liters/hour.

In fact, excessive fluid loss can be fatal, because water is essential for human life: It constitutes nearly 60% of body weight and about 72% of lean body mass and forms the basis for all body fluids, among them blood. As water is the principal constituent of the body, even a 9% to 12% fluid loss can have serious consequences.

The body fluids have vital functions: They contribute in the transportation and absorption of nutrients, allow muscle contraction, and help in eliminating waste. For this reason, it is essential to maintain the correct parameters of these fluids, especially blood parameters, such as blood volume and blood pressure. In effect, the body tries to defend blood volume as much as possible in hypohydration situations: Water passes from inside the cells to the bloodstream. Through this fluid exchange, dehydration causes a redistribution of body water, which largely derives from depletion of the water content of muscles and skin. Thus, depletion of body levels of fluid can significantly stress the body, impairing physical performance.

Consequently, dehydration should be limited and, better still, prevented. To prevent dangerous dehydration, the brain stimulates the thirst center, inducing the hypohydrating individual to drink more fluids. Yet if fluid intake cannot balance fluid loss, dehydration becomes more severe. The body tissues start to dry out, to such an extent that cells may shrivel and malfunction.

Symptoms of dehydration include thirst; dry mouth, skin, and mucous membranes; decreased sweating and urine output; headache; muscle weakness; excessive fatigue and tiredness; dizziness; cramps; fever; low blood pressure; and in the most severe cases, damage to the internal organs, confusion, delirium, or even unconsciousness.

Dehydration and Heat Illnesses

Several researchers (among them Jay Hoffman, Julian Bailes, and Vincent Miele) believe that many symptoms of dehydration show a connection between dehydration and heat illnesses. Heat illnesses include heat cramps (painful involuntary spasmodic muscular contractions), heat syncope (loss of consciousness because of a temporary decrease in the blood supply to the brain), heat exhaustion (great weakness and elevation of pulse rate and temperature), and heat stroke, a life-threatening condition in which the body temperature may rise to 110 °F (43 °C) and many organs, such as the heart, kidneys, and even the brain, may suffer damage. A euhydrated individual can cool his or her body through the evaporation of the sweat secreted by the sweat glands situated all over the body. On the contrary, these researchers claim, a dehydrated person has limited ability to regulate his or her temperature by sweating and/or by skin blood flow. In this way, they maintain, dehydration may cause heat illnesses. Therefore, these researchers warn athletes against the synergistic interaction that may occur between heat and exercise-induced dehydration. To minimize the risks of thermal injuries, they encourage athletes to adopt adequate preventive measures, recommending, among other strategies, hyperhydration.

Other scholars (among them Marius Nielsen and Timothy Noakes) claim that postrace core temperatures of between 102.2 °F (39 °C) and 105.8 °F (41 °C) are usual in athletes who exercise at high intensities, because the magnitude of deep body temperature elevation is proportional to metabolic rate. Regarding a possible connection between dehydration and heat illnesses, they cite research results that show that whereas skin temperature is related to air temperature and is independent of the level of exercise, on the contrary, core temperature is related to the level of exercise and quite independent of the environmental conditions. For these reasons, they doubt if there is a close connection between dehydration and heat illnesses and reject the hyperhydration technique. Also, the 2007 Position Stand by the American College of Sports Medicine states that hyperhydration does not provide a clear physiological or performance advantage over euhydration.

Variability Factors

All researchers agree, however, that many variability factors can decrease or, vice versa, increase exercise-induced dehydration. Dehydration can be worsened by the following factors:

Environmental and Climatic Conditions: High air temperatures (greater than 80 °F, or 27 °C), high relative humidity (above 60%), high radiant heat load from surfaces (e.g., black asphalt), sprinkler systems running before practice, high altitudes (more than 6,600 feet, or 2,000 meters, above sea level), low-speed air movement (lower than 9 miles, or 15 kilometers, per hour) during exercise, long journeys in hot environments to reach the event venue, absence of air conditioning in athletes' living and sleeping accommodations, and insufficient graduality in the acclimatization process.

Health and Fitness Conditions: Chronic illnesses such as diabetes, asthma, kidney diseases, cystic fibrosis, heart conditions, and epilepsy; present or recent flu; viral infections; gastroenteritis; vomiting or diarrhea-causing illnesses; previous heat-related illnesses; use of medications such as antihistamines, diuretics, some blood pressure medications, and psychiatric drugs; rare or irregular participation in sports or physical activities; and excessive body mass index (BMI).

Clothing and Equipment: Wearing of heavy, dark-colored garments and uniforms that do not facilitate sweat evaporation and the use of complete protective equipment with helmets and/or insulating, bulky, leather, or rubber parts when the subject is unaccustomed to it.

Specific Characteristics of Some Physical Activities: High exercise intensity and duration, specific sports rules that limit the opportunities for fluid replacement during scheduled breaks, scarce availability of water and/or beverages (e.g., in cross-country racing or skiing), and inadequate time for drinking.

Athletes' Gender and Age: Being a female athlete (women have a greater percentage of body fat, and the water content of fat cells is very low), being an older athlete (seniors' ability to conserve water in their body is reduced; their thirst sense is less acute), and being a pediatric athlete (in children, the body water and electrolyte turnover is higher than in adults).

However, there is great variability in sweating rates among individuals, even if they are exercising in trials where conditions are standardized.

Prevention

Prevention can be achieved through organizational measures and water and salt intake strategies.

Organizational Measures

The following measures may be taken:

- Schedule gradual and increasing exposure to intensity, duration, and protective equipment, taking into account activities other than exercising.
- Schedule regular breaks to limit excessive physical activity and to permit fluid replacement.
- Acclimatize to high-temperature, high-humidity, and/or high-altitude venues; limit practice during the first days; and avoid the hottest part of the day.
- Wear lightweight, light-colored, loose-fitting garments.
- Gradually accustom yourself to protective equipment.
- Monitor exercise-induced weight loss, which is primarily due to water loss.

Water and Salt Intake Strategies

Intake of water and salt should be regulated as follows:

- Remember that thirst may not be an effective indicator of hydration status while exercising, because it is not perceived until body water deficit reaches approximately 2%.
- Consume fluids so as to be euhydrated before, during, and after exercise.
- Limit consumption of caffeine- and alcohol-containing drinks, as they increase urine output.
- Consume drinks and foods that can prevent and/or replace excessive water and salt losses, such as sports drinks, fruit, and vegetables.
- Choose chilled water and drinks with temperatures ranging from 50 °F (10 °C) to 72 °F (22 °C).

Dental Injuries

Dental injuries are the most common orofacial injuries that occur in sports, and treatment can involve considerable expense. There is a 10%-per-year chance of an orofacial injury for those playing contact sports and a 33% to 50% chance of an orofacial injury during an athlete's career. Of all sports injuries, 13% to 39% are dental related. Most of these injuries are preventable, however, with correct use of a good mouthguard.

Classification

Most dental injuries are classified by location: soft tissue injuries or injuries to the teeth.

Soft Tissue Injuries

Soft tissue injuries are often difficult to assess initially because of excessive bleeding. Most of the injuries are lacerations to the lips, cheek, gingiva, mucosa, frenulum, and tongue—all composed of highly vascular tissue. These injuries are mainly treated by obtaining good hemostasis, careful cleansing, and suturing. When suturing the lips, the physician needs to make sure that the vermillion border of the lip approximates well.

Injuries to the Teeth

There are either avulsions (the entire tooth is knocked out), luxations (the tooth is still in place but in the wrong position), or fractures.

Anatomy of the Tooth

The hard exterior of the tooth is the enamel. The subsequent deeper layers are the dentin and the pulp when in reference to the crown—the portion of the tooth that is not below the gum line. The root of the tooth, below the gum line, includes the periodontal membrane, cementum, dentin, and pulp.

Avulsion

Once a tooth is completely knocked out, it is imperative for a dental professional to try to reimplant it as soon as possible. It is important not to handle the tooth by its root, sterilize it, or scrub it. It should be rinsed with clean water prior to efforts to reimplant the tooth back into its socket. (Primary or "baby" teeth are unsuitable for reimplantation.) If immediate reimplantation is not possible, the tooth should be transported in Hanks' Balanced Salt Solution or cold whole milk. If none of these is available, then the next best transport media in order are saline solution, under the patient's tongue, and in water. Do not transport on ice or wrap the tooth in gauze. Reimplantation is best done within 30 minutes of the injury. Hank's Balanced Salt Solution can keep a tooth viable for about 24 hours, whereas the other transport media can keep the tooth viable for only a few hours.

Luxation

There are three types of luxation: (1) extruded (the tooth is higher than it should be/than the surrounding teeth), (2) lateral displacement, and (3) intruded (the tooth is lower than it should be/than the surrounding teeth). For both, the extruded tooth and the laterally displaced tooth, repositioning on the field can be done. The intruded tooth should not be repositioned. Immediate consultation should be done with a dental professional as soon as possible, whether or not the tooth has been repositioned.

Fracture

The broken tooth should be saved in the best transport medium available (see above). These can be extremely painful problems, especially if the pulp is exposed. It is important to try to minimize contact of the exposed pulp to air, other teeth, or the tongue, because it will be highly painful. Transport the athlete and the tooth fragment to the dentist immediately.

Mouthguards

A good mouthguard should cover the upper and/or lower teeth and gums, be fitted so as not to misalign the jaw and throw off the bite, be light, be strong, be easy to clean, and allow the athlete to communicate and breathe easily without moving or manipulating the mouth protector. Often, a proper mouthguard will have a 3-millimeter (mm) labial thickness, a 2-mm palatal thickness, and a 3-mm occlusal thickness. The common types of mouthguards available are stock, boil-and-bite, vacuum custom, and pressure-laminated custom. Ninety percent of mouthguards are store bought, and 10% are custom fitted.

The stock and boil-and-bite types are the cheapest, but they are also the least sturdy and often are too thin to protect the teeth well. Seventy percent to 90% of the occlusual thickness is lost in the molding process for the boil-and-bite mouth protector. They are also not capable of being modified to accommodate athletes with poor bite occlusion or other dental issues. They often interfere with speech and breathing.

Vacuum mouthguards are made from a stone cast of the maxillary arch. They are good for single-layer mouthguards. These guards allow better communication and stay in place well.

The laminated mouthguard consists of two or three layers of ethyl vinyl acetate, and it is molded over a cast. Its advantages are that it wears longer and it is possible to place inserts for increased thickness.

The American Dental Association estimates that mouthguards prevent 200,000 injuries annually in high school and college football. The cost of tooth reimplantation and follow-up exams can total $5,000. If a tooth is not properly preserved, the costs can be from $15,000 to $20,000.

Dermatology in Sports

Athletes experience a wide range of dermatological conditions that can be related to their sports training and competition and to the environment in which they train and compete. Athletes can also experience other non–sports-related general dermatological conditions, such as acne and eczema, which can be exacerbated by their respective sport. Skin conditions can affect an athlete's performance and, in some cases, can temporarily exclude the athlete from participation in the sport. Prompt and accurate care of skin conditions can reduce the time out of training and competition. Dermatologists should not only diagnose and treat such skin conditions, but they should also play a role in the education and prevention of skin disorders in athletes.

General Skin Care

General skin care is important in athletes to maintain the skin barrier and allow the skin and sweat glands to function correctly. The skin is subject to trauma, friction, and other environmental injury during sports. Xerosis (dry skin) is often seen in athletes due to a combination of factors, including the need for taking multiple showers after competition and training, due to the cold-weather environment in winter sports and the continuous immersion in chlorinated water in water sports. Athletes with a history of atopy (the genetic tendency to develop the classic allergic conditions—rhinitis, atopic dermatitis, and asthma) will also be at increased risk for xerosis and worsening or inducing of their atopic dermatitis. A gentle soapfree skin cleanser should be used whenever possible, followed by a light moisturizer after each shower. If acne, frictional, or occlusion folliculitis is a problem, an antibacterial soap or benzoyl peroxide–based wash can be added for the infection-prone areas, followed by a light, nongreasy moisturizer. Each athlete should use only his or her personal soap, and soap should not be shared. Towels should also not be shared with other team members. Skin should also be protected from friction and trauma by using appropriately fitted protective gear and pads. Inappropriately fitted sports equipment can lead to contact irritant dermatitis and friction blisters of the skin. Any skin disorder should be promptly assessed and treated to ensure rapid resolution and continued participation of the athlete in his or her sport at peak-performance level.

Athletes can present with general non–sports-related dermatoses, or they can have worsening of a preexisting dermatosis, such as acne. Acne can be exacerbated due to sweating/perspiration and sunscreen if used by the athlete. Acne mechanica can be a problem for athletes where friction, sweat, and occlusive forces coincide, such as around helmet straps, tight-fitting uniforms, and other sports equipment. As well as following standard acne treatment with oral antibiotics such as minocycline or doxycline, athletes need to wash acne-prone skin with a benzoyl peroxide or salicylic acid preparation immediately after participation in their sport to reduce the time the skin is exposed to sweat. Application of a topical acne antibiotic such as clindamycin lotion to the involved areas should then follow. It should be remembered that some medications, including doxycycline for acne, can render the skin photosensitive and more prone to sunburn. Athletes should be warned of this risk, and an oilfree sunscreen should be used. Absorbent cotton garments can help absorb sweat and prevent friction from contact with equipment.

Sports-Associated Skin Conditions

Athletes can present with dermatologic conditions associated with their sport and its mechanics, and dermatologists should be familiar with these characteristic skin findings of the sport. For example, turf toe presents as tendinitis in the great toe of athletes who play soccer and football on turf. Footwear designed for turf can assist in preventing this injury. Athlete’s nodules occur in surfers and boxers from recurrent friction or trauma on the dorsal feet and knuckles. These injuries can be mistaken for other dermatological conditions such as acute gout instead of turf toe or an infective or neoplastic process instead of athlete’s nodule. It is important to recognize that these injuries are a consequence of the athlete’s respective sport in order to ensure their appropriate treatment and prevention.

Foot care is important for all athletes, especially runners. Runners are at risk for corns, ingrown toenails, dystrophic toenails, and talon noir on the feet. Corns can develop due to improperly fitting shoes or due to existing bony abnormalities of the feet. Salicylic plasters and mechanical paring can relieve corns, and padding is needed to protect the area. Referral to a sports surgeon may be needed to assess the underlying foot abnormality. Nail dystrophy, such as discoloration, onycholysis, and subungual hyperkeratosis, can be seen due to repetitive trauma on the nail from the shoe in sports such as tennis, other racquet sports, and basketball and can be occasionally mistaken for onychomycosis. Hemorrhage into the nail from sports trauma can sometimes be mistaken for melanoma, and a nail biopsy should be performed if a melanoma is suspected. Ingrown toenails and nail dystrophy can be prevented by shoes being properly fitted and the nails being trimmed straight across.

Runners and other athletes involved in sports with mechanical shearing and frictional forces on the feet and also the hands are also at risk for calluses and frictional blisters. Calluses can be reduced mechanically or be padded for protection. In some sports, calluses may provide a competitive advantage, and the athlete may only reduce them in the off-season. The treatment of frictional blisters involves cleansing and protection with a synthetic dressing. Skin care of areas exposed to weight-bearing forces and equipment contact surfaces is essential to reduce the risk of injury to these important areas. Athletes should be educated on the care, treatment, and prevention of these common injuries. Correct fitting of running shoes and sports equipment can reduce the likelihood of friction blisters developing. Moisture-wicking socks can also help prevent blisters on the feet.

Skin Protection

Protection of the skin from the environment is also important for athletes. Athletes are at risk for environmental skin injuries from exposure to ultraviolet (UV) light, cold, and water. Winter athletes are at risk for cutaneous cold injuries, such as frostbite and cold panniculitis. Multiple layers of warm protective clothing can help prevent these skin injuries. Both summer and winter athletes are at risk for sunburn and skin neoplasms. Often, training and competition programs are played during the highest-UV times of the day, increasing the chance of sunburn in athletes. Chronic sun exposure and multiple sunburns increase the risk of skin photoaging and skin cancer, including melanoma. Athletes and their coaches should be educated on the correct sun protection strategies. Ideally, the sports and training schedules should be outside the high-UV times, but this is not always possible. Winter sports athletes are also at risk for sunburn on exposed skin, and the UV intensity is much higher at high altitude than at sea level. Regular application of sunscreen on exposed skin is essential, and sun protective clothing such as hats should be used where possible. Sunscreen preparations in the form of sprays and gels are usually preferred by athletes when participating in sports, rather than lotions and creams. Appropriate sunscreens should offer broad-spectrum protection from UVA and UVB and be water resistant with a high to very high sun protection factor (SPF) rating of 30+ to 50+. High–UV protection clothing ranges are also available to provide better sun protection for athletes. Some laundry washing powders such as SunGuard by Rit also confer clothes with a UV protection factor after washing to reduce UV radiation through clothing. Eye protection should also be worn by athletes whenever possible to prevent eye UV injuries.

Skin Infections

Athletes are at risk for infective conditions from viral agents, bacteria, fungi, and parasites. Close contact during sports, the hot humid conditions of locker rooms, sharing of sports equipment, and inadequate cleaning of sports equipment can predispose athletes to a variety of skin infections. The dermatologist's role is not only to treat the infection but also to advise and educate athletes and coaches regarding the appropriate prophylactic measures to reduce the risk and prevent infection from spreading to other competition and team members. Herpes gladiatorum, from herpes simplex virus-1 (HSV-1), is most commonly seen in wrestlers and can be proven by positive HSV-1 culture. Staphylococcal and streptococcal infections can also be spread by similar close contact during sports. These infections should be treated with appropriate oral agents. Infection can be avoided by careful skin hygiene, with showering before and after sports participation; adequate regular cleaning of sports equipment; and preventing any athlete with an active skin infection from competing until the skin infection is treated and healed.

Conclusion

Good skin care and use of well-fitting shoes and sports equipment can prevent skin and nail trauma and frictional injury. Athletes and coaches should be educated on correct skin and nail care and be aware of the skin injuries specific to their sport. This can help prevent these conditions and enable the athletes to maintain training schedules and optimal performance. Athletes should also be aware of the risks of melanoma and other skin neoplasms plaguing sports associated with UV exposure. Adequate sun protection is essential for these athletes. Some sports-related skin conditions and injuries require a dermatologist referral, while other injuries can be treated with simple cleansing and dressings. Non–sports-related skin conditions should never be ignored as a differential diagnosis in athletes.

Detached Retina

The wall of the eye is made up of three layers. The outermost layer is called the sclera; the innermost layer is the retina. The retina is further divided into an outer layer of pigmented epithelium and an inner layer of neural tissue. When the inner neural tissue separates from the outer pigmented epithelium, this abnormal condition is called *retinal detachment.* There are three types of retinal detachment, depending on the mechanism:

1. *Rhegmatogenous.* This is the most common. A break or tear in the inner neural layer allows vitreous fluid from within the eye to seep into and hydro-dissect the external epithelial layers.
2. *Traction.* Increased tension from retinal adhesions pulls the inner and outer layers of the retina apart. The formation of poorly structured retinal vessels, such as in diabetic retinal disease, is a common cause of tractional retinal detachment.
3. *Exudative.* Fluid from retinal vessels leaks between the outer layer of pigmented epithelium and the inner neural layer, separating the layers. There is no tear or break in the retina, but the fluid often accumulates from inflammation or because of a tumor.

Most retinal detachments occur in persons between the ages of 40 and 70 and are often seen after cataract surgery. Additionally, those with proliferative retinopathy from diabetes or sickle cell disease are at increased risk for traction-type retinal detachment due to blood vessels pulling the retina away from the back wall of the eye.

Specifically, in the field of sports medicine, retinal detachments can be due to various causes. Direct trauma to the eye from high-velocity objects (e.g., racquetballs, paintballs) causes vitreoretinal traction from globe compression and decompression. The detachment may not be immediate. This can be prevented in a majority of cases by wearing proper eye protection. Blunt trauma to the eye or facial area in sports such as boxing and mixed martial arts can lead to retinal detachments, although rarely. More likely are retinal tears that can be found on routine eye examinations. Additionally, athletes with severe nearsightedness (myopia) are more prone to retinal detachments. This seems related to pressure changes in the eye due to straining. This may be seen in weight lifters or scuba divers. Rapid acceleration or deceleration (drag racing) may also place an individual at increased risk for retinal detachment.

Signs and Symptoms

Retinal detachment is usually not painful. Rather, patients may complain of wavy, cloudy, or distorted vision. They may describe seeing flashes or floaters. Visual field loss is usually sudden and unilateral and progresses from the edges to the center. This leads to poor visual acuity (20/200 or worse).

Management

If retinal detachment is suspected, urgent evaluation by an ophthalmologist is required. Surgical repair is often necessary. Time is critical because an important consideration is the length of time the retina is detached before repair. Untreated retinal detachments can lead to blindness in the affected eye.

Prognosis

The majority of retinal detachments can be repaired surgically. Many postsurgical patients obtain visual acuity of 20/70 or better. Some repaired retinas will redetach, usually within 6 weeks following surgery. Continued follow-up with an ophthalmologist is prudent.

Detraining (Reversibility)

Athletes and exercisers worry that their performance or fitness levels will diminish if they cannot train because of injury, illness, travel, or other circumstances. Although there is some truth in the "Use It or Lose It" warning often given by doctors, therapists, trainers, and coaches, the process of becoming detrained, or deconditioned, is not that simple.

Detraining is a reduction or complete loss of fitness as a result of not training. What happens during a period of detraining depends on the physical condition of the person before stopping an activity, how long that person stops training, and which area of fitness is affected by the inactivity (e.g., strength, aerobic capacity, or flexibility).

Various studies have shown that detraining can result in decreased $\dot{V}O_2max$ (the ability to take in, transport, and use oxygen for fuel; see below), diminished breathing function, increased heart rate, and an early lactate threshold (the point at which intensive exercise causes a buildup of blood lactate), as well as loss of strength and flexibility. In general, stopping training produces a significant loss in conditioning after 2 to 6 weeks. Following are some evidence-based, specific examples of how detraining may affect various physical functions.

Effects of Detraining

$\dot{V}O_2max$

Highly trained athletes show a 5% drop in $\dot{V}O_2max$ during the first 3 weeks of inactivity. A slower decline occurs during the following weeks. (*Journal of Applied Physiology*, Volume 63, 1987)

Endurance athletes who reduce or cease training do not fall to the levels displayed by persons who have never trained. (*Journal of Applied Physiology,* December, 1984)

Persons with low to moderate aerobic capacity show little effect of detraining during the first 3 weeks, but $\dot{V}O_2max$ declines to untrained levels after several additional weeks. (*Georgia Tech Sports Medicine & Performance Newsletter,* February, 2000)

Respiratory Capacity

After 5 months of intense training followed by a period of inactivity, swimmers show a 50% decrease in respiratory capacity after the first week. (*Medicine & Science in Sports & Exercise,* Volume 17, 1985)

Stroke Volume

Stroke volume (the amount of blood pumped with each heartbeat) begins to decrease as soon as training is stopped. One study showed a 10% decline within 12 days, and another indicated a 12% drop 2 to 4 weeks after the last training session. (*Exercise*

Physiology, "Deconditioning and Retention of Adaptations Induced by Endurance Training," 1998)

Blood Volume

Blood volume in endurance athletes is reduced by 5% to 12% within 48 hours. (*Journal of Applied Physiology,* Volume 60, 1986)

Strength/Muscle Mass

Detraining may result in a decrease of muscle mass and strength. (*ACSM Resource Manual for Guidelines for Exercise Testing and Prescription, 2005*)

High-intensity training may help a person maintain any gains in strength for longer periods after training has stopped. (*Exercise Physiology,* "Deconditioning and Retention of Adaptations Induced by Endurance Training," 1998)

Heart Rate

Resting heart rates increase with inactivity, which indicates a decline in cardiovascular endurance. However, among well-conditioned athletes, the rates do not change significantly after the first 2 to 3 weeks of inactivity. (*Sports Medicine,* Volume 33, 2003)

Maximal heart can decrease from 5 to 13 beats/minute with aerobic training and increase from 4 to 10 beats/minute with tapering or detraining. (*Sports Medicine,* Volume 29, 2000)

Flexibility

Among older adults, the components of fitness most affected by detraining are lower extremity flexibility after 2 to 4 weeks of detraining and agility/balance after 6 weeks of detraining. (*British Journal of Sports Medicine,* August, 2005)

Sports Performance

The exact effect of detraining on performance is difficult to determine because of the many variables involved, including the physical condition, the intensity and duration of training, and the nature of the sport.

Endurance performance is markedly impaired if training is stopped for 4 weeks. (*Medicine and Science in Sports and Exercise,* March, 2001)

Endurance capacity is reduced by 21% after 4 weeks of detraining. (*Journal of Applied Physiology,* October, 1993)

In highly trained individuals, interruption of training causes a decline in sports performance. Marathon runners posted a 25% decrease in endurance after 15 days of inactivity. Swimmers showed a 14% decrease in maximal arm power after 4 weeks of not training. (*Medicine & Science in Sports & Exercise,* September, 2006)

Among soccer players, detraining may result in a decrease in the time to exhaustion by 24% in 5 weeks. However, a training break of 2 weeks does not appear to produce a significant change in time to exhaustion. (*Research Quarterly,* Volume 40, 1969)

Minimizing the Effects of Detraining

Whatever the potential loss of conditioning, it can be minimized in several ways. Cross-training (participating in other sports or exercise programs) allows an athlete to remain active while not training specifically for his or her sport. For example, water running or brisk walking might be substituted for jogging, distance running, or skiing. Upper body lifts can be performed when an injury prevents lower body training. Resistance training outside the pool might be continued even though a swimmer has to stay out of the water for a period of time. In some cases, athletes may be able to continue participating in their respective sport or activity, but at a less intense or frequent level.

The good news regarding detraining is that, for most exercisers, resuming a training program within 6 weeks may restore previous levels of fitness in less time than it might have taken if those individuals had started from a completely untrained level.

Diabetes in the Young Athlete

Diabetes mellitus (DM) is a chronic endocrine disorder characterized by hyperglycemia (elevated blood sugar), caused by decreased insulin secretion by the pancreas, decreased insulin sensitivity at the tissues, or both. Children with DM have many lifestyle adjustments to make to regulate their blood glucose (sugar), but in general, DM should not limit their ability to participate in sports. In fact, physical activity is an important aspect of maintaining health and preventing the long-term complications of DM. Regular exercise helps children with diabetes achieve and maintain a healthy weight, minimize the addition of more and/or higher doses of diabetic medications, and helps control blood glucose levels, cholesterol, blood pressure, and cardiovascular functioning.

Prior to beginning a new exercise program, diabetic children should be evaluated by an endocrinologist or pediatrician. In a juvenile population, the biggest risks of exercise involve hyperglycemia or hypoglycemia (low blood sugar) during or postexercise. In older individuals with diabetes, other long-term health consequences of poorly controlled diabetes predispose to injury. These include neurologic, eye, and kidney problems, as well as cardiovascular disease. These are beyond the scope of this entry, which will focus on diabetes management and exercise in a younger population.

Types of Diabetes Mellitus

The two types of DM are as follows:

Type 1 DM accounts for 10% to 15 % of all cases of diabetes and is the most common type of diabetes in children. It is characterized by the destruction of pancreatic beta cells, leading to deficient insulin production but normal insulin sensitivity at the tissues.

Type 2 DM accounts for the majority of the other 85% to 90% of cases. It is characterized by variable abnormalities in insulin secretion and insulin sensitivity. It begins with poor insulin sensing, thus inhibiting the body's ability to draw glucose out of the bloodstream and into the cells. Eventually, Type 2 DM can progress to pancreatic beta cell destruction, leading to impaired insulin production and secretion. With increasing childhood obesity, Type 2 DM is on the rise.

Other forms of pediatric diabetes include secondary diabetes, caused by some other medical condition, such as cystic fibrosis or Down syndrome, and maturity-onset diabetes of the young (MODY). New categories of DM are being added as we learn more about genetic and environmental predisposing factors. But in general, it is most important to know if the pediatric athlete's disease is more similar to a Type 1 or Type 2 DM. Also, knowing about the child's general diabetes control regimen is important in anticipating his or her response to athletic activity and medical treatment. Thus, in this entry, variations of DM will only be referred to under the global categories of Type 1 and Type 2.

Types of Diabetes Mellitus Treatment

The primary goal of diabetes management is to keep blood glucose (sugar) close to the normal range without causing hypoglycemia. There are various medication regimens to help achieve this goal. For some individuals with Type 2 DM, this may include a form of insulin. For Type 1 DM, insulin is always indicated. All types of insulin must be injected using a pen or syringe, or a pump (there are no pill forms), but different types of insulin vary in onset, peak, and duration of action. Rapid-acting insulins take effect within 10 to 15 minutes of injection, peak within 1 to 2 hours, and last for 3 to 5 hours. Long-acting insulins take 1 to 3 hours to begin lowering glucose, have a steady level of control with no peak, and wear off in around 24 hours. Short-acting, intermediate-acting, and premixed combination insulins have onsets, peaks, and durations somewhere in between depending on the type and brand.

There are a variety of oral and noninsulin injectable medications that help with glucose control, particularly for Type 2 diabetics. It is important to know if a child is on oral agents that could contribute to hypoglycemia (e.g., meglitinides and sulfonylureas).

Hypoglycemia

Exercise has an insulin-like effect on blood glucose. Glucose is drawn out of the blood as the muscles require energy to work, thus putting diabetic athletes taking insulin or other medications that lower the glucose level at risk for hypoglycemia. Multiple factors contribute to the variability of such exercise effects: (a) blood glucose concentrations before initiating exercise, (b) the time relation of exercise to meals, (c) basal/bolus (long-acting/short-acting) insulin doses, (d) an individual's physical fitness level, (e) his or her insulin sensitivity, and (f) the adequacy of his or her counterregulatory hormone responses to exercise.

In people without DM, insulin levels decrease during exercise, but in DM patients who take injectable insulin, the levels do not decrease with activity. Increased insulin impairs liver glucose production and can induce hypoglycemia within an hour of initiating exercise. Counterregulatory hormones (e.g., glucagon, catecholamines, growth hormone, and glucocorticoids), which normally increase glucose levels, may be impaired in patients with long-standing diabetes. Also, exercise improves insulin sensitivity in skeletal muscle, leading to postexercise, late-onset hypoglycemia. This can occur more than 24 hours after activity and is especially dangerous if it occurs when the athlete is asleep and unaware of the symptoms.

In general, the signs and symptoms of hypoglycemia occur when blood glucose drops below 70 milligrams/deciliter (mg/dl), but this number varies among individuals. Sweating, rapid heart rate, palpitations, hunger, nervousness, trembling, headache, dizziness, and mood changes are early symptoms. Unfortunately, these are often hard to differentiate from the responses experienced during vigorous exercise. If the blood glucose level continues to fall, more severe symptoms may be observed, which include fatigue, blurry vision, impaired thought, loss of coordination, aggression, confusion, seizures, and loss of consciousness.

Each individual has his or her own specific response to hypoglycemia, and ideally, the parents, coach, and team medical support should be familiar with these prior to the child's participation in sports.

Every athlete should have an action plan to use when hypoglycemia is suspected. The following is a guide:

1. He or she should test the blood sugar level with a glucometer.
2. If the level is low, he or she should eat or drink foods with simple sugars, such as three glucose tablets, a few jelly beans, some honey, half a cup of fruit juice, or other quickly absorbable sugary food (the amount and type of emergency snack should be discussed ahead of time with the athlete's doctor).
3. The blood sugar should be tested again in about 15 minutes, and if the number is below 100 mg/dl or the child does not feel well, he or she should not return to play.
4. After a hypoglycemic episode, the child should be monitored closely with frequent glucometer testing.
5. Medication and pre-exercise snacks should be reviewed and adjusted to help prevent future episodes.
6. Athletes should always have sugar available, as well as a glucagon kit (glucagon has the opposite action of insulin).

Hyperglycemia

In DM children who produce or take too little insulin and/or have poor baseline control, high-intensity (anerobic) exercise leads to increases in blood glucose levels. High-intensity exercise is associated with increases in catecholamines, free fatty acids, and ketones (ketones are the toxic by-products produced when the body burns stored fat instead of glucose for energy), all of which decrease the muscles' utilization of glucose and increase the blood sugar.

In the well-controlled athlete, these changes may be transient (decreasing in less than an hour), but poor insulin balance along with stress regarding sports performance may increase counterregulatory hormones and perpetuate the hyperglycemia.

In Type 1 DM, hyperglycemia and ketosis lead to a severe condition known as *diabetic ketoacidosis* (DKA). It involves a severe lack of insulin, which if left untreated could lead to coma or even death. Symptoms of DKA include nausea, vomiting, weakness, abdominal pain, dehydration, heavy breathing, and fruity-smelling breath.

As with hypoglycemia, diabetic athletes need a plan for suspected hyperglycemia, such as the following.

Type 1 DM

If fasting glucose (blood sugar ≥4 hours after eating a meal) is ≥250 mg/dl, check for ketones. If positive, the athlete should not exercise and should be treated for DKA. (This involves hydration, insulin, and possibly other medical support.) If fasting glucose is between 251 and 350 mg/dl and ketones are negative, it is important to hydrate, but it is okay to perform physical activity. If fasting glucose is >350 mg/dl, regardless of the ketones result, the athlete should hydrate, should not return to activity that day, and should have dietary/medication adjustments made.

Type 2 DM

If the fasting glucose of a child with Type 2 DM is ≤350 mg/dl, he or she should hydrate but may return to play. If the glucose is >350 mg/dl, the athlete should hydrate, should not return to activity that day, and should have dietary/medication adjustments made.

Prevention

Each athlete with DM should have a care plan for training as well as for matches/games/races. These should be familiar and available to the parents, coach, and team medical support staff and should include the following:

Blood glucose monitoring equipment and directions

- A medication list with doses and directions
- Hypoglycemia and hyperglycemia action plans along with ketone test strips for Type 1 DM
- Doctor and parent contact information
- The athlete should also have a medical alert tag with him or her at all times.

Fasting glucose should be checked, and the pre-exercise meal should be ingested 1 to 3 hours before the activity, should consist of low–glycemic-index foods (complex carbohydrates, not simple sugars), and should include protein to ensure continuous, but not too rapid, glucose absorption. Immediately before the activity, the athlete should check his or her blood sugar again, with an ideal goal of 120 to 180 mg/dl. The child should continue to monitor his or her blood glucose throughout the sporting activity, supplement with carbohydrates when needed, and continue to hydrate and reassess every 30 to 60 minutes depending on his or her baseline control and exercise levels.

Often, as athletes become more experienced with monitoring their glucose control and training habits, these intervals may be lengthened. Seasoned athletes often get to a level of awareness of their personal responses to exercise such that they know when to consume extra carbohydrates or check their blood sugar based on their exercise duration and/or symptoms.

Those using insulin should inject in areas away from exercising muscles approximately 1 hour before activity, as exercise, massage, and heat can increase the rate of absorption. If possible, the athlete should try to anticipate the intensity and duration of the activity to better adjust the insulin dosing and carbohydrate intake. In general, as the intensity and duration of the activity increase, less insulin is required.

Insulin Pumps

DM individuals using insulin pumps receive insulin through a continuous subcutaneous (under the skin) infusion. They may have basal insulin settings that are constant or vary throughout the day. In addition, pump users have bolus insulin doses administered prior to meals. Insulin pump settings may be adjusted prior to sports participation, and requirements may change as the child becomes more fit.

Depending on the activity, the child's preference, and the endocrinologist or pediatrician's recommendation, pump users may discontinue the pump during sports participation and switch to injectable insulin. If the pump is removed before physical activity, hyperglycemia is more of a risk, and a long-acting injectable insulin should be used appropriately. If the pump is continued during activity, pump malfunction or detachment (e.g., from contact or sweat) may lead to hyperglycemia, overinsulinization, and subsequent hypoglycemia. Insulin pump athletes who experience hyperglycemia or hypoglycemia should always have their pumps examined immediately.

Conclusion

While general guidelines may be helpful for a diabetic child athlete, diabetes is a very individual disease. Thus, parents and children should work closely with their doctors to develop a care plan and make it known to coaches and others involved in the athlete's sports activity. The athlete should keep a log of glucose levels, the dosing of insulin and other medications, dietary intake, and exercise to better understand his or her individual dietary and medication needs with various activities. Such knowledge, with ongoing adjustments, will improve glucose control and help prevent hypoglycemia/hyperglycemia. Staying active and diligently trying to improve and maintain glucose control will not only enhance sports participation but also minimize the long-term sequelae of diabetes.

Diabetes Mellitus

Diabetes mellitus is a condition characterized by a relative insulin deficiency resulting in an abnormal fuel-hormone response, especially when challenged by the ingestion of food. This abnormal fuel-hormone response involves decreased storage and utilization of fuels and results in elevated blood levels of glucose, free fatty acids, and ketones. Diabetes results from a deficiency in the insulin-secretory mechanism of the beta cells of the pancreas, a faulty insulin receptor site on the cell surfaces of liver, adipose, and muscle tissue, and/or a metabolic defect in the cell itself.

There are two basic types of diabetes, insulin dependent and non–insulin dependent. Insulin-dependent diabetics are usually under 20 years of age at the onset of the disease and constitute less than 10% of the diabetic population. Their symptoms at the onset of diabetes are acute, coming speedily to a crisis: Metabolic ketoacidosis and insulin reactions are frequent, insulin production is decreased, the potential for developing maximal sports performance capacity is reduced, and hyperglycemia usually results from the marked reductions in glucose storage and utilization. Non–insulin-dependent diabetics, however, are generally over 40 years of age at the onset of diabetes; they are overweight and constitute more than 90% of all diabetics. Most have a family history of diabetes, the appearance of their symptoms is slow, they show a delayed insulin response to eating a meal, and hyperglycemia often results owing to the failure of the liver to retain glucose and to a small impairment in glucose oxidation.

Insulin-dependent diabetes treatment requires insulin replacement therapy, which must be appropriately balanced with the dietary intake and energy expenditure. The goal of treatment is to normalize the storage and utilization of metabolic fuels by attempting to keep the blood glucose level as close to normal as possible.

The non–insulin-dependent diabetic exhibits a delayed rise in insulin secretion in response to eating. In other words, instead of reaching a peak insulin secretion in response to a carbohydrate meal in 1 hour, the response is delayed until 2 hours. This type of diabetic also has less liver retention of glucose, which leads to increased blood sugar in the circulation after a meal and a somewhat lower than normal rate of utilization of glucose by muscle and adipose tissues. The majority of such diabetics are overweight or obese and have a low oxidation rate for carbohydrates, which is believed to be because the interaction of insulin at the cell surface or within the cell itself has been reduced. Aerobic exercise can enhance this vital interaction of insulin at the cellular level.

Inadequate physical activity and excessive caloric intake are the two most important environmental factors influencing the development of diabetes. Endurance exercise programs have a great potential for the restoration of normal metabolism, since both loss of weight and endurance training enhance the action of insulin—that is, make it more potent. Moderate sustained activity will result in a gradual reduction in blood glucose as the exercising muscle takes up and uses that glucose for energy. This decrease will frequently last for 1 or more days after the exercise ceases. Endurance exercise also increases cellular sensitivity to insulin, thus the same amount of insulin will allow the cell to use an increased amount of sugar.

The use of exercise in the treatment of diabetes is certainly not new: It was recommended as a therapy for the disease as far back in antiquity as 600 BCE by Chao Yaun-Fang, an eminent Chinese physician of the Sui Dynasty.

Through the years, many noted specialists have recognized the value of regular physical activity to the diabetic and have encouraged their patients to exercise. However, they offered this advice sporadically and in an unspecific way. In contrast to diet and insulin therapy, exercise was not given priority in the treatment of diabetes. It is now quite evident that exercise is critical to the prevention and management of diabetes, and thus sports, especially aerobic sports, are to be encouraged.

Today, there is an increased recognition that individuals with diabetes mellitus can participate in sports and derive benefits equal, in terms of enjoyment and improved good health, to those achieved by nondiabetics. In addition, exercise, when integrated with a total diabetes treatment plan, offers unique advantages in terms of improved blood glucose regulation.

Exercise has advantages specific to the diabetic. First, exercise increases the receptivity of muscle to insulin. Normally, a given amount of insulin will cause a certain amount of glucose to be picked up by a muscle cell. If that cell is exercised, the amount of glucose that is picked up is significantly increased. Thus, the same amount of insulin will allow increased amounts of glucose to be transferred from the bloodstream into the muscle.

Second, exercise helps by decreasing excess fat and increasing the body cells' sensitivity to insulin. Obesity itself reduces sensitivity to insulin, thereby increasing a person's chances of acquiring diabetes and the complications from the disease. It is estimated that exercise and diet alone, by preventing obesity, can eliminate the occurrence of most adult-onset diabetes.

Third, exercise reduces the triglycerides and low-density lipoproteins in the blood, which leads to better control of the diabetic state. In addition to these advantages, which are unique to the diabetic, exercise also affords the diabetic the same (more than 30) cardiovascular, pulmonary, circulatory, and emotional benefits that everybody else receives from exercise, such as feeling better, having a better outlook on life and oneself, and having more energy.

Thus, having diabetes should make one want to be physically active and is no contraindication to sports participation. Indeed, diabetics have been superstars in all sports, from Jim "Catfish" Hunter in baseball to Ham Richardson and Bill Tilden in tennis.

Exercise does pose a potential problem for the insulin-dependent diabetic. The release of insulin from a subcutaneous injection is steady and does not fall off during exercise as it does in the nondiabetic. In fact, if the insulin is injected in an exercise site, such as the leg of a runner, insulin release is markedly enhanced by exercise. This means that the liver will not release glucose into the bloodstream, whereas in the normal person, a decline in insulin levels during exercise triggers the liver to release glucose into the bloodstream. Thus, the release of stored glycogen in the diabetic's liver as glucose in the bloodstream is reduced. This is partially offset by the fact that the diabetic's ability to manufacture glucose is enhanced. However, the net effect is reduced liver glucose output, thus rendering the insulin-dependent diabetic potentially at risk for hypoglycemia or low blood sugar unless he or she either decreases the intake of insulin or increases the intake of carbohydrates before engaging in unusually strenuous prolonged exercise. Most diabetics would find either alternative quite desirable.

Exercise therefore affords a reduction in insulin requirements and a liberalization of carbohydrate intake in the insulin-dependent diabetic. For many people with adult-onset diabetes, exercise can eliminate insulin requirements entirely and return glucose tolerance to normal. In a word, it "cures" the disease.

Well-regulated diabetics have an exercise energy metabolism that is not different in principle from that of similarly trained nondiabetics. Exercise reduces the level of blood sugar by enhancing muscle glucose uptake in diabetics and nondiabetics alike. The insulin receptors in diabetics have been shown to become more sensitive in response to exercise. Thus, even when the level of circulating insulin is extremely low, glucose utilization by muscle and other tissues is increased. This is true in both juvenile and adult-onset diabetes.

Moderate to intense exercise increases tolerance for glucose in both the nondiabetic and the diabetic. This is believed to be the result of the not yet fully understood effects that exercise has on glucose metabolism for as long as 24 to 48 hours after the period of exertion. During this postexercise period, replenishment of muscle and liver glycogen occurs. As compared with the pre-exercise or resting state, a greater proportion of the sugar and starch (carbohydrate) the diabetic eats goes toward replenishing muscle glycogen. Since glucose uptake by muscle and glycogen resynthesis in the muscle and the liver require a minimal concentration of insulin, the diabetic experiences an improvement in glucose tolerance, while insulin requirements are diminished.

Exercise also enhances the utilization of free fatty acids and ketone bodies, as well as glycogen in liver and working muscle.

Insulin is necessary for transporting the building blocks of protein (amino acids) into the muscle. In prolonged starvation and uncontrolled diabetes, the muscle protein, when broken down during exercise, is not replenished, which causes the muscle to begin wasting away. When the disease is controlled, however, increased exercise brings on rapid muscle growth (hypertrophy). Thus, diabetics can engage in every sport, including weight lifting and body building, where increasing muscle bulk is of paramount importance.

The message for the diabetic is loud and clear:

Exercise is mandatory for maximal control of your disease, and daily exercise through sports will very likely retard the development of vascular complications. Your cardiovascular system can become conditioned as quickly as that of the nondiabetic. There is no exercise or sport you should avoid. Your only risk is in developing hypoglycemia with sustained exercise for more than 40 minutes, and your carbohydrate intake and/or insulin administration can be adjusted accordingly. There are diabetics running in marathons and actively pursuing every competitive endurance sport.

Diarrhea

Diarrhea is generally defined as an increase in the frequency and liquidity of bowel movements. Diarrhea can vary from semisolid to watery and can be classified as *acute* if its duration is less than 4 weeks and *chronic* if it is greater than 4 weeks. Diarrhea and related symptoms such as abdominal cramping and an increased urge to defecate with high-intensity exercise are fairly common; in up to 50% of athletes, these symptoms will occur at least occasionally.

Acute Diarrhea

In healthy athletes, most cases of acute diarrhea are infectious in origin, including viral gastroenteritis, food poisoning, and traveler's diarrhea. Athletes, especially those participating in college athletics, are at higher risk for acute diarrhea due to person-to-person contact with other athletes in locker rooms and athletic training rooms, during practices and competitions, in dormitories and other close living arrangements, and while eating and traveling together. It is not uncommon for infectious diarrhea to spread quickly through a team's players and staff due to this environment.

Acute diarrhea can be caused by viruses, bacteria, and parasites. The leading viral cause of acute diarrhea in older children and young adults is noroviruses (formerly known as Norwalk-like viruses). These viruses are more likely to also cause nausea and vomiting than bacteria and parasites, especially in children. Rotaviruses and Hepatitis A can also cause viral diarrhea. Bacterial causes include *Campylobacter, Escherichia coli, Salmonella,* and *Shigella.* Another bacterial cause is *Clostridium difficile,* which is more likely to occur after the treatment of another infection with antibiotics. *Giardia* and *Entamoeba histolytica* are the most common parasitic causes of diarrhea.

Most cases of acute diarrhea are spread via the fecal-oral route, meaning that the infectious material from the stool is ingested by a new host. The methods by which this can occur include eating food prepared by infected food handlers, sharing eating utensils with an infected person, and eating or drinking contaminated water or food. Another mechanism of acquiring acute diarrhea is eating food that has been improperly prepared or stored (also known as food poisoning).

Symptoms of acute diarrhea include increased frequency and liquidity of stools, abdominal pain and cramping, and sometimes fever, nausea, and vomiting. If the patient has bloody stools, it is suggestive of a bacterial infection. In evaluating patients with acute diarrhea, the history should include questions about what they have eaten recently, whether they have had contact with anyone with similar symptoms, whether they can keep fluids down without vomiting, and how frequently they are urinating. It is also important to ask about travel, camping, or drinking of well or freshwater that has not been appropriately treated. On physical exam, it is important to evaluate for dehydration, assess orthostatic vital signs, and rule out an acute abdomen by checking for peritoneal signs.

Most cases of acute diarrhea are self-limiting and will resolve with just supportive care, so laboratory testing in not done routinely. Reasons for doing laboratory tests include grossly bloody stools, severe diarrhea resulting in dehydration, illness that is not improving after 48 hours, body temperatures greater than 38.5 °C (101.3 °F), severe abdominal pain, and diarrhea in the immunocompromised or the elderly. If further testing is indicated, the usual tests would be stool for fecal leukocytes, stool culture, stool for ova and parasites (three separate samples required), and *Clostridium difficile* toxin if there is a history of recent antibiotic use.

As stated above, most cases of acute diarrhea will resolve with time and supportive management with rest, oral or intravenous hydration, and bismuth subsalicylate (Pepto-Bismol). Antidiarrheal medications are generally not recommended, as diarrhea helps clear the offending pathogen and using medications may help control the symptoms temporarily but might delay full recovery. Athletes with acute diarrhea should be isolated from teammates to prevent its spread to the team and be educated on proper hygiene, such as hand washing.

When traveling to regions with high rates of food-borne disease, athletes and staff should be educated on habits that help avoid traveler's diarrhea. These include avoiding drinking tap water, unpasteurized milk, and iced drinks; eating food only when it is piping hot; and avoiding raw vegetables and fruits that cannot be peeled. Prophylactic treatment with antibiotics is not recommended for most travelers, but athletes and staff are often included in groups for which preventative treatment should be considered. Prophylactic treatment generally consists of bismuth subsalicylate twice daily and a fluoroquinolone antibiotic once daily.

Exercise-Induced Diarrhea

High-intensity exercise, especially long-distance running and other endurance activities, are a frequent cause of diarrhea, abdominal cramping, and an urge to defecate, also known as "runner's trots." There are a number of mechanisms that have been suggested to explain this phenomenon. One favored hypothesis is gut ischemia, caused by the shunting of blood flow away from the gastrointestinal (GI) tract to the cardiovascular and muscular systems. This can be exacerbated by dehydration. Another theory is that exercise increases the amounts of circulating catecholamines, such as epinephrine and norepinephrine, and other peptides with activity in the GI tract, such as gastrin, motilin, secretin, and vasoactive intestinal peptide, resulting in an increased transit speed of the intestinal contents. Another suggested mechanism is stimulation of the gut by the bouncing and vibrations from prolonged exercise.

The evaluation of an athlete with diarrhea caused by exercise is focused on determining if there is an underlying cause for the symptoms, as exercise-induced diarrhea is a diagnosis of exclusion. Some authors have called exercise a "stress test for the GI tract," and exercise may reveal an otherwise asymptomatic or mildly symptomatic GI condition. History and exam should concentrate on findings suggestive of irritable bowel syndrome, lactose intolerance, hyperthyroidism, parasitic infections, antibiotic use, exercise-induced anaphylaxis or urticaria, laxative abuse (seen in athletes competing in sports with weight classes and those with female athlete triads), and inflammatory bowel disease. Additional testing would include the tests mentioned above in the evaluation of acute diarrhea and flexible sigmoidoscopy or colonoscopy, especially in athletes over the age of 40, who have a higher risk of colon cancer.

Once other conditions have been ruled out, treatment of exercise-induced diarrhea should include attempting to have a bowel movement before exercise, maintaining proper hydration, and avoiding caffeine (a GI stimulant), nonsteroidal anti-inflammatory drugs (NSAIDs), and high-sugar beverages 2 to 3 hours before exercising. Symptoms also tend to improve as fitness increases; so, over time, symptoms may gradually resolve with continued training. Excess dietary fiber should also be avoided. Antidiarrheal medications, such as loperamide, can decrease sweating, so most authors recommend avoiding them, but they can be used in cases with a history of extreme urgency resulting in soiling.

Dietary Supplements and Vitamins

Athletes often seek dietary supplements to enhance performance. A *supplement* is a substance added to the diet to make up for a dietary deficiency or to enhance the diet and possibly athletic performance. In ideal circumstances, supplements should not be used as a substitute for an optimal diet. This entry provides an overview of some popular performance-enhancing supplements.

Products that are classified as vitamin and mineral supplements are required to meet U.S. Food and Drug Administration (FDA) standards, while those supplements classified as simply "dietary supplements" are not. In addition, supplements are not required to meet the same safety requirements as over-the-counter or prescription drugs or food ingredients. Furthermore, they are not held to specific manufacturing standards that would guarantee the purity or potency of the product. Finally, the FDA is prohibited from removing a product from the market unless it can prove that the product poses a health risk. Thus, most health risks of supplements are discovered after the product has been on the market and has caused health problems.

Supplements may be classified as those derived from macronutrients (protein, carbohydrate, and fat) or micronutrients (vitamins and minerals), and herbal-based products. The following sections outline some common supplements.

Fats

Medium-chain triglycerides (MCT) contain fatty acids that are shorter in length than most fatty acids and, thus, are absorbed more rapidly. Some of the potential benefits of MCTs are that they are a readily available energy source, are sparing of lean body mass, increase the metabolic rate, are sparing of glycogen, and increase fat use for fuel. However, several studies assessing MCTs and performance have found no benefit for endurance or strength.

Omega-3 fatty acids are a group of unsaturated fatty acids that cannot be synthesized by the human body and are thus essential to consume in the diet. Potential benefits of omega-3 fatty acids include reduced muscle soreness, improved blood flow and nutrient delivery, improved aerobic metabolism, reduced inflammation, and improved muscle recovery. However, numerous studies show no evidence of any performance benefits from omega-3 fatty acid supplementation.

Conjugated linoleic acid (CLA) is part of a group of unsaturated fatty acids found in beef, lamb, and dairy products. Performance claims include fat loss and increased strength and muscle mass. Studies in humans are mixed, with some reporting a significant decrease in body fat and others reporting no significant changes in body fat, strength, muscle mass, or fat oxidation. There have been no adverse effects of CLA supplementation. Further research on performance benefits is warranted.

Proteins

Branched-chain amino acids (BCAA) are a group of essential amino acids designated by their branched structure. They include leucine, isoleucine, and valine. During prolonged exercise, BCAA may play a role in delaying central nervous system fatigue, be used as an energy source, and prevent immunosuppresion. However, studies are mixed, and supplemental BCAA have not been shown to improve performance or delay fatigue, although positive effects have been reported in studies examining immune response during prolonged exercise.

Glutamine is a conditionally essential amino acid and can be synthesized by the body under normal conditions. Under physiologic stress, glutamine may be needed at higher rates than the body is able to synthesize, and supplementation may therefore be beneficial. Benefits may include decreased exercise-induced stress, improved recovery, decreased muscle catabolism, and increased muscle mass. However, study results have been mixed, with some evidence of enhanced immunity and other evidence suggesting no performance, body composition, or immune benefits.

Arginine is another conditionally essential amino acids. Arginine functions in protein synthesis and in the detoxification of ammonia and plays a role in the production of other biologically active compounds. Arginine may increase growth hormone secretion and the synthesis of creatine and nitric oxide.

Carbohydrates

Glycerol is a 3-carbon sugar alcohol used as a carbohydrate-like fuel. Glycerol may benefit athletes exercising in hot and humid environments by helping them retain extra water. However, there is also evidence of significant side effects. At high doses, glycerol supplementation appears to cause headaches, dizziness, nausea, and a predisposition to hyponatremia.

Pyruvate is a 3-carbon compound produced by the metabolism of sugar. It has been suggested that supplementing with pyruvate may increase aerobic endurance and decrease body fat. Studies have found no evidence of enhanced aerobic performance or of fat loss. Also, severe adverse gastrointestinal effects have been reported with high pyruvate doses.

Vitamins

Vitamin E is a powerful antioxidant. Athletes are subject to increased oxidative stress from exercise. Thus, the potential benefits of supplemental vitamin E for better aerobic performance, greater strength, and reduced oxidative damage have been studied. Evidence suggests no performance or strength benefits, but vitamin E may prevent oxidative damage. Good sources of vitamin E include plant oils, nuts, seeds, and wheat germ.

Vitamin B_6 is a water-soluble vitamin necessary for protein and energy metabolism. Inadequate vitamin B_6 levels have been linked to decreased athletic performance; thus, exercise may increase the need for vitamin B_6. Adequate vitamin B_6 may be consumed in a balanced diet; therefore, supplementation is generally not necessary. Good sources of vitamin B_6 include liver, chicken, bananas, potatoes, and spinach.

Thiamin is a water-soluble vitamin particularly important for carbohydrate energy metabolism. Athletes who consume high-carbohydrate diets must also consume appropriate amounts of thiamin or performance may be diminished. Studies have found no benefit of thiamin supplementation above the recommended levels. Good sources of thiamin include peanuts, wheat germ, green peas, collard greens, oysters, liver, and nutritional yeast.

Vitamin B_{12} is a water-soluble vitamin important for DNA (deoxyribonucleic acid) synthesis, red blood cell formation, and nerve development. B_{12} injections are commonly given to athletes before competition; however, there is no benefit of B_{12} above the recommended levels. Supplementation of vitamin B_{12} may be appropriate for vegan athletes, who are commonly deficient. Good sources of vitamin B_{12} include fish, dairy products, beef, eggs, poultry, and fortified cereals.

Niacin is a water-soluble vitamin involved in energy production from carbohydrate, fat, and protein. There is some evidence that niacin supplementation may facilitate the regulation of body temperature in athletes. However, other studies have reported negative effects with niacin supplementation, including reduced endurance due to altered fuel metabolism. There is no evidence that niacin requirements increase with exercise; thus, supplementation is not necessary given an adequate intake. Good sources of niacin include beef, pork, chicken, eggs, milk, and wheat flour.

Vitamin C is a water-soluble vitamin that functions as an antioxidant. It is also important for connective tissue synthesis, formation of neurotransmitters, and generating energy from fatty acids. Vitamin C needs may be increased for athletes, especially those participating in endurance events. The increased requirement of vitamin C may be met through food; thus, supplementation is generally not necessary. Good sources of vitamin C include citrus fruits, kiwis, broccoli, Brussels sprouts, and red or green peppers.

Minerals

Phosphorus is a mineral required in bone formation, and it also plays a role in energy metabolism. "Phosphate loading" is a strategy used by some athletes to decrease the accumulation of hydrogen ions and to delay fatigue. However, there is limited evidence of performance improvement with high phosphorus intake. Furthermore, there may be long-term consequences of excessive phosphorus intake as it may decrease bone density. Good sources of phosphorus include milk, cheese, yogurt, nuts, oatmeal, and asparagus.

Potassium is a mineral and the main electrolyte found in cells. It is important for muscular contraction, nerve impulses, and water balance. Potassium lost in sweat does not typically have an impact on performance in a well-nourished athlete. Good sources of potassium include oranges, bananas, potatoes, tomatoes, and blackstrap molasses.

Iron is a mineral necessary to form oxygen-transporting proteins in blood and muscle. Iron deficiency has been shown to have detrimental effects on exercise performance. Female athletes commonly have some degree of iron deficiency due to increased needs. Iron supplementation may be warranted for athletes with any form of iron depletion. However, excessive iron supplementation has not been shown to be beneficial and may even lead to iron overload disease. Good sources of iron include red meat, oysters, egg yolks, tofu, whole grains, salmon, and raisins.

Herbals

Chinese ginseng (*Panax ginseng*) is a plant that has been used for centuries in Asian cultures to help reduce fatigue, increase vitality, improve health, and attain longevity. Results from the scientific literature investigating Chinese ginseng and athletes show no clear improvement in performance. However, there is limited evidence of greater benefits in older individuals (>40 years) and if taken at a sufficient dosage for a sufficient period of time (>8 weeks).

Tribulus terrestris (puncture vine) is frequently used as a medicinal tonic and dietary supplement. Benefits of tribulus supplementation may include increased testosterone production, mood enhancement, elevated sex drive, and strength and muscle gains. Despite these claims, several studies looking at tribulus supplementation in athletes have found no elevation in testosterone, reduction in fatigue, or changes in strength and body composition.

In summary, supplementation may be beneficial for athletes and depends on the diet as well as on sport-specific requirements. Seeking advice from a trained professional is recommended.

Dietitian/Sports Nutritionist

With the expansion of professional sports franchises and the increasing number of Olympic sports, the participation of elite athletes today is on the rise. Healthful nutrition is important throughout the life span, because suboptimal nutritional status may impair training and sportive performance. Appropriate nutrition during training is one of the key elements for success in a competition. Increased energy expenditure during training needs the enhancement of caloric intake to maintain body weight, and an addition of 500 to 1,000 calories or more per day is needed in certain activities. The consumption of a wide variety of foods is necessary for these additional caloric needs. Adequate amounts of all nutrients essential for the formation of new body tissues and for the proper functioning of the energy systems should be considered. A balanced intake of carbohydrate, fat, protein, vitamins, minerals, and water is all that is necessary.

Sports nutrition is an established discipline that specializes in the nutrition of athletes. A good command of general nutrition and exercise science, an understanding of their interrelationship, and the knowledge of how to practically apply sports nutrition concepts are needed in applied sports nutrition.

If two athletes are equally talented, equally well trained, equally motivated, and equally well coached, good nutrition can make the difference. Good nutrition will optimize performance. Athletes need to consume nutrients in proper amounts, but specialized knowledge is needed to develop an appropriate nutritional strategy. Good health should be the main goal, without which the best performance will not be achieved. A sport nutritionist, who is able to provide an appropriate and well-fitting nutritional plan, is essential in a sports team.

Sports nutrition is the application of knowledge of nutrition to create a daily eating plan, which focuses on providing fuel for training, enhancing the repair and rebuilding process of strenuous physical work, optimizing performance in sportive events, and promoting overall health and wellness. The term *athlete* includes not only elite athletes; it also refers to any individual who is regularly involved in sports activities.

The primary responsibility of a sports dietitian is the counseling of individuals and groups on daily nutrition for performance and health. This involves translating the latest scientific evidence into practical recommendations; tracking and documenting the outcomes of nutrition interventions; serving as a food and nutrition information resource for athletes, trainers, and parents; and providing sports nutrition education. .

The following services are provided by the sports nutritionist:

Individual Nutrition Counseling

- Evaluating athletes' diet, body composition, and energy balance to improve athletic performance and health
- Providing counseling about optimal nutrition to enhance training goals, competition, disordered eating, travel, and supplementation
- Helping athletes achieve and maintain body weight (body mass, body fat, and muscle mass)
- Controlling the hydration status of athletes
- Considering the medical problems of athletes (food allergies, bone mineral disturbances, gastrointestinal disturbances, iron depletion, and iron deficiency anemia, etc.)
- Coordinating nutritional care as a member of multidisciplinary sports teams
- Evaluating nutritional supplements for legality, safety, quality, and efficacy
- Counseling for the appropriate use of supplementation
- Counseling athletes' families, physicians, trainers, and other health professionals
- Developing educational materials and providing training (e.g., in food selection and preparation)
- Developing and supervising nutrition policies and procedures

Food Service and Menu Development

- Coordinating/managing food production, training table menus, and catering
- Coordinating nutrition for domestic and/or international travel
- Managing budgets for nutritional supplements
- Planning dietary menus for the table and for travel
- Suggesting pre-, during-, and postexercise fluids and snacks

Nutrition Education for Teams, Groups, or Wellness Programs

- Providing educational presentations on various nutritional topics for sportive performance
- Providing resources for trainers, teachers, food service staff, and parents
- Providing nutrition education for food service staff

Professional Development

- Managing registration and continuing-education activities
- Keeping up to date on nutritional issues and research related to sports nutrition

Appropriate selection of foods and fluids, intake timings, and choice of supplements are recommended by a position paper of the American Dietetic Association, Dietitians of Canada, and the American College of Sports Medicine. During times of high physical activity, sufficient intake of carbohydrates and proteins is warranted, and fat intake should provide essential fatty acids and fat-soluble vitamins. Energy from fat should be at least 20% to 25%, and adequate food and fluid consumption could help optimize sportive performance, improve recovery time, and prevent decrease of blood glucose. Hydration of athletes before and after exercise is also highly recommended. Careful reviewing of the athlete's health, nutritional status, and drug use and energy requirements is required, and nutritional advice should be provided by a sports nutritionist whenever possible.

Diffuse Axonal Injury

Sports-related closed-head injuries essentially follow the same clinical spectrum as is seen in nonathletic closed-head injuries. Injuries range from the common *cerebral concussion*, a form of mild traumatic brain injury (TBI), to the most severe, *diffuse axonal injury* (DAI). Though severe closed-head injuries are relatively rare in organized athletics, occasionally tremendous force transfers will occur between players involved in a collision. The impact can result in massive structural damage to the brain, clinically manifested as prolonged loss of consciousness or even coma.

Epidemiology

In DAI, the outcome is rarely death, but frequently it is coma. Up to 90% of patients with severe DAI remain in a persistent vegetative state. Those patients who do wake up often remain profoundly impaired. DAI has hence been found to be the most significant cause of morbidity in patients with TBI. With its high degree of chronic debilitation, DAI potentially becomes a highly stressful family problem exacerbated by staggering medical costs.

Anatomy

The brain has three main components: the cerebrum, the cerebellum, and the brainstem. The cerebrum comprises a left and right hemisphere connected by a large bundle of nerve fibers, the corpus callosum. The cerebral hemispheres are divided into lobes corresponding to the section of the overlying skull: temporal, parietal, and occipital. The cerebellum and brainstem are located posterior and inferior to the cerebral hemispheres.

Brain tissue consists of 40% gray matter and 60% white matter. Gray matter is dark in color because of the relatively high proportion of nerve cell nuclei present. White matter consists mostly of axons covered with lightly colored myelin, an insulating protein sheath. Brain cells include neurons and glial cells. Glial cells make up 90% of the brain cells and exist to provide essential support functions to neurons. Neurons are nerve cells that send and receive electrochemical signals to and from the brain and the distal nervous system. Each consists of a cell body with branching dendrites (signal receivers) and a long projection called an axon, which conducts the nerve signal. Bundles of axons called nerves are in the body's periphery and are referred to as *nerve tracts* within the central nervous system.

Primary Injury

As the name suggests, DAI is a widespread insult to the brain axons, in contrast to a focal brain injury such as a contusion, laceration, or hematoma. The injury is the result of traumatic shearing forces that typically occur when the head is subjected to rapid acceleration/deceleration or severe rotational forces. Motor vehicle accidents are the most frequent cause of DAI. Severe DAI is almost always due to vehicular injury. DAI has been documented in practically every sporting event that potentially involves a sudden head deceleration from a high-speed collision with an immovable object.

The major cause of damage in DAI is the disruption of axons through shear injury. *Shear injury* refers to the damage sustained to brain matter as tissues of varying density slide over each other in response to forces produced in a sudden acceleration/deceleration impact. Axonal tissue disruption is greatest in those areas where the density difference is greatest. For this reason, the majority (two thirds) of DAI lesions occur at the gray/white-matter junction. The regions of the brain most commonly injured are the frontal and temporal lobes, followed by the corpus callosum. The DAI affecting the corpus callosum is more frequently unilateral and may be hemorrhagic due to close proximity to blood vessels. Consequently, the involvement of the corpus callosum carries a relatively poor prognosis. The brainstem typically remains unaffected, which helps explain why DAI rarely causes death.

Secondary Injury

DAI was traditionally believed to be the result of primary injury—that is, the mechanical forces absorbed at the time of impact. It is now understood that a series of secondary biochemical processes, which occur in response to the primary injury, are largely responsible for the axonal injury. The precise nature of these processes has not been fully elucidated to date, but the essential microscopic characteristic of DAI has been determined to be axonal separation. Specifically, the injury cascade is triggered on impact by shear forces, which cause an axonal disruption or tear. This results in misalignment of the cytoskeletal elements in the axon and impairment of nerve product (neurotransmitter) transport. These transport products rapidly accumulate and cause a local swelling that, once it is large enough, triggers a split of the axon into two pieces. The injured axon then draws back toward the cell body and forms what is known as a retraction ball. This retraction ball is the pathologic hallmark of DAI. The portion of the axon distal to the tear will degrade and eventually die. The earliest signs of this secondary injury process are seen beginning 4 hours after the primary impact, but it may continue to evolve over days to weeks.

Because axonal damage in DAI is ultimately the result of secondary biochemical processes of delayed onset, the head-injured athlete, who initially appears to be well, may deteriorate later. This is because the injury is frequently more severe than initially realized. The examining physician should have a high index of suspicion for DAI in any patient whose brain CT/MRI (computed tomography/magnetic resonance imaging) scan appears normal but who has obvious symptoms of severe head trauma, for example, unconsciousness. The degree of microscopic injury is typically higher than visualized using current imaging techniques, and the clinical presentation tends to reflect this point.

Clinical Spectrum

DAIs have a wide spectrum of severity, ranging, like cerebral concussion, from mild to severe. The clinical presentation depends primarily on the extent and location of axonal disruption. DAI commonly results in instantaneous loss of consciousness, and greater than 90% of patients experience profound and prolonged impairment of neurological function, typically manifested in a persistent vegetative state. The chance that a patient will continue to remain in this state is greater when axonal lesions are observed in the cerebral white matter and corpus callosum. The prognosis worsens as the number of lesions increases, especially if it is associated with hemorrhage.

Diagnostic Imaging

Although 50% to 80% of DAI patients have a normal CT scan on presentation, 80% will eventually demonstrate multiple areas of injury on CT scan. Severe cases of DAI exhibit characteristic features on CT scan in the acute setting, most notably small hemorrhages, less than 2 centimeters in diameter, located in the cerebral hemispheres at the gray/white-matter junction, as well as the in the corpus callosum. An abundance of DAI lesions in the corpus callosum can result in deficits of information transfer between the two sides of the brain, resulting most often in hearing deficits. In the setting of DAI without coma, the injury often results in neuropsychological impairment dominated by executive and memory dysfunction. For the nearly 10% of patients who experience a return to any form of normal function, this improvement will be seen within the first year.

An MRI scan is more sensitive than a CT scan and is the preferred method of imaging for DAI. However, CT scanning is more easily available and practical in emergency settings, and it remains a vital tool in the acute investigation of head injury. In an acute setting where DAI is suspected clinically yet CT scan findings are negative, MRI is then considered, as it may demonstrate lesions not visualized through CT scanning. It has been discovered that MRI can be used to reliably assess and quantify the volume of white matter lesions resulting from DAI. In general, patients with greater DAI volume have poorer functional outcomes. Along these lines, MRI may be useful in stratifying injury severity and may possibly play a role in predicting the duration of coma in DAI patients.

Sports-Related Injury

From a sports medicine perspective, DAI most commonly occurs in motor sports, where closed-head injuries account for the vast majority of head injuries. Motor sports aside, the injury is occasionally seen in severe athletics-related head trauma. Of note is a recent study that asked whether the location of impact influenced DAI patterns. It was found that the likelihood of DAI increased 11-fold in patients sustaining a lateral impact (vs. frontal and oblique). When DAI is associated with an open-head injury in motor sports, the outcome is always catastrophic. However, DAI accounts for less than 5% of all closed-head injuries in motor sports, in large part due to strictly instituted safety measures. These include restraining the helmeted driver with a shoulder harness into a safety cell within the vehicle, which itself is designed to dissipate the forces of a crash. In addition, professional motor sports mandate the immediate presence of emergency medical providers. All told, these measures have resulted in several examples of complete recovery from mild to moderate DAI, with some of the drivers able to return to competition following a period of rehabilitation. This is an exception, however, because for the majority of athletes who sustain DAI, complete neurologic recovery is uncommon; hence, return to a collision or contact sport is usually not a realistic goal.

It must be stressed that the major difference between athletic and nonathletic head injury is that the injury to the athlete is often preventable. DAI currently lacks a specific treatment protocol beyond what is typically followed for severe closed-head injury, including limiting increases in intracranial pressure. Cognitive rehabilitation can be beneficial. On a microscopic level, research has demonstrated that dendritic restructuring might occur, with some regeneration possible in mild to moderate injury.

Discoid Meniscus

Discoid meniscus is a term used to describe an abnormally block-shaped and potentially loose meniscus in the knee joint. It is believed to be a congenital condition present at birth. It occurs in approximately 5% of the population, and 25% of the time it occurs in both knees. In many cases, it does not cause symptoms; however, in some young children, it can cause “snapping knee” syndrome. In older children, a discoid meniscus can tear after an injury to the knee. A discoid meniscus that is very loose or that tears may require surgery.

Anatomy

A *meniscus* is a shock absorber cushion that sits between the cartilage of the femur (thighbone) and the cartilage of the tibia (shinbone). Each knee has two menisci—a medial (inner) meniscus and a lateral (outer) meniscus. A discoid meniscus occurs in place of the lateral meniscus 97% of the time. The normal lateral meniscus is crescent shaped when looked at from above, with the opening of the crescent facing the center of the knee. The normal lateral meniscus is also shaped like a wedge from the front, so that the crescent tapers toward the center of the knee joint. A discoid meniscus resembles a complete circular disc instead of a crescent from above and is block shaped (i.e., it does not taper toward the center of the knee). In addition, the normal lateral meniscus is properly anchored to the tibia and femur by ligaments so that it is stable inside the knee. A discoid lateral meniscus may lack these attachments and may be very loose within the knee.

Causes

It is unclear what causes a discoid meniscus. A discoid meniscus is currently believed to be a congenital malformation and not a developmental variant, because a normal meniscus never resembles a discoid meniscus during its development. One theory is that when a developing meniscus does not form proper attachments to the tibia and femur, it is very loose, and to compensate for this instability, it develops discoid features, such as being circular and block shaped.

Symptoms

Many people with a discoid meniscus never have any symptoms. It is likely that in these cases, the discoid meniscus is properly attached and not loose. Young children who have a discoid meniscus that is not properly attached to the knee present with "snapping knee" syndrome. In these cases, the child experiences episodes of dramatic snapping and popping in the knee. These snaps occur spontaneously as the knee straightens and usually produce temporary pain and apprehension. In very young children (between the ages of 3 and 4), the snapping may be audible but is usually painless. The snap represents the loose discoid meniscus moving more than it should inside the knee. Older children with a discoid meniscus that is properly attached often do not have any symptoms unless they injure their knee. These patients have a higher risk of tearing their discoid meniscus after a trauma. They present with pain and swelling on the outer aspect of the knee after a knee injury.

Diagnosis

A history of snapping inside the knee in a young child should alert the practitioner to evaluate for a discoid meniscus. On physical exam, the clinician should feel for a dramatic clunk on the outer aspect of the knee as the knee is flexed and rotated (McMurray test). Sometimes a bulge may be visible on the outer aspect of the knee with knee flexion. The clunk and bulge likely represent an unstable discoid lateral meniscus. Because discoid menisci occur in both knees 25% of the time, the other knee should be carefully examined as well.

A discoid meniscus is not visible on X-ray. However, secondary changes such as squaring of the femur can be seen on X-ray, suggesting the possibility of a discoid meniscus. When a discoid meniscus is suspected, a magnetic resonance imaging (MRI) scan should be performed. The MRI scan will often show the block-shaped, circular appearance of a discoid lateral meniscus.

In some cases, the meniscus may only be partially discoid in shape but still lack proper attachments. These are termed *incomplete* or *partial discoid menisci,* and often they appear normal on an MRI scan. Therefore, the gold standard for diagnosing a discoid meniscus is knee arthroscopy. Arthroscopy allows the surgeon to directly visualize the meniscus and to probe it to test its stability. Discoid menisci are usually classified based on their appearance (complete, disc shaped or incomplete, crescent shaped) and their stability (stable or unstable to probing).

Treatment

Treatment of a discoid meniscus depends on the patient's symptoms and the stability of the meniscus. A stable discoid meniscus that does not cause pain is usually just observed over time. A young child with a snapping knee that does not cause pain also does not require surgery. Physical therapy is often recommended for these patients to strengthen the knee. Surgery is reserved for patients with a discoid meniscus who develop pain, swelling, locking, or catching of the knee. These symptoms suggest that the meniscus is unstable and is prone to tearing or has already torn. In some patients, a discoid meniscus is incidentally discovered on an MRI scan or during knee arthroscopy for another reason. If these patients do not have any symptoms related to their discoid meniscus, no specific treatment is recommended.

Surgery

Surgery is recommended for most discoid menisci that cause symptoms. A discoid meniscus is most commonly treated with knee arthroscopy. During arthroscopy, the surgeon will view the meniscus to determine if it is a complete or incomplete discoid meniscus, using a small arthroscopic probe to test its stability and carefully looking for any tears in the meniscus. Depending on these findings, the surgeon will decide how to proceed.

In the case of a complete discoid lateral meniscus, most surgeons will first attempt to reshape the meniscus. This process is termed discoid *saucerization,* and it is done using small arthroscopic instruments to cut away the central portion of the disc-shaped meniscus so that it resembles a more normal crescent shape. This treatment represents a recent change in the management of discoid menisci. In the past, when a discoid meniscus was encountered during surgery, most physicians removed the entire meniscus (termed *total meniscectomy*). As we have come to understand the importance of the meniscus as a shock absorber, many physicians now favor saucerization (or *partial meniscectomy*), as opposed to complete excision. The idea is to preserve the crescent-shaped part of the meniscus so that the meniscus can maintain part of its shock-absorbing function after surgery.

Following saucerization, the surgeon will carefully assess the stability of the remaining meniscus. If the discoid meniscus is lacking proper attachments, it will be abnormally loose when assessed with the arthroscopic probe. In these cases, the meniscus must be reattached to the knee capsule in the area where it is not properly attached. The process is called meniscal repair and can be done using small instruments to place sutures across the meniscus and into the capsule surrounding the knee.

In some cases, a tear may be noted in the discoid meniscus itself. Depending on the appearance and location of the tear, the surgeon will decide how to proceed. If the tear is in the central portion of the meniscus, which would normally be cut away during saucerization, then the surgeon will just remove the tear during this process. If the tear is in the part of the meniscus that remains following saucerization, the surgeon can elect to repair the tear with meniscal sutures or selectively remove the portion of the meniscus containing the tear.

After Surgery

Following knee arthroscopy, crutches are necessary for a few days while pain and swelling of the knee are present. If the patient has undergone saucerization only (without meniscal repair), the knee is allowed to move without a brace, and the patient can then be weaned from crutches as soon as possible. Physical therapy is usually necessary for 6 weeks, after which the patient is allowed to return to full activities. If a meniscal repair was performed, a brace is often used to limit motion, and crutches may be necessary for 4 to 6 weeks. Return to full activity following a meniscal repair occurs after a course of physical therapy at about 3 to 4 months after surgery.

Diuretics

Diuretics are a group of medications typically used to treat high blood pressure or congestive heart disease, but they have also been abused by athletes to gain a competitive advantage or to cover up evidence of the use of other performance enhancers.

A *diuretic* is anything that causes a person to produce more urine from the kidneys. There are many different kinds of diuretics, and they act on the kidney in slightly different ways. Medications such as hydrochlorothiazide (HCTZ) or furosemide affect the small blood vessels in the kidney. This changes how blood flows through the kidney and causes more free water to be filtered from the blood. Osmotic diuretics such as mannitol work in a different way. Free water is drawn out of the blood by the kidneys by way of elaborate concentration gradients, producing very dilute urine very quickly.

As urine is produced, electrolytes and minerals are lost in the urine. In addition, toxins and chemicals are cleared from the body. The athlete also loses free water from the blood. Diuretics are commonly used in medicine to treat high blood pressure or congestive heart failure. During this treatment, electrolytes such as potassium and sodium are carefully monitored and sometimes have to be supplemented.

Diuretics are used for therapeutic purposes and can be abused for enhancing athletic performance. Athletes may surreptitiously use diuretics for several reasons. Wrestlers and boxers use them to rapidly lose weight so they can compete in a specific weight class. Bodybuilders use them before the competition to dehydrate themselves and enhance muscle definition. Diuretics are sometimes used by athletes who are trying to cover up the use of other performance-enhancing substances and beat a drug test. This is one of the reasons why drug testing in sports includes tests for the presence of diuretics. The presence of some of these diuretics in a drug test is considered as grounds for disqualification unless a documented medical reason for using the diuretic is presented to the competition committee prior to the event.

There is a process, however, to ensure that an athlete is able to use a substance that could be otherwise considered a doping agent, such as insulin or albuterol, in a medically responsible way to treat an illness or condition. A Therapeutic Use Exemption is not valid if an athlete's urine contains a diuretic in association with threshold or subthreshold levels of a prohibited substance.

There can be significant side effects from the use of diuretics. Rapid shifts in electrolytes can cause deadly heart arrhythmias or seizure. They can cause dehydration and symptoms such as dizziness, fatigue, confusion, headache, or syncope (passing out). In addition, electrolyte abnormalities and dehydration can contribute to muscle cramping and worsening of asthma symptoms. Dehydration and diuretic use can contribute to kidney damage and renal failure.

Diversity in Sports

Traditionally, discussions of diversity have focused on race, gender, age, religion, disability, and sexual orientation. It should also be noted that *diversity* can also encompass socioeconomic background, affiliated socioeconomic conditions (e.g., education, location), and marital status. What does diversity mean for sports and athletics? It fosters the promotion of the uniqueness of individuals as they demonstrate their skills and abilities in sports. Diversity is the basis for the provision of equitable opportunities for all individuals to participate in sports and athletics (with or without modifications), whether it be as athletes, coaches, training staff, or administrators.

Diversity in athletics benefits the individual athlete, the team, and the community, providing exposure to people of different cultures and experiences. In addition, sports diversity can improve team performance and increase productivity as well as decrease team attrition and provide an attractive variety to sponsors of athletic teams and events. Diversity in sports can also foster commuting and cooperation and understanding between countries. One major example is the modern Olympic Games, which were founded on a culture of seeking excellence and promoting tolerance and cultural diversity and exchange. The International Olympic Committee (IOC) expects and demands respect for individuals of all cultures, races, sexes, and abilities. As a complete review of diversity in sports is beyond the scope of this entry, the entry will briefly review some of the major moments pertaining to diversity in sports in the areas of gender, race, and disability, as well as briefly touching on the participation of children and senior citizens in sports and athletics.

Gender and Sport

As men have been freely able to participate in sports throughout history, most discussions of gender diversity and sports focus on women's issues. In the ancient Olympic Games, women were banned not only from participating but also from watching the games—because men competed in the nude. Women first participated in the modern Olympic Games in 1900, at the time of the second Olympiad, but in golf and tennis only. Throughout history, sports-minded women were generally hampered by social and cultural norms, such as having to be "ladylike," and, thus, were discouraged from participating in sports that did not support wearing a skirt.

American women were similarly held back from participation in organized sports. Throughout much of American history, women were considered the weaker sex and discouraged from participating in sports, due to the unladylike activities as well as to an unfounded concern for the reproductive health of the participants. Although not in formal sports, women did participate in athletic activities, such as the early Native American religious dancing and physical contests in worship. Settler women maintained their athleticism, participating in activities of daily living, such as sailing and fishing, as well as in more recreational fitness activities, such as dancing and racing. With the development of modern sports in the 1800s (mostly designed for men by men), women gradually increased their participation in organized sports. By the end of the 19th century, sports for women became more formalized, organized by employers for physical fitness or arranged by various sporting clubs.

Owing to the medical establishment's concern for their reproductive health, women's formal sports and athletic education lagged behind women's sports and athletic participation. Amateur and professional sports clubs, leagues, and competitions were steadily increasing in number, although with varying degrees of success and longevity. One more notable example was the All-American Girls Baseball League during World War II. Women's teams, with the help of runners such as Wilma Rudolph, also began to integrate around World War II. After the feminist revolution of the 1960s, as well as due to the social changes of the time, the state of women in sports would change for all time with Title IX of the Education Amendments of 1972.

Title IX required equity in sports opportunity, equipment, funding, and playing time within any educational institution receiving federal funds. Since Title IX, high school women's sports participation is nearly 10 times what it was in 1971. College women's sports participation has tripled, and there are also an increasing number of sports available to women, including rugby, weight lifting, triathlons, and professional basketball leagues. Women have also increased their participation in men's athletic activities, including high school football, high school baseball, and high school wrestling. Although not as much as men, female athletes have also achieved greater status in American culture. In the same manner as it benefited nonminority women athletes, Title IX also benefited female athletes of color. We must remember that although significant gains have been made, opportunities for male athletes are still greater than for female athletes throughout the sports arena and especially in areas of power and decision making.

Title IX has also decreased the effects of homophobia in sport. Although not specifically written for this purpose, Title IX has been used to address discrimination based on gender stereotypes and sexual orientation (i.e., not masculine enough = gay; a too athletic woman = lesbian). Addressing homophobia, whether or not with the use of legislation, can not only challenge stereotypes but also improve team chemistry and performance and decrease the incidence of suicide, hate crimes, and other destructive behavior.

Race, Ethnicity, and Sport

The term *race,* initially used in the mid-1800s by cultural scientists, was meant as a small and insignificant descriptor of different people. Though many would eloquently and publicly rebut the degradation of the word, over time *race* developed its pejorative nature, creating an artificial hierarchy of betters and lessers. The topic of race and race relations in America is often used to describe two groups: (1) black Americans (i.e., African Americans) and (2) white Americans (i.e., Caucasian Americans). Racial inequality in America, however, led to the struggles of many different groups, in addition to the two above. Slavery and indentured servitude affected the Native Americans, Asian Americans, Latin Americans, and other nonwhite ethnic groups. Discrimination, as it was for blacks, was also legalized for Asian Americans with the Chinese Exclusion Act of 1882 and for other ethnic groups with the National Origins Act of 1924.

Just as the definition of race was not straightforward, so too has been the struggle for equality. Rights and freedoms for all Americans have been gradually granted in multiple constitutional amendments and laws throughout our nation's history. For example, the post–Civil War Reconstruction Period created laws allowing blacks and whites to be "separate but equal." Unfortunately, this doctrine failed and degraded to simply "separate," and segregation, from birth to death, pervaded society until the mid 20th century. Sports, a microcosm representing society, was equally affected.

African Americans have been participating in athletics and athletic activities since colonial times. A fair portion of that participation was either as individual athlete (e.g., in track-and-field events or in boxing) or in a separate league (e.g., the Negro Baseball League from the 1880s to the 1960s), although there were some notable exceptions. With the success of black athletes, like Jack Johnson, a heavyweight boxing champion, in the early 1900s, some football teams attempted integration. These efforts failed, largely due to economic factors, as the Great Depression affected supporting monies. Many professional sporting teams would, however, conduct preseason and postseason games and series with black teams, during which many noticed that the competitive level of the non–Major League teams was high. This "barnstorming" provided an initial venue for black athletes to be seen by an integrated audience.

Major League Baseball was the first organized professional league to integrate successfully. One man hailed for helping to break the color barrier in baseball is Jackie Robinson. Jackie Robinson, the first African American noted for playing on an integrated professional baseball team, joined the Brooklyn Dodgers in 1947. This landmark moment started the tidal wave of American baseball integration. Although not without opposition, from within his own team, from general spectators and Dodger fans, and from opposing teams, Robinson persevered in adversity and went on to become the Rookie of the Year in 1947. Robinson was quickly joined by Satchel Paige, Hank Aaron, and Willie Mays—all praised for their skill in the game. Within the next 12 years, integration in American baseball was complete. Until his death in 1972, Robinson was also a big proponent of African American involvement in nonathletic positions (e.g., coaching, management, and ownership). For his steadfast example and praiseworthy skills, Jackie Robinson was inducted into the National Baseball Hall of Fame in 1962. Professional football and, last, professional basketball integrated their teams after World War II.

About the time of Jackie Robinson's rise to fame in baseball and baseball's integration, America was becoming integrated as well. Just as sports can reflect society, society can likewise mirror sports. With the integration of baseball, and other professional sports, came increased public awareness that integration was possible and could be successful. Integrated teams, such as the Brooklyn Dodgers, had record seasons and were winning the World Series. Two historical legal events that fostered societal integration were a Supreme Court decision and a congressional bill that became law. In the *Brown v. Board of Education* Supreme Court decision of 1954, the court ruled unanimously that applying the "separate but equal" clause in public schools was invalid and in opposition to the Constitution. The second event involved the passing of the Civil Rights Bill of 1964, which promotes equity and prohibits discrimination based on race, color, religion, or national origin with regard to activities conducted within a public area or establishment, as well as with regard to employment and pay.

Despite the Court's decision and this groundbreaking legislation, integration still had, and continues to have, its difficulties. Integration saw the end of many long-standing black establishments. With integration came the demise of the Negro Baseball Leagues, as all their great players were transferring to the national leagues, resulting in a smaller talent pool and loss of media coverage, fans, and sponsorship. A moving away from black culture also began at that time and continues to this day. Not all well-founded black entities were lost, however. The American Tennis Association, home of Arthur Ashe and Althea Gibson, still continues today, supporting the development of young African American tennis players within their communities. With their sound basis in African American communities, two other well-known black establishments survived integration: Motown and historically black colleges and universities.

Integration also saw the opening up of entities (e.g., educational, physical, socioeconomic, and medical) once closed to African Americans. Black athletes are now free to participate in any sport of their choice. Although their numbers are increasing, African American athletes still face discrimination in the type of sports in which they participate as well as in the positions they typically assume within those sports. They are more often seen in revenue-producing sports, such as football and track, than in more privileged sports, such as horseback riding and swimming. Eighty percent of college-going African American women athletes participate in two sports: basketball and track. Stereotyped as being natural, physical athletes, African American athletes are often funneled toward positions that require quickness and jumping, while white athletes are given positions that involve decision making, such as quarterback and pitcher. This mindset carries into the sports management arena as well. Black athletes more often find themselves in the dependent position of player than in the power position of owner or manager. Few blacks include themselves among the ranks of professional team owners, and none of those maintain controlling interests in those professional clubs. Black athletes, particularly the women, also may not receive the same amount of endorsements and public engagement opportunities. Although integration has taken place, the extent and quality of that integration is still in question.

Disability and Sport

Participation in sports benefits all individuals of all abilities. Participants develop an improved level of physical fitness as well as an improved mood state, experiencing less depression and anxiety. Disabled individuals should also benefit from sports participation; however, society has not always permitted their participation. When people attempt to assimilate disability and sports, they have three general reactions. The first is that the two cannot be brought together—"disabled," to some, implies an inability to perform many of the skills required in sports. Another reaction is that sports for the disabled should be a separate entity from the able-bodied sports arena. The last is an integrated view—that everyone should be able to participate, although some game modifications may be required.

Disabled Americans quietly face discrimination daily. For wheelchair-bound and other impaired individuals it could be difficult, if not impossible, to access public buildings, rooms, and other structures and activities. This lack of access served to sequester them from public view and public life. The sports world for disabled Americans was often limited to rehabilitative efforts. One notable exception was the development of the Special Olympics, with the aid of Eunice Kennedy Shriver and the Kennedy Foundation. The Special Olympics promotes the physical health and activity of the cognitively disabled.

The treatment of disabled Americans changed with the Americans with Disabilities Act of 1990, which prohibits discrimination by or in public services, activities, or entities because of a disability. Since that time, disabled Americans are experiencing greater access to public areas. For example, crossing the street can be conducted without difficulty, as sloping sidewalks help aid the transition to ground level. Gently sloping ramps provide access to public buildings that are otherwise inaccessible. Even fitness clubs have increased their accessibility to disabled individuals; however, equipment in the clubs may not always be accessible. In athletics, the law helped increase the participation of disabled children and adults in more mainstream activities, occasionally in modified sports, such as football and softball, two of the most commonly modified sports. Athletes with disabilities now receive athletic scholarships to school. Curricula for physical education teachers now include discussion and understanding of adaptive methods in athletics. The number of physical education and fitness classes for disabled individuals in colleges and universities has increased as well. Even equality of rehabilitation, which was the founding principle of physical activity for the disabled, has improved. The Americans with Disabilities Act also improved public awareness, perception, and understanding of disabilities and the issues facing disabled individuals. The act also fostered the standardization of various fitness facilities and equipment, such as the height of ski lifts, to benefit all individuals. The Paralympics, a division of the International Olympic Committee founded in 2001, has provided the world with a view of the elite, disabled athlete. Although inroads have been made, challenges in sport for the disabled still exist, in equality in access, education, funding, and representation.

Age and Sport

Although no landmark legislation exists to bolster it, participation in athletics for those at the more extremes of the age spectrum is steadily increasing. Children and senior citizens are both participating in sports more than in past years.

Children and Sport

Throughout the years, children's athletics has revolved around the arena of "free play," during which children may run around and play tag or take part in other, more unstructured games with few developed rules. Over the past 30 years, participation of children in organized sports has increased. Unfortunately, the amount of "free play" activities (e.g., recess, tag) has seen a concomitant decrease during the same time.

Sports participation by children has many benefits. Organized play allows for the development of rules that can augment the safety of athletes. Children participating in athletic games also have the opportunity to interact with their peers, in addition to improving their motor skills. As they learn to operate within the rules of the game, they also begin to learn game strategy. An additional benefit of child sports participation is that the participants will have a head start on being the adult athletes of tomorrow.

As with many activities with benefits, organized sports participation has some caveats as well. With the decrease in unstructured activities has come a decrease in routine physical activity in schools (e.g., physical education and recess) and in the home, leading to obesity and its associated health and psychosocial outcomes. The American Academy of Pediatrics, in a combined policy statement from the Committee on Sports Medicine and Fitness and the Committee on School Health, recommends the following with regard to organized school sports: Organized sports should complement unstructured play time (e.g., recess at school) so as to promote and continue a habit of leisure physical activity, and organized sports should be developmentally appropriate, to avoid too early participation in some sports and discouragement and athletic injury. One method of making sports more in line with children's development is alteration of the sporting event, by a change in the structure of the game, the field, the number of players on the field, the equipment used, or the total amount of time played.

Seniors and Sport

It is becoming increasingly evident that reaching old age does not necessarily mean a person has to act and feel old. The days of "weak" and "feeble" elders are quickly waning. In fact, research is demonstrating that continuing physical fitness and activity throughout one's lifetime can help prevent or ameliorate many of the symptoms of "aging," such as decreased aerobic power, decreased muscle mass and strength, decreased tissue elasticity, and decreased bone density. With or without this knowledge, older adults in the United States have demonstrated increasing participation in athletic activities, either as new participants or as those continuing their participation over the years. Sports leagues are growing in number for older athletes, including amateur, professional, and regularly scheduled national competitions, such as the Senior Olympics of the National Senior Games Association.

Conclusion

Diversity in sports and athletics provides the opportunity to involve the entire community, regardless of gender, race, disability, or age. This integrated community involvement can help promote tolerance as well as cultural sharing. With the past history of sport integration and the current level of sport diversity, the sports arena has come a long way but still has a long way to go.

Doping and Performance Enhancement: A New Definition

A new definition of doping, in accordance with the World Anti-Doping Code of 2003, considers basically three facts: (1) the use of substances or methods able to artificially increment the performance of athletes, (2) that these substances will be harmful to the health of athletes, and (3) that it is against the spirit of the games.

Doping is contrary to the principles of the Olympics and sports medicine ethics. Doping is forbidden, as are recommending, proposing, authorizing, or facilitating the use of any substance or method included in this definition.

Types of Tests for Drugs

Urine and/or blood samples may be used for tests concerning drugs. Basically, according to the World Anti-Doping Code (WADA), there are two types of antidoping control to be done.

Controls In-Competition (IC)

The "in-competition" doping controls are done immediately after the end of a sports activity. In this type of control, the whole menu of substances and methods proposed by WADA in its "Forbidden List of Substances and Methods" is used.

Controls Out-of-Competition (OOC)

The "out-of-competition" controls could be done at any moment: during the training, in the house of the athlete, or even close to a competition.

The substances controlled in both kinds of tests are not the same. According to the Code, the out-of-competition tests include only anabolic agents, beta-2 agonists, agents with anti-estrogenic activity, diuretic and masking agents, and all banned methods. Stimulants, narcotics, and cannabis are not analyzed in this type of control.

List of Substances and Methods Banned by WADA

Every year, the prohibited list of WADA is revised by the List Committee and, after being ratified by the Health, Science and Medical Committee, it goes to the Executive Committee for approval. After that, the list is published on the Internet on October 1, and the prohibitions come into effect on January 1 of the coming year.

The list is used by all stakeholders, ensuring a real harmonization all over the sports world and the political world. The list opens with a sentence that mentions that "the use of any drug should be limited to medically justified indications" and begins by mentioning substances prohibited at all times.

To consult the current complete list with examples and explanations, please refer to the WADA site, http://www.wada-ama.org, under the head "Prohibited List."

Adverse analytical findings (AAFs) (for the year 2007) are that in non-Olympic sports, there is a 2.08% failure rate in doping tests, whereas in Olympic sports, that number is 1.93%. These numbers can be used to estimate the number of athletes using illegal substances. The total number of tests performed in non-Olympic sports (2.08) is greater than in Olympic sports (1.93), the average being 1.97%. This number can work well to estimate the number of athletes who use dope. The total number of doping control tests in the year 2007 was 293,898, which shows a clear increase in testing.

If we compare the findings of previous years, we find a percentage of increase from 1.62 in 2003 to 2.13 in 2005, but then a decrease to 1.96% in 2006. Perhaps this is a signal that the fight against doping is being won, particularly since education against doping is being emphasized for young people.

In 2007, WADA found that the most used doping substance was anabolic steroids (47.9%), followed by beta-2 agonists (16.4%), cannabinoids (11.9%), stimulants (8.2%), glucocorticosteroids (5.9%), and other substances (2.47%).

Among anabolic agents, the most prevalent substance to be found was testosterone (69.8%), followed by nandrolone (8.7%) and stanozolol (7.45%). Perhaps the athletes still believed that because testosterone is an endogenous hormone, the laboratories will find it difficult to detect.

Among stimulants, we see that amphetamines are still the most common (54%), followed by cocaine (13%) and ephedrine (6%). Cocaine is not used as a performance-enhancing drug because it is expensive, has a short action, and is easy to detect. It is mostly used as a social drug, although it is detected in the doping control.

The percentages of adverse findings among five sports were as follows: cycling, 3.91%; boxing, 3.16%; weight lifting, 3.02%; baseball, 2.69%; and basketball, 2.47%. Most of these are professional sports, and we can imagine projecting these findings onto the four big professional leagues in the United States, even if American football is not an Olympic sport.

As mentioned before, and must be always stressed, the AAF expressed in these results is *not* equal to an antidoping rule violation (ADRV). We must first exclude all the Therapeutic Use Exemptions (TUE) and provide the possibility of a fair and timely hearing for the athlete. But, no doubt, the AAFs are a very useful indicator.

Doping Control in Blood: A New Technology

Drawing blood samples to detect some doping substances or doping methods began in the Olympic Games of Sydney in 2000, and this method was very much in use in the Athens (2004) and Beijing (2008) Olympics.

It is possible to increase oxygen transportation and delivery to the tissues in the blood. In the first case, this includes blood transfusions, the use of hemoglobin substitutes, and an increase of red cells with erythropoietin (EPO). Blood transfusion is classified as autologous (the blood donor is the same person) and allogeneic (the blood donor is a different person). The technique of flow cytometry successfully identified mixed antigenic populations in patients who were transfused with at least 1 unit of homologous blood.

The most common use of hemoglobin substitutes in doping is the hemoglobin-based oxygen carriers (HBOCs). Genetically modified NESP (novel erythropoiesis–stimulating protein or darbepoietin alpha, another synthetic form of EPO) is strong and long-lasting. A blood test developed by scientists at the Australian Institute of Sport has been used during the last two Olympic Games and was instrumental in detecting the use of NESP by several cross-country skiers in Salt Lake City.

There is also the possibility of using the "natural" way to produce EPO by decreasing the tension of oxygen, which tends to simulate altitude and helps in altitude training. Direct and indirect methods can be applied to detect exogenous EPO. To increase oxygen delivery to the tissues, athletes are using allosteric modulators, natural or synthetic, such as Efaproxiral (RSR 13). Artificial substitutes for red blood cells may also be used as doping. They provide immediate oxygen delivery, and the compatibility is universal. The shelf life is much greater than for red cells. The raw material is bovine hemoglobin, and it is processed to remove infectious agents.

The correct technique of blood sampling is as follows: After notifying the athlete, have him or her relax for 10 minutes before undergoing a venous puncture by a phlebotomist. During this time, the digitally controlled oscillator (DCO) should provide an explanation of the sampling procedure. After selecting the kit and verifying its integrity, the numbers are verified and the labels placed on the tubes. The phlebotomist asks for the nondominant arm, places the tourniquet, and cleans the skin. After inserting the needle, the tourniquet is removed, as is the blood sample.

If the blood screen is for hematological parameters, only one sample of 3 milliliters (ml) of whole blood is analyzed. Therefore, the tube used should contain an anticoagulant. The contents should be gently mixed and sent to the laboratory.

For analysis of whole blood for evidence of prohibited substances and methods, such as blood transfusions, two blood samples are collected. The volume should be 3 ml per sample. The tubes again contain an anticoagulant. The contents should be gently mixed two or three times and sent to a laboratory. For analysis of serum for prohibited substances, two samples should be taken in tubes that have a silicon serum separator gel and a clotting activation factor. The tubes should be inverted gently five times to accelerate clotting. The samples should then be placed in the two specially adapted containers; the athlete finally seals them and completes the paperwork. In the Winter Olympics of Turin, a special Berlinger kit was designed by the Chief of Doping Control, and the waiting time for the athlete was much reduced in the process, because the blood sample was hermetically sealed before centrifugation.

Gene Doping: The Future Technology

The future of doping is considered by WADA to be gene doping. It has already been mentioned in the list of banned substances since 2000, and gene manipulation is defined by the agency as "the non-therapeutic use of cells, genes, genetic elements, or modulation of the gene expression, having the capacity to enhance athletic performance."

Since the mapping of the human genome, it is evident that it could be used, as common medications are, to try to increase the athlete's performance. The agency concerns were expressed by its chairman in a recent publication: "Gene doping may represent a new frontier in athletic performance enhancement, but we are working hard to ensure that these emerging medical techniques are not used to create super athletes."

Genetic potential was considered as one of the most important factors of performance in athletes, and until now this potential could not be altered. It is possible that genetic screening at an early age—that is, comparing the human genome and better conditions of genetic potential in each sport—will be used to select and train better athletes according to their abilities.

The use of viral factors to deliver a gene to the athlete is the most effective and also the most expensive method to be used, although compared with nonviral factors, viral factors have a higher toxicity and can produce an immune reaction that may sometimes cause rejection. The nonviral factors are effective only locally, and in consequence, they have fewer general effects. They are easy to prepare and have less risk of contamination.

Today, gene doping may be a reality in athletes. The production of the red cell through genetically modified erythropoietin, which may not be detectable by a urine test; muscle hypertrophy in healthy subjects using myostatin; and the production of new vessels that should be useful to increase oxygen transfer in the tissues of athletes are all possibilities.

It is possible to find in the literature three studies that clearly show this tendency. The Belgian Blue is a type of cattle known to have a bigger muscle mass than conventional cattle. On examining the expression pattern and sequence of the gene in normal and double-muscled cattle, a mutation within the myostatin gene was found. *Myostatin* is a negative regulator of muscle growth in cattle as well as mice.

Viral expression of insulin-like growth factor 1 (IGF-I) without resistance training produced a 14.8% increase in mass. Combined with training, this produced a 31.8% increase in muscle mass in mice. These results suggest that a combination of resistance training and overexpression of IGF-I could be an effective measure for attenuating the loss of training-induced adaptations.

Scientist from South Korea and the United States developed a Marathon Mouse, an engineered mouse that ran 1,800 meters (m) before quitting and stayed on the treadmill longer than the normal mice, which could run only 900 m. The genetically engineered animal has been given an enhanced protein that turns it into an "endurance athlete" and makes it resistant to weight gain.

Today, gene doping is still a question mark. Can it be stopped, or will the cells multiply, causing diseases and later death? Will the immunological risk be uncontrolled, and will it complicate the response of the body? Will cell mutations be transferred to the following generations? The medical, ethical, and legal implications will be evaluated by physicians and scientists dealing with such techniques.

The Science and Medical Committee of the WADA established a Gene Doping Panel in 2005, chaired by Professor Theodore Friedman, a pediatrician who is the director of the gene therapy program at the University of San Diego. He believes that this technology is evolving very rapidly, considering that the science involved is not very difficult and can be carried out by well-trained people in thousands of laboratories all over the world. Many scientists believed that already in the Beijing Olympics some degree of gene doping was possible.

Will it be possible to detect gene doping? In the opinion of many scientists, the answer is yes. If we revisit the story of doping, this same question was asked many times, and the answer was always yes. Anabolic steroids have been detected, including testosterone. Masking agencies and hormones have also been detected, as well as synthetic steroids.

The UNESCO Convention Against Doping in Sport

It is important to understand that WADA is a private entity that brings together the Olympic Movement and the governments of participating countries. Were WADA to have its legislation approved by the governments or to collect the proper fees from them, it would be a problem, because the countries will not accept norms or transfer funds to such an entity. To solve this problem, the General Conference of UNESCO approved a Convention Against Doping in Sport, which was subscribed by 30 members in December 2006. More than 196 countries have already ratified the convention, and this number is growing steadily. It defines the Accredited Doping Laboratories, the Anti-Doping Organizations, antidoping rules violation, and the terms *athlete, code, competition,* and *doping control,* as well as the criteria of *no advance notice, out-of-competition, in-competition, prohibited list,* and *therapeutic use exemption.*

During the first Conference of Parties to the International Convention Against Doping in Sport, a chairperson, four vice-chairs, and a speaker's position were established, and the Rules of Procedure were adopted. Other key items for discussion included administration of the Fund for the Elimination of Doping in Sport, building antidoping capacity around the world, and consideration of a monitoring framework in support of the convention. The Conference of Parties also adopted the 2009 Prohibited List.

Doping and Performance Enhancement: Historical Overview

The use of doping—that is, using drugs for performance enhancement in sports and otherwise—has a long history. The first document related to the use of doping agents was a painting of the Chinese emperor Shen-nung, in 2737 BCE, showing him using ephedrine in his tea. This emperor is considered to be the father of Chinese medicine and is believed to have introduced the art of acupuncture. He also classified the medicinal herbs according to their pharmacological effects.

In the ancient Olympic Games, at the end of the 3rd century BCE, the athletes believed that drinking herbal teas and eating mushroom could increase their performance during the competitions. In South America, stimulants—ranging from the virtually harmless maté tea and coffee to strychnine and cocaine—were used to increase performance. Spanish writers report the Inca Indian runners chewing coca leaves to help them cover the distance between Cuzco and Quito, in Ecuador.

In 1886, 10 years before the inauguration of the modern Olympic Games, the first fatality caused by doping was reported, when a cyclist named Linton died after an overdose of a stimulant in a race between Bordeaux and Paris.

Origin of the Word *Doping*

The origin of the term *doping* is controversial, but it seems to have come from a South African dialect. For the Boers, it means an infusion used in religious festivities—the "doop." And according to Burstin, during the construction of the North Channel in Amsterdam, workers used the term *doopen* when referring to increasing their capacity to work. In 1889, the term *doping* appeared in an English dictionary, meaning "a drug used to stimulate horses." From the horses in the hippodrome, the term soon began to be applied to people in the stadiums. The modern definition of *doping,* as used by the World Anti-Doping Agency (WADA) in 2000, is any substance or method that (a) is used to increase the performance of an athlete, (b) is harmful to the health of the athlete, or (c) is against the values of the game. When two of these three conditions are present, a substance or a method may be banned by inclusion in the "List of Forbidden Substances" of the WADA.

Doping in the First Olympic Games (1886–1932)

The modern Olympic Games were inaugurated by Baron Pierre de Coubertin in Athens in the year 1896. The philosophy of the Baron was that competing in the games was more important than winning them, and as a consequence of that, the incidence of doping was very low, restricted to some contamination in cycling and track-and-field events. The substances used to increase performance were cocaine, ephedrine, and strychnine, mixed together in a small pellet.

In 1928, during the Winter Games in St. Moritz, Switzerland, sports physicians from many countries decided to create the International Federation of Sports Medicine (FIMS) to protect the health of Olympic athletes and provide a forum to discuss their problems. The first international sports federation to ban the use of doping agents in sports was the International Association of Athletic Federations (IAAF), in 1928. Until 1932, the Olympic Games were held regularly, excluding the years of World War I.

In Germany, Hausschild developed pervitin in 1934, and in England, methedrine was synthesized—both being used for night flights, long marches, and other endurance events during World War II. Amphetamines were produced for the first time in 1938 and were also used as a strong stimulant during the period of the war.

The Olympic Games From 1936 to 1960

From 1936 to 1960, the Olympic Games were held regularly, excluding only the period of World War II. In 1936, the Berlin Olympic Games were used by Germany as a political instrument to promote the Aryan race. Thus, the ideals of Coubertin were shattered, as winning the games became much more important than simply competing in them. The substances most used after World War II were amphetamines and anabolic steroids, synthesized substances similar to the male hormone testosterone. Anabolic steroids were first used after World War II, when U.S. Army physicians were faced with the rehabilitation of the prisoners from Germany's concentration camps. Those physicians discovered that the male hormone was the only substance that could increase muscle mass.

In 1954, athletes started to use anabolic steroids to increase muscle mass and consequently to achieve more power. First introduced to weight lifting and bodybuilding athletes, this substance reached all track-and-field events and then other sports. In 1960, at the Olympic Games in Rome, a cyclist from Scandinavia died in the road competition after an overdose of a stimulant. The name of the athlete was Jensen, and he had used isopropylamine and amphetamine, ingested with coffee.

Because of bad press for the Olympic movement, Lord Porrit was appointed to create a Medical Commission in the Executive Committee of the International Olympic Committee (IOC). In the Tokyo Olympic Games, testing for drugs was done on cyclists during some competitions, but due to many difficulties, it could not be totally implemented. After that, Dr. Albert Dirix wrote a letter to Avery Brundage, president of the IOC, demanding strong action against doping in sport.

At the Congress of Moscow, in 1962, the IOC passed a resolution against doping. Lord Porrit became an honorary member, and the young Prince Alexander de Merode of Belgium was appointed to chair the Medical Commission and to fight against the use of doping agents in sports. The members of the Medical Commission held their first meeting in Lausanne, Switzerland, on September 27, 1967.

Doping controls directed by the IOC Medical Commission were in place for the Winter Olympic Games at Grenoble, France, and for the Summer Olympic Games at Mexico City in 1968.

The Olympic Games From 1968 to 1980

The IOC's first list of banned pharmacological classes was published in 1968, and it included the following substances:

- Psychomotor stimulant drugs
- Sympathomimetic amines
- Miscellaneous central nervous system stimulants
- Narcotic analgesics

Italy and Uruguay adopted antidoping legislation in 1971, and in the next year, anabolic steroids were added to this list just before the Montreal Olympic Games.

For the Montreal Olympic Games in 1976, the same list was maintained, and two beta-2 agonists were permitted: salbutamol and terbutaline. There was a caveat: The IOC Medical Commission was to be informed prior to their use, which was the origin of the Therapeutic Use Exemption (TUE). During this period, doping was found in all Olympic Games, except the Moscow Games in 1980. Many observers believe that in fact doping was a part of those games, but that because of the political climate at the time, the test results were not clinically analyzed.

The control of anabolic steroids in Montreal in 1976 is considered an important cornerstone of the fight against doping, because this substance had been widely used by athletes for more than 20 years.

The Olympic Games From 1984 to 2000

At the Olympic Games in Los Angeles, there were 11 positive cases, a high number. False medical certificates of hypertension were used in Los Angeles to justify the use of beta blockers. Diuretics were very much in evidence in sports where the category of the athlete is dictated by weight. Blood transfusions were used in cycling, and physical manipulation of urine was done in weight lifting. Once again, the IOC Medical Commission modified the list of banned pharmacological classes in 1987, now including beta blockers and diuretics. Restricted substances and forbidden methods of administration were also included in this list, to prevent the use of local anesthetics and corticosteroids, as well as blood transfusions and the physical manipulation of urine.

Probenecid was also detected in the Pan American Games of Caracas a year before the Los Angeles games, and it was included in the list as a pharmacological manipulation of urine. A system of escorts was also created by the IOC Medical Commission to accompany the athletes after their notification, in order to avoid physical manipulation of urine in the dressing rooms.

In the 1968 Summer Olympics Games at Seoul, it was believed that the athletes had learned their lesson and that only a few positive controls would be detected. Unfortunately, many cases were detected. After those games and after the discovery of erythropoietin (EPO) and human growth hormones (HGH) at the Winter Games of Calgary, the IOC Medical Commission banned peptide hormones. Anabolic steroids were changed to androgenic anabolic steroids, including beta-2 agonists. Since the use of anabolic steroids was often stopped 15 days before the games to avoid detection, out-of-competition doping control started after the Olympic Games in many international sports federations. This was also conducted by the IOC.

Doping at the Olympic Games in Barcelona, Spain, was not a major issue, and only five cases were detected, two of them after the use of clembuterol. The other cases were caused by strychnine, norephedrine, and mesocarb use. After those Games, there was a new change in the list of banned pharmacological classes and methods. The concept of "related substances" was changed to include not only the chemical structure but also pharmacological action. For this reason, a new class of anabolic agents was established, including the anabolic androgenic steroids and also the beta-2-agonists.

The pharmacological class of beta blockers was removed from the banned area and placed on the restricted list, but it was still banned in some sports, such as shooting, archery, pentathlon, equestrian, diving, and sailing. The most important decision after these games was to include the possibility of blood sampling of athletes, in conjunction with urine sampling, to permit better determination of blood transfusion and the use of hormones.

At the 100th anniversary of the Olympic Games, in Atlanta in 1996, there were two athletes detected using anabolic steroids. However, 10 athletes from Russia and Bulgaria tested positive because of Bromantan, a new stimulant amphetamine type of drug produced by the Russian army. These athletes, penalized by the IOC Medical Commission, were later on reinstated by the Tribunal Arbitral of Sports (TAS) because Bromantan was not on the list of banned substances. After Atlanta, Bromantan was added to the list before the next Winter Games.

For the Sydney Olympic Games, the banned list included three peptide hormones and one prohibited method, and the term *marijuana* was changed to *cannabis*. Blood samples were collected for those participating in aerobic sports, and these and urine samples were both collected after the opening of the Olympic Village but before the beginning of the competitions (see Table 1).

The Founding of WADA

In 1968, after the Tour de France, which had concomitant problems around doping, the International Olympic Committee called for an international congress, the result of which was the creation of

Table 1 Doping Tests Performed in the Olympic Games, 1978–2008

Games	*City*	*Number of Tests*	*Stimulants*	*Anabolic Steroids*	*Others*
1972	Munich	2,079	7		
1976	Montreal	1,896	3	8	
1978	Mexico	667	1		
1980	Moscow	1,645	0	0	
1984	Los Angeles	1,887	1	11	
1988	Seoul	1,998	2	3	4
1992	Barcelona	1,842	3	2	2
1996	Atlanta	1,795	0	2	0
2000	Sydney	2,052	1	3	4
2004	Athens	2,800	2	7	5

the World Anti-Doping Agency, or WADA. In 2003, the world antidoping code was established, with a complete list of banned substances and methods. Today, this agency works in the areas of medical science, education, and ethics. The Independent Observer Programs audit doping controls in world and regional competitions, and the Outreach Program is directed at athletes in major competitions.

Doping and Performance Enhancement: Olympic Games From 2004 to 2008

Doping and performance enhancement are much more severely regulated than ever before following the 2000 Olympics. The World Anti-Doping Agency (WADA) was established, and the International Olympic Committee (OIC) established a Disciplinary Committee to rule on the elimination of athletes who were found to have banned substances in their systems in the Winter Games at Salt Lake City, and at the Olympiad in Athens, a month-long "Olympic period" was established wherein doping controls were conducted on all athletes participating in the games inside and outside Greece. Out of 2,800 controls performed, 11 positives were discovered, predominantly in weight lifting.

After the games were completed, there were 14 positives. Three of these were refusals by the athletes to participate in the tests, one of them even a gold medalist! For the first time in history, human growth hormones were found in the blood of 380 athletes. All cases were judged by a Disciplinary Commission formed by three IOC members, with the final approval of the Executive Committee. The Medical Commission randomly supervised doping control and the medical care of the athletes.

The same system was maintained for the Turin Winter Games, in 2006. The IOC established an Olympic period, from the opening to the closing of all Olympic Villages. During this time, 616 urine samples and about 300 blood samples were collected from the athletes. Only one female athlete, from Belarus, from the biathlon team, had an adverse analytical finding (AAF) for stimulants. The laboratory in Turin worked under a temporary accreditation by WADA, assisted by 11 directors of accredited laboratories in the Games.

The Beijing Games were one of the best-organized Olympic Games, and the doping control was excellent. President Jacques Rogge called for an Olympic Games with zero tolerance in the area of doping, and a record number of tests were conducted, both before and during the competition. In the period from the opening of the Olympic Village until 2 days after the closing ceremony, the IOC performed 4,770 urine and blood tests. At this time, 15 violations were detected, including six horses being given forbidden substances.

After the Tour de France in the same year, the Laboratory of Doping Control in France was able to detect a new type of erythropoietin (EPO), a continuous erythropoiesis receptor activator (CERA). Because of that, the IOC asked for a review of the urine samples of Beijing athletes collected after January 1, 2009, in Lausanne. These results were publicized at the end of May 2009, and six other athletes were punished.

Dual-Energy X-Ray Absorptiometry (DEXA)

Dual-energy X-ray absorptiometry (DEXA) is an advanced form of X-ray technology used to assess the strength of the bones and their weight-bearing capacity by measuring the density of various minerals (such as calcium) in the bone. It is the most routinely done bone mineral density (BMD) test and is the most accurate in detecting loss in bone mass (osteoporosis).

Peripheral dual-energy X-ray absorptiometry (p-DEXA) is a type of DEXA test. It measures the density of bones in the arms or legs, such as the heel (calcaneus), shinbone (distal tibia), or kneecap (patella).

Relevance in Sports Medicine

In sports, a decrease in the bone density means increased risk of fractures due to the reduced ability of bones to bear stress as well as the frequent occurrence of trauma during athletic contests. DEXA scans can play a pivotal role in the early detection of osteoporosis, especially in women athletes, who are at higher risk. Determining a person's BMD can help detect if a person is at increased risk for an osteoporosis-related fracture. It can also be used to decide whether prescription medicine therapy is needed to help reduce the risk of such a fracture. It may help in deciding whether the bone loss is significant enough to reduce the workout plan for such athletes. Additionally, if a patient has a fracture or is planning to have orthopedic surgery, a diagnosis of osteoporosis might affect the surgical plan.

Mechanism

A DEXA scanner produces two low-dose X-ray beams, each with distinct energy peaks. These are passed through the lower spine and the hip as these are the most common regions to be fractured owing to osteoporosis. The soft tissues absorb one of the peaks, whereas the bone absorbs the other. The amount of X-rays of each beam that pass through the bone are sensed by a detector. Subtracting the soft tissue absorption and comparing the amount of the two beams records the BMD. The result depends on the thickness of the bone, since weak bones allow more of the X-rays to pass through them than do normal bones.

Procedure

During the central DEXA examination, the patient lies on a table with an X-ray generator below him, and an imaging device, or detector, is positioned above. The spine is assessed by supporting the patients' legs on a padded box to flatten the pelvis and lower (lumbar) spine. For the hip, the patient's foot is placed in a brace so that the hip is rotated inward. The detector passes over the regions and records the images. The procedure may take 15 to 20 minutes.

The p-DEXA machines are portable units and give results in a few minutes. During peripheral tests, the finger, hand, forearm, or foot is placed in a small device, and the bone density is recorded.

Lateral vertebral assessment (LVA) is a low-dose X-ray examination of the spine that is performed on the DEXA machine. It is an additional test to screen for vertebral fractures.

Analyzing Results

A DEXA scan result can be scored in two ways:

1. T *score:* This number compares the bone density with that of a young adult of the same gender having an optimal peak bone density. It is recorded as numbers of standard deviations below the average. It estimates the gradual bone loss and the increased risk of developing fractures.

   - *T* score of greater than –1: normal
   - *T* score of –1 to –2.5: osteopenia (low bone mass) and a risk for developing osteoporosis
   - *T* score of less than –2.5: osteoporosis (diagnostic)

2. Z *score:* This number compares results for people of the same age, size, weight, ethnicity, and gender. It assesses whether there are factors other than the normal wear and tear that are contributing to the bone loss. A *Z* score of less than –1.5 indicates factors such as thyroid abnormalities, malnutrition, medication interactions, alcoholism, and tobacco use. Further tests may be required.

Conditions Suggesting a DEXA Scan

All factors that predispose a person to the risk of bone loss suggest a DEXA scan. According to The National Osteoporosis Foundation's guidelines, women over 65, younger postmenopausal women having osteoporosis risk factors, as well as those with specific fractures should undergo a scan. Men who are affected due to advancing age or having any clinical condition causing bone loss should also proceed with a scan.

Other major conditions include the following:

- A fracture following a minor fall or injury
- A hip fracture in adult life or in maternal history

- Low body weight or thin stature
- A thyroid or parathyroid condition, such as hyperthyroidism or hyperparathyroidism
- A medication that causes bone loss, such as corticosteroids, various antiseizure drugs, certain barbiturates, high-dose thyroid replacement drugs, or oral contraceptives
- Type 1 diabetes, liver disease, kidney disease, or a family history of osteoporosis
- X-ray evidence of vertebral fracture or other signs of osteoporosis
- Early menopause (at age less than 45 years) or a history of amenorrhea for more than 1 year before menopause
- Other related disorders, such as rheumatoid arthritis or celiac disease
- Poor health, lifelong low calcium intake, or low physical activity
- Cigarette smoking, excessive alcohol intake, or caffeine consumption

Precautions

The following precautions must be taken before a DEXA scan:

- DEXA scans are not advised in pregnancy to prevent exposure of the fetus to radiation.
- Calcium supplements should be stopped for at least 24 hours before the test.
- A gap of 10 to 14 days is mandatory if another similar procedure, including X-rays with contrast media (e.g., barium enema, thyroid tests), has been performed.

Advantages of DEXA

DEXA has several advantages:

- DEXA scans are much more accurate than standard X-rays because X-rays show changes in bone density only after 20% to 40% of bone loss, whereas a DEXA scan can detect even a 1% change.
- Because they are low dose, less radiation exposure occurs (about 0.01 millisieverts [mSv]) with DEXA scans than with computed axial tomography (CAT) scans or X-rays.
- DEXA is less costly than other tests.

Current Medical Uses

DEXA can serve a variety of purposes:

- DEXA is the technique most often used to diagnose osteoporosis accurately.
- It is effective in estimating the effects of treatment for osteoporosis and other conditions that cause bone loss.
- The DEXA test can also assess an individual's risk for developing fractures.
- In children, DEXA scans are being used to determine bone development and the efficacy of treatment in conditions such as nutritional rickets, Turner syndrome, and so on.
- It may be used by pediatricians in diagnosing and monitoring the treatment of disorders of bone mass acquisition.

Dysmenorrhea

Dysmenorrhea is a syndrome that encompasses a cluster of unpleasant symptoms experienced during the onset of a woman's menstrual cycle. The defining symptom is lower abdominal and pelvic cramping. Many other symptoms can occur as well (see list below). Symptoms begin during the hours surrounding the start of menstrual flow and continue for 24 to 48 hours. Roughly 75% of adolescent women experience some degree of dysmenorrhea, making it the most common gynecologic complaint in this age-group.

The diagnosis can be further categorized into primary dysmenorrhea and secondary dysmenorrhea. In the primary form, no specific medical abnormality can explain the symptoms. Primary dysmenorrhea represents 90% of cases, is associated with a normal menstrual cycle, and is not associated with pelvic pathology. Symptoms usually begin 6 to 12 months after menarche, when menstrual cycles become regular and ovulatory. Secondary dysmenorrhea commonly appears 1 to 2 months after menarche or after age 25. Causes of secondary dysmenorrhea include endometriosis, anatomic reproductive tract abnormalities, surgical adhesions, pelvic inflammatory disease, uterine fibroids, or ovarian cysts.

Symptoms of Dysmenorrhea

- Pelvic and abdominal cramps
- Diarrhea
- Nausea
- Tachycardia
- Vomiting
- Facial blemishes
- Loss of appetite
- Flushing
- Headaches
- Sleeplessness
- Backaches
- Depression
- Leg aches
- Irritability
- Sweating
- Nervousness
- Weakness
- Dizziness

Dysmenorrhea and Exercise

Anecdotal claims assert that physical activity alleviates symptoms of dysmenorrhea. Lay magazines and websites often include these statements. A comprehensive review of the literature in 2008 showed no well-designed studies to prove these claims. Many studies cited had methodological flaws and contradictory results. Yet the belief remains popular. As exercise does not adversely affect symptoms or menstrual irregularities and exercise has numerous other physical and emotional benefits, patients should be encouraged to maintain their routine as tolerated. The dysmenorrheic athlete should be evaluated and treated similarly as a sedentary individual.

Etiology of Primary Dysmenorrhea

The physiologic etiology is generally attributed to the effects of prostaglandins, specifically $PG_{F2\alpha}$ and PG_E. These compounds are released during the second half of a woman's menstrual cycle as a result of falling hormone levels. They are linked to uterine contractions, decreased uterine blood flow, and increased sensitization of pain fibers. As the prostaglandins distribute through the systemic blood stream, they also affect other organ systems. Medical inhibition of prostaglandin synthesis leads to reduction of symptoms.

Behavioral factors can also influence the disease course. Stress can lead to worsening of symptoms. Cultural taboos surrounding the menstrual cycle can influence associated behaviors. Benefits of secondary gain (e.g., time off work) can also be considered. The incidence of dysmenorrhea increases significantly among relatives. Whether this is related to a genetic predisposition or learned behavior is not known.

Clinical Evaluation

A thorough history and physical examination are essential during the initial evaluation. The medical history should include age at menarche, menstrual cycle length and regularity, sexual and obstetric history, risk factors for sexually transmitted infections, and whether the patient had previously undergone abdominal or pelvic surgery. Additionally, family history and evidence of increased psychological stress are important keys to the underlying etiology.

The physical exam should include a brief evaluation of major organ systems and should focus on the abdomen and pelvis. By definition, the examination of a patient with primary dysmenorrhea will be normal. During the pelvic exam, attention should be paid to signs of secondary etiologies. A scarred external cervical os may indicate cervical stenosis. Inflammation and purulent discharge suggest infection, and appropriate cultures should be taken. Occasionally, the clinician may see tissue consistent with endometriosis in the vagina or on the cervix, which implies more extensive pelvic involvement. A bimanual exam may reveal reproductive tract abnormalities or abnormal pelvic masses.

Diagnostic Tests

Most cases of dysmenorrhea can be diagnosed and managed with a thorough history and physical examination. However, if abnormalities reveal themselves, additional testing may be necessary. Also, if a patient with presumed primary dysmenorrhea does not respond to medical management, she may benefit from further testing. Pelvic imaging with ultrasound is the initial step. Based on the results, referral to a specialist in gynecology may be indicated.

Treatment

Primary dysmenorrhea is easily managed in an outpatient clinic. Social, physiologic, and predisposing factors need to be addressed. Treatment of secondary dysmenorrhea depends on the underlying etiology and is beyond the scope of this entry.

Behavior modification can be explored if the initial history and physical exam suggest social triggers. Methods to decrease stress, including meditation and yoga, may be beneficial, particularly around the onset of menses. A conscious effort to decrease work and family-related demands during this time can also reduce the symptoms.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the usual first-line treatment. These medications inhibit prostaglandin synthesis, thereby decreasing pelvic and systemic symptoms. Clinical testing has not proven the superior efficacy of any one type or brand of NSAID. Ideal dosing begins 1 to 2 days prior to the onset of menses and continues for 3 to 4 days. Adequate pharmacological dosing is crucial; subtherapeutic dosing is often ineffective.

Patients whose symptoms respond only partially to NSAIDs can consider pharmacological contraceptive options for further relief. These medications act by decreasing endometrial growth over the course of the menstrual cycle. Less endometrial growth limits the production of prostaglandins. Options include oral, vaginal, or transcutaneous combination contraceptives or intramuscular, subdermal, or intrauterine progesterone contraceptives. Selection should be tailored to each patient, with close attention paid to the side effects of each type.

Nonpharmacological treatment can be very effective, and patients often successfully treat themselves with these modalities. Vitamin E inhibits prostaglandin synthesis by a different mechanism from that of NSAIDs and has shown positive effects. Dosage is 200 international units (IU) twice daily. Omega-3 fatty acids also aid in decreasing symptoms by decreasing the potency of uterine prostaglandins. Heating pads placed about the pelvis during symptom flares can also significantly decrease pain.

E

Ear Infection, Outer (Otitis Externa)

Otitis externa, also known as "swimmer's ear," is defined as an inflammation of the external ear canal. It is the most common medical (nonorthopedic) problem seen in athletes involved in aquatic sports. Otitis externa can be classified into five different types: acute diffuse, localized, chronic, eczematous, and malignant or necrotizing. By far, the most common is acute diffuse, on which this entry focuses.

Anatomy

For purposes of study, the ear is divided into three parts: (1) the outer or external ear, (2) the middle ear, and (3) the inner ear. The inner ear contains the organs of hearing (cochlea) and balance (vestibule and semicircular canals). The middle ear is the space between the tympanic membrane (eardrum) and cochlea and contains the three ear bones, or ossicles, that transmit sound vibrations from the tympanic membrane to the cochlea. The outer or external ear includes the pinna or auricle, the visible part of the ear; the auditory or external ear canal; and the outer surface of the tympanic membrane. The functions of the external ear are to direct sound to the tympanic membrane and to protect the middle and inner ears from injury. The external ear canal averages 2.5 cm in length and is lined with skin. The skin of the outer third overlies cartilage and contains hair follicles and glands that produce oil and cerumen (ear wax). The inner two thirds of the canal have bony walls with a thin, tightly adhered layer of skin with no hair or glands (Figure 1).

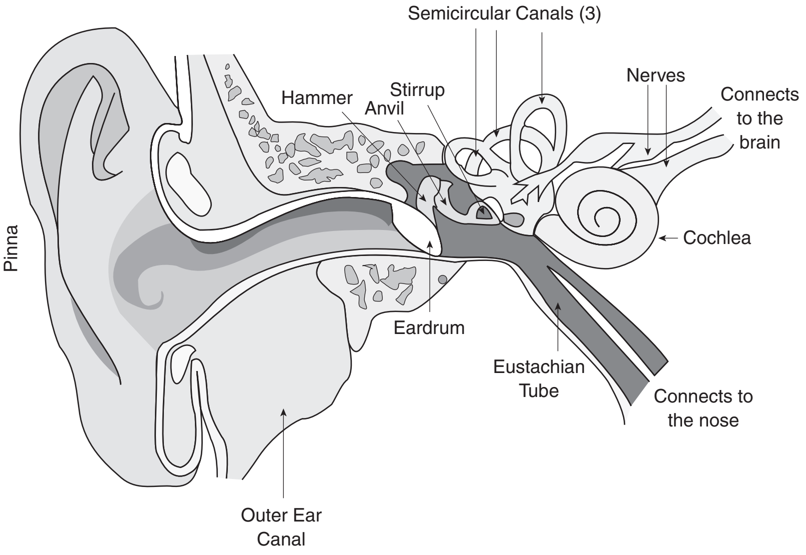

Figure 1 Anatomy of the Ear

Epidemiology

As mentioned above, acute otitis externa (AOE) is one of the most common medical problems seen in aquatic athletes, but it does not affect only athletes. The annual incidence is between 1 in 100 and 250, and 10% of all people will have a case of AOE in their lifetime. Approximately 7.5 million prescriptions are written annually in the United States for treatment of AOE. People living in warmer climates and those who have more water exposure are more likely to be affected.

Swimming in polluted or inadequately chlorinated water also increases the risk. A history of allergic rhinitis, asthma, or eczema increases the risk by three times.

Causes

AOE is believed to be caused by a number of different factors. *Cerumen* (ear wax) is thought to be important in maintaining a healthy environment in the external ear canal. Being slightly acidic, it helps inhibit infection. Its lipid nature also helps protect the skin of the canal from damage due to excess moisture. People who produce inadequate cerumen, thus, have an increased risk of AOE. If cerumen is removed by regular cleaning or excessive water exposure, then that important barrier is eliminated. This may cause the ear canal to itch. If the skin of the ear canal is then injured by attempts to scratch the canal with a cotton swab or other device, it provides a portal for bacteria to infect the skin. Other ways in which the lining of the canal can be injured include tools used to remove excess cerumen, irrigation, or hearing aids.

Another mechanism for infection is when there is too much cerumen production or if there is an underlying skin disease that causes increased sloughing of skin cells. The excessive debris can then trap water in the canal, resulting in skin maceration and creating an excellent culture medium for bacteria. A third means by which AOE can occur is as a result of purulent secretions from an acute otitis media (middle ear infection) in patients with a ruptured tympanic membrane or tympanostomy tubes.

While most cultures of patients with AOE show that the infection is caused by many bacteria simultaneously, the most commonly isolated bacteria are *Pseudomonas aeruginosa* (20%–60%) and *Staphylococcus aureus* (10%–70%). These organisms are present in most swimming pools, hot tubs, and natural bodies of water. Some studies have shown a correlation between water quality and risk of AOE, but even water that has been properly treated will still have these pathogens.

Symptoms

The first presenting symptom of AOE is often itching (pruritus). Then over the next 24 to 48 hours, the itching will progress to a gradually increasing otalgia (ear pain). This pain is often intense and may be disproportionate to findings on exam. Patients will also sometimes complain of pain worsened by chewing. Patients also often have a feeling of fullness in the ear, and some may develop drainage (otorrhea). The drainage is usually thin and clear to white, but it may become thicker and yellow or green without treatment. If the swelling or drainage is severe enough, the patient may develop hearing loss in the affected ear.

Diagnosis

Physical examination can usually help make the diagnosis of AOE straightforward. The classic finding is tenderness with pressure on the tragus (the small cartilaginous projection anterior to the external canal) and/or pulling on the pinna. Visualization of the external canal with an otoscope generally shows diffuse ear canal redness and swelling. Evidence of debris is also often seen. AOE can mimic otitis media (middle ear infection) as it can cause redness of the tympanic membrane, but pneumatic otoscopy or tympanometry will show normal tympanic membrane mobility in AOE, while mobility will be limited or absent in otitis media. Lymph node enlargement is often noted in the periauricular and cervical nodes. Fever is rare, but when it is present, it is generally low grade. If the temperature is >38.3 °C (101 °F), then other diagnoses should be considered.

Treatment

Treatment of AOE usually involves three facets: clearing of debris, topical medications, and pain control. For medications to be delivered to the infected tissue, it is essential to clear any excess debris from the external ear canal. Most authors recommend gentle lavage with body temperature water, saline, or hydrogen peroxide; some investigators believe that this alone may be therapeutic in many cases of AOE, but this has not been studied adequately. Others believe that lavage should only be done if the tympanic membrane can be fully visualized and determined to be intact, which is rarely possible due to the edema of the canal.

Other methods to clear debris include using a soft-tipped suction device or a cotton swab with the cotton fluffed out, under direct visualization with the otoscope.

Topical medications are then administered. Most medications are combinations of a low pH antiseptic, an antibiotic, and/or a corticosteroid. Examples of antiseptics include aluminum acetate, acetic acid, and boric acid. Common antibiotics include aminoglycosides (gentamicin, tobramycin, neomycin), quinolones (ciprofloxacin, ofloxacin), and polymyxin B. The most common corticosteroids are hydrocortisone and dexamethasone. There have been multiple studies comparing the efficacy of different medications, but most have shown little difference in outcome. One recent meta-analysis of these studies showed no difference in clinical outcomes when comparing antiseptic alone versus antibiotics, quinolone versus nonquinolone antibiotics, and steroid/antibiotic combinations versus antibiotics alone. However, studies have shown that adding topical steroids to the treatment regimen did result in quicker symptom resolution. The lack of difference in outcome suggests that the choice of which agent to use should be based on the patient's preference, cost, and ease of administration.

Systemic antibiotics, while prescribed in 20% to 40% of cases, are generally not recommended for multiple reasons. Most of the oral medications prescribed do not have efficacy against *P. aeruginosa* and *S. aureus*. Adverse effects are much more common with oral antibiotics than with topical preparations. Topical administration of antibiotics allows for concentrations 100 to 1,000 times that of systemic medications. Systemic antibiotics also have a higher risk for selecting out resistant organisms. Systemic antibiotics should be considered only if there is concomitant otitis media or if the patient is not responding to topical preparations.

For most patients, 3 to 4 drops of these medicines should be administered and held in the ear for 3 to 5 minutes. If the external canal is obstructed due to edema, ear wicks composed of cellulose or ribbon gauze can be used to make the administration of the medication more efficacious. If the tympanic membrane is perforated or a tympanostomy tube is present, ototoxic agents, which include the antiseptics and aminoglycosides, should be avoided; the quinolone agents have been approved by the Food and Drug Administration (FDA) for use in these patients.

Pain relief should also be a major goal in treatment of AOE. Mild to moderate pain can usually be controlled with over-the-counter acetaminophen, ibuprofen, or naproxen. More severe pain may require narcotic preparations. Topical anesthetic drops are generally not recommended as they can mask the progression of disease.

Ideally, the patient should avoid water sports for 7 to 10 days, but competitive swimmers are usually allowed to return in 2 to 3 days once pain and drainage are resolved. When they return, they should wear ear plugs and a tight-fitting swim cap to keep moisture out of the ear.

Most cases of AOE will show significant improvement in 48 to 72 hours. If there is no significant improvement by this time, the clinician should reexamine the patient, consider alternative diagnoses, perform aural cleaning, and consider changing medications.

Prevention

There are a number of recommendations to prevent AOE in aquatic athletes and patients who have a history of the disease. The most important method is to make sure to remove all water from the external canal after swimming. This can be accomplished by using a hair dryer on the lowest setting or by using drying and acidifying drops. There are several commercial products available, but many swimmers use a homemade 1:1 mixture of rubbing alcohol and white vinegar, the two main components of the commercial products. Tight-fitting swim caps are also recommended. Some authors recommend the use of ear plugs, while others believe that these can abrade the ear canal and may increase the risk of recurrence of AOE. Other recommendations include avoidance of trauma to the external canal from overaggressive cleaning with cotton swabs and avoiding swimming in polluted bodies of water and pools with inadequate chlorination.

Ear Injuries

Sports-related ear injuries are not uncommon and may affect the external, middle, or inner ear. Direct trauma to the auricle commonly occurs in wrestling and rugby and may result in the infamous "cauliflower ear." External ear infection is so common in swimmers that it has come to be referred to as "swimmer's ear." Middle ear injury may involve perforation of the eardrum, and inner ear barotrauma is often associated with diving. In this entry, we will review the evaluation and management of the most common sports-related ear injuries.

Auricular Hematoma

Auricular hematomas result from blunt trauma to the ear, most commonly in contact sports such as boxing, wrestling, and rugby. The skin overlying the anterior ear is thin and tightly adherent to the underlying cartilage, so it does not easily slide over the cartilage when direct force is applied. Instead, there is a shearing force between the perichondrium and the underlying cartilage, and the blood vessels supplying the cartilage are torn. Blood accumulates between the perichondrium and the cartilage, resulting in a hematoma. Complications of the hematoma may include necrosis and infection of the underlying cartilage because of loss of blood supply from the torn perichondrial vessels. Also, the subperichondrial hematoma actually stimulates new cartilage formation, leading to an asymmetric deformity often called "cauliflower ear."

Athletes with an auricular hematoma will present with painful swelling of the external ear and loss of ear landmarks. Timely evaluation by medical staff is important as those athletes who wait several days for treatment are at risk for significant fibrosis, which may require surgical debridement. The key components to treatment are (a) complete evacuation of the hematoma, (b) elimination of the perichondrial dead space, and (c) approximation of the overlying tissues.

The ear is initially anesthetized with 1% or 2% lidocaine and sterilely prepped. A curvilinear incision following the natural curve of the pinna is made using a blade along the entire length of the hematoma. The hematoma is then removed with gentle suctioning. Studies have shown that simple needle aspiration is not adequate in removing the clot. Following evacuation of the clot, the dead space is eliminated using a dental roll, button, or silicone splint, which is fit firmly over the area of the incision. The dental roll or button is sutured in place with through-and-through sutures, and antibiotic ointment is applied to the incision and suture sites. The athlete should return in 1 to 2 days to ensure adequate evacuation of the clot and then have the sutures removed in 7 to 10 days.

Otitis Externa

Otitis externa (OE) is an infection of the external ear canal. Heat, humidity, and water in the ear canal from swimming or bathing are associated with OE; they can cause irritation and breakdown of the protective barrier. Studies have shown that the incidence of OE is nearly 2.5 times greater in swimmers than in nonswimmers, thus leading to the common term *swimmer's ear*.

Early symptoms of OE may include pruritus, otalgia, erythema, and discharge from the ear. Pain may be worsened with manipulation of the auricle or direct pressure on the tragus. In more severe cases, the pain may be accompanied by edema, purulent discharge, and lymphadenopathy. If left untreated, it can progress to malignant (necrotizing) otitis, with concomitant temporal bone osteomyelitis. Examination may reveal a narrowed external canal due to edema, with erythema, debris, and purulent discharge. There is often erythema of the tympanic membrane (TM), which may lead to incorrect diagnosis of otitis media.

The most common causative organism is *Pseudomonas aeruginosa,* accounting for up to 50% of cases in some studies. *Staphylococcus aureus* is the next most common cause, followed by other aerobic and anaerobic bacteria such as *Escherichia coli,* streptococci, *Proteus,* and *Klebsiella.* Fungal causes account for less than 10% of cases but may be more common in patients with diabetes.

Treatment involves cleansing of the ear canal, pain control, and topical antimicrobials. Cleansing is accomplished with gentle irrigation and suction and may be followed by use of acetic acid or isopropyl alcohol to help dry the canal as tolerated. The first-line antimicrobial is usually a fluoroquinolone preparation used twice daily for 5 to 10 days. Most current preparations include a steroid such as hydrocortisone or dexamethasone, which has been shown in some studies to decrease the duration of symptoms by nearly a day. If the OE infection is refractory to topical treatment or becomes severe, a course of oral antibiotics may be warranted. One must also evaluate for fungal superinfection, which can be treated with topical clotrimazole or tolnaftate.

OE in swimmers may be prevented by using swim caps or ear plugs. The ear canal can also be dried by acetic acid or alcohol drops or by using a hair dryer after swimming or bathing. Irritation of the ear canal with cotton swabs should be avoided.

Exostosis

Auditory *exostoses* are bony outgrowths that result from chronic exposure to cold water, often seen in swimmers, surfers, or divers. They are from the temporal bone and protrude into the external canal. They are often found bilaterally, often with multiple bony growths in each ear canal. More severe disease is found in cold-water surfers and is correlated directly with frequency and time of water exposure. These bony growths may result in debris accumulation, pain, hearing loss, or recurrent ear infections since they block the ear canal and prevent its cleansing. Surgical excision is the treatment for those with severe disease. Prevention includes consistent use of earplugs and limiting the duration and frequency of exposure to cold water.

TM Perforation

Traumatic TM rupture may occur when an athlete hits the water with significant force (such as during water skiing) or is struck by a wave, as is commonly seen in surfers. In scuba diving, rupture can occur due to dysfunction of the eustachian tube, which leads to failure to equalize pressures. Patients with recurrent otitis media have an increased risk of traumatic rupture due to scarring of the TM.

The most common complaint is that of ear pain and conductive hearing loss, but patients may also have vertigo, tinnitus, or blood in the external ear canal. Treatment should include topical antibiotic drops to avoid infection. Patients should avoid getting water or any foreign material in their ear until the perforation heals. Most TM ruptures will heal spontaneously within 1 month, but patients should be observed closely to ensure that infection does not develop and unhealed perforations are referred to otolaryngology in a timely fashion.

Barotrauma

Inner ear *barotrauma* is an uncommon complication of diving that may lead to sudden sensorineuronal hearing loss and vertigo. It is caused by damage to the round or oval window by an inability to equalize pressures. Evaluation includes an otologic referral and high-resolution temporal bone CT scan. Treatment may involve diagnostic tympanotomy and sealing of the round and oval window membranes.

Eating Disorders

Disordered eating (DE) refers to a wide spectrum of maladaptive behaviors and attitudes about weight, body image, and food. At one end, it may be an unintentional caloric restriction, with fewer calories consumed than required for daily expenditure, thus leading to mild weight loss, slight hormonal disturbances, and a decline in sports performance. At the other end, DE may involve extreme body image delusion and life-threatening behaviors that meet the criteria for psychological diagnosis of an eating disorder such as anorexia nervosa or bulimia nervosa.

Types of Disordered Eating

Anorexia nervosa is defined as a serious life-threatening disorder characterized by deliberate self-starvation, as well as the following:

- Refusal to maintain body weight at or above a minimal normal weight for age and height
- Intense fear of gaining weight or becoming fat, even though underweight
- A disturbance in the way one's body weight/shape is experienced (self-evaluation, denial)
- Amenorrhea (absence of at least three consecutive periods)

Anorexia has two subtypes: (1) a restricting type and (2) a binge-eating/purging type.

Bulimia nervosa is a serious life-threatening disorder characterized by recurrent episodes of binge eating usually followed by self-induced vomiting or some form of purging as a means of controlling weight (e.g., vomiting, laxatives, diuretics, other medications, fasting, and excessive exercise). It also includes the following:

- There is a feeling of loss of control during a bingeing episode.
- The binge eating and inappropriate compensatory behaviors both occur on average two or more times a week for 3 months or longer.
- Self-evaluation is unduly influenced by body shape and weight.
- The bingeing/purging does not occur exclusively during periods of anorexia.

Bulimia is subdivided into purging type (i.e., use of vomiting, laxatives, diuretics, or enemas to rid the body of the consumed calories) and nonpurging type (i.e., use of other inappropriate compensatory behaviors such as fasting or excessive exercise).

Eating Disorder Not Otherwise Specified (EDNOS) is a term used in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV*) to encompass eating disorders that do not fall under the more strictly defined "anorexia" or "bulimia." EDNOS includes the following:

- All the criteria for anorexia are met, but the individual has regular menses.
- All the criteria for anorexia are met, but despite significant weight loss, current weight is within the normal range.
- All the criteria for bulimia are met but less frequently than twice a week for 3 months.

In addition, there are some "unofficial" terms that are sometimes used in the sports community:

Anorexia athletica: a subgroup of athletes with eating disorder symptoms that do not permit a diagnosis of anorexia nervosa or bulimia nervosa to be made and would therefore fall within EDNOS.

Orthorexia nervosa: individuals who take their concerns around eating "healthy" foods to dangerous and/or obsessive extremes.

Individuals at Risk for Developing Disordered Eating

While anyone is at risk, some populations have a higher risk of developing DE. These include women, female athletes, athletes in aesthetic and/or weight class sports, athletes started in sports-specific training early in life, those who have experienced transitions (e.g., a new coach, starting college) or traumatic events (e.g., a breakup, parents' divorce, a death in the family), and those who have felt pressure to reduce weight, improve sport performance, look better in uniform, or achieve a body type consistent with societal ideals.

Published prevalence rates of DE vary depending on how the information is collected, but up to 47%

of female high school athletes and 62% of female college athletes have been reported to have DE.

Athletes in particular are often susceptible to DE because of overconformity to the "sports ethic." The sports ethic emphasizes sacrifice for the game, seeking distinction, taking risks, and challenging limits. Although the sports ethic is meant to promote positive concepts, an athlete may strive so greatly that he or she transforms these positive norms into deviant behaviors to be successful. One example is the use of banned substances to get an edge. Another is extreme dietary habits and playing through unhealthy symptoms.

Health Risks of Disordered Eating

Eating disorders have both short- and long-term consequences for health. They include the following:

- Depression and anxiety
- Decreased coordination, balance, and muscle function
- Fluid/electrolyte imbalances
- Acid-base abnormalities
- Anemia
- Heart arrythmias
- Dental caries and esophageal tears in those who repeatedly vomit
- Delayed stomach emptying and constipation
- Osteoporosis and fractures
- Infertility
- Bad lifestyle habits that can lead to full-blown, life-threatening disorders
- Increased suicide attempts
- Six times the mortality rate in anorectics compared with the general population

Recognizing Disordered Eating

A variety of signs and symptoms may suggest DE. These include the following:

- Decreased concentration, energy, muscle function, coordination, and speed
- Increased fatigue and perceived exertion
- Longer recovery time needed after workouts, games, and races
- More frequent muscle strains, sprains, and/or fractures
- Slowed heart rate and low blood pressure
- Reduced body temperature and sensitivity to cold (i.e., cold hands and feet)
- Complaints of light-headedness and dizziness
- Complaints of abdominal pain
- Avoidance of water or excessive water intake
- Preoccupation with food
- Ritualistic eating and/or avoidance of certain foods
- Prolonged or additional training above and beyond that required for the sport (e.g., extra sit-ups and laps)
- Perfectionism
- Excessive concern with appearance
- Personality shifts (e.g., more withdrawn and isolated, acting excessively upbeat in an attempt to mask the problem)

Treatment

Treatment of those with eating disorders usually requires a multidisciplinary approach. This is important for parents, coaches, and patients to remember, as different disciplines bring different areas of expertise in helping an individual recover.

One common approach involves a physician, a nutritionist, and a mental health specialist (e.g., psychologist, psychiatrist). It is important to find out whether the patient can be managed effectively as an outpatient or requires hospitalization, medical supervision, nutrition education, and psychological support. Family members, friends, teammates, coaches, and others can help support the individual who is struggling and try to help keep him or her on track.

How to Get Help for a Person With Disordered Eating

Initially, the individual should be addressed in a private setting without peers around. Behaviors or changes that have become evident should be mentioned while focusing on concern for the individual. People are often resistant to admitting that they have an eating problem and to accepting help. But the earlier an intervention is made, the better the likelihood of a positive outcome. Providing information for the individual to gain some self-awareness is a good beginning. But having professional help early is vital, as most DE is about much more than food and weight.

Prevention Tips for Those Working With Athletes

With society's emphasis on appearance, and the focus of some sports on leanness and/or aesthetics, it is understandable that many athletes develop DE. There are some sports that have weight requirements (e.g., wrestling, lightweight rowing). But a transparent protocol should be developed to make the weigh-in procedures as stressfree as possible. These include preseason athlete assessment to determine if certain weight categories are realistic for an individual. This should be done by someone other than the coach (e.g., trainer, nutritionist). Weight goals should be presented early on, without changing target weight for athletes. Coaches should not provide unhealthy weight loss tips. Whether coaching weight-restricted or open-weight sports, coaches should minimize focus on appearance and weight and instead emphasize performance and health.

Elbow, Osteochondritis Dissecans of the

Osteochondritis dissecans (OCD) *of the elbow* is an acquired injury to the outer end of the humerus (arm bone) in the elbow joint. The part of the humerus most commonly injured is called the *capitellum*. The OCD lesion occurs in the bone directly underneath the cartilage of the capitellum and can be thought of as a stress fracture to a small area of the bone. After the injury, this area of the capitellum is not strong enough to support the cartilage over the top of it. If the injury progresses, eventually the cartilage over the top of the OCD can crack. OCD of the elbow is most commonly seen in gymnasts and baseball pitchers, who place high stress on their elbows during sports. Elbow OCD does not usually result from a single injury but is thought to be an overuse syndrome occurring from repetitive microtrauma to the capitellum.

Anatomy

The elbow joint is the space between the humerus and the two forearm bones: the radius and the ulna. The inner portion of the humerus and the ulna form a hinge joint at the inner aspect of the elbow (near the body). The outer portion of the humerus is called the *capitellum,* and it directly contacts the radius at the outer portion of the elbow joint (away from the body). The bone directly underneath the cartilage in the elbow is called the subchondral bone, and its purpose is to support the cartilage lying over it. It is the subchondral bone that initially gets injured in the OCD of the capitellum.

Causes

OCD of the elbow most commonly occurs in gymnasts and baseball pitchers in the capitellum portion of the humerus. Gymnasts use their arms as weight-bearing joints while doing handstands and handsprings. Because the elbow is shaped so that it is angled inward (points in toward the body with palms up and arms extended), the compression force of a handstand or handspring is concentrated on the outer aspect of the elbow joint. Repetitive microtrauma from thousands of handstands can cause a small stress fracture to develop in the subchondral bone of the capitellum. This is the first stage of elbow OCD.

For baseball pitchers, the pitching motion places tremendous stresses at the elbow joint. During a pitch, the inner aspect of the elbow (humerus-ulna part of the elbow joint) experiences a distraction force, while the outer aspect of the elbow (capitellum-radius portion of the elbow joint) experiences a compression force. Similar to a handspring, the pitching motion places a repetitive compression force across the capitellum. After thousands of baseball pitches, a pitcher can acquire a stress fracture in the subchondral portion of the capitellum. If pitching continues, the injured capitellum will eventually lose its blood supply and will no longer be able to support the cartilage over the top of it. Over time, this cartilage can crack and break loose.

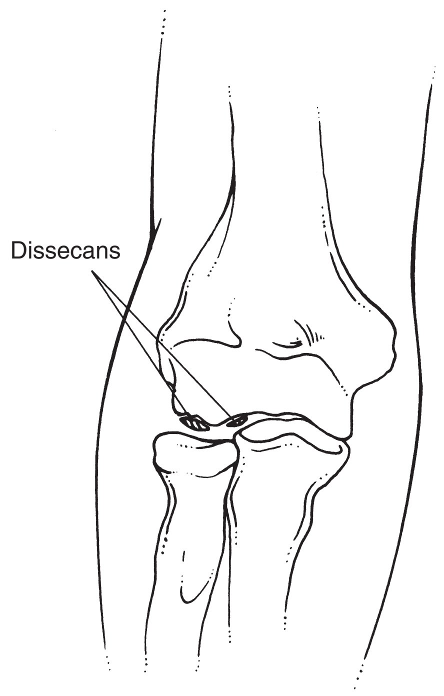

Figure 1 Osteochondritis Dissecans of the Elbow

Note: Loose or detached bodies in the elbow joint occur with powerful, repetitive motions that place stress on the joint, as in gymnasts and baseball pitchers.

Symptoms

OCD of the elbow occurs in gymnasts, baseball pitchers, and other overhead athletes aged 12 to 16 who present with aching elbow pain at the outer part of the elbow, which is worse with activity. If the cartilage over the OCD lesion is cracked and injured, the elbow will often swell. At this stage, the athlete is usually unable to fully extend the elbow. Mechanical symptoms such as catching or locking in the elbow may also be noted.

Diagnosis

A gymnast or baseball pitcher who presents with elbow pain with throwing or handstands may have an OCD of the elbow. On physical exam, the elbow joint is carefully inspected to look for signs of swelling. The outer aspect of the elbow is palpated for tenderness. The patient is asked to fully flex and extend the elbow, and the motion is compared with the other elbow.

On an X-ray, the OCD lesion can appear as an irregularity in the subchondral bone of the capitellum (see Figure 1). Since many OCD lesions of the elbow are not seen on an X-ray, a magnetic resonance imaging (MRI) scan is often obtained when the diagnosis is suspected. The MRI scan helps determine if the cartilage over the lesion is intact or cracked. If the cartilage is cracked, there will often be joint fluid underneath the lesion, which can be seen easily on the MRI scan. An MRI scan may also be useful in identifying any loose bodies (broken-off pieces of cartilage) in the elbow that may not be seen on an X-ray.

Like OCD of the knee and ankle, OCD of the elbow is also classified as "stable" or "unstable." Stable lesions involve only the subchondral bone; the overlying cartilage is not broken. In unstable lesions, the overlying cartilage is cracked. Making this determination is important because stable lesions tend to heal well with rest and activity restriction. Unstable lesions do not heal as well and if left untreated can completely break off, forming a "loose body."

Treatment

As with OCD in other joints, the most important factors involved in planning treatment are the age of the patient and the stability of the lesion. In general, most stable lesions in younger children who are still growing heal without surgery. For partially unstable lesions in growing children or for stable lesions in patients who are already grown, a short period of nonsurgical management is often attempted. However, if the OCD lesion does not heal after 3 to 6 months, then surgery is recommended. Unstable OCD lesions and most lesions in patients who have finished growing are treated with surgery.

Nonsurgical Treatment

The most important principle for nonsurgical treatment of elbow OCD is to stop the repetitive activities that are causing pain. For baseball pitchers, this means no throwing. For gymnasts, this implies no weight-bearing activities on the arms. Bracing or immobilization of the elbow may be necessary for a short period of time if the pain is significant. Compliance with these measures is often difficult in high-level athletes.

Activity restrictions are continued for at least 3 months. During this time, the physician may obtain serial X-rays to check for healing of the lesion. After 3 months, activities are gradually increased, with a planned return to pitching (for baseball players) or handstands (for gymnasts) at approximately 6 months after the diagnosis. Full healing of the lesion can often take anywhere from 3 to 12 months.

Surgery

Surgery is recommended for unstable OCD lesions and for lesions that do not heal after an appropriate period of nonsurgical management. Surgical intervention commonly involves elbow arthroscopy, although sometimes a larger incision may be necessary. During arthroscopy, the surgeon will directly look at and feel the cartilage over the top of the lesion on the capitellum. Depending on the appearance and feel of the cartilage over the lesion, the surgeon will decide how to proceed.

In some cases, the cartilage over the lesion will appear normal (with no cracks) but will feel like a softened mass. In these cases, the surgeon may drill tiny holes through the cartilage and across the OCD lesion. This technique is called *transarticular drilling*. The idea is to stimulate the underlying subchondral bone to bleed, which will allow it to heal. If the lesion is very large or if the cartilage is partially cracked, the surgeon may also perform internal fixation. In these cases, metal or bioabsorbable screws or bone pegs are placed across the lesion to provide stability and compression.

In some cases, the cartilage will be completely destroyed over the lesion or would have broken off to form a loose body. In these cases, the surgeon will often just remove the cartilage. The underlying subchondral bone will then be exposed. The surgeon may then elect to perform a *microfracture procedure,* in which a tiny pick is used to create small holes in the subchondral bone. These holes will bleed, and a blood clot will eventually form over the OCD lesion. Over time, the blood clot can repair the lesion with a fibrous form of cartilage. Newer cartilage transplantation techniques are often reserved for patients who have already had the microfracture procedure done but still have pain.

After Surgery

After surgery, the patient may initially be placed in an elbow brace to limit movement. Elbow motion is slowly increased over time. Physical therapy is often initiated to help the patient regain elbow motion and strength. The patient is not allowed to resume sports activities until the lesion is felt to have healed. This can take anywhere from 3 to 12 months. Return to overhead sports is difficult for some athletes following this procedure. Baseball pitchers may need to switch positions to be able to compete without pain. Some gymnasts are unable to return to their previous level of play after this injury.

Elbow and Forearm Injuries

Injuries to the elbow and forearm can result from acute trauma as well as overuse. Acute traumatic injuries, such as fractures and dislocations, usually result from a fall on an outstretched hand/arm (FOOSH). In children, forearm fractures account for greater than 50% of all fractures in the pediatric age-group. Acute injuries can occur in any sport where falls on the outstretched hand are common, including basketball, football, soccer, and track-and-field events.

Overuse injuries of the elbow and forearm are common in sports that use the upper extremities and require repetitive training, such as weight lifting, golf, tennis, and gymnastics. These injuries are also seen commonly in throwing sports, such as baseball and softball.

Anatomy

The radius and ulna are the bones in the forearm, with articulations proximally and distally. The elbow joint comprises the articulations between the radius, ulna, and humerus. The distal humerus has two main articulating surfaces, namely the *capitellum,* which articulates with the radial head, and the *trochlea,* which articulates with the coronoid and olecranon of the ulna. The elbow joint has three articulations: (1) the proximal radioulnar joint, (2) the radiocapitellar joint, and (3) the ulnohumeral joint. The radioulnar and radiocapitellar joints allow supination and pronation of the forearm, with the radius pivoting around the ulna. The ulnohumeral joint allows flexion and extension of the elbow. Stability of the elbow is provided by the bony hinge below 20° and greater than 120° of flexion. Between 20° and 120° of flexion, the ligaments and capsule are the main stabilizers of the elbow (Figure 1).

The elbow develops from multiple ossification (new bone formation) centers, which makes the elbows of children and adolescents vulnerable to injuries such as fractures and apophyseal injuries. The growth plates at the ossification centers are susceptible to traction or shearing forces. The ossification centers follow a predictable order of formation, allowing for determination of bony maturity, based on their radiographic appearances. The order of appearance is as follows: Capitellum (age 1–2 years),

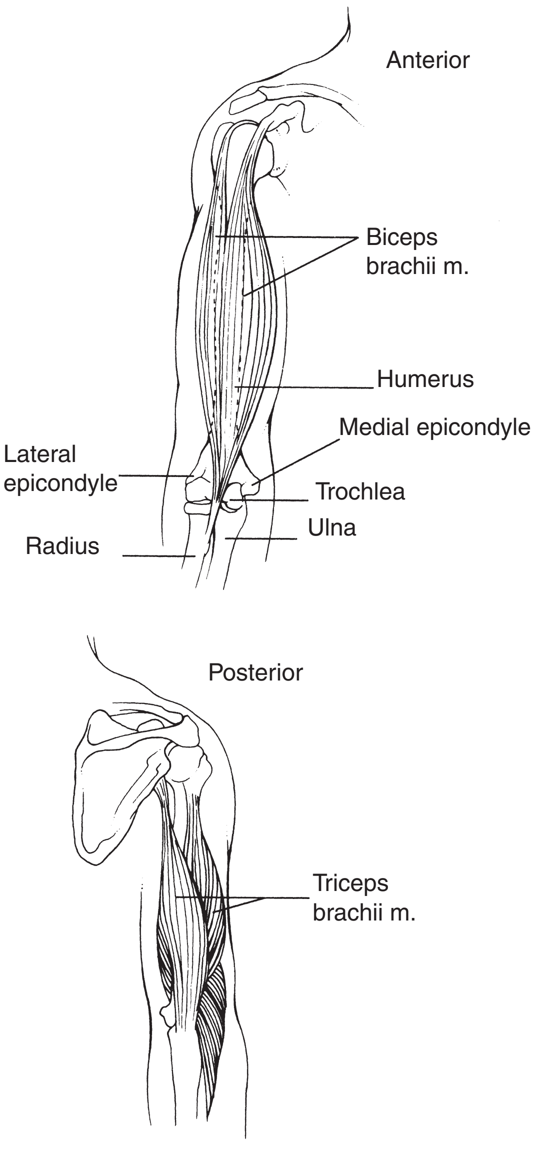

Figure 1 Anatomy of the Elbow

*R*adial head (age 3 years), *I*nternal (medial) epicondyle (age 5 years), *T*rochlea (age 7 years), *O*lecranon (age 9 years), and the *E*xternal (lateral) epicondyle (age 10 years in girls and 11 years in boys) (mnemonic "CRITOE"). Most (80%) of the growth of the humerus occurs proximally, so there is less remodeling potential at the elbow when fractures occur there.

There are three ligaments composing the ulnar collateral ligament (UCL) complex on the medial aspect of the elbow: anterior oblique, posterior oblique, and transverse. The anterior oblique ligament is divided into anterior and posterior bands. The anterior band of the anterior oblique ligament provides most of the stability of the elbow. It is most prone to injury from acute or repetitive valgus strain.

The lateral collateral ligament (LCL) complex on the radial aspect of the elbow comprises four ligaments: (1) the radial collateral ligament (RCL), (2) the lateral ulnar collateral ligament (LUCL), (3) the accessory lateral collateral ligament (ALCL), and (4) the annular ligament (AL), which wraps around the radial head. The LCL complex functions to stabilize the elbow against varus and external rotatory stress. The LUCL helps control posterolateral rotatory motion in the elbow. Rotatory instability in the elbow is caused by injuries to the LCL at the humeral insertion, primarily of the LUCL and RCL.

The biceps, brachialis, brachioradialis, and triceps muscles compress the elbow joint and provide stability. The lateral elbow is stabilized by the extensor and the supinator muscles. The common extensor muscle group, which inserts on the lateral epicondyle, consists of the extensor carpi radialis brevis, the extensor digitorum, the extensor digiti minimi, the extensor carpi ulnaris extensor pollicis, and the supinator. The deep extensors of the forearm originate from the ulna and the radius and include the supinator, the abductor pollicis longus, the extensor pollicis longus and brevis, and the extensor indicis. The medial elbow is stabilized to a small degree by the flexor-pronator muscle group. The common flexor muscle group consists of the pronator teres, the flexor carpi radialis, the palmaris longus, and the flexor carpi ulnaris. The deep flexors of the forearm include the flexor digitorum superficialis and profundus, the flexor pollicis longus, and the pronator quadratus.

Three main nerves supply the elbow and forearm: the ulnar, median, and radial nerves. The ulnar nerve has a superficial course, passing behind the medial epicondyle and lying over the UCL and anteriorly to the medial triceps muscle. The ulnar nerve is fairly mobile, which allows it to slip out of the cubital tunnel in some people. Because of its superficial course, the ulnar nerve is the most commonly injured neurological structure in sports. The median nerve courses under the ligament of Struthers in the medial arm alongside the brachial artery, into the antecubital fossa medial to the biceps muscle, and under the pronator teres and bicipital aponeurosis. The radial nerve travels from the posterolateral arm at the level of the distal third of the humerus toward the anterior aspect of the elbow. The radial nerve divides into the superficial radial nerve and the deep branch, the posterior interosseous nerve, which supplies the extensor muscles of the forearm. The posterior interosseous nerve runs close to the radial neck and under the supinator, passing the arcade of Frohse, where it can be compressed.

Evaluation of Injuries

Details of Injury

Important details to obtain from an athlete with an elbow or forearm injury include the patient's age, the dominant hand, the sport and position played, and which arm is injured. Additional details should include the duration of symptoms and what the actual complaint is, whether it is pain, instability, or lack of function. Throwing athletes may complain that they are unable to throw the ball as far or as accurately as before injury. Athletes in sports such as volleyball or tennis may complain that they are unable to hit the ball as hard. The presence of mechanical symptoms such as catching or locking may suggest an injury to the joint, such as osteochondritis dissecans (OCD), a bony injury, or a loose body. The presence and distribution of neurological symptoms such as weakness or paresthesias may suggest an injury to the neck, brachial plexus, or peripheral nerves.

Determining the mechanism of injury is very important to help narrow the type of injury. Acute traumatic injuries, such as a fall on an outstretched hand, result in different injuries from those with a more gradual onset resulting from repetitive overuse. Obtaining details regarding alleviating and aggravating factors/activities can also help narrow the differential diagnosis. Elbow instability usually occurs with hard throwing or with activities involving weight bearing on the arms, such as gymnastic maneuvers or push-ups. For throwing athletes, additional details to note include the style of throwing, the types of throws/pitches, the volume of pitches/throws, the velocity and accuracy of throws, and any training errors, as well as which phase of throwing produces symptoms. Pain that occurs during cocking and late acceleration is consistent with ulnar-sided injury resulting from valgus stress to the elbow. Symptoms that occur during deceleration and follow-through suggest posterior impingement and stress injuries. Localizing the symptoms can help focus on the most probable diagnosis. For instance, posterior elbow pain usually occurs during hyperextension.

Physical Findings

With injuries to the elbow or forearm, there may be swelling, bruising, or deformity of the arm. The athlete may be unwilling to move the arm and may hold the arm in various positions to minimize pain. For instance, an injured athlete may hold his or her arm straight and not want to bend it. A *joint effusion* (fluid in the joint) may result in loss of the indentations next to the olecranon.

The point of maximal tenderness to palpation of the elbow and forearm can help localize the injured structure. Bony tenderness usually indicates a fracture or other bony injury. Tenderness of muscles may indicate a muscle injury or muscle spasm.

The elbow can move in the following directions: flexion, extension, and forearm supination and pronation. Flexion should be from 0° to 145° ± 10°, pronation at about 80°, and supination at about 85°. Injuries may result in decreased range of motion of the elbow and forearm. Decreased extension is suggestive of a chronic flexion contracture or an injury to the joint. The wrist can be flexed and extended. Range of motion of the wrist can also be decreased with injuries to the elbow and forearm.

There are a number of special stress tests that can assess the functional integrity of the UCL (medial aspect) in an athlete with an injured elbow. These tests include the valgus stress test, the milking maneuver, and the moving valgus stress test. The valgus stress test should be performed with the elbow flexed to 30°. The patient's hand and wrist are fixed between the examiner's arm and body, and a valgus stress is applied to the elbow. The milking maneuver is performed with the elbow flexed to 70°. The examiner supports the patient's elbow with one hand and applies a valgus force to the elbow by tractioning the patient's thumb, similar to milking a cow. By placing the elbow in this position, the valgus throwing position is re-created, keeping the shoulder externally rotated, which reduces the effect of shoulder rotation on UCL assessment. The moving valgus stress test is performed with the shoulder abducted to 90°. The examiner applies a valgus (toward the midline) stress to the elbow as the shoulder is fully externally rotated. The examiner maintains the valgus force while quickly extending the elbow to about 30°, similar to the acceleration phase of throwing. A positive test reproduces pain at the UCL. The pain usually occurs maximally between 120° and 70° of flexion as the elbow is extended.

Certain injuries to the elbow can result in instability of the elbow. Varus laxity (instability of the lateral elbow) is very uncommon. Varus stress testing is performed by applying a varus (away from midline) force to the lateral elbow while flexing the elbow to 30° with the forearm in full pronation. A positive test reproduces pain or laxity in the lateral elbow. Posterolateral (behind) instability of the elbow can be assessed with the lateral pivot shift apprehension test. The pivot shift test is performed with the patient lying supine. The injured arm is placed overhead with the elbow in supination while the examiner applies a valgus and axial force to the elbow. A positive test causes pain or a sense of apprehension. With the elbow in extension, the elbow is then flexed, noting any reduction "clunk," which usually occurs between 40° and 70° of flexion. A reduction clunk indicates posterolateral instability, as the radial head moves backward when the elbow rotates around the axis of the UCL.

The valgus extension overload test evaluates potential impingement of the elbow. The test is performed by placing the athlete's arm quickly in maximal extension with the forearm pronated. While the elbow is hyperextended, a valgus force is applied. Pain caused by this maneuver is consistent with posterior impingement of the olecranon in the olecranon fossa.

Tendinopathies can be identified with resisted muscle testing. Resisted forearm supination, wrist extension, or third-digit extension with the elbow in full extension causing pain over the lateral epicondyle may indicate an injury to the common extensor tendon. Symptoms of lateral epicondylosis can also be reproduced with passive palmarflexion while the elbow is extended. Symptoms of common flexor tendinopathy may be reproduced by resisted wrist palmarflexion or pronation and passive wrist dorsiflexion/extension with the elbow extended. Grip strength is another resisted muscle test to assess pain.

Injuries to the neck or shoulder may cause elbow or forearm pain. In athletes with elbow and forearm injuries, the neck, bilateral shoulders, elbows, and wrists should be assessed to rule out other injuries. There may be decreased muscle strength and possibly neurological abnormalities, such as numbness or tingling. Other factors may contribute to elbow or forearm injuries, such as poor core trunk stability, weakness of the leg muscles, weak shoulder muscles, and poor shoulder and scapular movement.

Investigations

X-rays of the elbow and forearm should be obtained in instances of acute trauma where fractures are suspected. Standard views include anterior-posterior (AP), lateral, and oblique. Some fractures may not be obvious on X-rays (occult). A posterior fat pad sign may indicate an occult joint fracture in children with otherwise normal X-rays. In chronic elbow pain, X-rays may indicate OCD, arthritis, or calcification in the muscle (myositis ossificans).

A computed tomography (CT) scan can give more bony definition and can indicate occult fractures. A bone scan can indicate stress fractures of the olecranon or medial apophysis. Bone scanning can also help determine bony activity and assess the healing potential of OCD. Magnetic resonance imaging (MRI) is the gold standard for soft tissue injuries, although ultrasound can be useful as well. MRI is being used more frequently for identifying stress fractures and occult fractures without radiation. A magnetic resonance (MR) arthrogram can diagnose complete and partial tears of the UCL.

Prevention of Injury

Types of injuries that can be seen in the elbow are shown in Table 1. Table 2 indicates the types of

Table 1 Elbow Injuries

Lateral Elbow	*Medial Elbow*	*Posterior Elbow*
Extensor tendinopathy	Flexor/pronator tendinopathy	Olecranon bursitis
Referred pain (cervical spine, upper thoracic spine)	Ulnar collateral ligament sprain	Triceps tendonitis
Synovitis of radiohumeral joint	Ulnar nerve compression	Posterior impingement
Radiohumeral bursitis	Avulsion fracture of the medial epicondyle (adolescents)	Dislocation
Posterior interosseous nerve entrapment (radial tunnel syndrome)	Medial apophysitis (adolescents)	Supracondylar fractures (children)
Osteochondritis dissecans (capitellum, radius)		Olecranon fracture
Panner disease		Olecranon stress fracture
Radial head fracture		Posterolateral rotator instability

Table 2 Forearm Injuries

Fractures of radius and ulna
Dislocations Monteggia injury (fractured ulna with dislocated radial head at elbow joint) Galeazzi injury (fractured radius with dislocated ulnar head at wrist joint)
Stress fractures
Forearm compartment pressure syndrome

forearm injuries. Prevention of elbow injuries can be achieved by learning the proper technique for a given sport. In throwing sports, athletes should be taught to use the kinetic chain and employ the power of the lower extremities to help add power to their throws. By taking a stride with the leg, athletes can transfer the power of the lower body to the arm. Athletes need to keep the elbow up when throwing to avoid losing power in their throws and to avoid having to "use more arm" to improve speed.

Modification of training risk factors, such as the type and volume of activity, can help prevent injuries, particularly in growing athletes. The amount of training should be gradually increased, in frequency, intensity, and duration, to avoid overuse injuries. The rules of the sport should be enforced by referees and coaches to avoid reckless play and dangerous training practices. In gymnastics, injuries can be minimized by using thicker mats, having spotters next to equipment to help prevent falls, and teaching athletes proper falling techniques.

In younger athletes, particular restrictions can help prevent injuries. For instance, in young baseball pitchers, pitches should be limited to less than 80 pitches per game, participation in one sport should be limited to no more than 8 months of competition per year, and breaking pitches should not be started until after 13 years of age. Adequate rest and recovery—at least 3 days between games—should be allowed to avoid fatigue and overuse injuries.

Preparticipation physicals can identify any muscle imbalances or previous injuries that may not have been fully rehabilitated. Targeted interventions can help resolve these issues. A proper strength-and-conditioning program for athletes participating in sports requiring use of the arms should include exercises to stretch the shoulder and elbow and strengthening of the rotator cuff and periscapular stabilizing muscles. Lower body and core strengthening is also important to prevent injuries to the elbow and forearm.

Return to Sports

In general, following an elbow or forearm injury, an athlete should have full, pain-free range of motion before returning to sports. Return to sports should be gradual, with progressive increase in activity.

Depending on the type of injury, a variable amount of time off from sports is required. If surgery is required, athletes may be off for up to a year. Some athletes may not be able to return to their sport after surgery. In athletes with OCD, ideally radiographic healing should be evident prior to return to sports, although this is not always possible. Athletes, especially overhead athletes, should be completely asymptomatic with all activities before returning to play. After traumatic injuries, such as fractures, there should be radiographic evidence of healing and return of full strength before returning to sports. After traumatic dislocations, most athletes will not resume upper extremity training for at least 3 months. For soft tissue injuries, such as tendinopathies, a period of rest allowing symptoms to resolve is indicated in addition to therapy. Activity can be resumed when symptoms improve.

Elbow and Forearm Injuries, Surgery for

The elbow and forearm are particularly important in throwing and overhead sports such as baseball, softball, and tennis. Occasionally, due to overuse or a traumatic injury, athletes may experience forearm or elbow pain, which prevents them from sports participation. Many of these injuries resolve after being treated conservatively with rest and rehabilitation. However, certain injuries require surgery to enable the athlete to return to his or her sport painfree. The goal of surgery in the elbow and forearm is to help athletes return to the level of sport that they were at prior to their injury. Surgery on the elbow and forearm is never done for the sole purpose of improving athletic performance; instead, surgery focuses on restoring the native anatomy and relieving pain.

Anatomy

The elbow joint is the space between the humerus and the two forearm bones: the radius and the ulna. The inner portion of the humerus and the ulna form a hinge joint at the inner aspect of the elbow (near the body). The outer portion of the humerus is called the *capitellum,* and it directly contacts the radius at the outer portion of the elbow joint (away from the body). Ligaments help support the elbow, connecting the humerus to the ulna and radius. The *ulnar collateral ligament* is a major elbow ligament that is located on the inner aspect of the elbow joint (near the body). The ulnar collateral ligament can be injured in pitchers and throwing athletes and may need to be surgically reconstructed if it does not heal on its own.

Muscles run from the humerus to the radius and ulna and to the bones of the hand. These muscles help flex, extend, and rotate the forearm and wrist. Occasionally, the muscle attachment on the outside of the elbow (away from the body) becomes irritated and inflamed. This condition is common in tennis players and is known as *lateral epicondylitis*, or "tennis elbow." Sometimes the muscles of the forearm swell in size while the athlete is exercising. This swelling can cause an increase in the fluid pressure inside the muscle compartment and cause pain and limitation of activities. This condition is called *forearm exertional compartment syndrome* and rarely may require surgery to release the tight covering of the muscles called the forearm fascia.

"Tommy John" Surgery

"Tommy John" surgery involves reconstruction of the ulnar collateral ligament of the elbow. This surgery got its name because it was initially performed in 1974 by Dr. Frank Jobe on a major league pitcher named Tommy John. After he underwent the surgery, Tommy John was able to pitch in more than 150 major league baseball games.

Ulnar collateral ligament tears usually occur in baseball pitchers, but they can also occur in tennis players, football quarterbacks, and javelin throwers. The ulnar collateral ligament is located on the medial epicondyle or inside the elbow and is the most important ligament in providing elbow stability during throwing. When the ulnar collateral ligament is injured, the athlete experiences pain on the inside of the elbow and often is unable to pitch or throw at high velocities.

Ulnar collateral ligament reconstruction surgery is performed through an incision on the inside part of the elbow. The old ulnar collateral ligament has poor healing potential and is replaced with a new transplanted ligament. The new transplanted ligament is usually obtained from the athlete's forearm, thigh, or foot (using a tendon that is not necessary for normal function). This tendon is transplanted over the old ulnar collateral ligament by looping it through holes in the bone of the humerus and the ulna. After surgery, the elbow is placed in an elbow brace, and the athlete begins the long process of rehabilitation. At approximately 1 year after surgery, the athlete may be able to return to pitching or throwing. Today, there are many major league pitchers who have pitched successfully after undergoing this procedure.

Elbow Arthroscopy

As with other joints, arthroscopic surgery can be performed on the elbow. Elbow arthroscopy is often done on baseball pitchers to remove loose pieces of cartilage called "loose bodies" in the elbow. It involves making portals (small holes) on the outside and inside part of the elbow, which connect into the elbow joint. A small camera is placed through a portal and is used to look inside the elbow joint. The anatomy of the elbow is evaluated, and if needed, small instruments can be placed in the elbow using a different portal. These instruments can be used for many purposes, such as to smooth bone spurs, to remove loose pieces of cartilage, or to loosen a tight, contracted elbow joint. Elbow arthroscopy often gives athletes relief from their elbow pain and may help improve range of motion in the elbow.

A condition called *osteochondritis dissecans* occurs in the elbow in gymnasts and baseball pitchers. Osteochondritis dissecans is similar to a stress fracture and affects a small area of cartilage of the elbow and the bone underneath it. With the help of elbow arthroscopy, the surgeon can treat osteochondritis dissecans without needing to make a large incision. This helps protect against infection and may also help athletes maintain range of motion in their elbow after surgery. The surgeon can use elbow arthroscopy to identify the osteochondritis dissecans lesion and either remove the injured cartilage or drill holes in the lesion to stimulate a healing response.

Biceps Tears

Biceps tears occur near the elbow joint and may occur in weight lifters and contact athletes. When the biceps is torn, the athlete loses elbow flexion strength and supination strength (the ability to rotate the forearm in the same direction, as when opening a doorknob). Biceps tears are often treated with surgical repair by making one or two incisions near the elbow crease to help the surgeon find the torn biceps and join it back to the radius bone, where it normally attaches. If the biceps tear is repaired quickly after it is injured, the athlete has a better chance to regain strength and elbow motion. At about 6 months after surgical repair, the athlete is able to resume normal activities.

Lateral Epicondylitis (Tennis Elbow)

Tennis elbow is a condition seen not just in tennis players but in all types of athletes. The condition is caused by inflammation in the wrist extensor muscles where they attach to the humerus. Pain occurs in the outside part of the elbow joint. Athletes often have pain with activities requiring extension of their wrist, such as a backhand stroke in tennis. Nonsurgical treatment most commonly results in significant improvement of tennis elbow. This includes rest, counterforce bracing, and physical therapy directed at stretching and strengthening the wrist extensor muscles. Counterforce bracing involves placing a strap on the arm just below the lateral epicondyle of the elbow. This strap takes the tension off the area on the outside of the humerus where the wrist extensor tendons attach to the lateral epicondyle.

In some cases, tennis elbow pain does not improve even with all the above treatment modalities. If pain persists, the athlete may elect to undergo surgical treatment. Some surgeons are able to relieve this condition by using elbow arthroscopy to debride (clean) the injured or abnormal wrist extensor muscle mass. More commonly, other surgeons will make a small incision in the area of the lateral elbow and remove a very small part of the abnormal muscle tissue while rubbing the elbow bone to cause bleeding and stimulate healing and formation of new tissue in this area. The athletes are usually able to return to sports 2 to 3 months following surgery, after a period of physical therapy designed to increase strength and range of motion in the elbow.

Forearm Exertional Compartment Syndrome

Forearm exertional compartment syndrome is rare but does occur in motorcross athletes and weight lifters. The motorcross athlete experiences extreme pain and fullness in the forearms when grasping the grips on the handlebars of the motorcycle. If it is severe enough, the athlete may begin to experience weakness, numbness, and tingling while riding. In these cases, surgery may be necessary to improve the condition.

To diagnose this condition, the pressure must be checked inside the forearm muscle compartment of the athlete. The sports medicine physician places a special pressure gauge needle in the athlete's forearm muscles both before and after the athlete exercises to determine if the pressure becomes significantly elevated after exercise. If exercise causes a large increase in the pressure inside the forearm muscles, then surgery is considered. During surgery, the pressure in the forearm muscle is decompressed by making an incision on the forearm and releasing the fascia or covering over the forearm muscles. This creates more room for the muscles to expand, leading to decreased pressure on the muscles following activity. When this pressure is decreased, the athlete no longer experiences discomfort and can usually return to normal activities in about 6 weeks.

Elbow Bursitis

A *bursa* is a small, fluid-filled sac, similar to a slippery water balloon, located at places in the body that are subject to excessive friction. When a bursa becomes inflamed or irritated, it responds with more fluid, resulting in pain due to increased pressure on the surrounding tissue.

Anatomy

The olecranon bursa resides at the elbow joint between the skin and the olecranon process of the ulna. Its function is to reduce friction between the skin and the olecranon process when the elbow is placed through a range of motion, mainly during flexion.

History

The most common complaint of a patient with olecranon bursitis is swelling or fullness of the bursae. Sometimes patients will complain of pain and warmth, but mainly they will have some tightness with flexion of the elbow. If there is significant pain and it is accompanied by redness and warmth, the bursa could also be infected. Often the bursa gets inflamed from a trauma, perhaps from landing on the elbow during sports or from external impact such as being tackled in a contact sport. It may also occur from leaning on the elbows on a hard surface for an extended period of time. Patients rarely have accompanying fevers.

Physical Exam

The examiner will find fullness/swelling overlying the olecranon. The area may be red and hot as well. One must take care to look for breaks in the skin or other signs of possible infectious sources. Red streaking on the skin may signify an overlying cellulitis.

Treatment

Treatment commonly involves minimizing the stress and forces to the area and the application of compression and ice. If there is concern about infection, the area should be sterilely prepared and the fluid aspirated, which should then be sent to the laboratory for cultures and sensitivities. Antibiotics should be started. If there are no signs of infection, the bursae can often be left alone.

Aspiration and injection of a corticosteroid to the bursae is another option, but it may be a little aggressive for this relatively benign process. If the patient is having severe pain, then an aspiration and injection may be warranted. Corticosteroids should never be injected into a bursa that is potentially infected. The risk of infection is higher for this superficial bursa than for other bursae. In the case of a severely infected bursa that does not improve quickly, the patient may need surgical intervention for a washout of the infection.

Conclusion

Patients with olecranon bursitis may always have a little residual swelling overlying the olecranon process thereafter. Often they may feel little nodules within the bursae as well. The risk of reinjury is increased, so care must be taken to avoid resting the elbows on hard surfaces or a repetition of the traumatic injury.

Elbow Dislocations

In children, the elbow is the most common dislocated major joint, whereas in adults, the elbow is the second most common, after the shoulder. Dislocations represent about 10% to 25% of all elbow injuries. Like other upper extremity injuries, elbow dislocations can occur from direct trauma, a FOOSH (fall on an outstretched hand) injury, or a strong directional or levering force on the elbow. Elbow dislocations typically occur in children older than 13 years, after the physes around the elbow are closed. Before this age, the physes are open and are the weakest point in the elbow. Therefore, traumatic forces tend to cause Salter Harris fractures rather than dislocations in young children. However, it is not uncommon to sustain a combined elbow fracture and dislocation. The highest incidence of elbow dislocations occurs in the under-20 age-group, and the majority are associated with sports activity.

Anatomy

The elbow is one of the most complex joints in the body, consisting of three articulations: ulnotrochlear, radiocapitellar, and proximal radioulnar. Elbow flexion/extension occurs mainly at the ulnohumeral and radiocapitellar articulation, whereas forearm pronation/supination involves the radiocapitellar and proximal radioulnar articulation. Normal range of motion (ROM) of the elbow is approximately 150° of flexion to 0° of extension, 90° of forearm pronation, and 90° of forearm supination. The elbow provides attachment sites for various muscle groups and ligaments. The primary stabilizers of the elbow are the ulnotrochlear articulation, the medial collateral ligament (MCL), and the lateral collateral ligament (LCL). The radial head and surrounding muscle bundles make up the secondary stabilizers of the elbow. The elbow joint is extremely congruent and stable due to the specific pattern in which each bone contacts and conforms to other structures within the elbow. Due to the configuration of these interactions, elbow fractures and/or dislocations need to be treated to near-anatomic alignment; otherwise, there can be a high complication rate. Complications include loss of ROM, structural instability, nerve palsies, and muscular weakness.

Clinical Evaluation

Elbow dislocations on physical examination may have an obvious deformity, diffuse joint pain and swelling, decreased or painful ROM, and crepitus. The normal anatomic triangle that is formed by the radial head, lateral epicondyle, and distal lateral tip of the olecranon process is disrupted with elbow dislocations. Any athlete who sustains trauma to the upper extremity and presents with any of those signs or symptoms should be evaluated for the possibility of an elbow fracture or dislocation. With such injuries, the examining physician must also assess the entire upper extremity for associated injuries. The force from a FOOSH injury can be transmitted from the hand up to the clavicle.

Several major nerves and vessels that traverse the elbow can be damaged or tethered. The radial nerve courses over the lateral epicondyle and radial head. Radial nerve function can be tested with middle-finger extension and sensation over the dorsal aspect of the thumb. The ulnar nerve sits within the ulnar groove between the medial epicondyle and olecranon and can be tested with finger abduction/adduction and sensation over the little finger. The median nerve courses over the anteromedial aspect of the distal humerus and elbow joint. Decreased sensation at the tips of the index or middle finger and/or decreased pinch strength with the thumb and index finger can indicate a median nerve injury. The brachial artery can also be injured as it travels with the median nerve across the elbow, after which it branches into the radial and ulnar arteries. Angiography may be needed if distal pulses are absent or diminished compared with the contralateral limb. Vascular injuries and forearm compartment syndrome are rare but have devastating consequences if missed. Any patient with neurovascular compromise should prompt more urgent intervention and reduction or be transferred to a facility capable of providing such treatment.

Various muscle groups insert on or originate from different sites on the elbow. If there is a concomitant elbow fracture and dislocation, the muscle groups can pull the bones or segments of fractured bones in different planes, causing displacement, shortening, and/or angulation. Such deformities will make elbow relocations more difficult.

Radiographs

Standard anteroposterior and lateral views of the elbow should be sufficient to diagnose most elbow dislocations. Remember the principle to radiograph the bone above and below the injured joint (i.e., image the arm and forearm bones if there is an elbow injury). Computed tomography with three-dimensional reconstructions can be helpful in assessing for intraarticular fragments and the congruity of the articular surfaces. Approximately 10% to 20% of elbow dislocations have an associated fracture. Typical fractures associated with elbow dislocations are radial head, olecranon, medial/lateral epicondylar, and coronoid process fractures. Elbow dislocations, specifically dislocation of the ulnohumeral joint, are described based on the position of the olecranon with regard to the humerus (posterior, anterior, lateral, and/or medial). The posterolateral elbow dislocation is the most common. It is rare to have a divergent dislocation, where the radius and ulna are separated from one another and the humerus.

Reduction Techniques

Prompt joint reduction is necessary with elbow dislocations and should not be delayed if there is neurovascular compromise. If orthopedic consultation is not available, examining physicians, if they feel comfortable, can attempt the reduction maneuvers given below or arrange for immediate transfer for orthopedic evaluation. In cases of complicated elbow fracture/dislocation, it is sometimes better to reduce and repair these injuries in the operating room.

Before any elbow reduction, the examiner should provide adequate pain relief with a local joint infiltration with an anesthetic. In the emergency room setting, intravenous or intramuscular sedative agents can be used adjunctively.

There are several elbow reduction techniques described in the literature, with the most common method being the traction-countertraction method. With this method, the patient is placed supine and the elbow slightly extended to 30° to 60°. Gentle longitudinal traction is placed on the wrist and/or forearm along the axis of the ulna while an assistant places countertraction on the upper arm. This helps disengage the dislocated articulation. Simultaneously, manual pressure and bony manipulation are used to correct any displacement of the olecranon seen on radiographs. Medial and lateral displacement of the olecranon should be realigned first with gentle forearm supination and pronation. For posterior dislocations, a posterior-directed force is placed on the distal humerus, while a downward and anterior-directed force is placed on the proximal forearm and olecranon. For anterior dislocations, a posterior-directed force is placed on the distal humerus along with a downward pressure applied to the proximal forearm. If these methods fail, the patient can be placed prone with the elbow hanging off the side of the examining table and the distal humerus resting against the table on a towel. A 5- to 10-pound weight can be hung from the wrist for several minutes to help fatigue the muscles. The steps above can be repeated. A noticeable clunk may be felt when the joint is relocated. If the elbow cannot be relocated, there may be an interposed bony fragment or soft tissue entrapment blocking reduction. These injuries may need further imaging (computed tomography), or the patient may need to be taken to the operating room for reduction.

After reducing the elbow, the examiner should evaluate for any joint instability and perform another thorough neurovascular exam. Joint stability can be tested with gentle elbow flexion/extension, forearm pronation/supination, and gentle varus and valgus stress testing with the elbow at approximately 300° of flexion. Check for any mechanical blocks or redislocations. Indications for surgical repair include any bony or soft tissue entrapment, any large associated fractures, or any instability after reduction.

Postreduction Care

For simple dislocations without any evidence of fracture or instability, patients can be treated with an arm sling for comfort, or a well-padded extension block splint can be used. The elbow is placed at 60° to 90° of elbow flexion with the forearm in neutral position in the splint. The patient should be given anticipatory guidance regarding the signs and symptoms of forearm compartment syndrome. Urgent orthopedic referral is indicated for any elbow that remains unstable, has re-dislocated, or has entrapment of either fractured fragments or soft tissue within the joint. Follow-up evaluation and repeat radiographs should take place at 1 week, and early, simple ROM exercises should be started at that time to prevent elbow stiffness. Prolonged immobilization can adversely affect outcome and time to recovery. Typical recovery period ranges from 3 to 6 months. Long-term complications may include stiffness, recurrent pain, arthritis, myositis ossificans, recurrent instability, ligament damage, contractures, or nerve injury.

Elbow Fracture

An *elbow fracture* is an injury to bone (humerus, radius, or ulna) usually caused by a fall on an outstretched hand (FOOSH) resulting in enough impact to break the cortex. Elbow fractures occur commonly in contact sports and constitute 10% of all fractures in children. Other mechanisms of injury include direct trauma or a strong directional force on the elbow. Any athlete who sustains trauma to the upper extremity should have a thorough evaluation of the elbow for the possibility of an elbow fracture or dislocation (see the entry Elbow Dislocations), as well as a thorough examination of the entire upper extremity for any associated injuries.

Anatomy and Clinical Evaluation

The elbow is one of the most complex joints in the body, consisting of three articulations: ulnotrochlear, radiocapitellar, and proximal radioulnar. The elbow is extremely congruent and stable due to the specific pattern in which the bones contact and conform to each other. Due to this configuration, anatomic alignment must be restored to decrease or minimize functional disabilities resulting from the injury. Common complications include decreased range of motion (ROM), structural instability, arthritis, nerve palsies, weakness, and heterotopic ossification.

Physical examination includes inspection for swelling or deformities. The anatomic triangle formed by the radial head, lateral epicondyle, and olecranon can be disrupted or swollen, indicating the presence of a joint effusion and intra-articular pathology. Normal ROM is elbow flexion/extension 0° to 150° and forearm pronation and supination 90° in each direction. A complete neurovascular examination must be performed because associated neurovascular injuries can occur.

It is helpful to categorize and evaluate elbow injuries by compartments. The *posterior compartment* involves the olecranon, triceps, and borders of the ulnar groove; the *medial compartment* contains the medial epicondyle, ulnar aspect of the olecranon, flexor muscle bundle, and ulnar nerve; the *lateral compartment* houses the radial head, lateral epicondyle, extensor muscle bundle, and radial nerve; and the *anterior compartment* includes the biceps, brachial artery, and median nerve. Focal bony tenderness, such as that over the radial head, might uncover subtle fractures.

Radiographs

Standard anteroposterior and lateral views of the elbow should be sufficient to diagnose most elbow fractures. Comparison views are particularly helpful in evaluating the pediatric elbow for fractures due to the presence of six primary ossification centers, which develop between 2 and 14 years of age. Computed tomography may identify intra-articular fragments and assess the congruity of the articular surfaces when internal fixation is being considered.

Certain radiographic signs can suggest the presence of an elbow fracture. The lateral radiograph is helpful to evaluate for a hemarthrosis (bleeding into the joint space) and bony alignment. The anterior fat pad "sail sign" or the presence of a posterior fat pad results from a hemarthrosis and suggests the presence of a fracture or other intra-articular pathology. Extra-articular fractures may not displace these fat pads, whereas joint infections and inflammatory processes may elevate these fat pads and mimic fractures. If the anterior humeral line and the radiocapitellar line do not cross the capitellum appropriately, then a fracture with displacement is suspected.

Radial Head and Neck Fractures

Radial head and neck fractures are the most common elbow fractures in adults. The radial head is palpated distal to the lateral epicondyle and radiocapitellar articulation. Forearm pronation and supination while an examining finger is placed over this region can help expose the radial head, examine its motion, and assess for focal tenderness. A radiocapitellar view is an oblique elbow radiograph with the forearm in neutral position and beam aimed 45° cephalad. This image can define the extent of the fracture (Figure 1).

Fractures that are nondisplaced, nondepressed, and without a mechanical block can be treated

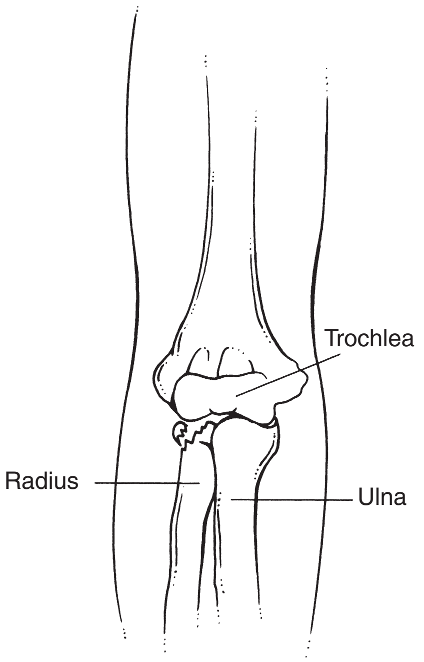

Figure 1 Fracture of the Radial Head of the Humerus

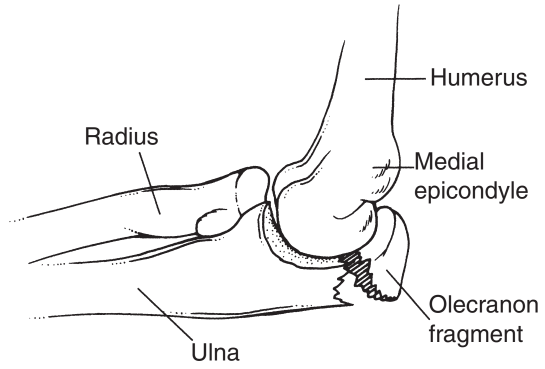

Figure 2 Olecranon Fracture

Note: A fall on the arm or elbow may cause a break across the point of the elbow (olecranon).

acutely with a long-arm posterior splint with the elbow in 90° of flexion and the forearm in neutral position, followed by early ROM exercises. Initial follow-up and repeat radiographs should occur within 1 week. Emergent orthopedic consultation is indicated for fractures with a mechanical block (clicking, catching, or locking), >2 millimeters (mm) of displacement, >10° of angulation, >30% of articular surface involvement, or comminution.

In skeletally immature children, the region is mainly composed of cartilage, so radial head fractures make up a small percentage of pediatric elbow fractures. Fractures that involve the growth plate (Salter-Harris classification) completely can cause a radial head translocation. Fractures with <4 mm of translocation or <30° angulation can be treated conservatively as above, and more displaced fractures can be referred to a pediatric orthopedist.

Olecranon Fractures

Olecranon fractures typically occur from direct trauma to the point of the elbow. Olecranon process and physeal (Salter-Harris classification) fractures are rare in children. The amount of displacement on radiographs is measured with the elbow in both a gently flexed (near 90°) and an extended position, as tolerated. Any comminution, >2 mm of displacement, any changes in displacement on flexed and extended radiographs, and anyone unable to actively extend the elbow (loss of triceps function) should be referred to an orthopedist.

A long-arm posterior splint with the elbow in approximately 60° of flexion can be used initially. The elbow should not be flexed past 90° because the pull of the triceps on the olecranon can cause further displacement (Figure 2). Nondisplaced fractures should have follow-up examination within 1 week.

Distal Humerus Fractures

Fractures in the distal humerus are categorized based on the level of the fracture in relation to the condyles.

Supracondylar/Transcondylar Fractures

Supracondylar fractures are the most common elbow fracture in children and are most common between the ages of 5 and 10 years. *Transcondylar* fractures break through at the level of the condyles and occur more frequently in elderly patients. Both fracture types have similar management plans. Any fractures that are displaced or with >20° angulation should be referred to orthopedics. Experienced providers can manage nondisplaced fractures with a long-arm posterior splint with the elbow in neutral position. Follow-up evaluation and repeat radiographs should take place in 2 to 3 days.

Intercondylar Fractures

Intercondylar fractures occur between the condyles and have intraarticular extension. These are the most common type of elbow fractures in adults. Intercondylar fractures should be referred for evaluation by an orthopedic surgeon.

Condylar Fractures

Condylar fractures occur through the condyles. Lateral condyle fractures are more common than medial. All condylar fractures should be referred to an orthopedic surgeon.

Epicondylar Fractures

The distal humeral epicondyles serve as attachment sites for the forearm flexor (medial epicondyle) and extensor muscle groups (lateral epicondyle). In adults, it is rare to have an isolated epicondylar fracture. In children, medial epicondylar fractures are the third most common elbow fracture, behind supracondylar and lateral condylar fractures. Minimally displaced fractures can be treated nonoperatively with splinting, as described for condylar fractures. Indications for orthopedic referral include >5 mm of displacement, nerve palsy, tissue entrapment, or varus/valgus instability of the elbow.

Fractures of the Coronoid/Capitellum/Trochlea

Isolated fractures of the coronoid process, capitellum, and trochlea are rare. Fractures of these structures typically occur with other injuries, such as an elbow dislocation. They are difficult to detect as the fragments can be small. These injuries should be referred to an orthopedic surgeon.

Follow-Up and Return To Sports

At the initial follow-up, if the fracture is stable on radiographs and there are no signs of instability or neurovascular compromise, a long-arm cast is applied, except for most radial head fractures. Elbow fractures are followed closely, with follow-up visits every 1 to 2 weeks with serial radiographic evaluation.

Immobilization is typically required for 6 weeks. Daily activities and simple exercises can be modified according to patient status. Early ROM exercises can prevent joint stiffness and shorten recovery time. In the initial stages of rehabilitation, obtaining a greater degree of motion is more important than gaining strength. Physical therapy can be prescribed to help regain ROM and strength soon after immobilization is discontinued.

The patient should be aware that some loss of extension can be expected (about 15°), but this should not affect function. It may take up to 3 months to recover full elbow ROM and strength. Vigorous sports activity can be allowed by approximately 2 to 3 months, with clearance for collision sports when almost full strength and ROM are achieved.

Elbow Sprain

Elbow sprains are commonly occurring injuries, yet they must be distinguished from other types of elbow injuries, such as fractures, dislocations, osteochondritis dissecans, growth plate injuries, congenital abnormalities, and common neurovascular injuries such as ulnar neuritis. A diagnosis of *elbow sprain* refers to an injury to either the medial or lateral ligament complexes of the elbow. The ligaments play important roles in maintaining elbow joint stability, particularly in the setting of functional movement such as throwing. For example, stresses across the medial elbow joint have been found to reach velocities of greater than 2,300 degrees per second during the acceleration phase of throwing, and valgus torque is reported to have reached 64 Newton meters (N m) in the late cocking phase. The static strength of the ulnar collateral ligament (UCL) measures about 32 N m in elbow flexion; thus, the remainder of medial elbow stability is provided by the bony and other soft tissue structures in the elbow. Elbow ligament injuries often occur in association with or as a result of other injuries, such as elbow dislocations. Medial injuries occur more frequently than lateral ligament injuries. The most common complication of either a medial (ulnar) collateral ligament or a lateral collateral ligament elbow injury is chronic structural or functional instability. This can lead to poor outcomes and a variety of complications, such as decreased range of motion (ROM), arthritis, nerve palsies, weakness, and heterotopic ossification. All athletes with elbow pain must be evaluated promptly for signs of ligamentous injury. The presenting history varies from acute or chronic elbow pain, clicking, catching, or snapping to a spectrum of giving way/subluxation with flexion/pronation in medial injuries or extension/supination with lateral injuries.

Mechanism of Injury

The most common mechanism of injury to the medial elbow involves repetitive valgus overload. The stress to the flexor-pronator muscle-tendon group and/or the UCL results in injury. In skeletally immature athletes, it is more common to experience a medial epicondylar injury, ranging from apophysitis to an acute avulsion fracture, diagnosed by widening or separation of the medial epicondyle on elbow radiographs. The spectrum of UCL injury ranges from minimal fraying to partial ligament tears to complete ligament tears. Lateral elbow injury is part of a spectrum on injury to the lateral elbow soft tissues, either from repetitive varus loading or following a traumatic elbow injury, such as an elbow dislocation.

Anatomy and Clinical Evaluation

The elbow is one of the most complex joints in the body, consisting of three articulations: ulnotrochlear, radiocapitellar, and proximal radioulnar. The elbow is extremely congruent and stable due to the specific pattern in which the bones contact and conform to each other. Stability is maintained at less than 20° and greater than 120° by the bony architecture. Between 20° and 120°, stability is maintained by the soft tissues. Normal ROM of the elbow is approximately 150° of flexion to 0° of extension, 90° of forearm pronation, and 90° of forearm supination. The elbow provides attachment sites for various muscle groups and ligaments. The primary stabilizers of the elbow are the ulnotrochlear articulation and the medial collateral (MCL) and lateral collateral (LCL) ligaments. The radial head and surrounding muscle bundles make up the secondary stabilizers of the elbow. Supination of the ulna results in a posterolateral displacement away from the trochlea in posterolateral rotatory instability (PLRI).

The medial ulnar collateral ligament (MUCL) consists of anterior oblique, transverse oblique, and posterior oblique bundles. The anterior oblique bundle is the most important structure that provides valgus stability to the elbow. It originates on the anteroinferior medial humeral epicondyle and inserts on the medial coronoid. The posterior oblique bundle originates on the posteromedial epicondyle and inserts posterior and proximal to the anterior bundle. The anteromedial joint capsule and the common flexor origin function as additional soft tissue–stabilizing structures to the medial elbow. The lateral ulnar collateral ligament (LUCL) complex consists of four structures: the LUCL itself, the annular ligament, the radial collateral ligament, and the accessory LCL. The posterolateral joint capsule, capsular insertion of the annular ligament, and common extensor origin function as secondary soft tissue restraints to the lateral elbow. Tenderness to palpation of either the MUCL or the LUCL is highly indicative of injury, and various stability-testing maneuvers must be performed to adequately assess elbow joint injuries.

Multiple techniques exist for performing a valgus stress test on the medial elbow. These tests are often positive for reproducing pain as well as demonstrating signs of associated instability. Valgus stress testing at 70° to 90°, the moving valgus stress test, and the milk test are all described techniques. The moving valgus stress test is positive when a valgus stress is applied during flexion/extension and pain is elicited at 70° to 120°. The milk test is positive when pain is elicited by having the patient reach under the affected elbow with the contralateral hand and grasp the ipsilateral thumb to apply a valgus stress. Any perceived laxity should be compared with the contralateral side.

The lateral pivot-shift test is the most sensitive examination technique described for assessing instability of the LUCL. The patient is placed in a supine position with the shoulder in external rotation and the arm overhead. The elbow is first fully extended and supinated. Valgus, supination, and axial compression forces are generated as the elbow is flexed. Rotary subluxation of the ulnohumeral joint may be reproduced at approximately 40° of flexion, with pain and a prominence of the radial head noted. Further flexion actually reduces the joint. Patients often experience significant apprehension during this maneuver. The push-up sign occurs when apprehension, subluxation, or dislocation occurs on terminal elbow extension from a flexed position in a wide-shoulder push-up position. The chair sign occurs when the patient arises from a seated position by pushing on the chair arms with the elbows flexed 90°, the forearms supinated, and arms abducted. This test yields a positive result when apprehension, subluxation, or dislocation occurs.

Imaging Studies

Standard anteroposterior (AP), oblique, and lateral views of the elbow should be sufficient to diagnose most bony abnormalities, such as fractures. The lateral radiograph is helpful to evaluate for a hemarthrosis and bony alignment. Comparison views are particularly helpful in evaluating the pediatric elbow for fractures due to the presence of the six secondary ossification centers. The apophyses slowly close by ossification as the elbow matures and are fully closed by approximately 16 years of age. MUCL injuries are far more common than medial epicondylar fractures once full skeletal maturity is achieved. Valgus stress views may be obtained, but they often fail to demonstrate the gross laxity detectable on physical examination.

Advanced imaging techniques such as computed tomography may identify intraarticular fragments and assess the congruity of the articular surfaces when internal fixation is being considered. Continuous fluoroscopy during the pivot-shift test and stress radiographs may be useful to confirm the diagnosis of recurrent elbow instability. Widening of the ulnohumeral joint or posterior subluxation of the radial head demonstrates PLRI. Musculoskeletal ultrasound techniques are developing and are increasing in popularity as they offer a dynamic imaging modality to assess joint instability during active ROM and valgus stress testing. True sensitivity and specificity of stress testing with any imaging study have not been determined.

Magnetic resonance imaging (MRI) or MR arthrography is the most sensitive and specific imaging study to reveal injury to the MUCL, showing edema within the ligament as well as differentiating partial-thickness from full-thickness tears. MRI is also useful in detecting osteochondritis dessicans, intraarticular cartilaginous loose bodies, and physeal maturity. Increased signal at the medial epiphysis on MRI in the absence of widening or displacement in a skeletally immature elbow indicates chronic medial injury consistent with valgus overload syndrome. MRI has a more limited role in demonstrating PLRI as it is difficult to assess the true extent of LUCL complex injuries; however, edema and structural integrity of the LUCL should be similarly identified as with the MUCL.

Treatment

Nonoperative treatment involves rest from activities that can aggravate both medial and lateral UCL ligament injuries that are not grossly unstable. Frequently, a period of immobilization of 3 to 4 weeks is necessary to prevent recurrent valgus/varus stresses even with activities of daily living. Operative treatment with elbow arthroscopy is a better definitive treatment of choice for athletes, particularly those involved in throwing activities or other overhead sports, and for those patients with gross or persistent instability despite an adequate trial of conservative treatment. Particularly for tears to the MUCL, surgical repair has met with varying degrees of success. Reconstruction remains the preferred intervention for unstable MUCL tears. A prolonged rehabilitation period of 12 to 18 months is necessary to ensure successful return to overhead activities.

Rehabilitation

Rehabilitation of an injured elbow is essential to restore strength and stability whether the injury is treated operatively or nonoperatively. When rehabilitation is initiated, a progressive program of ROM, strength, and multiplanar exercise such as throwing may take weeks to months to complete. A comprehensive core strength training program as well as an evaluation of sport biomechanics, such as pitching technique, is an essential part of any successful rehabilitation program. The consequences of untreated or inadequately treated elbow instability due to ligament or other soft tissue injury include stiffness, osteophyte formation, ulnar neuritis/neuropathy, soft tissue/synovial hypertrophy, or signs of impingement such as pain, locking, crepitus, and/or loss of extension. In conclusion, many elbow sprains, particularly when associated with valgus overload and repetitive microtrauma, are potentially preventable in athletes. It is strongly suspected that an MUCL sprain is a precursor to a complete UCL tear. Therefore, prompt evaluation and early intervention can minimize the risks of permanent injury or long-term sequelae.

Electrical Stimulation

Fractures are common sports injuries. In athletes, fractures result in many missed games and practices as well as countless medical visits. Most fractures heal with conservative treatment, which includes rest from sports and immobilization. However, some fractures result in either delayed (slow) healing or nonunion (incomplete healing). Electrical stimulation promotes bone growth and repair of fractures in athletes. Consequently, this may accelerate a fracture's ability to heal. It is used as a last resort to heal delayed and nonunion fractures, before surgery is recommended, and also as an adjunct therapy to surgery itself.

Mechanism of Bone Healing and Electrical Stimulation

Bone is living tissue made up of many different types of cells in an organized structure. Bone is constantly undergoing the process of renewal and repair. When a bone breaks, the body immediately begins the repair process.

Bone heals through a number of phases in a process called *remodeling*. It has a dynamic (constantly changing) environment. Old bone is removed by cells called *osteoclasts*, and new bone is formed by *osteoblasts*. Generally, bones heal better and faster in children than in adults. A solid union (complete healing) of a fracture usually occurs in 3 months. Other factors that affect bone healing include the type and location of the fracture.

Bone healing is based on its position and the amount of stress that is put on it. This is known as *Wolfe's law*. A long bone will return to a shape that is mechanically the most suitable for its function. Examples of long bones include the femur and the tibia in the leg.

Mechanism and History of Electrical Stimulation

Studies suggest that electrical stimulation may activate cellular pathways that promote bone healing. When the correct amount and type of energy are applied to bone, calcification as well as mineralization of the repair are encouraged.

Electrical stimulation has been used for decades to aid healing of fractures that are difficult to heal. In the 1950s, scientists determined that electrical current affects bone healing. Fukada and Yasuda showed that there is a relationship between electricity and the formation of callus. They showed that bone is piezoelectric, meaning that it causes the separation of charge when stressed.

When stress is applied to the bone, the concave (curved in) side has a positive charge, and the convex (curved out) side has a negative charge. This is particularly significant in long bones. When the bone is positively charged, osteoblastic (bone building) activity occurs. When there is a negative charge, osteoclastic (bone absorption) activity occurs. Electrical stimulation changes the electrical potential across the bone to stimulate osteoblastic activity. It therefore replicates the negative potential created at fracture sites by the body's electrical impulses.

Electrical Stimulation and Sports Injuries

Historically, electrical stimulation has been used to heal long-bone fractures. It has also been effective in treating nonunion of carpal navicular fractures. Electrical stimulation has been used after spinal fusions in athletes. Electrical stimulation may also have a role in healing sports-related stress fractures and stress fractures of the foot and the spine. A solid, bony union (complete healing of the fracture) gives the best results. However, some athletes return to sports with a fibrous union (painfree nonunion). It is important to monitor the athlete for recurrent or new symptoms that are problematic.

This treatment modality offers another option to bone grafting, which has been used previously. In addition, it avoids the risks of an open operative procedure. These include bleeding, infection, risk, discomfort, and the high costs of repair.

Types of Electrical Stimulation

There are three types of electrical stimulation: (1) direct current (DC), (2) capacitive coupling (CC), and (3) pulsed electromagnetic field therapy (PEMF). DC is the most invasive of these since it involves surgical intervention. In this form of therapy, the electrical stimulation device is implanted in the patient near the fracture site. DC eliminates the need for patient compliance, which may be especially difficult in athletes.

CC and PEMF are noninvasive electrical bone growth stimulations that involve a portable unit. Success of these treatment modalities partly depends on athlete compliance. CC is delivered from a battery pack to two wires. The wires are attached to skin electrodes. The electrodes (skin pads) are positioned on one side of the fracture or fusion site. The treatment is generally given for 24 hours a day until healing occurs.

PEMF is applied by an external coil for several hours per day. Treatment coils (placed in a brace or on the skin) are applied directly onto the skin. In PEMF, a treatment coil is positioned directly on the fracture site. A treatment unit is programmed to deliver the therapy. This is based on the requirements of the athlete's specific fracture. A small electrical current, produced by the treatment unit, travels to the treatment coil. A pulsating electromagnetic field is produced around the fracture. The electromagnetic field produces a small electrical current similar to the initial current. This stimulates the fracture to heal.

Ultrasound

Ultrasound is another form of therapy to treat fractures. It is used to heal new fractures, as well as for part healing of older fractures. Animal and clinical studies report good to excellent results using ultrasound to heal fractures. However, it is important to consider that treatment outcome in athletes depends on the site of the nonunion, how much time has passed from the time the fracture occurred, and how stable the nonunion is.

Ultrasound stimulates piezoelectric forces, which promote fracture healing in athletes. The exact mechanism by which ultrasound works is not known. It may be accomplished by mimicking signals sent by the body that promote osteoblastic activity and, therefore, fracture healing. Another proposed mechanism is that the bone absorbs sound waves from the ultrasound. This causes chemicals necessary for bone healing, such as calcium, to move across the bone's surface and promote fracture healing.

Application time for ultrasound treatment is minimal; it generally takes 30 minutes. The ultrasound is applied on the skin through a window in the immobilization device if the athlete is casted. This restricts the athlete's motion. The ultrasound device is connected to a power source on a wall.

A number of different factors affect bone healing, and electrical stimulation and ultrasound offer additional options for athletes with fractures that are difficult to heal.

Electromyography

Electromyography (EMG) is the study of muscles and nerves. The test includes two components: (1) nerve conduction studies (NCS) and (2) the electromyogram (EMG). While technically EMG refers to the electromyogram part of testing, it is used colloquially to refer to the entire electrodiagnostic testing process.

The ability to record electrical activity during active muscle contraction was first discovered in 1849, but it was not recorded until 1890. In the 1920s, that signal was displayed on an oscilloscope, and EMG testing, albeit rudimentary, was first developed. As the technology for electrical circuits evolved, so did the technology to observe, record, and edit electrical activity generated from muscle. Today's machines are quite sensitive to the minute electrical changes seen in active muscle membranes.

Although EMG testing can provide a wealth of objective information, it is best used as a complement to history and physical examination rather than as a substitute for it. Testing can help confirm a diagnosis, provide a diagnosis, assess chronicity, judge severity, localize a lesion, and predict recovery.

Athletes may suffer from a multitude of different injuries, and EMG testing can help characterize and diagnose some of these. Nerve injury typically presents with weakness, numbness and tingling (paresthesias), or a painful sensation (dysesthesias), and it can be evaluated by EMG testing. Even with symptoms of sprain or strain, an EMG can be useful to rule out any other underlying problem, particularly if the symptoms continue despite appropriate treatment. While this list is not comprehensive, EMG testing can be helpful for specific injuries such as carpal tunnel syndrome, "pinched nerve" (radiculopathy), ulnar neuropathy (at both the wrist and the elbow), and "stingers."

Nerve Conduction Studies

NCS allow for noninvasive evaluation of the characteristics of peripheral nerves. Some of the characteristics evaluated include onset of response (latency), amount of response (amplitude), and speed of response (velocity).

Recording electrodes are placed over the area of interest, and stimulation is given at a predetermined distance. Data collected include latency, amplitude, and velocity. These data can then be compared with control values ("normal" values). Generalized controls are published in a variety of texts, but each EMG lab will ideally establish its own controls based on its equipment and testing methods. The above characteristics can be affected by temperature, age, gender, and height, all of which must be taken into account when grading the data.

Testing can be further divided into the study of sensory and motor nerves. There are multiple methods and sites to test the peripheral nerves. This helps eliminate false-negative or -positive testing and ensure accuracy of results. Many states allow physicians as well as qualified (and in some cases certified) nonphysicians, such as physical therapists or chiropractors, to perform nerve conduction testing.

The electrical stimulation lasts less than 1 millisecond and is typically felt as an "electric shock." It is generally not regarded as painful but rather as an unpleasant stimulation.

Needle Examination

EMG, or needle testing, quantifies the electrical potential of muscles at rest and muscles in action. Muscles at rest should be electrically silent and when stimulated can be studied to determine the type of pathology. Muscle is also tested with a slight and then full contraction for further characterization. The contraction produces a motor unit action potential (MUAP). This unit of muscle activity can be analyzed for its speed of firing, size of contraction, and duration of firing. These data can help determine whether pathology is originating from the nerve or muscle. The size of the MUAP can help characterize the onset of findings, grossly measured as newer or older than 6 months.

The needle examination is administered by physicians specialized in neuromuscular testing. Testing is performed with a sterile disposable needle and requires an intimate knowledge of anatomy. The needles are not hollow (except for specialized needles used to test and inject medication), so they are not as painful as a hollow bore needle. Despite that difference, needle testing is still regarded as unpleasant to painful.

Electrodiagnostic results are oftentimes dependent. Patterns suggesting acute injuries can be present within days of injury, but for ideal assessment, testing should be done at 3 weeks or more from the onset of symptoms. After nerve injury, there is a process of degradation of the nerve (Wallerian degeneration). Testing before that process has taken place (generally 3 weeks) may result in false-negative test results. Testing and results also change with time. Nerve degeneration and nerve healing will yield different results at follow-up testing.

Electrodiagnostic studies are not standardized. Investigations are frequently modified by the practitioner to answer the diagnostic question. Subsequently, testing can be shortened or lengthened depending on the findings and the need for further investigation.

The Electrodiagnostic Consultation

EMG testing should be used as a complement to a thorough history of symptoms and physical examination findings. While an EMG report contains raw data, it is more than simply that. It also contains interpretation of the data that can help make a diagnosis; confirm a diagnosis; and assess location, age, and severity of injury, as well as predict recovery. Prediction of recovery depends on the type of injury and the time of testing (from the onset of injury) and, subsequently, may be best done with repeat testing. Injuries to nerves, injuries with underlying mechanical problems, or injuries slow to progress are often seen in athletes. EMG testing can be helpful to diagnose, grade, and predict recovery in these cases.

It is also important to stress that despite the presence of pain, loss of function, or any other symptom, EMG testing is not always positive. As EMG testing is used specifically for nerve injury or muscle pathology, testing outside those parameters will yield a "normal" test, despite symptoms. Negative EMG testing does not imply lack of symptoms. Rather, it implies the lack of pathologic nerve or muscle injury.

Electrotherapy

Electrotherapy is a therapeutic modality that uses electrical currents to improve a wide variety of musculoskeletal conditions. Physical therapists traditionally use these modalities as a component of a comprehensive treatment program to improve impairments and functional limitations that may be caused by an injury. Within the body, there are naturally occurring electrical impulses that travel down the nerve to stimulate a muscle to work. This is a normal physiological mechanism.

Electrotherapy modalities have the following in common: (a) a source of electrical current (battery, outlet), (b) lead wires to conduct the current, and (c) electrodes, coated with a conductive medium, that are placed on the skin to transmit the current into the body.

Electrotherapeutic Modalities

Iontophoresis

Iontophoresis is the introduction of charged ions across the skin using low-voltage direct current. The active electrode is placed over the area to be treated, and a second dispersive electrode, which completes the electrical circuit, is placed on the body away from the first electrode. The active electrode is the one with the same polarity as the drug ions, which causes the drug to be driven across the skin. The drug used most often is dexamethasone sodium phosphate, which can help decrease inflammation often caused by tendinitis or bursitis. Acetic acid can also be used to eliminate calcium deposits from a joint.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) is a form of electrical stimulation that can help with pain control. Pain relief can be achieved through two mechanisms. The first is the gate control theory. This proposes that electrical stimulation inhibits transmission of painful stimuli from the spinal cord to the brain. This is called high-rate or conventional TENS, and it uses high-frequency, low-intensity pulses. No muscle contraction occurs. The second theory is that electrical stimulation can stimulate the release of the body's own natural endorphins and enkephalins. This is often called low-rate or acupuncture-type TENS, and it uses low-frequency, high-intensity pulses. Mild muscle contraction occurs. Currents are superficial with TENS due to high skin resistance to the pulse frequencies. TENS may be used to help control acute pain (postoperative) or pain in more chronic conditions, such as low back pain and complex region pain syndrome (CRPS).

Interferential Current

Interferential current (IFC) is similar to TENS, but it uses two different channels with medium frequencies. The currents intersect and interfere with each other, producing a current that is said to penetrate the skin more deeply and more comfortably, thus providing pain relief to deeper tissues. It is claimed that IFC may be effective for pain control in acute, subacute, and chronic pain conditions, but TENS is often as effective.

Electrical Stimulation With Direct Current

Electrical stimulation with direct current is used when the nerve has been affected by injury and the patient is no longer able to produce a voluntary muscle contraction (denervated muscle). The type of pulse it generates produces a twitch response in the muscle. Traditionally, direct current was used to produce muscle activity with the intention that it would prevent muscle atrophy. Recent studies have not supported this outcome, except in some cases of chronic facial nerve palsy (Bell palsy).

Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) is used when the nerve is intact. This type of current may be used to produce a strong muscle contraction similar to what is done voluntarily. This modality is most commonly used to increase muscle strength. To optimize this effect, the electrical stimulation should be as high as the athlete can tolerate. The athlete should attempt to perform a voluntary contraction in conjunction with the electrically generated contraction. NMES is also used to decrease spasticity, to decrease muscle spasm, and to enhance local circulation.

Functional Electrical Stimulation

Functional electrical stimulation (FES) is a form of NMES that is applied during functional activities. It has been used recently in the treatment of spinal cord injuries, hemiplegia due to stroke, and children with cerebral palsy. The electrodes are placed on the motor points of the muscle(s) needed for the functional activity, for example, walking and/or relearning hand function after a stroke.

High-Voltage Pulsed Current

High-voltage pulsed current (HVPC) is a form of electrical stimulation that can help decrease swelling after an acute injury, such as ankle sprain, thus helping with pain control. This kind of electrical stimulation has also been shown to be effective in wound healing, especially with decubitus ulcers.

Contraindications

Standard contraindications on the use of electrical stimulation include the presence of a cardiac pacemaker, active bleeding/infection, malignancy in the area being treated, and stimulation directly over a metal implant. Athletes should have intact sensation in the affected area and should have an understanding of the intervention being used.

Emergency Medicine and Sports

Many recreational activities and sports, particularly those in which children participate, do not have medical coverage on site. Consequently, many injuries that occur in sports are seen by doctors in emergency rooms for acute care. The Centers for Disease Control and Prevention (CDC) in the United States reports more than 30 million emergency room visits annually for injuries. The focus of emergency room care is immediate stabilization and accurate diagnosis. Emergency doctors must triage, assess, and provide initial care for athletes with injuries. Ongoing management and follow-up are done elsewhere, outside the emergency room.

Injuries sustained by athletes range from very minor (bruises, contusions) to more severe (spleen lacerations, multiple fractures). Most injuries that occur as a result of sports are not life threatening, but many musculoskeletal injuries (ligament or tendon tears, cartilage injuries, broken bones) require expert care to ensure appropriate rehabilitation in order to allow athletes to return to sports safely. The role of the emergency doctor is to make the appropriate diagnosis and then to ensure the appropriate follow-up for athletes.

When to Go to the Emergency Department for a Sports Injury

Severe sport injuries are not common, particularly among adult recreational athletes. However, some injuries can be life threatening, and immediate medical attention in an emergency room should be sought. Potentially serious injuries may be indicated by the following characteristics:

- Deformity of a bone or a joint
- Localized tenderness or pain
- Decreased level of consciousness/loss of consciousness
- Drowsiness, confusion, and disorientation
- Persistent vomiting
- Leakage of clear fluid from the ears or nose
- Different-sized pupils/pupils that don't react to light
- Change in vision
- Seizure
- Neck pain following an impact
- Significant bleeding from a wound
- Severe pain
- Difficulty in breathing after a blow to the chest, head, or neck
- Inability to bear weight
- Pain that gets worse with activity
- Significant swelling or bruising

The presence of any of these symptoms should prompt immediate medical attention.

Diagnosis of Injury

When an athlete presents to the emergency room with an injury, the emergency doctor must make an accurate diagnosis to start appropriate initial management and to be able to give appropriate advice to the athlete. To do that, the doctor follows a standard approach to trauma, which includes a primary survey, resuscitation as necessary, secondary survey, and definitive care. The doctor will assess the severity of the injury by taking a thorough history, performing a thorough physical examination, and carrying out necessary diagnostic tests.

Primary Survey

The primary assessment includes measurement of vital signs and a rapid assessment of the essential functions of all organs. The goal of the primary survey is to identify any life-threatening conditions and to start any necessary resuscitation measures as soon as possible. The primary survey includes an assessment of the *A*irway/cervical spine, *B*reathing, *C*irculation, *D*isability, and *E*xposure/environment (ABCDE). This is a stepwise assessment, and each step must be completed before moving on to the next step. Any problems with the airway, breathing, or circulation in an injured athlete must be dealt with immediately by the emergency doctor before moving on to assess the extent of other injuries. The ABCDE primary survey is described in detail in the entry Fieldside Assessment and Triage.

The majority of sports injuries do not require an extensive primary survey, and assessment proceeds quickly to the secondary survey.

Secondary Survey

The secondary survey involves a thorough, systematic head-to-toe exam to detect any non–life-threatening injuries, with detailed examination of the injured body part to determine the nature and extent of injury. It includes taking a thorough history and possibly investigations to help make a diagnosis.

History

When assessing a patient with a sport-related injury, the emergency doctor must obtain some important details from the athlete and/or witnesses about the injury to help make an accurate diagnosis. The doctor will ask questions, including what sport/activity the patient was playing, the mechanism of injury, and what immediate treatment/interventions occurred at the time of injury. Other questions the doctor may ask include where the injury hurts; whether there was any popping, cracking, or snapping at the time of injury; and whether there had been previous injuries to the same body part and, if so, what treatment had been given.

Physical Examination

The doctor will perform an appropriate physical examination, depending on the location and nature of the injury. For musculoskeletal injuries, a complete musculoskeletal exam of the athlete must be performed by the doctor to help make the diagnosis. The doctor will look for signs that may indicate an orthopedic injury, such as swelling, loss of function, redness or discoloration, bruising, deformity or abnormal appearance, tenderness, or abnormal range of motion. Abnormal findings on physical examination may prompt the doctor to organize investigations.

Investigations

If there is a concern that an acute bony injury has occurred, such as when there is significant swelling or deformity, X-rays can be obtained in the emergency room. Soft tissue injuries and some nonacute bony injuries (such as stress fractures) may require further imaging, such as ultrasound, computed tomography (CT) scan, magnetic resonance imaging (MRI), or bone scan. These investigations are usually organized for a later date in the outpatient department.

Range of Injury and Initial Triage

Athletic injuries can be relatively trivial or more serious. Classification of injury can help with the diagnostic process. Categories of injury include

the *extent* of injury—local or multiple;

the *nature* of injury—blunt or penetrating trauma; and

the *severity* of injury—mild, moderate, or severe.

The first diagnostic task for an emergency doctor is to determine if the injury is localized or multiple. Local injury involves only one anatomic region of the body (extremities, head, abdomen), whereas multiple injury involves two or more anatomic areas of the body (head and abdomen, neck and extremities). The distinction between local and multiple trauma may be difficult to figure out initially for a variety of reasons. For instance, some injuries may initially be occult and may take time to manifest (spleen laceration). In addition, an athlete who is unconscious or has an altered level of consciousness may be unable to verbalize the areas of injury. Furthermore, some athletes may hide symptoms of injury because they do not want to be prevented from participating in their sport. Therefore, determination of injury as local or multiple is a dynamic process and may change over time as new evidence becomes available.

After the extent of injury has been determined, the emergency doctor focuses on the anatomical region of injury and ascertains the nature of the injury (blunt vs. penetrating). The vast majority of injuries result from blunt trauma. It is important to distinguish between blunt and penetrating injuries because this will guide the evaluation in the emergency room based on expected internal injuries.

Finally, the severity of injury must be determined. Severity of injury, ranging from mild to severe, determines the extent of investigation and intervention required, as well as the disposition of the patient. Most athletes with mild and moderate injuries will have minimal investigation and intervention and will be discharged from the emergency room with outpatient follow-up. Severe injuries require more investigation and intervention, and most patients will be admitted to hospital.

Types of Injury

Details of diagnosis and management of specific injuries are covered in other entries in this encyclopedia. Table 1 gives the general principles of investigations and emergency room management for general categories of injuries that doctors may see and treat in the emergency room.

Table 1 Emergency Room Management of Injuries

Injury	*Investigations*	*Initial Management*
Sprains/strains	Usually none X-rays if possibility of fracture	PRICE[a] Immobilization as necessary
Lacerations	Usually none	Suturing/steristrips/dermabond as required
Joint dislocations	X-rays pre- and postreduction	Reduction under sedation Appropriate immobilization
Fractures	X-rays Rarely CT	Appropriate casting/splinting
Internal bleeding/organ injury	Ultrasound, CT as necessary	Fluid resuscitation as necessary Surgical consultation Surgery may be required
Head injury	CT scan if concerning features (i.e., vomiting, decreased level of consciousness, focal neurological abnormalities, seizure)	Observation Neurosurgical consultation if significant findings on CT
Eye injuries	Slit lamp exam	Possibly ophthalmology consultation
Dental injuries	Possibly panoramic dental X-rays after dental consultation	Dental consultation

Note: a. PRICE = *p*rotection, *r*est, *i*ce, *c*ompression, and *e*levation.

Management/Discharge Instructions

For athletes with minor or moderate injuries who are sent home from the emergency room, the emergency doctor will provide information about the diagnosis and what to do to make the injury better. Most acute musculoskeletal injuries should be treated with *p*rotection, *r*est, *i*ce, *c*ompression, and *e*levation (PRICE) in the first 24 to 72 hours following injury.

> *P*rotection: This consists of appropriate bracing and immobilization.
>
> *R*est/relative rest: When an injury occurs, sports and exercise should be stopped immediately to avoid worsening the injury. In the first 24 to 72 hours, all sports activity should be avoided. After this acute period, relative rest means avoiding activities that may exacerbate the injury.
>
> *I*ce: Ice packs help decrease inflammation and pain.
>
> *C*ompression: Tensor bandages may help decrease swelling in soft tissue injuries.
>
> *E*levation: Raising the injured body part above the heart level helps decrease inflammation.

PRICE should be started as soon as possible following an injury to help minimize and control inflammation and swelling and, therefore, help decrease recovery time. Time off from sports can be reduced by 50% to 70% if PRICE is started within the first 24 hours of injury.

In addition to recommending PRICE, the emergency doctor may advise the athlete to take anti-inflammatories, such as ibuprofen, to help decrease the pain and swelling. The doctor may prescribe nonsteroidal anti-inflammatories (NSAIDs), such as Naprosyn or Toradol, for more serious injuries.

Emergency room doctors should also make sure that athletes with injuries are seen by an appropriate specialist as soon as possible after discharge from the emergency room. For athletes with broken bones, follow-up should be arranged with an orthopedic surgeon in a fracture clinic. For other injuries, follow-up should be arranged with a doctor who is knowledgeable about sports injuries. For some soft tissue injuries, such as ankle sprains and shoulder tendinitis, the emergency room doctor may also advise the athlete to start physiotherapy to help heal the injury.

Return to Sports

One of the most common questions an athlete with an injury will ask is "When can I return to my sport?" Most of the time, the emergency room doctor will not be able to give a definite answer to that question. It is difficult for emergency room doctors to guide athletes with regard to return to play at the time of initial assessment in the emergency room because a number of factors will affect the timing of return to play. These factors include the severity of the injury, the extent of the injury that may require further imaging outside the emergency room, and response to therapy. It is therefore appropriate that patients be sent for follow-up to a doctor knowledgeable in sports injuries, who can assess the patient's recovery process and help guide the patient's return to sports once the athlete has completed a rehabilitation program designed for his or her specific injury.

EPICONDYLITIS

Epicondylitis is an overuse injury involving the muscles and tendons that originate on the epicondylar region of the distal humerus. It is fairly common, with lateral epicondylitis ("tennis elbow") and medial epicondylitis ("golfer's elbow") constituting the majority of elbow pain seen in sports medicine clinics. In this entry, we will discuss the anatomy of the elbow as well as the pathology, evaluation, and treatment options for lateral and medial epicondylitis.

Lateral Epicondylitis

Henry J. Morris first described "lawn tennis elbow," now referred to as *lateral epicondylitis*, in 1882 (Figure 1). The annual incidence of lateral epicondylitis is approximately 1% to 3% of the general population, with the majority of patients being 35 to 40 years old or older. Men and women are affected equally. Lateral epicondylitis typically occurs in racquet and throwing sports but can result from work-related injury as well. The etiology is believed to be overuse and repetitive microtrauma from eccentric contractions of the extensor muscles. The injury occurs between the extensor carpi radialis brevis and the periosteum of the lateral epicondyle. A microscopic invasion of immature fibroblast and nonfunctional vascular buds leads to an "angiofibroblastic tendinosis," first described by Nirschl in 1979. Scarring and calcifications develop within the degenerated tendon, with little to no inflammatory cells present; the term *epicondylitis* is a misnomer, as "itis" implies the major cause to be an inflammatory process, and anatomical studies do not support this. Studies have shown that this area is extremely hypovascular—that is, it does not receive a generous blood supply—thus limiting its potential to heal.

For proper evaluation and accurate diagnosis, the examiner must have a good understanding of elbow anatomy. The elbow is a hinge joint that can flex, extend, and rotate. The medial trochlea of the distal humerus articulates with the ulna, allowing for flexion and extension. The lateral capitellum of the distal humerus articulates with the radial head. The radiocapitellar and radioulnar articulations allow for rotation of the elbow joint. Valgus stability is provided by the medial collateral ligament complex, comprising the anterior, posterior, and transverse bundles, with the anterior bundle being the primary stabilizer. Rotational and varus stability are provided by the lateral collateral ligament complex, comprising the radial collateral ligament and annular ligament. Elbow flexion is facilitated by the biceps brachii, brachioradialis, and brachialis muscles. The triceps and anconeus allow for elbow extension. The supinator and biceps brachii are the major supinators, while the pronator quadratus, pronator teres, and flexor carpi radialis muscles are the major pronators. The median, ulnar, and radial nerves all traverse the elbow joint, providing sensory and motor innervation. The brachial, radial, and ulnar arteries are the major vessels of the elbow.

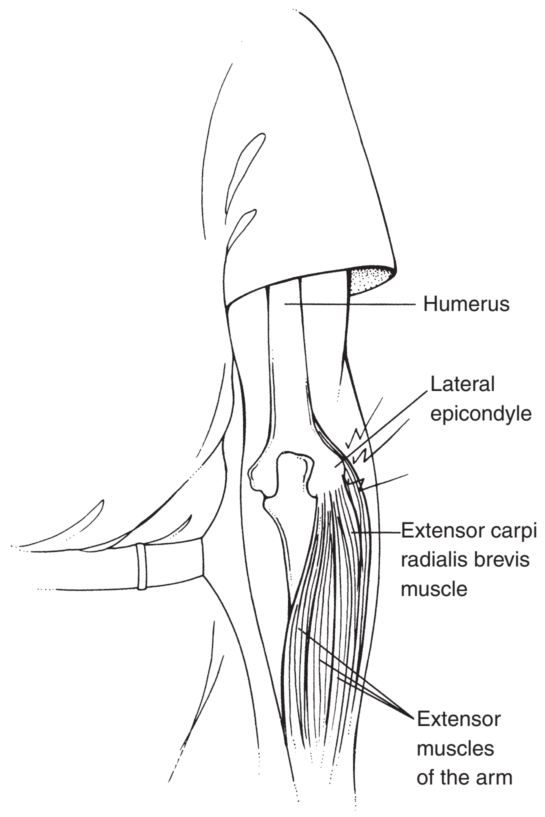

Figure 1 Tennis Elbow (Lateral Humeral Epicondylitis)

Patients with lateral epicondylitis often complain of weak grip and pain along the extensor surface of the forearm. Physical exam shows tenderness to palpation along the lateral epicondyle and extensor carpi radialis brevis. Pain is reproducible with resisted wrist extension, resisted supination, and resisted long finger extension.

The majority of cases are diagnosed clinically, but imaging can help if the presentation is less clear. Plain radiographs (X-ray films) are usually normal but may show a calcification around the epicondyle in 20% of patients. Ultrasound is a noninvasive modality increasingly used both for diagnosis and to guide treatment of epicondylitis. Calcifications, tears, or a thickened, degenerative tendon may be seen, and selective injections and/or tendon fenestration may be done under ultrasound guidance. Magnetic resonance imaging (MRI) is the most sensitive imaging technique, but its utility is usually limited to preoperative imaging. Images may reveal tendon thickening, edema, microtears, and fibrovascular proliferation.

Nonoperative management is the mainstay of treatment for epicondylitis. Treatment may start with rest, ice, activity modification, and "watchful waiting," or it may include medications, bracing, injections, home exercises, physical therapy, or other modalities. Topical nonsteroidal anti-inflammatory drugs (NSAIDs) may be beneficial for pain control; however, there has been no conclusive evidence that oral NSAIDs have the same benefit. Topical medications such as nitric oxide and nitroglycerin have been shown to reduce pain and tenderness; however, more studies are required.

Wrist splints and proximal forearm bands are two of the most common orthoses used for treatment of lateral epicondylitis. The wrist splint decreases wrist extension, thereby relieving the tension on the tendons. The forearm band decreases the full contractile force on the extensor origin. There has been no evidence that one is more effective than the other or that bracing is more effective than other treatment modalities. Various physical therapy modalities have been studied as adjuvant therapies. Strengthening and stretching have been shown to reduce pain in the acute phase. Manipulation and deep friction massage may aid in breaking up adhesions; however, long-term improvement has not been shown to occur. Ultrasound and iontophoresis may reduce pain and increase functionality.

Extracorporeal shock wave therapy (ESWT) has not consistently been shown to improve symptoms. It can also result in pain, redness, swelling, or hematoma. Cortisone injections into the region of the epicondyle have been shown to have high success rates at short-term follow-up; however, studies have shown that there is no long-term benefit and there may be an increased risk of recurrence. Autologous blood injection is believed to stimulate bone and tendon healing, but more studies are needed. Botulinum toxin injection has shown significant reduction in pain in one study but can result in finger paresis and weakness of finger extension. Dextrose injections or prolotherapy may improve pain. Acupuncture may also provide some short-term relief. Ultrasound-guided percutaneous tenotomy, which involves fenestration of the degenerated tendon, has been shown to improve symptoms and functioning level in patients with chronic epicondylitis. All these treatment options are viable options for those with refractory symptoms, prior to considering surgery.

Surgical intervention is reserved for patients with chronic epicondylitis who have failed conservative treatment after 6 months to 1 year. Open surgery includes release or lengthening of the extensor carpi radialis brevis tendon, excision of the diseased tendon, anconeus transfer, denervation, or release of the posterior interosseous nerve. Arthroscopic repair involves release of the tendon or excising of the degenerative fringe. This has been shown to have outcomes comparable with those of open surgery.

Medial Epicondylitis

Medial epicondylitis, commonly known as "golfer's elbow," is an overuse injury at the flexor-pronator tendon origin on the medial epicondyle (Figure 2). Medial epicondylitis is much less common than lateral epicondylitis, making up approximately 10% to 20% of epicondylitis diagnoses. Similar to lateral epicondylitis, it commonly occurs in people ages 30 to 40, and men and women are equally affected. It often occurs in the dominant arm. Excessive valgus stress, rapid wrist flexion, and forearm pronation lead to degenerative changes, as in lateral epicondylitis. Pronator teres and flexor carpi radialis muscles are most commonly affected. Golfers are commonly affected due to an improper swinging technique.

Medial epicondylitis presents with an insidious medial elbow pain, worsened with activity. Physical examination reveals tenderness to palpation at the medial epicondyle, pronator teres, and flexor carpi radialis. Pain is worsened with resisted wrist flexion and forearm pronation. Throwers may also have a flexion contracture or decreased range of motion. In overhead athletes, it is important to rule out medial collateral

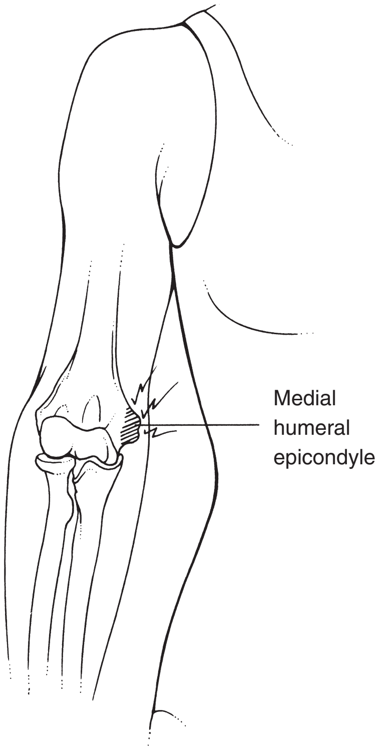

Figure 2 Medial Humeral Epicondylitis, or "Golfer's Elbow"

ligament damage and primary ulnar neuropathy. Medial collateral ligament damage can be determined by a valgus stress test or the milking test, which is performed by pulling the thumb while the elbow is flexed and forearm supinated. The Tinel sign at the cubital tunnel is usually negative in epicondylitis. If positive, it may suggest an ulnar neuropathy. The differential diagnosis of medial elbow pain also includes ulnar collateral ligament (UCL) sprain, flexor-pronator mass injury, and ulnar nerve entrapment.

Plain radiographs may show some calcifications or bony abnormalities. In younger throwing athletes, it is important to rule out an avulsion or medial apophysitis, indicative of "Little League elbow." If the diagnosis remains unclear after a thorough history and physical examination, ultrasound and MRI are other imaging options. The general approach to treatment for medial epicondylitis is similar to that for lateral epicondylitis, with therapy and bracing being first line; however, injections are used with much less frequency due to concern for damage to the UCL or ulnar nerve. Surgery is reserved for refractory cases.

Conclusion

Epicondylitis is a common cause of elbow pain in athletes with repetitive arm movements, especially throwers, golfers, and tennis players. A good understanding of the anatomy and pathophysiology is important to make the correct diagnosis. Most cases of epicondylitis respond to nonoperative therapies; however, full recovery may require more than a year of treatment. Important factors that lead to epicondylitis should be corrected as part of the treatment regimen. For tennis, these include proper strokes, appropriate grip size, lighter frames, and a less tightly strung racquet. In golfers, proper club weight, length, grip, and swing biomechanics can improve outcome. If pain persists or delays return to sport, surgical intervention may be warranted.

Epidemiology of Sports Injuries

Epidemiology is the study of the distribution and determinants of varying rates of diseases, injuries, or other health states in human populations for the purpose of identifying and implementing measures to prevent their development and spread. The initial development of the theory and methods of epidemiology focused on applications to infectious and communicable diseases. However, in his classic article "The Epidemiology of Accidents," John Gordon (1949) recognized that injuries conformed to certain biological laws as do infectious diseases and, therefore, could be studied by the application of basic epidemiologic principles. Application of epidemiologic concepts and methods to the characterization and prevention of accidental injury followed. By the early 1960s, epidemiologic techniques were also being applied to sports injury problems. As illustrated in Figure 1, the volume of sports injury research has more than doubled every 10 years since that period of time.

The most well-known and universally accepted model of the epidemiologic approach to sports injury prevention was first proposed by Willem van Mechelen and his colleagues. As illustrated in Figure 2, the injury problem must first be identified and described in terms of the incidence and severity of sports injuries. Then the factors and mechanisms that play a part in the occurrence of sports injuries have to be identified. The third step is to introduce measures that are likely to reduce the future risk and/or severity of sports injuries. Finally, the effect of the measures must be evaluated by repeating the first step.

The epidemiologist in sports medicine is concerned with quantifying injury occurrence (*how much*) with respect to *who* is affected by the injury, *where* and *when* injuries occur, and *what* is their outcome (Step 1), for the purpose of explaining *why* and *how* injuries occur (Step 2) and identifying strategies to control and prevent them (Steps 3 and 4). The study of the distribution of varying rates of injuries (i.e., who, where, when, what) is referred to as descriptive epidemiology. The study of the determinants of an exhibited distribution of varying rates of injuries (i.e., why and how) and the identification and implementation of preventive strategies is referred to as analytical epidemiology.

Descriptive Epidemiology

Descriptive epidemiology is by far the most common type of epidemiologic research that has been published in the sports injury literature. Yet to date, not all sports are sufficiently represented in this literature. For example, sports such as competitive swimming, cycling, and figure skating attract large numbers of participants, yet there are few published epidemiologic studies of injury in these sports. There are also few published studies representing a variety of other Olympic sports, including archery, canoeing/kayaking, shooting, and table tennis (summer sports), and

biathlon, bobsleigh, skiing (cross-country, free style, Nordic combined, and jumping), curling, and luge (winter sports). Figure 3 is a diagram illustrating the important aspects of the descriptive epidemiology of sports-related injuries. These components are discussed below with the purpose of highlighting their various contributions to understanding the distribution of sports injuries.

How Many Injuries?

In descriptive epidemiology, the researcher attempts to quantify the occurrence of injury. The most basic measure of injury occurrence is a simple count of injured persons or fatalities. For example, in the 25th Annual Report of the National Center for Catastrophic Sports Injury Research (NCCSI), we learn that there have been 25 heatstroke deaths in football during the past 10 years, an unacceptable number given that heatstroke deaths are preventable with the proper precautions.

To investigate the rate and distribution of injuries, it is necessary to know the size of the source population from which the injured individuals were derived, or the population at risk. The two most commonly reported rates in the sports injury literature are *incidence* and *prevalence.* Prevalence rates pertain to the total number of cases, new or old, that exist in a population at risk at a specific period of time. Prevalence rates published in the sports injury literature include rates for specific conditions such as chronic brain injury among retired boxers, wrist pain among gymnasts, radiologic abnormalities of the thoracic-lumbar spine among swimmers, or scoliosis and fractures among young ballet dancers.

The two types of injury incidence most commonly reported in the sports injury literature are clinical incidence and incidence rates. *Clinical incidence* refers to the number of incident injuries divided by the total number of athletes at risk and usually multiplied by some *k* value (e.g., 100). In the sports injury literature, these rates have most often been presented as the number of injuries per 100 athletes but are also reported as the number of injuries per 100,000 participants, as seen in publications arising from the NCCSI. However, clinical incidence does not account for the potential variance in exposure of participants to risk for injury. For example, a sidelined or second-team player who sees little or no contact during a game is not at the same risk of sustaining injury as a healthy first-team player. During the past two decades, there has been a trend in the published literature for studies to report incidence rates rather than clinical incidence.

Incidence rate refers to the number of incident injuries divided by the total time at risk and usually multiplied by some *k* value (e.g., 1,000). It is the preferred measure of incidence in research studies because it can accommodate variations in exposure time of individual athletes. Different units of time at risk, varying in precision, have been used to calculate incidence rates in the recent literature. These include reporting the number of injuries per *k* athlete exposures (an athlete exposure is defined as one athlete participating in one practice or game in which there is the possibility of sustaining an athletic injury), per *k* time exposures (one time exposure is typically defined as one athlete participating in 1 hour of activity in which there is the possibility of sustaining an athletic injury), or per *k* element exposures (one element exposure is defined as one athlete participating in one element of activity in which there is the possibility of sustaining an athletic injury). Examples of exposure elements include vaults, pitches, bike trips, and climbs. The logistics of acquiring the appropriate data are usually a major factor in determining what the unit of risk will be and whether it will represent actual or estimated exposure.

A difficulty that may arise in comparing incidence rates from different studies relates to the injury definition employed. A review of the sports injury epidemiology literature reveals that few common operational definitions exist for injury. Definitions include criteria such as the presence of a new symptom or complaint, decreased function of a body part or decreased athletic performance, cessation of practice or competition activities, and consultation with medical or training personnel. Clearly, if injury is defined differently across studies, a meaningful comparison of injury rates is compromised due to different criteria for determining numerator values. Notably, soccer (football) and rugby unions have recently published methodological consensus statements that identify definitions and methodology to ensure consistency and comparability of results in studies examining injury in their sports. It is expected that consensus statements regarding injury research in other sports will follow.

Who Is Injured?

As might be expected, injury rates are most often categorized according to sports participation and the way in which participants are organized for sports (e.g., amateur or recreational, high school or college). In addition to participation level, injury rates are also reported relative to player position and gender. Given the variance in injury definitions across studies, perhaps the most reliable within- or across-sport comparisons arise from those studies that use a common, exposure-based injury definition and surveillance protocol and where certified athletic trainers and therapists or other health professionals record the injury data. Examples include research reports arising from the National Collegiate Athletic Association Injury Surveillance System, the Canadian Intercollegiate Sport Injury Registry (CISIR), and the U.S. High School Reporting Information Online system.

Where Does the Injury Occur?

Determination of "where" injury occurs involves identification of the anatomical and situational locations of injury. Anatomical locations include the body region of injury (e.g., upper extremity) as well as specific body parts (e.g., shoulder, ankle). Identification of commonly injured anatomical locations alerts sports medicine personnel to injury sites in need of special attention during preparticipation musculoskeletal assessment. Information on high–injury risk locations also provides important "targets" for preventive measures. For example, pursuant to the documented high risk of ankle and knee injuries in sports such as basketball and European handball, recent prevention studies have focused successfully on designing and implementing pre- and in-season proprioceptive and balance training programs. Similarly, the introduction of rules mandating the use of full face shields dramatically reduced the rate of facial and eye injuries in youth hockey. Most sports injury studies have reported injury location as a percentage value. However, some recent studies report incidence rates of injury for specific anatomical locations.

Environmental locations provide information on the distribution of injury by indicating where in the environment or setting the injury occurred. Environmental locations reported in the sports injury literature include the surface or terrain on which the activity takes place, such as natural grass versus artificial turf in soccer; the apparatus used or event, such as the balance beam or parallel bars in gymnastics; the geographical location, such as beach versus court volleyball; where on the court or field of play the injury occurred, such as the key in basketball; and whether the injury occurred during practice or in a competition. Information on high-risk settings is, of course, useful in identifying important subjects for further study, including the application of preventive measures.

Early research on environmental location reported place factors as percentage values. However, once again, more recent studies tend to report incidence rates. The importance of providing both types of information—percentage values and incidences rates—is perhaps best underscored by comparisons of injury between practice and competition. For many sports, the number of injuries incurred during practice is much greater than the number incurred in a competition, most likely because much more time is spent in practice than in competition. However, when incidence rates are compared, the common finding is a higher incidence of injury in competition. Competitors are much more likely to be playing at greater intensity and speeds in competition and tournaments than in practice, thus increasing the risk of sustaining an injury.

When Does the Injury Occur?

As Figure 3 indicates, the next characteristic of injury distribution is the *when* of injury occurrence. Time factors are typically expressed in terms of injury onset and timing of injury. There are two broad categories of injury onset that differ markedly in their etiology. Injuries that occur suddenly are often termed *acute* or *sudden-impact* injuries and are usually the result of a single, traumatic event. Common examples include wrist fractures, ankle sprains, shoulder dislocations, and hamstring muscle strain. Overuse injuries are more subtle and develop gradually over time. They are the result of repetitive microtrauma to the tendons, bones, and joints. Common examples include tennis elbow (lateral epicondylitis), swimmer's shoulder (rotational cuff tendinitis and impingement), Little League elbow, and shin splints. An injury history may actually involve both categories of injury onset, such as when an acute injury is superimposed on a chronic mechanism. However, this third injury category is not often distinguished in the epidemiologic literature on sports injuries. Most epidemiologic studies in the sports injury literature do not distinguish between acute and overuse injuries. However, this is an important oversight, particularly in etiological studies, given that the risk factors for overuse and acute injuries are not necessarily the same. The importance of identifying onset of injury is also important, given the growing evidence of overuse problems in sports, particularly among child and adolescent athletes. Baseline information on incidence of overuse injury is important if we are to fully comprehend the impact of these injuries and the role of injury countermeasures.

Examples of timing of injury include the time spent in practice, time of day, and time of season when an injury occurs. It stands to reason that if rates are higher during a particular time, then efforts to better understand the risk factors for increased incidence at that time are in order, and appropriate preventive measures should be applied to reduce risk during that time. For example, if the proportion of injuries is shown to be greater during the latter part of games, as has been shown in several studies and sports, then fatigue could be considered as a possible contributing factor. Although count data are sufficient to explore the relation between injury frequency and time in practice or competition for most sports, incidence rate data are necessary for a meaningful analysis of injury risk relative to time of season.

What Is the Outcome?

Injury outcome or severity can span a broad spectrum from abrasions to fractures to those injuries that result in severe permanent functional disability (i.e., catastrophic injuries) or even death. In the epidemiologic literature on sports injuries, injury severity is typically indicated by one or more of the following: injury type, time loss, residual symptoms, and economic costs. Assessment in each of these areas is important in quantifying the extent of the injury problem. It may be, for example, that injury incidence is similar in two sports; however, the severity of injury may vary considerably between these sports.

Injury Type

Identification of common injury types is important because it alerts sports medicine personnel to injury types in need of special attention (e.g., anterior cruciate ligament [ACL] injuries) and directs researchers in identifying and testing related risk factors and preventive measures. Most injury studies report injury types in general terms, such as contusion or fracture, with few specifics on the type of fracture, grade of injury, and so forth. Injury types are generally reported as percentage values; however, some recent studies also provide incidence rate values, particularly for specific injury types such as concussion, ACL injury, and so forth. This latter approach facilitates analysis of risk factors and preventive measures related to these injury types.

Time Loss

A useful measure of injury severity, and one often used in the literature on sports injuries, is the duration of restriction from athletic performance subsequent to injury. Most studies reporting time loss use days lost from practice or competition as a measure of injury severity. These time loss data are often categorized by time periods (e.g., 7 days or less), indicating the degree of severity. Although the use of days lost from participation may be among the more precise representations of injury severity in the literature, this approach is not without problems. For example, subjective factors such as personal motivation, peer influence, or coaching staff reluctance/encouragement may determine if and when players return to play. Accessibility to a health care professional and location of injury may also affect the decision of when to return to play.

Clinical Outcome

Clinical outcome includes factors such as reinjury, nonparticipation, and residual effects. An unfortunate outcome of many injuries, at all levels of sport, is reinjury. It is believed that unresolved residual symptoms from previous injury predispose an athlete to recurrent injury at the same site. As will be discussed in more detail below, an athlete with previous injury who returns to participation is characterized by a changed injury risk profile, particularly if the original injury has not been properly rehabilitated. Although few studies provide rate data for reinjury, it is noteworthy that many recent etiological studies of sports injuries include previous injury in their risk factor analyses.

Another important but infrequently researched aspect of injury outcome relates to the frequency of season- or career-ending injuries. An important question to address is how many athletes drop out of their sport, either temporarily or permanently, due to injury. This would seem an especially important area of interest in children's and youth sports where the number of dropouts is high. Data on season-ending injuries of young athletes in games such as football, gymnastics, cross-country running, and wrestling have been provided in a few studies.

Perhaps the most important question one can ask related to injury severity concerns the residual or long-term effects of injury. Although engaging in physical activity has many health benefits, there is also the risk of injury, which may have long-term consequences on the musculoskeletal system, resulting in reduced levels of physical activity. If residual symptoms are slight, they may only require the individual to modify his or her sporting level. In some cases, however, functional limitations resulting from injury may preclude further participation in sports. In extreme cases, such as catastrophic injury, serious physical damage may result in permanent, severe functional disability, such as quadriplegia, or even death. Surprisingly, with the exception of the NCCSI, which has been tracking nonfatal (i.e., causing permanent severe functional disability) and other catastrophic injuries in high school and college sports since 1982, few studies have reported on the long-term effects of injury. This is an important area of investigation given the potential for increased risk of osteoarthritis among injured participants, particularly those with injuries requiring surgery.

Economic Costs

Financial costs may be either direct or indirect. Direct costs are those incurred in conjunction with medical treatment (e.g., treatment, medication), and indirect costs are those associated with the loss of productivity because of increased morbidity and mortality levels. Although there have been several attempts to estimate these costs for a few selected sports and injury types, comparison of results has been hampered by differences in health care and wage compensation systems. Studies need to show how high the economic impact of sports injuries is on public resources in order to win the much needed funds for sports injury epidemiology research.

Analytical Epidemiology

In the past, good descriptive data have led directly to suggestions for injury prevention that, once implemented, have helped control and prevent the occurrence of severe sports injuries such as eye injuries in hockey and spinal injuries in football. Other preventive measures supported by research include improved training for high school wrestling coaches, increased awareness of pathogenic weight control in gymnastics, and rules against checking from behind in ice hockey. However, in the recent sports injury epidemiology literature, there has been a promising and observable transition to approaches that are etiologically rather than descriptively based.

Risk Factors

The epidemiologic approach to sports injuries is rooted in the assumption that injuries do not happen purely by chance, so an important part of sports injury epidemiology is the identification of the factors that contribute to the occurrence of athletic injury. It should be understood, however, that this process is not an isolated one. Risk factor analyses should be driven by a need to better understand the factors leading to injury in order to test and ultimately intervene with effective prevention strategies.

Risk factors may be classified as intrinsic or extrinsic. Intrinsic risk factors are individual biological and psychosocial characteristics predisposing a person to the outcome of injury, such as previous injury, strength, or life stress. Extrinsic risk factors are factors that have an impact on the sports participant "from without" and include factors such as the coach's qualifications, playing time, and surface conditions. Risk factors can also be divided into modifiable and nonmodifiable factors. Modifiable risk factors refer to those that can be altered by injury prevention strategies to reduce injury rates. Although nonmodifiable risk factors such as gender or age may be important considerations in many studies of injury prediction, it is above all important to study the factors that are potentially modifiable.

What complicates the identification and quantification of risks is that causality associated with injury is both extremely complex and dynamic in nature. Willem Meeuwisse and colleagues, in their article "A Dynamic Model of Etiology of Sport Injury: The Recursive Nature of Risk and Causation" (2007), proposed a dynamic recursive model that accommodates a multifactorial assessment of causation in athletic injuries and emphasizes the fact that adaptations occur within the context of repeated participation in sports (both in the presence and in the absence of injury) that alter risk and affect etiology in a dynamic, recursive fashion. In this model, intrinsic factors are viewed as factors that predispose the athlete to react in a specific manner to an injury situation. However, what is important to understand is that intrinsic factors are not constant and may change in response to injury or to absence of injury (i.e., adaptive changes such as increased intrinsic strength).

Once the athlete is predisposed, extrinsic or "enabling" factors such as faulty equipment, poor field conditions, or coaching behavior may facilitate manifestation of injury. For example, a quarterback who injured his shoulder during a tackle may have been predisposed to this injury by his history of previous shoulder dislocation (i.e., the intrinsic risk factor) and an enabling factor such as wet field conditions, which resulted in the athlete slipping and being tackled (i.e., the inciting event). According to the dynamic recursive model, extrinsic risk factors, like intrinsic risk factors, are also subject to change in the context of repeated participation in sports. For example, rule changes or equipment may result in risk modification, thus changing susceptibility to injury.

Analysis of sports injury risk factors has produced a number of significant injury predictors—including factors such as age, gender (specific to the sport and the type of injury), previous injury, and stressful life events—that have shown consistent results across multiple studies. However, much of the remaining body of literature suffers from one or more of the following limitations: (a) injury definitions and methods of injury data collection that are extremely variable, (b) use of clinical incidence rather than incidence rates (i.e., rates based on hours or sessions of exposure) to distinguish high-risk athletes, (c) failure to account for the different categories of injury onset, and (d) inappropriate analyses for detecting multifactorial risks. As a result, much of this research should be viewed as initial work in the important search for injury predictors, work that may provide interesting variables for manipulation in other study designs.

Injury Prevention

Once the analytical evidence points to an association between certain risk factors and injury, thereby establishing a degree of predictability for those participants who are likely to sustain injury, the next step in epidemiologic research is to seek ways to prevent or reduce the occurrence of such an injury (i.e., Step 3, Figure 2). Testing the suggested preventive measure to determine its effectiveness is an important aspect of the analytical epidemiologic process and fulfills the ultimate goal of epidemiology—prevention. Ideally, the effectiveness of injury prevention measures should be tested prior to recommending their general implementation.

The effectiveness of a preventive measure can most reliably be determined by employing an intervention study in which subjects are randomly assigned to treatment and control groups. Two general types of intervention studies are preventive trials and therapeutic trials. A therapeutic trial is conducted among subjects with a particular injury to determine the ability of an agent or procedure (e.g., taping, bracing) to diminish symptoms or prevent recurrence of that injury. A preventive trial involves the evaluation of whether an agent or procedure reduces the risk of incurring injury among those free from injury at enrollment in the study. In practice, there has been very little research designed to determine the effectiveness of injury prevention measures. Ethical, cost, and feasibility issues no doubt combine to preclude experimental research. However, the results of recent investigations of sports injury prevention strategies have been encouraging. Balance training appears to decrease the risk of lower extremity injuries, especially ankle injuries. Multiple interventions using warm-up and balance training are also effective. And the use of equipment such as breakaway bases, helmets, mouthguards, and face shields along with bracing of specific joints have resulted in a decrease in sports injuries.

Conclusion

Although sports injury epidemiology is a relatively new field, it has made great strides in the quest to prevent sports injuries. Advances in the field over the past 50 years include the following:

- Transition to approaches that are etiologically rather than descriptively based
- Publication of consensus statements that identify definitions and methodology to ensure consistency and comparability of results in studies examining injury in their respective sports
- Emergence and growth of multiple sports injury surveillance systems
- Increasing use of exposure-based injury rates (i.e., incidence rates)
- Increasing use of multivariate study designs with sufficient sample size
- Improvements in the number of large-scale, grant-funded studies
- Recent and successful initiatives of the Oslo Sports Trauma Center to organize World Congresses focusing on sports injury prevention

Existing epidemiologic research has already resulted in rule changes, equipment standards, improved coaching techniques, and better conditioning of athletes. However, many challenges remain. For example, there is a paucity of epidemiologic research in some sports with long Olympic histories and/or worldwide popularity, such as archery, canoeing/kayaking, and cross-country skiing. There is a need for national sport bodies to implement comprehensive sports injury surveillance systems. Otherwise, prospective, cohort studies are logistically difficult to initiate, leading researchers to use less robust designs. And finally, there is a need for translational research to examine the factors that influence the likelihood of a prevention strategy being adopted by the target population. In the future, sports injury epidemiologists also need to expend more collaborative effort to ensure that important research findings are successfully implemented and evaluated.

Epidural Hematoma

Epidural hematomas are a type of head injury involving bleeding into the space between the skull and the dura, the outermost layer of the protective structures surrounding the brain. They can occur as a sports injury when a traumatic force applied to the head is sufficient to cause a deformity of the skull and damage to the underlying middle meningeal artery. The high pressure of the blood coming from the arterial circulation causes the dura to separate from the skull, creating the classic lens shape hematoma that can expand quickly, placing significant pressure on the brain. They are a relatively rare type of head injury in sports, but epidural hematomas are very serious injuries that can lead to significant disability or death. Early recognition of the warning signs and quick medical attention are paramount to a good outcome.

Anatomy

The brain is protected inside the skull by three separate layers of tissue (*meninges*). The innermost layer, the *pia mater*, is a thin and delicate membrane that lies on the surface of the brain. The second layer, the *arachnoid mater*, covers the brain and pia mater but does not follow the contour of the involutions of the brain. The outermost layer, the *dura mater*, provides a thicker and tougher layer of protection.

These layers define three potential spaces for blood to collect. The *epidural space,* between the skull and the dura, the *subdural space,* between the dura and arachnoid layers, and the *subarachnoid space,* between the arachnoid and pia layers, each have their own potential sources of hemorrhage. The pia mater is too closely adhered to the brain and too fragile to act as a barrier for blood, and therefore, there is no potential space between the pia and the brain for a hemorrhage to form.

The epidural space is prone to blood collection due to the presence of a series of arteries that supply blood to the meninges, the *meningeal arteries*. The largest meningeal artery, the middle meningeal artery, is the source of most epidural hematomas because of its location near the temporal skull. Although the majority of epidural hematomas are the result of arterial injury (85%), they may also develop following injury to a meningeal vein or dural sinus, vascular structures that are also located in or near the epidural space.

Mechanism of Injury

An epidural hematoma can occur in sports as the result of an impact to the head. An epidural hematoma forms when the head impact is of sufficient force to either pull the meninges away from the inner table of the skull or cause a skull fracture. The vascular structures mentioned above, especially the middle meningeal artery, can be compromised in this setting, leading to bleeding and hematoma formation.

Given that the blood in the meningeal arteries is coming from the arterial side of the circulatory system and is, therefore, under high pressure, epidural hematomas typically expand at a much faster rate than hematomas that are formed from venous blood, such as subdural hematomas. The quickly expanding epidural hematoma increases intracranial pressure and can lead to damage of the underlying brain, brain herniation, or death.

Risk Factors

For an athlete, the baseline risk of developing an epidural hematoma is primarily a function of the type of sport being played, the equipment being used, and the playing technique of the athlete. While high-velocity contact sports, such as football, ice hockey, and lacrosse, may carry the most inherent risk, the use of proper equipment, especially helmets that meet the requirements set forth by the National Operating Committee on Standards for Athletic Equipment (NOCSAE), can greatly lower the risk. It is important to recognize, however, that epidural hematomas can occur in any sport in which an athlete experiences a head trauma. Certain sports that involve high velocities, less intentional contact, and little, if any, protective equipment, such as soccer and field hockey, may also pose additional risk.

Signs and Symptoms

The first sign of injury occurs shortly after the head impact and typically involves a change in consciousness. This change can span the spectrum from mild confusion to complete loss of consciousness. If the athlete remains conscious, he or she often has many of the signs and symptoms that are typically seen in concussion, such as headache, nausea, dizziness, and lack of coordination. The classic presentation of an epidural hematoma, however, involves what is known as the lucid interval. After the initial decrease in consciousness, which can last for several minutes, the athlete can improve significantly or even completely. During this time, the physical examination can be completely normal, and the athlete may appear unaffected. At this stage, the epidural hematoma is still small enough to be asymptomatic. As it expands, however, the increasing pressure inside the skull puts the brain at risk, leading to a quick return of symptoms. Continued expansion of the hematoma can then lead to rapidly progressive symptoms, coma, and even death. The lucid interval typically lasts only a few minutes, while the subsequent deterioration can occur even faster.

It should be noted that the presenting signs and symptoms of epidural hematoma are similar to those of other head injuries, including concussion. Often, the main difference is in the time course of symptoms. If any athlete develops new symptoms several minutes after a witnessed impact or if there is any perceived clinical worsening, emergency medical services should be notified immediately.

Clinical Evaluation

As with any athletic head injury, care should be taken on the field to first assess the "ABCs" (*a*irway-*b*reathing-*c*irculation) and evaluate the possibility of cervical spine trauma, instituting cervical immobilization when appropriate. Level of consciousness should then be noted using the Glasgow coma scale. Any language, memory, or orientation abnormalities should also be noted. A physical examination should then be performed to evaluate for skull fracture or any focal neurologic abnormality, including pupillary, visual field, and fundoscopic examinations, followed by a careful assessment of strength, sensation, reflexes, coordination, and gait. Any evidence of fracture or focal neurologic abnormality warrants activation of emergency medical services.

Following the on-field assessment, appropriate monitoring and serial examinations should be carried out to document any changes in signs or symptoms. If any worsening is noted, the patient should be further evaluated in a hospital setting. Care should be taken to establish an accurate timeline of events; the accurate documentation of findings will help clarify the athlete's postinjury course.

Diagnostic Tests

The presence of an epidural hematoma is usually confirmed with a computed tomography (CT) scan of the head. Magnetic resonance imaging (MRI) of the brain can also be used. While the MRI may provide more information regarding damage to the brain itself, it is more expensive, requires more time, and is not available at every medical facility. The initial diagnosis, therefore, is typically made with a CT scan. Acutely, epidural hematomas appear hyperdense (bright) on CT scan, are classically lens shaped, and are located in the temporal area.

Management

Athletes with a suspected epidural hematoma should be immediately transferred via emergency medical services to the nearest emergency facility. Once the hematoma is confirmed, the patient should be evaluated for surgical intervention. Surgery includes evacuation of the hematoma as well as repair of the vascular structures and skull, as needed.

Prevention

As with other head injuries in athletics, proper technique, well-fitted and certified equipment, and adherence to the rules of play are paramount in preventing an epidural hematoma.

Return to Sports

No athlete should return to participation in contact sports as long as he or she is still symptomatic from any head injury. In the case of an epidural hematoma, contact sports should be avoided indefinitely.

Epstein-Barr Virus, Infectious Mononucleosis, and Splenomegaly

Infectious mononucleosis (IM) accounts for considerable morbidity and even mortality in physically active young adults. In the United States, IM has a peak incidence between 15 and 21 years of age, and 1% to 3% of college students may become infected yearly. There is no evidence that IM is more prevalent or less prevalent in athletes.

Etiology

IM is caused by the Epstein-Barr virus (EBV), which is a member of the herpes virus family. It is excreted in the saliva and infects only humans. IM is transmitted by close contact between susceptible individuals and both symptomatic individuals and asymptomatic carriers, with an incubation period of 30 to 50 days.

Clinical Signs and Symptoms

Typical symptoms include a 3- to 5-day prodrome of headache, anorexia, and malaise, which is followed by fever, fatigue, nausea/anorexia, rash, exudative tonsillopharyngitis (may mimic streptococcal pharyngitis), tender lymphadenopathy (especially postauricular lymphadenopathy), hepatomegaly/hepatitis, and splenomegaly, typically lasting 2 weeks. Mild liver function elevation, atypical lymphocytosis (>10%), and heterophil antibodies confirm the clinical diagnosis. However, symptoms can be minimal and may be overlooked. In one study, less than half of the military cadets who converted from negative to positive serologically (IgG [immunoglobulin G]) for EBV had an illness over their 4 years of training that was clinically recognized as IM. Infection acquired during childhood often displays minimal or nonspecific symptoms, and many adults without a history of IM have antibody evidence of prior subclinical infection. The characteristic peripheral blood smear and monospot may be the only clinical diagnostic clues in those with minimal symptoms.

IM can cause rare neurologic, respiratory, hematologic, and/or cardiovascular complications. With the exception of the rare presentation of airway compromise, the most worrisome complication associated with IM is spleen rupture. A clinical dilemma for practitioners caring for these active patients involves determination of the timing for safe return to activity and the risk of spleen rupture. As lymphocytic infiltration and spleen enlargement occur in the first few weeks of infection, the normal tissue anatomy and support structures become distorted, increasing fragility of the spleen. This puts the spleen at risk for subsequent rupture, at times with minimal and/or no trauma involved.

Diagnosis and Management

Supportive evidence may be obtained from hematology or chemistry laboratory tests. Atypical lymphocyte count >10%, mildly elevated liver transaminases, and a positive heterophil antibody testing (monospot test) should confirm IM in a patient with a compatible clinical picture. If IM is suspected in a heterophil-negative patient or if a more exact time of disease onset is desired, EBV-specific antibodies (viral capsid IgM [immunoglobulin M], viral capsid IgG, EBV nuclear antigen) can be ordered.

In nearly all patients, IM is self-limited, and supportive care is the treatment for uncomplicated IM in athletes. The role of antivirals and corticosteroids in improving clinical status and reducing time until return to play remains unclear.

Spleen Rupture and Return to Sports

The increased morbidity and even mortality in patients without a functional spleen makes the decision-making process for return to sports after IM an important one. There are no studies published that accurately assess the risk of spleen rupture after IM. The risk of spleen rupture has been extrapolated from the general population studies to be approximately 0.1% to 0.5%.

Before athletes return to play, they should be afebrile, well hydrated, and asymptomatic, with no palpable liver or spleen. An approach toward rehabilitating the IM patient may be started as soon as the spleen is not endangered by the activity. If we could simply put our hands on the patient's abdomen and tell who was at risk for spleen rupture after IM, no clinical dilemma would exist. However, no studies presently exist that safely predict prospective risk. There is poor correlation in identifying splenomegaly by clinical history and examination, clinical symptoms, duration of illness, measured spleen size without baseline studies, or liver enzyme elevation. This makes it difficult to predict when an athlete with IM may safely return to full participation. The very sick, febrile, dehydrated athlete is an easy decision. It is the athlete with minimal symptoms who feels healthy enough to return to early competition who presents the clinical dilemma. Most IM spleens are enlarged, but not all are palpable, and most livers are neither enlarged nor palpable. There has been no definitive correlation identified between the enlargement of the spleen and blood liver/enzyme parameters. Accordingly, it is difficult to estimate spleen size or the risk of rupture of the spleen from blood values, assuming that the most enlarged organs run the greatest risk of rupture.

Imaging is generally not necessary, as it is not possible to estimate how safe it is for an individual patient to return to activity on the basis of absolute ultrasonography values, especially with the wide variability encountered in normal values. This is especially true considering that athletes tend to be at the extremes of size norms. If imaging is obtained to evaluate spleen size, ultrasound is preferable in that it is easy, noninvasive, and reliable and does not expose the patient to radiation. Further studies to correlate normal spleen size and body mass indices are needed. The judicious use of computed tomography (CT) or magnetic resonance imaging (MRI) may be useful in difficult cases when early return to play is contemplated.

The time frame for return to play after IM needs to be individualized. Despite the lack of evidence-based data to guide the decision-making process, some generalizations may be extrapolated from the limited literature and past clinical experience. There is a parallelism in the curves generated for the size of the spleen and liver and the blood tests that imply normalization within 28 days. Most spleen ruptures occur between the 4th and 21st day, with only a few occurring beyond 28 days after diagnosis. Based on the overall clinical impression, return to play after 1 month may be safe, but further studies are required to corroborate this clinical impression and the standardization of timing, as the insensitivity of the manual spleen examination and the rare reports of spleen rupture after 4 weeks are still areas of concern.

The decision for return to play after IM should be individualized on a case-by-case basis with recognition of all risk factors. All strenuous activity, weight lifting, contact sports, and even roughhousing should be limited in all patients with IM for the first 2 to 3 weeks. As previously mentioned, the spleen seems most vulnerable during the first 21 days, as most spleen ruptures generally occur during that period. Limited noncontact aerobic activity may be permitted beginning 3 weeks from diagnosis/symptom onset as long as the patient is afebrile, well hydrated, and asymptomatic, with no palpable spleen. This recommendation assumes that participants avoid any activities that put the spleen at risk for traumatic injury. The return to full activity must be individually paced, and abrupt changes in the progression of exercise should be avoided.

Conclusions

No strong evidence-based information supports use of a single parameter to predict the safe return to sports participation. The current consensus is that athletes be afebrile, well hydrated, and asymptomatic, with no palpable liver or spleen. Clinical judgment incorporating these criteria 1 month after diagnosis has been suggested as a safe predictor for gradual return to competition. These conditions for return to play do not guarantee that the spleen has returned to normal size and compliance or that the risk of spleen rupture has returned to baseline. For those athletes participating in contact sports who wish to return to sports in an earlier time frame or those with an equivocal examination, radiographic modalities may be used to help determine true liver and spleen size. Further studies are required to support this practice.

Erythropoietin

Erythropoietin (EPO) is a naturally occurring hormone that stimulates the production of new red blood cells (RBCs), a process called hematopoiesis. Athletes have used EPO to increase red blood cell mass as a way of gaining a competitive advantage, particularly in endurance sports.

RBCs deliver oxygen to peripheral tissues, including muscle. Exercising muscles use oxygen to produce energy. Well-trained muscles with adequate oxygen supplies can remain in aerobic metabolism longer. This means that the fuel that the body uses is metabolized efficiently with fewer waste products. Anaerobic metabolism (i.e., the breakdown and use of fuel stores in the body without the use of oxygen) occurs the longer the muscle is used and is much less efficient. In fact, during anaerobic glycolysis, only a small percentage of the potential energy is gained from each molecule of glucose used. In addition, lactic acid is produced as a by-product that builds up in the muscle. As more lactic acid accumulates, the muscle becomes sore, fatigued, and less efficient. Besides delivering oxygen, hemoglobin (a protein in RBCs) also acts as a buffer for lactic acid. EPO stimulates the production of more RBCs and so improves the potential for aerobic exercise metabolism.

EPO is a growth factor made primarily in the kidneys in response to hypoxia (low oxygen levels). Its production is stimulated by physical stress, such as exercise or exposure to high altitude where oxygen levels are lower. In fact, athletes have recently started to harness this phenomenon by sleeping in tents with slightly lower than normal oxygen levels to simulate high-altitude conditions and stimulate endogenous EPO. This method is considered safe if done properly and is legal with regard to competition.

EPO works by stimulating bone marrow to produce more RBCs and by improving the survival of existing RBCs. RBCs usually have a life span of about 120 days. In the setting of serious illnesses such as kidney failure or AIDS or during cancer chemotherapy, the life span can be shorter, and the production of new cells is diminished. The result is called "anemia of chronic disease." Recombinant, or synthetic, EPO has been used in medicine to treat this condition, and in future, it may have a role in treating certain brain injuries and in wound healing.

EPO has been abused by athletes as a blood-doping agent since the late 1980s, and has been banned since the 1990s. It is an injectable substance and can be effective for 6 weeks after administration. Sports governing bodies such as the World Anti-Doping Agency (WADA) employ several methods to expose and prevent doping with substances such as EPO. Certain athletes, such as competitive cyclists, have to agree to random searches of their homes or workout facilities for evidence of banned substances. Blood and urine tests are performed to search for traces of exogenous EPO, which is chemically different from naturally occurring EPO.

As an additional screening test, hematocrit and hemoglobin levels are measured in athletes. Hematocrit is the percentage of whole blood made up by RBCs. Hematocrit levels in healthy adults range from approximately 36% to 46%. Hemoglobin levels are expressed as the number of grams of oxygen-carrying protein per deciliter of whole blood. A normal hemoglobin range is 14 to 16 grams/deciliter. The use of EPO increases hematocrit and hemoglobin levels significantly. Allowing for individual variation and the fact that exercise increases these values, there are physiologic ranges for hematocrit and hemoglobin above which doping has to be suspected.

EPO use has significant risk. There are inherent risks from infection and adulteration of the product whenever an injectable chemical is used. In addition, there is a significant risk of complications from polycythemia, increased numbers of RBCs, and viscosity of the blood. Thrombosis (blood clots) can occur, leading to deadly pulmonary emboli, strokes, or heart attack.

Exercise Addiction/ Overactivity Disorders

Exercise addiction or overactivity disorders can be diagnosed in patients who attempt to control their bodies and define their identity by overinvolvement in exercise activity. This overinvolvement often has addictive properties, thereby producing a rigid commitment to exercise routines, with symptoms of withdrawal when exercise is reduced or diminished. Experts estimate that at least 4% of Americans struggle with excessive exercise. While women are more often associated with eating disorders and a preoccupation with weight, it is men who are more likely to become addicted to exercise. College-age men are twice as likely as their female counterparts to exercise to excess. They are also more prone to becoming irritable and tense if there is a missed scheduled workout.

Symptoms

Warning signs of exercise addiction include exercising alone, a rigid exercise routine, exercising for more than 2 hours per day, a fixation on weight loss or calories burned, exercising when sick or injured, exercising to the point of pain and beyond, and skipping work or other obligations to complete exercise routines. The symptoms of exercise addiction and overactivity disorders are often the same as those for anorexia and bulimia. These overlapping symptoms are obsessive concerns over being fat, body dissatisfaction, and binge eating. The consequences of exercise addiction can be severe: Most excessive exercisers eventually develop overuse injuries, which can have long-term repercussions. Female exercise bulimics also cease to have periods, a condition called exercise amenorrhea. When a woman's menstrual cycles stop, it means her estrogen levels have dropped to those of a postmenopausal woman. Estrogen, of course, is vital for the normal development of bone—which reaches its peak in women in their mid-20s. If a woman's estrogen levels dip too low during this critical time, she may start losing bone mass instead of building it.

Symptoms that are solely concerned with overactivity are high levels of activity and feeling uncomfortable with rest or relaxation, dependence on activity for self-definition and mood stabilization, use of rationalization and other defense mechanisms to support involvement in an activity, fatigue, decreased concentration, reduction in performance, loss of emotional vigor, soreness, and stiffness.

Causes

Exercise addiction and overactivity disorders are most often associated with body image disturbance. Individuals with a healthy body image have positive self-evaluations and accurate perceptions about their body shape and size. Body image disturbance is marked by negative self-evaluations and is indicated when an individual's perceptions of shape and size differ from reality. Cultural body ideals are defined by the communications media and are largely unrealistic for the vast majority of the population.

Studies also indicate that overactivity disorders can be associated with depression, anxiety, and other mood-related disturbance. Compulsive exercise becomes a way to regulate negative feelings, and this may lead to excessive dependence on exercise.

Diagnosis

Currently, the American Psychiatric Association does not recognize excessive exercise and overactivity disorders as primary disorders. Excessive exercise is known to be a symptom of bulimia nervosa. The current *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition text revision (*DSM-IV-TR*), describes excessive exercise as exercise that "significantly interferes with important activities, occurs at inappropriate times or in inappropriate settings, or when the individual continues to exercise despite injury or other medical complications." In the case of bulimia, exercise dependence is a way to control body weight, to maintain appearance, or to compensate for a binge-eating episode as opposed to or in addition to purging. This is known as non–purging-type bulimia nervosa. Rather than purging after episodes of binging, the bulimia patient fasts or exercises excessively to prevent weight gain or to achieve weight loss. Individuals with anorexia nervosa may also engage in excessive exercise as a method to achieve weight loss. There is a continuum of behavior known as excessive exercise and exercise dependence. Many researchers have concluded that exercise dependence occurs in the presence of a formal eating disorder. Other studies have indicated that exercise dependence exists in individuals without body image disturbance or with a preoccupation with thinness. They have concluded that it is a primary disorder that results in exercising for the sake of exercising itself.

Treatment

The treatment of overactivity disorders and exercise dependence varies according to the symptoms and the associated symptoms. Overactivity disorders can become quite dangerous if not addressed early on. It is important that a differential diagnosis be made between activity disorder with and activity disorder without the presence of an eating disorder.

Individuals with these disorders are often treated on an outpatient basis. Reducing physical activity, restoring it as a healthy behavior, and developing other coping tools to manage feelings of depression and anxiety are part of the treatment of these disorders. Seeking the guidance of a mental health professional and a physician is always recommended.

Exercise and Disease Prevention

Historically, physical exercise has been linked to conventional sports and associated with athletes. Currently, physical exercise is of great interest to many recreational practitioners, who enjoy exercise as a fun and useful way of improving health and well-being. The concept of exercise as a part of sports training has been extended to exercise as a means of improving the health of athletes. This entry will provide an overview of the role of exercise in disease prevention and of guidelines for performing health-related exercise.

The terms *physical activity, physical exercise,* and *physical fitness* are sometimes used interchangeably, although they are actually quite different concepts. *Physical activity* is any body movement produced by muscle action that increases energy expenditure. *Physical exercise* refers to planned, structured, systematic, and purposeful physical activity. *Physical fitness* is a set of attributes related to a person's ability to perform physical activities that require cardiorespiratory capacity, endurance, strength, or flexibility and is determined by a combination of regular activity and inherited ability. Another widely used concept is *health-related physical fitness,* consisting of those components of physical fitness that have shown a relationship with health. Health-related fitness has been characterized by an ability to perform daily activities with vigor and by traits and capacities that are associated with a low risk for the development of chronic diseases and premature death.

Role of Physical Activity/Exercise and Fitness in Disease Prevention

Physical Activity/Exercise and Disease Prevention

The Physical Activity Guidelines Advisory Committee, formed by the U.S. Department of Health and Human Services, in 2008 reviewed the existing scientific literature to identify the current evidence to develop a comprehensive set of specific physical activity recommendations. The review found strong scientific evidence that physically active people have higher levels of health-related fitness and a lower risk of developing a number of disabling medical conditions than do people who are inactive. These findings are summarized below.

Health Benefits of Regular Physical Exercise

Physical exercise reduces the risk of . . .

- early death
- developing heart and cardiovascular diseases
- developing obesity
- developing diabetes
- developing high blood pressure and high (bad) cholesterol
- developing certain types of cancer
- developing depression and anxiety

Physical exercise also . . .

- improves immune system activity
- tones muscles and preserves or increases muscular mass, preserving function and independence
- strengthens bones and joints
- increases coordination and balance, reducing the risk of falls and bone fractures
- helps in the control of body weight and improves “body image”
- promotes well-being and social integration

Health Benefits of Regular Physical Exercise

The review found that both children and adults benefit from regular physical activity. For children and adolescents, physical fitness and health status are substantially enhanced by frequent physical activity. Compared with inactive young people, physically active children and youth have higher levels of cardiorespiratory endurance and muscular strength, less body fat, more favorable cardiovascular and metabolic disease risk profiles, enhanced bone health, and reduced symptoms of anxiety and depression.

In *adults and older adults,* strong evidence demonstrates that more active men and women have lower rates of all-cause mortality, coronary heart disease, high blood pressure, stroke, Type 2 diabetes, metabolic syndrome, colon cancer, breast cancer, and depression than less active adults. In addition, physically active adults and older adults also exhibit a higher level of cardiorespiratory and muscular fitness, have a healthier body mass and composition, and have a biomarker profile that is more favorable for preventing cardiovascular disease and Type 2 diabetes and for enhancing bone health.

For *older adults,* strong evidence indicates that being physically active is associated with higher levels of functional health, a lower risk of falling, and better thinking ability. Regular physical activity also helps people with arthritis or other rheumatic conditions affecting the joints by improving pain management, function, and quality of life.

Physical Fitness and Disease Prevention

In adults, cardiorespiratory fitness is a powerful predictor of cardiovascular and all-cause morbidity and mortality. This is true for apparently healthy individuals and people with chronic diseases, such as Type 2 diabetes, hypertension, metabolic syndrome, and several types of cancer. This association is independent of adiposity, indicating that people who are overweight can benefit from improving their fitness level. Additionally, muscular strength, a component of physical fitness, may reduce the risk of death and of some diseases in adults, regardless of whether they are overweight/obese or not and whether they have a high or low cardiorespiratory fitness level.

Physical fitness also improves the health of children and adolescents. A recent review found that fitness reduces body fat and cardiovascular disease risk factors; reduces depression, anxiety, and fatigue; and improves skeletal health, self-esteem, academic performance, and quality of life in pediatric cancer patients/survivors.

Additive Effects of Physical Activity/Fitness and Other Risk Factors on Health Status

In addition to their individual effects on health status, low physical activity and low physical fitness often occur with other risk factors, leading to an additive negative effect on health. Obesity, for example, often occurs simultaneously with low physical activity and fitness. Individuals who are both obese and inactive/unfit have higher morbidity and mortality than those who are either obese or inactive/unfit but not both. Consequently, a change in one of those risk factors produces positive health benefits. Sedentary obese people who become physically active improve their health status, even if their weight status does not change. And those who both become physically active and lose weight achieve even greater health benefits. The debate about whether inactivity or obesity more strongly influences health status is not important from a public health perspective. The recommendation for both conditions is to increase physical activity.

Prescription of Exercise for Disease Prevention

There is little doubt that regular exercise benefits health. To help children and adults obtain these health benefits, the Physical Activity Guidelines Advisory Committee, on behalf of the U.S. Department of Health and Human Services, has provided specific recommendations for healthy physical activity in different populations.

Health-Related Exercise for Children and Youths

Children and youth should participate in 60 or more minutes of moderate to vigorous physical activity each day. Their activity should include the following types of physical activity on 3 or more days per week: (a) resistance exercise to enhance muscular strength in the large muscle groups of the trunk and limbs (e.g., push-ups, sit-ups), (b) vigorous aerobic exercise to improve cardiorespiratory fitness and cardiovascular and metabolic disease risk factors (e.g., cycling, walking, swimming), and (c) weight-loading activities to promote bone health (e.g., jumping, running).

Health-Related Exercise for Adults

The intensity of physical activity can be moderate or vigorous. Moderate-intensity activity is generally equivalent to a brisk walk that noticeably accelerates the heart rate. Vigorous-intensity activity is exemplified by jogging, and it causes rapid breathing and a substantial increase in heart rate. On average, 1.5 hours per week in moderate-to-vigorous physical activity will lead to a 20% reduction in risk of all-cause mortality, compared with less than 0.5 hour per week of moderate-to-vigorous physical activity. Additional amounts of physical activity are associated with additional reductions but at smaller magnitudes.

Current physical activity recommendations indicate that adults should do at least (a) 150 minutes (2 hours and 30 minutes) a week of moderate-intensity aerobic physical activity, (b) 75 minutes (1 hour and 15 minutes) a week of vigorous-intensity aerobic physical activity, or (c) an equivalent combination of moderate- and vigorous-intensity aerobic activity. Aerobic activity should be performed in episodes of at least 10 minutes and preferably should be spread throughout the week. Adults should also do muscle-strengthening activities, such as weight training, push-ups, sit-ups, carrying heavy loads, and heavy gardening, at least 2 days a week.

Health-Related Exercise for Older Adults

Because the exercise capacity of adults tends to decrease as they age, older adults generally have lower exercise capacities than younger persons. Thus, they need a physical activity plan that is of lower absolute intensity and amount (but similar in relative intensity and amount) than is appropriate for fitter people, especially when they have been sedentary and are starting an activity program. In contrast to what many people would think, the capacity for training and improvement in older people is, in relative terms, as high as in younger people. The current literature shows that strength gains after resistance training (8- to 16-week programs) in older adults (over 60 years) range between 10% and 82%.

For older adults at risk of falling, strong evidence exists that regular physical activity is safe and reduces falls. The programs of exercise for older adults should follow the same guidelines described above for adults but adapted to their possibilities. This exercise should include balance training, moderate-intensity muscle-strengthening activities, and participation in moderate-intensity walking activities. When older adults cannot meet the recommendations because of chronic conditions, they should be as physically active as their abilities and conditions allow. All older adults should avoid inactivity. Some physical activity is better than none, and older adults who participate in any amount of physical activity gain some health benefits.

Conclusion

Given the importance of physical exercise to general health status and disease prevention, people of every age, gender, and race/ethnic group should be physically active most days of the week and should strive to meet the new guidelines. Schools, sports centers, health organizations, and governmental institutions must work together to help people achieve this goal. Physicians should counsel their patients to be physically active and to meet the new guidelines.

Exercise and Heart Murmurs

Heart murmurs are extra sounds that originate from within the heart itself. Some murmurs are innocent and cause no problems for the patient, while others can be from dangerous or even life-threatening sources. Sometimes murmurs can affect exercise capacity and exercise tolerance—that is, how much or how long someone can exercise. Figuring out the source of the murmur can be a relatively easy process, but treatment varies greatly depending on the etiology.

Anatomy

The heart is composed of four chambers, two atria and two ventricles. The atria have thin muscle walls and help fill the ventricles completely with their contractions. The ventricles are larger cavities and have thicker muscle walls to help pump the blood either to the lungs or through the rest of the body.

Blood flows in from the body to the right atrium and passes through a set of valves, called the tricuspid valves, to the right ventricle. The right ventricle pumps the blood through the pulmonic valve to the pulmonary artery and then to the lungs. The blood returns to the heart into the left atrium and then passes through the mitral valve to the left ventricle. The left ventricle, the thickest of the four chambers, pumps the blood through the aortic valve to the aorta and out to the rest of the body.

Causes of Heart Murmurs

Murmurs can originate from innocent or concerning sources within the heart. Innocent murmurs are caused by the sound of blood flowing within the heart. To understand this more fully, it helps to think of the relationship of the left ventricle and the aorta (and the right ventricle and the pulmonary artery) as a large bucket and a pipe. The pipe is fixed to a wall, and the water is being thrown from the bucket into the pipe. Some of the water will go into the pipe and some will miss and hit the wall around the pipe. The same thing can happen in the heart. The left ventricle contracts with a powerful force, trying to force all the blood out of the aorta into the rest of the body. Not all the blood gets to the aorta with each contraction. Some of the blood misses and hits the wall of the heart around the aorta. This blood then swirls around in the heart, and this swirling can cause extra noise, which is heard as an innocent murmur.

Other heart murmurs come from sources within the heart—namely, the heart valves. (Certain genetic or congenital issues can also cause murmurs, but they are covered in another entry.) The valves in the heart normally open and close like a door, allowing the blood to go through at the appropriate times or preventing blood from passing when it should not. Valves can malfunction in one of two ways: They can become very stiff and not be able to open properly, or they can become loose and not be able to close properly. When valves get stiff, a condition known as *stenosis,* the blood has to pass through a smaller or narrower opening, which can cause extra noise and be heard as a murmur. When valves get loose, leading to a condition known as *insufficiency* or *regurgitation,* the blood can leak back through the incompletely closed valve and also cause extra noise, which can be heard as a murmur.

Diagnosis

Heart murmurs are diagnosed by a combination of physical examination and diagnostic imaging. During the exam, the physician listens to the heart with a stethoscope. Different types of murmurs can sound differently and have different qualities to them (loud, soft, harsh, blowing, etc.). Some other maneuvers, such as squatting and standing, can change the sound of the murmur and help determine what type of murmur is present. Sometimes the physical exam does not give the physician enough information to determine exactly what type of murmur is present. In these cases, an echocardiogram, an ultrasound test of the heart, is ordered. The echocardiogram will give information about the structure of the heart valves, whether the valves are functioning normally, and whether the blood flow is normal or altered.

Treatment

Identifying the cause of the murmur and the severity of the dysfunction determines how it will be treated. The echocardiogram results are combined with the patient's symptoms (shortness of breath, swelling in the legs, low exercise tolerance, etc.). Some innocent murmurs do not require any treatment, and the physician will follow the murmur over time to make sure it does not change. Other murmurs that are caused by the heart valves not functioning correctly but only mildly impaired may be treated with medications to help control the flow of blood and reduce the complications of the murmur. Some valves are moderately impaired, but the patient's symptoms can range from mild to very severe; the combination will determine if medications are enough. Then, there are times when the heart valves are severely impaired and need to be treated with surgery to replace the valve.

Heart Murmurs and Athletic Participation

The extent to which someone with a heart murmur can exercise depends on two main factors: the cause of the heart murmur and the patient's symptoms. Athletic participation guidelines have been developed for patients with different types of valve problems. The most recent update of these is published in the 36th Bethesda Conference on Eligibility Recommendations for Competitive Athletes With Cardiovascular Abnormalities. In general, the ability of a patient to exercise with a murmur is determined on an individual basis between patient and physician, taking into account the severity of the valve disease, the type of exercise desired, the patient's symptoms, and the overall health/other diseases of the patient.

Exercise and Mitral Valve Prolapse

The mitral valve is located between the upper (atrium) and lower (ventricle) chambers of the left side of the heart. Normally, it allows blood to flow from the top to the bottom chamber only. *Mitral valve prolapse* (MVP) is a condition in which the mitral valve is loose and somewhat "floppy," so that it doesn't shut as firmly as it should. It may close with a faint click or may permit a tiny amount of blood to leak through, producing a heart murmur. A large prolapse can actually allow blood to seep back into the left atrium, a condition called *mitral regurgitation*.

Symptoms

Many people with MVP live their whole lives without symptoms. Those who do have symptoms may experience heart palpitations, chest pain, fainting, shortness of breath, decreased stamina, or fatigue with periods of weakness. These symptoms should prompt medical attention and evaluation.

Prevalence

Approximately 2% to 4% of the population has MVP to some extent. It seems to run in families, so a genetic component is likely, but this relationship is not clearly understood.

Diagnosis

These patients may be identified by using a stethoscope to listen over the anterior chest wall for certain sounds. Typically, patients with MVP may have a midsystolic click and/or murmur of mitral regurgitation. The diagnosis is usually confirmed by echocardiography to image the mitral valve and look for the abnormal structure and motion of the valve. An electrocardiogram is often done as well to look for evidence of irregular heart rhythms.

Complications

It should be emphasized that MVP is generally not considered to be a life-threatening or a progressive condition in the vast majority of patients. In fact, MVP is considered to be one of the most benign heart conditions that cause murmurs.

The two main concerns for those with MVP are the long-term effects of mitral regurgitation and the potential development of a heart infection called endocarditis. The backflow of blood from the ventricle to the atrium (regurgitation) can lead to enlargement of the cardiac chambers and weakening of the heart muscle. In rare cases, this can potentially lead to heart failure. Only about 5% of those with MVP have a large enough regurgitation to cause any problem.

Endocarditis is a rare but potential occurrence anytime there is an irregular or damaged heart valve. To decrease the risk of this infection, doctors prescribe antibiotics to patients with MVP before any procedure, such as dental work, that is likely to introduce bacteria into the bloodstream.

In general, the greatest risks for unfavorable outcomes with MVP, including severe progressive mitral regurgitation (requiring valve surgery) and endocarditis as well as (less commonly) strokes/emboli, dangerous arrhythmias, and sudden death, appear to be associated with severe, substantial structural abnormality of the mitral valve.

Recommendations for the Athlete

The heart is a muscle, and like any muscle, it gets stronger with exercise. Aerobic exercise strengthens the heart and makes it more efficient and is generally recommended for those with MVP if they do not have significant symptoms. In most cases, MVP is not a barrier to high levels of athletic performance and/or competition.

People bothered by chest pains or palpitations are sometimes given medications such as beta blockers. These drugs slow the heart rate during exercise. Active lifestyles can still be continued, and aerobic exercise is recommended with appropriate monitoring.

Sudden cardiac death due to isolated MVP is rare, particularly in relation to exercise and in trained athletes. Such events are probably not more frequent than in the general population and occur predominantly in patients older than 50 years with severe mitral regurgitation and/or systolic dysfunction. Some individuals with MVP appear to be part of a connective tissue spectrum disease expressed as a tall, thin habitus, thoracic cage deformity, and joint hypermobility for which there is a risk, albeit low, of progression to aortic dilatation or sudden death.

The following are recommendations for the athlete from the American College of Cardiology, as outlined in the 36th Bethesda Conference, 2005:

1. Athletes with MVP—but without any of the following features—can engage in all competitive sports:
   a. Prior syncope, judged probably to be of arrhythmogenic origin
   b. Sustained or repetitive and nonsustained supraventricular tachycardia or frequent and/or complex ventricular tachyarrhythmias on ambulatory Holter monitoring
   c. Severe mitral regurgitation assessed with color-flow imaging
   d. Left ventricular systolic dysfunction (ejection fraction less than 50%)
   e. Prior embolic event
   f. Family history of MVP-related sudden death
2. Athletes with MVP and any of the aforementioned disease features can participate in low-intensity competitive sports only as defined in the Bethesda Guidelines.

Exercise During Pregnancy and Postpartum

Exercising prior to conception and continuing physical activity during pregnancy has many benefits for the mother and the child. Even if exercise is not begun until late in the pregnancy, exercise is beneficial as long as certain guidelines are followed.

Benefits of Exercise to the Mother

Regular exercise during pregnancy has many benefits. It helps the mother sleep better and improves the mother's energy and mood. It improves posture, muscle tone, strength, and endurance. It helps reduce backaches, constipation, and bloating. It may also help prevent or treat gestational diabetes and also help prepare a woman to cope with the pain of labor.

Effects of Exercise on the Fetus

In a healthy woman, there is little effect on the fetus during exercise. Extreme heat (≥102.5 °F) can be harmful to the fetus, but even with pregnancy increasing the mother's core temperature, exercising women have not been shown to routinely reach such extremes in temperature. In pregnant athletes performing intense exercise, fetal heart rates have been shown to remain normal. Even late in pregnancy, fetal oxygenation has not been shown to be impaired during intense exercise. The placentas of exercising women have improved blood flow and gas exchange efficiency for the fetus. There is a correlation between consistent weight-bearing exercise throughout pregnancy and reduced birth weight. Exercising women are more likely to experience labor a week earlier than sedentary women (not preterm labor), which may contribute to the lower birth weight of the child. Babies of exercising women have less behavioral and biochemical evidence of stress during late pregnancy and labor. Also, while the long-term follow-up data are limited, it appears that beginning/continuing weight-bearing exercise during pregnancy has no adverse effects on postnatal growth, health, or neurodevelopment, and in small studies, it has been shown to be even beneficial. Long-term studies are needed to better characterize such effects.

Maternal Changes During Pregnancy

Because there are many changes to a woman's body when she is pregnant, it is important to realize that these may affect the ability to perform certain types of exercise. The extra weight a pregnant woman carries will make her body work harder than prior to pregnancy. Her center of gravity is forward and upward because of her enlarging breasts and uterus, making it easier for her to lose her balance and also increasing her likelihood of back pain. The hormones produced during pregnancy cause the ligaments that support the woman's joints to be more relaxed, making the joints more mobile and at increased risk of injury.

Exercise can increase maternal core body temperature, but in general, pregnant women have a lower resting temperature and sweating threshold because of better heat dissipation (from plasma volume expansion, increased blood flow to the skin, and better heat exchange across the skin). Blood volume rises at 6 to 8 weeks' gestation and peaks to an increase of 40% to 50% by the middle of the second trimester. Cardiac output and stroke volume also increase, allowing exercise to be well tolerated in pregnancy. Such cardiac reserve decreases after 28 to 32 weeks' gestation, however, contributing to the need to decrease activity toward the end of pregnancy. Additionally, vigorous exercise usually is accompanied by increases in blood pressure and cardiac output. This response is blunted in pregnancy; thus, vigorous exercise would lead to shunting of blood away from the fetus and should be avoided.

Pregnancy leads to increased oxygenation, allowing pregnant athletes to achieve increased levels of oxygen consumption during exercise as efficiently as nonpregnant athletes. However, changes in maternal oxygenation are amplified in the fetus, so sustained maternal acidosis or hypoxia will eventually lead to fetal acidosis or hypoxia. Avoiding prolonged anaerobic activity can decrease this risk.

Before Starting an Exercise Program

It is important to review an exercise plan with the pregnant woman's physician before beginning, including the type of activity she would like to perform. Modifications may then be made to decrease risks of injury and fall and minimize extreme elevations in blood pressure and heart rate. If she is at risk for complications of pregnancy, including preterm labor, premature rupture of membranes, or vaginal bleeding, exercise is probably not safe. In addition, if she has conditions such as hypertension or diabetes, her exercise routine should be modified and monitored carefully, and medication adjustments may be needed. Thus, clearance from her doctor before beginning an exercise routine during pregnancy is extremely important.

Safe Exercise

Consensus on the safe limits of exercise during pregnancy is not easily obtainable. In general, for healthy women, the American College of Obstetricians and Gynecologists (ACOG) recommends 30 minutes or more per day of moderate exercise. Moderate exertion here means that the woman is able to talk comfortably during exercise (to keep her heart rate in an acceptable range). Walking, swimming, stationary cycling, and aerobics are all good exercises to choose. Running is acceptable in women who were runners prior to pregnancy, as long as balance is good and exertion levels are within range. Strength training can help improve muscle tone and reduce some of the aches and pains of pregnancy.

Exercise should be stopped immediately if the woman experiences shortness of breath, chest pain, dizziness, headache, muscle weakness, calf pain or swelling, vaginal bleeding, amniotic fluid leakage, preterm labor, or decreased fetal movement.

While no study has shown a negative effect of moderate-intensity aerobic exercise on pregnancy outcome, safe parameters have not been clearly established.

Exercises to Avoid During Pregnancy

Contact sports such as basketball, soccer, or hockey should be avoided because of the risk of abdominal trauma, with consequences to the mother and fetus. Sports with increased risk of falls (downhill skiing, ice skating, gymnastics, horseback riding, etc.) should also be avoided. Scuba diving is absolutely contraindicated because of the risk of fetal decompression sickness.

Safety Issues to Consider

If a pregnant woman is just starting an exercise program, she should begin slowly to acclimate to exertion. She should wear comfortable footwear and avoid rocky or unstable terrain when running or cycling. Because maternal joints are more lax in pregnancy, ankle sprains and other injuries may occur. She should drink plenty of fluids and avoid exercising in extremely hot weather. The risk of overheating can be minimized by wearing sensible clothing and avoiding saunas or hot tubs after exertion. Pregnant women should not exercise at altitudes above 6,000 feet (1,828.8 meters). Also important, pregnant women should remember to consume enough calories to compensate not only for pregnancy (about 300 extra calories daily [1 calorie = 4.2 joules]) but also for the added energy burned during a workout.

During the second and third trimesters, pregnant women should avoid exercises that involve lying flat on their backs, as this decreases blood flow to the womb. Exercise that involves standing upright for long periods of time should also be avoided. Avoiding the supine position after 20 weeks and avoiding excessive bouncing in the third trimester are reasonable precautions. By week 24, exercise should be tapered off according to tolerance and comfort level.

Postpartum Exercise

Many of the maternal physiologic changes during pregnancy remain for up to 6 weeks after delivery. Having a cesarean delivery, a difficult childbirth, or other complications may extend recovery time. Women have different recovery rates, so return to prepregnancy training regimen should be done gradually based on individual responses to exercise and after discussion with a doctor. Moderate weight reduction during nursing is safe and has not been shown to affect neonatal weight gain. In addition, exercise in the postpartum period is correlated with decreased risk of postpartum depression.

Conclusion

Each pregnant woman is unique and should be evaluated by a physician before starting an exercise program. The changes the mother and fetus undergo during pregnancy must be kept in mind when deciding on an exercise routine. This routine will need to be modified throughout the pregnancy, with avoidance of prolonged supine and prone positions toward the latter part of pregnancy. Contraindications to exercise exist, and physical activity should be stopped if warning signs occur. If exercise is performed wisely and cautiously, it can have positive effects on the mother and the child.

Exercise Physiologist

For decades, exercise physiology has existed as a research discipline within the context of several umbrella organizations. With the emphasis on research, exercise physiologists found themselves concentrating on publishing their findings, with little time devoted to the development of the profession of exercise physiology. Hence, the conversion from physical education to exercise science to exercise physiology is still evolving.

To help with the change process, the American Society of Exercise Physiologists (ASEP) was founded in 1997. The mission of the ASEP leadership is to promote ASEP as the professional organization of exercise physiologists to ensure the professionalism of exercise physiology. The leaders are committed to the professional development and credibility of exercise physiologists.

The researchers Peter Karpovich at Springfield College and Thomas K. Cureton at the University of Illinois, along with pioneers such as A. H. Steinhaus at George Williams College, John Holloszy at Washington University, Charles Tipton at the University of Iowa, and Phil Gollnick at Washington State, and the authors of exercise physiology textbooks (David H. Clarke of the University of Maryland, Harold B. Falls of Southwest Missouri State College, P.-O. Astrand of Stockholm, and Robert A. Robergs of the University of New Mexico, Albuquerque) have helped through their research to promote exercise physiology.

Professionalism and Exercise Physiology

Concern for health, fitness, and well-being has resulted in shared research efforts throughout the last half of the 20th century. Academic scholars in exercise physiology have helped other professionals to understand that regular exercise improves physiological, mental, and emotional health. Today, there are board-certified exercise physiologists (EPCs) with an interest in exercise as medicine, others who are interested in rehabilitation, and still others who are interested in health care or athletics.

The ASEP leadership has played a central role in gaining visibility and acceptance for exercise physiology as a credible health care profession. They developed the ASEP accreditation process, which defines exercise physiology. They also developed the board certification program to hold exercise physiologists accountable to a code of ethics and standards of practice.

In addition to protecting the public, the significance of the code is that students and professionals in the study and application of exercise physiology to health care and athletics can turn to it for guidance in professional conduct. Adherence is based on the belief that exercise physiologists are self-regulated, critical thinkers who are accountable for maintaining a high level of competence in the practice of exercise physiology.

Exercise physiology includes (a) the identification of the physiological mechanisms underlying physical activity; (b) the comprehensive delivery of treatment services concerned with the analysis, improvement, and maintenance of health and fitness; (c) the rehabilitation of individuals with heart disease and other chronic diseases and/or disabilities; and (d) the professional guidance and counsel of athletes and others interested in sports training and human adaptability to acute and chronic exercise. The ASEP defines an exercise physiologist as a person who has an academic degree in exercise physiology or who is board certified to practice exercise physiology.

Research and Scholarship

From a historical perspective, exercise physiologists were first physical educators who taught "physiology of exercise" in health and physical education departments. Since the earlier work with sports and athletics, exercise physiologists have been involved with research that deals with the integrated physiological responses of the mind and body.

There are many reasons for the interest in exercise physiology research. Among them are the benefits of understanding the physiology of regular exercise, how athletes adapt to training, and the rehabilitation of patients. Exercise physiology helps coaches and athletes understand oxygen consumption and what limits it, energy transfer and expenditure along with what constitutes a proper recovery, the oxygen transport system and weight resistance exercise, and the best way to develop sprinters and endurance athletes.

Exercise physiologists are also interested in diet, optimal nutrition, and athletic performance, as well as dehydration, heat problems, stress of altitude and thermoregulation, body composition, energy balance, and weight control. Their work has contributed substantially to a better understanding of the relationship between cardiac output and oxygen consumption ($\dot{V}O_2$). They helped develop and refine noninvasive carbon dioxide (CO_2) rebreathing procedures to measure cardiac output in their own laboratories and then set out to clarify the relationship and importance of heart rate (HR), stroke volume (SV), and arteriovenous oxygen difference ($a - \dot{V}O_2$diff) to improvements in exercise $\dot{V}O_2$.

Early exercise physiologists recognized the physiological relationship between the heart and lungs at rest and during exercise. Their work continues today with many papers dealing with the circulatory cost of breathing, expiratory flow limitations, pulmonary gas exchange, alveolar-to-arterial oxygen (O_2) exchange, ventilation-to-perfusion distribution, and the role of the respiratory muscles in endurance exercise. Many publications demonstrate an interest in aerospace physiology, particularly with reference to its effects on oxygen transport and lean muscle mass.

Whether it is evaluating the criteria for maximal oxygen consumption ($\dot{V}O_2$max) or the role of skeletal muscle mass, exercise physiologists have an interest in the determinants of $\dot{V}O_2$max. Whether it is a function of maximal cardiac output, blood volume, hemoglobin, or systemic tissue extraction, each area of study remains an important research question. Likewise, changes in the neuromuscular junction, muscle fiber hypertrophy, and chronic changes in skeletal muscle with aerobic and anaerobic training are important research topics, as are overtraining and the energy adaptations that occur with exercise.

Exercise as Medicine

At the heart of exercise physiology is the emphasis on exercise prescription, using $\dot{V}O_2$, metabolic equivalents (METs), HR, and rating of perceived exertion (RPE). Both aerobic training and high-intensity resistance training are associated with a lifestyle that decreases the risk factors for cardiovascular disease. When exercise is properly prescribed, not only does it help with the pathology of cardiopulmonary diseases, weight management, diabetes mellitus, osteoporosis, arthritic diseases, and neuromuscular diseases, but it also changes behavior, lowering the risk of premature disease and death. Exercise reduces the strain of stress, anxiety, and depression associated with stressful lifestyles. Increasingly, these findings have become a shared philosophy with health care professionals and scientists from various fields of study, including physicians, psychologists, psychiatrists, physiologists, biochemists, nurses, physical therapists, and other clinicians.

There are important adaptations to exercise both at rest and during exercise, especially the decrease in HR and the increase in SV to produce an effective cardiac output (Q) and increase the amount of oxygen available to the muscles for muscle contraction. There are also skeletal muscle changes (e.g., an increase in mitochondria, enzymes, fuel substrate, and myoglobin) that increase the work capacity of muscles. Maximal exercise changes include an increase in maximal SV, Q, and $\dot{V}O_2$max, in addition to larger expired ventilation volume and other changes that allow for greater physiological work.

As health care professionals, EPCs are researchers, educators, and clinicians. They provide health care services that help maintain, restore, and promote health and well-being. Their clients include anyone who is interested in better health and athletes who are engaged in sports training. Treatment is often in the form of exercise as medicine, whether it is for flexibility, strength, or endurance. They use metabolic analyzers to determine the client's $\dot{V}O_2$ and other physiological indicators of health and fitness. They may also consult and practice with a variety of other professionals for the rehabilitation of individuals with a wide range of symptoms and disabilities.

Exercise Physiology

Today's exercise physiologists are indebted to the rich history of academic programs in health and physical education. For many years, physical educators with an interest in sports physiology taught the "physiology of exercise" course in the college major. Significant concerns arose about the quality of the physical education major, resulting in many health and physical education departments changing to kinesiology or exercise science. Many of these departments offered doctorate degrees in kinesiology with a concentration in exercise physiology for the benefit of exercise physiologists.

Interest in exercise physiology in the United States developed during the 1960s, when exercise physiologists initiated adult fitness programs to increase physical fitness. During the 1970s, exercise physiologists worked with the medical community to develop cardiac rehabilitation programs to treat patients with myocardial infarction (MI). Additionally, many academic exercise physiologists actively engaged in research activities that focused on sports training to improve athletic performance. The prevailing view was that research is necessary to enable athletes to perform better. Advances in the scientific understanding of regular exercise and sports training support the value of exercise physiology.

When the American Society of Exercise Physiologists (ASEP) was founded in 1997 as a nonprofit professional organization of exercise physiologists, it was unclear to many in academia why it was needed. However, after decades of membership in nonexercise physiology organizations, academic exercise physiologists have become more aware that the students of kinesiology and exercise science majors experience considerable difficulty in locating credible career opportunities in the public sector. It is now recognized that research is only one component of exercise physiology.

The professional services rendered by the ASEP are important to instill professionalism in exercise physiology because of the challenges faced by exercise physiologists. In fact, to further encourage the professional development of exercise physiologists, the ASEP leaders introduced two electronic journals. Given the interest in research, the *Journal of Exercise Physiologyonline,* a peer-reviewed electronic research journal, was established in 1998 to feature original exercise physiology research, reviews, and editorials. Also, given that academic exercise physiologists prepare to become health care professionals, it was important to engage in discussions about professionalism. Hence, the *Professionalization of Exercise Physiologyonline* (*PEPonline*) was created in 1998. It was the first journal to publish articles on professionalism and professional development in exercise physiology.

Clarification of Titles

While it is common to hear exercise physiologists referring to themselves as "physiologists," the ASEP philosophy is driven by a more definitive and professionally appropriate title. For instance, since there is a doctorate degree in physiology, a person should not refer to himself or herself as a physiologist in everyday conversation unless he or she has that degree. This point and other similar inconsistencies have been published in *PEPonline.*

Similarly, since there is an undergraduate degree in exercise physiology, a person should not use the title Exercise Physiologist unless the person has that degree or has earned the EPC (board-certified exercise physiologist) credential. This is why a degree in exercise science or kinesiology is not a degree in exercise physiology, just as a physical therapy assistant cannot claim to be a physical therapist. To the ASEP leadership, this thinking plays a pivotal role in promoting the practice of exercise physiologists.

ASEP and Historical Perspectives

The ASEP leaders are aware that many exercise physiologists think of exercise physiology as a subdiscipline of exercise science. However, while exercise physiology could not have evolved into the profession it is today without the vision and work of its pioneers, the idea that it is an integrated science or a discipline that falls under exercise science is not true. Yet the ASEP leaders do not disagree that exercise physiology is an integration of many sciences. This thinking is integral to understanding its history and the context of exercise physiology as a health care profession.

Like other professions, the historical aspects are noteworthy, particularly in reference to the first exercise physiology textbook, *Physiology of Bodily Exercise,* by F. LaGrange in 1889, along with the first edition of *The Physiology of Exercise,* published by J. H. McCurdy, plus scientific work, research, and mentoring by Peter Karpovich

(Springfield College), Arthur H. Steinhaus (George Williams College), H. A. De Vries (author of the 1966 text *Physiology of Exercise*), B. Ricci (who published the 1967 text *Physiological Basis of Human Performance*), H. B. Falls (author of the 1968 text *Exercise Physiology*), Per-Olof Astrand and Kaare Rodahl (authors of the *Textbook of Work Physiology,* 1970), D. K. Matthews and E. L. Fox (authors of *The Physiological Basis of Physical Education and Athletics,* 1971), Thomas K. Cureton (University of Illinois), Elsworth R. Buskirk (University of Minnesota), John Holloszy (Washington University), Charles Tipton (University of Iowa), J. A. Faulkner (University of Michigan), Phil Gollnick (Washington State University), M. L. Pollock (University of Florida), Jack Wilmore (University of Texas, Austin), and D. L. Costill (Ball State University).

Clearly, this list represents only a small number of the contributors to exercise physiology. Many individuals, including textbook authors such as Bruce J. Noble, Michael Pollock, Scott K. Powers, and Edward T. Howley (authors of *Exercise Physiology*); Sharon A. Plowman and Denise Smith (the first female authors of an exercise physiology text, *Exercise Physiology for Health, Fitness, and Performance*); George Brooks (author of *Exercise Physiology: Human Bioenergetics and Its Applications*); William D. McArdle, Frank I. Katch, and Victor L. Katch (authors of *Essentials of Exercise Physiology* and other texts); and Robert A. Robergs (author and coauthor of several texts, including *Fundamentals of Exercise Physiology: For Fitness, Performance, and Health; Clinical Exercise Testing and Prescription Theory and Application;* and *Exercise Physiology: Exercise, Performance, and Clinical Applications*), have contributed significantly to the growth of the profession.

The difference between the 20th-century sports medicine perspective and the 21st-century ASEP perspective is that the ASEP leaders have declared their commitment to the professional development of exercise physiology as a health care profession, not just as a research discipline. This thinking is focused appropriately on the ASEP accreditation process that drives board certification, thus holding exercise physiologists accountable to their code of ethics and standards of practice. The significance of the code is that both students and professionals in their study and application of exercise physiology to health and wellness, rehabilitation, athletics, and sports training can turn to the code for guidance in their professional conduct.

Commitment to Professionalism and Scientific Thinking

Now that the ASEP leaders have defined exercise physiology as the identification of the physiological mechanisms underlying physical activity; the comprehensive delivery of treatment services concerned with the analysis, improvement, and maintenance of health and fitness; the rehabilitation of individuals with heart disease and other chronic diseases and/or disabilities; and the professional guidance and counsel of athletes and others interested in athletics, sports training, and human adaptability to acute and chronic exercise, there is every reason to think of exercise physiology as a profession. Also, since exercise physiologists have an academic degree in exercise physiology or are board certified by ASEP to practice exercise physiology, they are qualified to interpret the physiological effects of exercise and identify the appropriate modality (e.g., cycling, running, lifting) to individualize the exercise prescription.

Exercise physiology is a scientific profession with interests in sports training and exercise as medicine. The ASEP leaders believe that the increase in the elderly population will drive the demand for regular exercise for developing cardiorespiratory and muscular fitness for health purposes. The elderly population is particularly vulnerable to chronic and debilitating conditions that require the exercise physiologist's services. On the other hand, the baby boom generation is entering the prime age for heart attacks and strokes, which will further increase the need for cardiac and physical rehabilitation. It will be important that the services are rendered by credible professionals.

Widespread interest in health will increase the demand for exercise physiologists. That is why a growing number of employers use exercise physiologists to evaluate health and muscular fitness, develop exercise programs for special populations, and teach safe exercise prescriptions to their employees. They understand that an active lifestyle (especially regular aerobic exercise) protects one from many diseases, particularly coronary heart disease, by decreasing low-density lipoproteins (bad cholesterol), increasing high-density lipoproteins (good cholesterol), and reducing triglyceride levels. In short, epidemiological evidence supports the hypothesis that increased physical activity decreases the rate of death from heart disease.

Health Care Professionals

Exercise physiologists are set apart from personal trainers and fitness instructors. They understand and know all too well the importance of their scientific education and the fact that it is driven by laboratory experiences and the critical thinking necessary to design and oversee exercise prescriptions for clients and athletes interested in improving their health-related fitness and/or athletic performance. For these reasons, exercise physiologists are uniquely qualified to work with the apparently healthy population, whether in fitness centers or corporate settings. That is why they are qualified to supervise exercise programs and design wellness interventions and other models of rehabilitative care and secondary prevention through regular exercise.

Only EPCs have the academic and hands-on depth of knowledge that makes them the first-choice health care professional in designing effective exercise training for wellness enhancement, cardiopulmonary rehabilitation, and prevention of muscular and orthopedic problems (particularly in the ergonomic and occupational fitness settings with regard to adults suffering from arthritis, back pain, and osteoporosis). This is also true for the management of stress, anxiety, and depression, as well as for sports training and for prescribing and monitoring exercise and training programs for special populations, such as children and senior citizens.

The exercise physiologists' standards of practice provide a framework for understanding the educational requirements for attaining professionalism and recognition through the application of exercise as preventive medicine. There is little doubt that exercise is medicine, yet exercise physiology is often thought of only in terms of the physiological mechanisms underlying sports performance. In fact, it is clear that exercise physiologists' interest in competitive sports and the limits of athletic performance (particularly maximum oxygen consumption) is still of prime importance today.

It should come as no surprise that the work of the ASEP leaders is to encourage the use of exercise as medicine. They also believe that the best professional to supervise the exercise prescription is the ASEP EPC. For this reason and others, there is considerable interest in the professionalism of exercise physiology. In fact, for many college teachers who have been involved in the evolution of physical education from exercise science or kinesiology to exercise physiology, the drive to develop exercise physiology as a health care profession is intense. Exercise physiologists are responsible to the public, not just to athletes. At one end of the spectrum is health, and at the other end is a huge role in rehabilitation. It is the exercise physiologist's responsibility to know both ends of the spectrum. There is little doubt that the ASEP leaders are working hard to fulfill the 21st-century view of exercise physiology.

Exercise as Medicine

As credible professionals with a strong scientific background, exercise physiologists recognize the positive impact that regular exercise has on many clinical conditions, longevity, and good health. Regular exercise increases the ability of the body to transport oxygen for use by the muscles. Along with the increase in heart rate during exercise, there is an increase in stroke volume (blood ejected from the ventricles per beat) at the same cardiac output (volume of blood ejected from the ventricles per minute). Other changes include a favorable lipoprotein profile, increased bone density, and stronger ligaments and tendons. Endurance training results in myoglobin and glycogen adaptations, along with an increase in the number and size of mitochondria and the enzymes specific to energy development within skeletal muscles.

Regular exercise increases the capacity to engage in physical activity and plays an important role in primary and secondary prevention of cardiovascular disease. In particular, there is an independent blood pressure–lowering effect (in certain groups with high blood pressure) with a decrease of 8 to 10 mmHg (millimeters of mercury pressure) in both systolic and diastolic measurements. Also, regular exercise helps correct the independent risk factor of inactivity and its relationship to the development of coronary artery disease. Numerous studies indicate that blood lipid reduction, smoking cessation, physical exercise, and weight control significantly decrease the rate of progression and, in some cases, even allow for regression in the atherosclerotic lesions in persons with coronary artery disease.

Exercise physiologists are in the driver's seat with both an opportunity and a responsibility to promote regular exercise, as well as teaching and counseling lifestyle changes in risk factors for diseases and disabilities and other health promotion strategies. They not only teach about the health problems resulting from obesity, but are part of only a few professions that actually teach, measure, analyze, and publish data about body mass index (BMI). They argue, as others do, that physical inactivity and level of fatness are strongly related to watching television. That is why exercise physiologists teach that losing weight and keeping it off is most successfully done when exercising on a regular basis.

This is an important point since exercise physiology is the only profession with the word *exercise* in its professional title. This should persuade physicians and others to use exercise physiologists to assess a baseline body composition, to incorporate exercise for the purpose of losing weight and gaining lean mass, and to improve body image and self-esteem through regular exercise. Physicians should incorporate EPCs in their practice, as they have done with physician assistants, particularly with regard to cardiovascular assessment of patients and exercise prescription guidelines for a healthier lifestyle.

Exercise physiologists should be the scientific cornerstone in the multidisciplinary approach to managing, if not preventing, obesity. Excess body fat can significantly impair the health of children and adults. Obesity is directly related to heart disease and diabetes. While there are many factors that may cause obesity, from endocrine and genetic disorders to diet and inactivity, the latter factors are the primary contributors to the difficulty in managing caloric balance. Regular exercise is very effective in decreasing body weight by increasing energy expenditure, which is also related to a decrease in caloric intake. The exercise should be primarily aerobic activity and not resistance training, since more calories can be expended during a shorter exercise period.

Regular exercise is a viable, cost-effective treatment for depression. In fact, exercise compares favorably with individual psychotherapy, group psychotherapy, and cognitive therapy. For example, in 1996, the Surgeon General released a report on physical activity and health that concluded that exercise has a beneficial effect in relieving symptoms of depression and anxiety and in improving mood. Evidence was also presented that exercise may protect against the development of depression.

Exercise is also recommended as an adjunct treatment with the more traditional treatment programs for schizophrenia, conversion disorder, and alcohol dependence. The evidence is clear. Exercise is a cost-effective treatment for many behavioral health conditions. Exercise physiologists need to be encouraged to pursue jobs in this area of health care, and equally important, the directors and administrators of these programs need to look to exercise physiology for qualified health care professionals.

For decades, exercise physiologists have encouraged sedentary clients and patients to adopt a more active lifestyle through developing individualized exercise prescriptions and carrying out assessments, followed by recommending walking and low-intensity jogging as a mode of exercise. When exercisers comply with the prescribed program, the improvement in exercise capacity is multifaceted, with changes occurring in the cardiovascular, respiratory, musculoskeletal, and metabolic systems.

Specifically, there is a lowering of the myocardial work requirement and improvement in the peripheral factors that increase oxidative enzymes, which helps with the use of oxygen delivered to the working muscles. There is a decrease in the oxygen cost at the same submaximal exercise intensity that parallels the decrease in the work of the lungs (i.e., the metabolic cost of breathing). The latter is facilitated by an increase in tidal volume, a decrease in the frequency of breaths, and an overall improvement in alveolar ventilation. These changes and others help delay the metabolic disorders associated with aging.

EPCs also understand the importance of including resistance training in an exercise program to improve health, increase functional capacity and independence, and prevent disease. Resistance training prevents a decrease in skeletal muscle mass and function during extended periods of inactivity and aging. Research indicates that adaptation to resistance training lowers the cortisol response to acute stress, increases total energy expenditure and physical activity in healthy and frail older adults, and has beneficial effects on bone strength, osteoarthritic symptoms, high blood pressure, lipid profiles, and exercise tolerance in post-MI patients and others with coronary artery disease.

Exercise physiologists are leaders in the science of exercise prescription, whether it is the use of resistance exercise or aerobic exercise, for persons with cancer, acquired immune deficiency syndrome, chronic fatigue syndrome, fibromyalgia, or arthritis. They understand that a typical resistance training workout consists of 8 to 10 exercises to cover the major muscle groups (e.g., chest, shoulders, arms, back, abdomen, thighs, and lower legs) and that the resistance should be moderate, which is defined as 30% to 40% of 1 repetition maximum (RM) for upper body exercises and 50% to 60% of 1 RM for lower body exercises. When 12 to 15 repetitions can be accomplished with little difficulty, the weight is increased. This progressive resistance strategy meets the requirements of the overload principle, which is the basis for improvement in muscle strength. Similarly, exercise physiologists apply the overload principle in aerobic training through the interplay of the following variables: intensity, duration, frequency, mode, and progression type. When the scientific principles of the exercise prescription are followed, aerobic power ($\dot{V}O_2$max) is increased 5% to 30%.

Physiology of Exercise Testing

Exercise is a practical and easy way to develop and maintain a healthy mind and body. It can be done alone or in a group with others, and it can be started at almost any age with positive benefits. Because exercise is medicine, it should therefore be administered in a prescriptive manner as any medicine would be, and it requires professional knowledge and credible credentials. Unfortunately, this isn't the case among many personal trainers and fitness instructors who enroll individuals in exercise programs without the scientific knowledge or academic training they should have to ensure that the programs are safe and beneficial.

This point was highlighted by M. E. Ciccolella and colleagues in their presentation of an overweight, sedentary, and middle-aged man who suffered a heart attack during his first workout with his "certified" personal trainer. During the workout, the man repeatedly asked to stop because he was experiencing fatigue, heat, thirst, breathlessness, and chest pain. The trainer responded to requests to stop and complaints of fatigue by questioning his client's masculinity and by continuing the workout. In the lawsuit that followed (*Rostai v. Neste Enterprises*), Rostai sued the trainer alleging that the trainer's conduct breached a standard of care that caused the heart attack. Specifically, Rostai alleged that the trainer failed to properly assess Rostai's physical condition and cardiac risk factors and that the trainer's training approach was too aggressive. These failures, according to Rostai, constituted a breach of duty that caused the heart attack to occur during the workout under his trainer's supervision. Had the personal trainer understood the physiological basis of the exercise prescriptive process and the diagnostic importance of an exercise test, he would have concluded that it was unsafe to push Rostai as he did.

Exercise physiologists understand that a graded exercise test is associated with an increase in sympathetic nervous system activity to increase heart rate and cardiac output. Smooth muscles of the arterioles dilate to allow for the increase in cardiac output without an exaggeration in systolic blood pressure. The increase in heart rate and systolic blood pressure (known as double product) increases the work of the heart, which increases its need for oxygen (i.e., myocardial oxygen consumption).

The work of the heart is also increased as the sympathetic nervous system initiates a release of epinephrine from the adrenal glands, which increases ventricular contractility, resulting in a larger stroke volume. With the increase in heart rate and stroke volume, cardiac output is increased to match the need for more oxygen to produce energy (in the form of adenosine triphosphate, ATP) for increased muscle contraction. The increased extraction of oxygen at the cell level (i.e., arteriovenous oxygen difference, $a - VO_{2diff}$) is facilitated by the increase in capillaries around the muscle fibers, the diffusion of oxygen from the blood into the muscles, the metabolism specific to muscle fiber types, and the substrate (carbohydrate and fat) within the fibers.

The delivery of oxygen to the active muscles by the circulation is also aided by an increase in expired ventilation, which results from an increase in the frequency of breathing and tidal volume. Other respiratory adjustments in diffusion and the ratio of alveolar ventilation to lung perfusion ensure adequate gas exchange to saturate the pulmonary blood with oxygen. The end result is that the contributions from the lungs, heart, and vascular system to oxygen transport, along with the adjustments at the cell level, facilitate cellular metabolism. Overall, these physiological responses allow for the body's metabolism to increase to 10 to 12 times that of the resting measures.

At rest, oxygen consumption ($\dot{V}O_2$) is around 250 milliliters (ml)/minute, depending on body size and metabolism. For example, at rest, on average, cardiac output is 5 liters (L)/minute, and tissue extraction is 50 ml/L (or 5 ml/100 ml of blood). It is a simple matter of multiplying cardiac output (5 L/minute) by tissue extraction (50 ml/L), which equals 250 ml/minute. With exercise, $\dot{V}O_2$ may increase to 3 L/minute, or 3,000 ml/minute. This means cardiac output would increase from 5 to 20 L/minute and tissue extraction ($a - \dot{V}O_2$diff) would increase from 50 to 150 ml/L. Hence, the cardiovascular adjustment during exercise is both central (cardiac output) and peripheral ($a - \dot{V}O_2$diff). For example, cardiac output may increase in accordance with adjustments in heart rate from 70 beats/minute (bpm) at rest to 190 bpm during exercise, with stroke volume (i.e., amount of blood ejected per beat) changing from 70 ml at rest to 106 ml during exercise (i.e., 20 L/minute = 190 bpm × 106 ml). The stroke volume during maximal exercise for untrained males may approach 120 to 130 ml, while for trained males it may be 140 to 160 ml.

For highly trained, elite athletes, maximal stroke volume may reach, or even exceed, 200 ml. The values for women are lower than those for men. Maximal stroke volume for untrained and trained women is 100 and 120 ml, respectively. Blood pressure generated by the left ventricle helps ensure that the blood is ejected into the vascular system. It may average a maximum of 190 to 200 mmHg. Because blood pressure is directly related to afterload (i.e., systemic vascular resistance) and left ventricular wall stress, cardiac workload is significantly increased during exercise. For example, with a heart rate of 190 bpm and a systolic blood pressure of 200 mmHg, the heart's need for oxygen would be 380 ml $(100\ g)^{-1}$ $minute^{-1}$ compared with the cardiac work at rest of 84 ml (e.g., heart rate of 70 bpm and systolic blood pressure of 120 mmHg).

The graded exercise test provides a noninvasive method of estimating the integrity of the heart, given the linear increase in cardiac output versus oxygen consumption, with heart rate contributing more to cardiac output than stroke volume (since it tends to increase minimally above 40% to 50% of $\dot{V}O_2$max). EPCs use the test to design individualized exercise prescriptions to assess the physiological effects of an exercise program. It can also be useful in assessing the role of different medications and/or arrhythmias at rest and during exercise as well as the effectiveness of coronary artery surgery. Although the exercise test after an acute MI has been shown to be safe, the ASEP leadership believes that the test is safer when there is a physician alongside the exercise physiologist, especially when dealing with a decrease in the subject's blood pressure or if it should plateau after moving to the next stage. Also, if there are changes in the electrocardiogram (EKG) changes or chest pain or should the subject ask to stop the test, medical support is always available to assist the exercise physiologist.

While there are several different devices for testing, the treadmill is the most commonly used piece of equipment. The Bruce protocol is historically the preferred treadmill test, especially in cardiac rehabilitation programs. However, there are numerous other testing protocols used to evaluate the subject's functional capacity. The Balke-Ware is an excellent test because of its constant treadmill speed of 3.3 miles per hour (mph) (1 mph = 1.61 kilometers/hour approximately) and grade increments of 1% every minute. During the test, the exercise physiologist looks for indications to continue the test or contraindications to stop the test. Indications for stopping the test include ST-segment changes and premature ventricular contractions (PVCs) that suggest myocardial irritability due to ischemia.

Exercise Prescription

To prescribe exercise safely, knowledge of exercise physiology is required. This means more than taking an exercise physiology course. It requires a comprehensive knowledge and integration of the exercise physiology coursework. Specifically, prescribing exercise on an individualized basis requires knowledge of the following academic courses:

exercise physiology, psychophysiology, sports nutrition, applied anatomy, sports biomechanics, and resting and exercise electrocardiography, with specific information regarding acute and chronic adaptations to regular exercise. Knowledge of cardiovascular and muscular physiology, and the relationship of both to systematic work placed on the body, along with knowledge of health and/or medical status, age, and gender considerations with respect to kilocalorie and metabolic equivalents (METs), are necessary to develop safe, individualized exercise prescriptions.

In addition to an understanding of overload and specificity as foundational concepts for preparing individualized exercise prescriptions, exercise physiologists must demonstrate knowledge of the frequency, duration, intensity, and type of exercise, and progression. The physiological benefits that result from individualized exercise programs are directly related to the work placed on the body. Work is defined as the combined effect of frequency, duration, and intensity of exercise. Frequency of aerobic exercise should be at least three times a week with the possibility of increasing to four to five times a week after several weeks or even a month of regular exercise. Exercise sessions should be gradually increased from 20 to 45 minutes, with emphasis on low to moderate exercise intensity.

The exercise prescription for rehabilitation is based on the subject's physical performance during the exercise test. In general, the test is divided into three parts: (1) 5 to 10 minutes of warm-up, stretching, and range-of-motion exercises; (2) 20 to 45 minutes of intermittent or sustained exercise; and (3) 5 to 10 minutes of cooldown. Intensity is usually gauged by heart rate, although there are other methods (e.g., METs, $\dot{V}O_2$max, and rating of perceived exertion [RPE]). A number of different exercise modalities can be used. Patients may exercise entirely using the treadmill, or they may alternate between the treadmill and the bicycle ergometer. Regardless of the training approach, it is always advisable to begin exercise at a low intensity (30%–50% of maximal capacity) and progress accordingly (50%–70% of maximal capacity). Exercise at low to moderate heart rate intensity during treadmill walking for a longer duration is better than exercising at a high intensity for a shorter period of time. It is not only safer; it also allows for an increase in the use of fat as energy substrate.

Energy Metabolism

Energy is necessary for muscle contraction, which is critical for human movement. Chemical substances such as carbohydrates, lipids, and proteins (to a small degree) provide the energy for movement by muscle contraction. The nutrients yield usable forms of energy (a process called catabolism) from the chemical activities (i.e., metabolism) that take place in the muscle fibers. Since the body's metabolism is increased with exercise, the oxidation or breakdown of the nutrients is increased to provide more energy in the form of ATP. The catabolism of glucose by way of glycolysis and the Krebs cycle supplies the electrons that produce energy within the electron transport chain (ETC). Fats can also be converted to compounds that are intermediate products in the catabolism of glucose. Depending on the work that is required of the fiber, not all of the glucose undergoes glycolysis. Some is combined with other glucose molecules to form glycogen (this process is called glycogenesis). When there is an increased need for glucose as a source of energy, the stored glycogen is broken down into glucose to undergo glycolysis. This process of converting glycogen into glucose is called glycogenolysis.

The purpose of bioenergetics (i.e., the conversion of foodstuffs into usable energy-rich phosphate compounds such as ATP) is to ensure cellular energy production. With regard to exercise, the energy within the ATP molecule is used for muscle contraction. The compound itself is a combination of a molecule of adenine and ribose (referred to as adenosine) linked to three phosphates. The bonds of the two outer phosphates represent potential energy. When the enzyme ATPase breaks these bonds, energy is released to do work. Indeed, the hydrolysis of ATP to adenosine diphosphate (ADP), inorganic phosphate (P_i), and energy is critical to the sliding of filaments, known as *myofibrils,* and muscle contraction.

Since ATP is the universal energy donor for cellular work, cells must be able to produce it. Fortunately, there are several pathways to ensure a constant supply. The most immediate is the ATP-PC (phosphocreatine) system. The hydrolysis of PC, which is also written as creatine phosphate (CrP), regenerates ATP by giving its phosphate to ADP to form ATP. The enzyme creatine kinase (CK) is involved in the donation of phosphate to ADP.

This process does not require oxygen. It is entirely anaerobic. All forms of intense exercise (e.g., sprinting, weight lifting, and gymnastics) are possible because of the phosphagen system.

Another metabolic pathway that produces ATP is glycolysis. It is an anaerobic pathway that ends with the breakdown of glucose into two 3-carbon molecules of lactic acid. The amount of ATP produced by anaerobic glycolysis (net, 2 ATP) is small compared with that produced by aerobic glycolysis. Since the oxidation of one molecule of glucose yields 36 ATP (or 38 depending on the cytoplasm shuttle), the majority of the energy must be developed from a pathway other than glycolysis. That pathway involves the Krebs cycle, from which hydrogen ions and their respective electrons are carried by the electron-accepting coenzymes (nicotinamide adenine dinucleotide [NAD^+] and flavin adenine dinucleotide [FAD^+]) to the electron transport system, where the electrons undergo numerous oxidation-reduction steps until oxygen becomes the final electron acceptor.

The third pathway is defined as aerobic ATP production. It involves glycolysis, the Krebs cycle, and the ETC. Oxygen is not used in the Krebs cycle, but it is the final electron acceptor of the ETC. Both the cycle and the chain work together to produce ATP via oxidative phosphorylation. The Krebs cycle is concerned with the removal of carbon dioxide molecules and supplying electrons to the ETC. Carbon dioxide leaves the cell to enter the blood to eventually be exhaled via the respiratory system. The electrons are passed through a series of cytochromes that undergo numerous oxidation-reduction steps and ultimately reduce oxygen. Critical to the survival of each cell is the generation of ATP within the electron transport system via oxidative phosphorylation. ATP synthesis drives muscle contraction. The increased intensity of contraction requires an increased supply and breakdown of ATP, which controls the rate of NADH (reduced form of NAD) oxidation in the ETC. The rate at which glucose can be metabolized is controlled by the rate at which oxygen is available as the final electron acceptor.

The need for ATP drives ATP synthesis, which regulates the rate of electron transport. Hence, with the increased muscular activity of exercise, which requires an increase in the utilization of ATP, the transport of electrons coupled with more protons from the cytosolic side increases ATP synthesis. The increased hydrolysis of ATP in skeletal muscle results in an increase in the concentrations of ADP. The increased ADP and the increased regeneration (i.e., reoxidation) of NAD^+ stimulate the Krebs cycle. As long as there is adequate oxygen at the cell level, the rate of ATP development is adequate to meet cellular metabolism. If there is inadequate oxygen to accept the electron flow—that is, if the energy demand exceeds the ATP production rate of the ETC—the reduced electron carriers, NADH and $FADH_2$, begin to accumulate. NADH can be oxidized to NAD to keep glycolysis operating for another minute or two at high-intensity exercise. Increasingly, then, energy for skeletal muscle work must come from anaerobic metabolism.

Knowledge of exercise metabolism is critical to designing an appropriate exercise program and prescription for clients and a training program for athletes. From gymnastics and sprinting to swimming and running, it is important that the exercise physiologist have a thorough knowledge of the three energy systems and the underlying cardiorespiratory physiology that supports cellular metabolism.

The Future

Health care issues and athletics represent a huge industry, with much riding on the professionals who help prevent fitness-related problems in clients, patients, and athletes, assisting in their rehabilitation and keeping them working, playing, and enjoying life. Unfortunately, there are too many "weekend warrior" personal trainers and instructors who aren't academically qualified to help athletes with knee problems or guide a post-MI patient safely in rehabilitation. Exercise physiology as a health care profession is thus relevant not only to college and professional athletes but also to young children with obesity and adults who do not have the knowledge to develop and/or maintain cardiovascular and muscular fitness. EPCs help by filling the void of decades past. Now, with accredited academic programs of study, they are credible professionals with state-of-the-art research- and evidence-based skills to work with the sports medicine community in developing health care programs for all individuals, including special populations (female, pediatric, older adults), employing rehabilitation regimes, nutrition, biomechanics, and applied anatomy to help them maintain a healthier lifestyle.

Exercise Prescription

With the American College of Sports Medicine's (ACSM's) recent release of the "Exercise Is Medicine" campaign, the role of exercise in health has been highlighted. The question now becomes "How should people exercise?" The answer is in the exercise prescription. An *exercise prescription* is a medical recommendation of exercise, including aerobic activity, resistance training, and stretching, for the purpose of achieving better health or an additional desired fitness benefit. It can be prescribed by physicians and other certified fitness experts, depending on the health of the patient. This entry discusses the key points of the exercise prescription.

Benefits of Exercise

Before prescribing exercise, it is important to define exercise and its importance to one's health. In essence, any activity that increases one's aerobic capacity, strength, and/or flexibility is exercise. Aerobic exercises, such as walking, jogging, cycling, swimming, dancing, and rowing, operate within the oxidative pathways; thus, proper breathing and adequate hydration and nutrition are important. Resistance training works to gain muscle mass, endurance, and strength and also depends on proper breathing and correct technique. Using free weights, weight machines, and/or elastic bands and tubing, individuals can perform several different types of resistance exercises, including isotonic, isokinetic, and isometric exercises. When counseling patients on resistance training, it is important to highlight the potential for delayed-onset muscle soreness. Stretching exercises, of which yoga and tai chi are currently popular, can be performed as static stretching exercises, as ballistic stretching exercises, or as proprioceptive neuromuscular facilitation exercises. An exercise prescription should include all three main types of activity: aerobic, resistance, and stretching.

The benefits of exercise extend to all those who participate and include the following: (a) decrease in all-cause mortality, (b) decrease in cerebrovascular events, (c) decrease in risk of cancer, (d) decrease in risk of Type II diabetes mellitus, (e) decrease in complications of Type II diabetes mellitus, (f) decrease in high blood pressure, (g) decrease in bone loss over time, (h) increase in strength and balance, (i) improvement in lipid profile (increased high-density lipoproteins, decreased triglycerides and low-density lipoproteins), (j) maintenance of optimal weight for health, (k) decrease in anxiety and depression, and (l) economic benefits to the individual, the community, and the workplace (decreased absenteeism, disability, and medical costs).

Although replete with benefits, exercise is not without its risks. The most concerning risk of exercise is the risk of exercise-related sudden death; those with coronary artery disease, hypertrophic cardiomyopathy, and recent acute myocardial infarction have two to six times this risk when compared with healthy individuals, whose risk is small. Additional risks of exercise include the risk of musculoskeletal injury, particularly sprains and strains, which depend on the individual's age and the exercise activity. Metabolic disorders can also occur with exercise, including hyperthermia and hypoglycemia. Last, exercise can result in hematologic disorders, such as hemoglobinuria, hematuria, and rhabdomyolysis.

Before Writing an Exercise Prescription

Once one has an understanding of exercise, its benefits, and its risks, one is ready to write an exercise prescription. Before beginning, it is important to know your patient! The age of the patient will alter the activities you prescribe. In addition, the patient's health history might further limit available activities. Particular attention should be paid to patients with the following medical conditions: cardiac disease, asthma and other pulmonary disorders, pregnancy, old age, osteoarthritis, and metabolic diseases, including obesity and diabetes mellitus. Not only might those patients require limited activity; their exercise activities might need to be supervised, such as within a cardiac rehabilitation program, and their interim follow-up visits might need to be more frequent. Exercise is contraindicated in patients with a history of recent acute myocardial infarction, unstable angina, dangerous dysrhythmias, aortic dissection, acute congestive heart failure, severe aortic stenosis, myocarditis, pericarditis, thrombophlebitis, intracardiac thrombi, pulmonary embolus, acute infection with fever, severe subaortic stenosis, complicated pregnancy, and uncontrolled metabolic disease.

Knowing the patient can extend beyond obtaining a health history. A physical exam and exercise testing might also be warranted, depending on the patient's age, health status, and risk factors for exercise-related sudden death. It is also important to assess the patient's readiness to participate in exercise activities. Is the patient in the precontemplative stage and therefore not even considered exercising; has the patient entered the contemplative stage, perhaps buying exercise equipment or exercising occasionally; or does the patient actively exercise on a routine basis? While discussing exercise with your patient, it is important to address any roadblocks to activity, particularly for precontemplators and contemplators, as well as previous exercise preferences and current exercise goals.

When prescribing exercise, one must also be aware of the current physical activity recommendations. ACSM and the American Heart Association (AHA) released new recommendations for physical activity in 2007. The ACSM/AHA 2007 recommendations focus on aerobic activity and resistance training. Aerobic activity can be moderate or vigorous in intensity, and the duration of activity depends on the intensity. Currently, it is recommended that healthy adults under age 65 participate in moderately intense aerobic activity for 30 minutes' duration at a frequency of five times per week. If the activity intensity is vigorous instead, it need last only 20 minutes in duration at a frequency of three times per week. Strength training, a new recommendation, involves 8 to 10 exercises performed at 8 to 12 repetitions at a frequency of two times per week. Also included in the 2007 recommendations, and varying per the patient's health status, are balance training and a monitored activity plan.

How to Write an Exercise Prescription

With the ACSM/AHA 2007 recommendations in mind, physicians and certified fitness experts should use the FITT principle when prescribing exercise. FITT is a useful mnemonic that stands for frequency, intensity, time, and type. The frequency determines how often the individual should exercise. Intensity designates how challenging the activity should be. Time describes how long the activity should proceed. Type defines the exercise activity itself. When considering an exercise program for a patient, it is also important to contemplate the patient's rate of progression within the exercise program, moving from an initial conditioning phase, to an improving conditioning phase, and, finally, to a maintenance condition phase. In general, it is better to increase the frequency first, followed by an increase in the duration of the activity. The last element to be increased is the intensity of the exercise.

Although the FITT mnemonic is helpful, one must alter the exercise prescription in the case of special populations (i.e., individuals with the conditions listed above as risk factors for exercise-related sudden death). Cardiac patients may require a multiphase rehabilitation program of graduated exercise, during which physical activity is physiologically monitored (via heart rate monitoring, assessment of the rate of perceived exertion, and electrocardiogram) and accompanied by significant patient education. Patients with arthritis might benefit from hydrotherapy. As exercise is a means of blood glucose control, diabetics would need to monitor their blood sugar for hypoglycemia, the most common side effect of exercising with diabetes. They may also need to adjust the types of activities they perform, should their diabetic neuropathy affect their balance or gait. Patients with hypertension, dyslipidemia, and obesity can generally follow the general guidelines; however, it must be noted that these conditions usually do not occur alone.

Conclusion

Exercise involves activities that increase aerobic capacity, strength, and/or flexibility. Physicians and certified fitness professionals should use the FITT principle when prescribing exercise. In addition, they must consider the patient's current health status, readiness to participate, and exercise preferences, as those issues may affect the patient's ability to participate in and respond to exercise.

Exercise Programs

Exercise is a potent stimulus to the human body, which, over time, can mediate changes in physiological structures and function. Although a single workout can create acute exercise stress, exercise training is the repeated use of a workout over time to achieve a specific fitness goal or health outcome. The outcomes of a training program will be specifically related to the program design of the workout. This underscores a major principle in exercise physiology, namely, *specificity of training*. Therefore, the outcomes of any exercise program will be specific to the type of workouts used and their ability to appropriately stress the physiological systems that they are targeting. Understanding the variables associated with exercise program design can provide insights into the creation of the exercise stimuli, which with training will alter function, improve structure, and ultimately enhance a specific health or fitness outcome.

While there are many different forms of exercise, the two major domains are related to cardiovascular endurance training and resistance training. Each of these exercise modes has a host of different types of programs within its domains, but they act as the two major forms of exercise used in all training programs. Endurance training is primarily directed at improving the cardiovascular system, while resistance training is directed at improving the neuromuscular system. In the process, each type of exercise program can have dramatic effects on other physiological systems, such as improving insulin resistance or enhancing toleration of metabolic acidosis. Ultimately, it always comes down to the specific exercise prescription used in a training program and its ability to stimulate the appropriately targeted physiological systems.

Finally, exercise prescriptions and training programs must be individualized so as to meet the needs of each person and be appropriate for his or her age, fitness level, and functional capacities to exercise. This type of individualized programming requires a careful medical screening, goal determinations, preliminary testing, and a needs analysis to have initial data from which to make program design decisions.

Cardiovascular Endurance Training Programs

Aerobic exercise is targeted at developing cardiovascular fitness and health. Maximum oxygen consumption ($\dot{V}O_2max$), or the amount of oxygen that can be extracted from the blood for use by tissues, primarily skeletal muscle, is one of the most common measures of aerobic fitness and the target of aerobic endurance training programs. Additionally, cardiovascular conditioning promotes ultrastructural adaptations in the heart (e.g., increased ventricular volume, increased collateral circulation in the heart) and improves peripheral tissue adaptations (e.g., increases in capillaries, improved insulin resistance, increased metabolic enzymes, increased numbers of mitochondria). Thus, the improvement of maximum oxygen uptake is mediated by many associated adaptations in the neuroendocrine and metabolic systems along with structural changes in the vascular system.

Variables in Program Design

An exercise session will typically start with a light warm-up (low-level exercise and stretching) and end with a cooldown (e.g., low-level exercise followed by stretching) to allow for a gradual increase and decrease in muscular activity and metabolic intensity.

The basic variables of an endurance training program design are as follows:

1. *Intensity:* This typically refers to the percentage of maximum oxygen consumption or percentage of maximum heart rate or heart rate reserve that results in a heart rate range for each individual to target during the exercise session. Exercise is typically done in a continuous form, but in some cases, intervals training might be used for more advanced athletic training programs. Ratings of perceived exertion (RPE) using the classic 6 to 20 Borg Scale can also be used to modify the intensity, especially when the heart rate range is predicted (e.g., using the Karvonen formula) rather than obtained directly from a graded exercise test (American College of Sports Medicine [ACSM], 2006). Program guidelines: Exercise with a target of 60% or 70% of the predicted maximal heart rate (HRmax = 220 – age) or 50% to 85% of the $\dot{V}O_2max$ when directly determined from a graded exercise test or 50% to 85% of the heart rate reserve (Karvonen formula: [(HRmax – HRrest) × %Intensity + HRrest]). The key is to target a lower range, with peak heart rates not going over the upper limit. With a graded exercise test for patient populations, the function capacity is set clinically at the upper limit where no ECG or symptoms exist.

2. *Frequency:* This refers to the number of times per week an exercise session should be planned. The ACSM recommends a frequency of three to five exercise sessions per week. For beginners, 48 hours of rest between exercise training sessions is recommended, and for advanced programs where exercise training is done each day, careful variation/periodization in the program whereby the same workout volume and intensity are not used each time is needed for optimal progression.

3. *Duration:* This refers to the length of time that an activity should be continued. The ACSM recommends that an exercise session be performed for between 20 and 60 minutes, not including warm-up and cooldown activities.

4. *Volume:* This refers to some measure of total work, including miles or kilometers covered, number of intervals, number of steps, and so on. The volume becomes an important factor in varying the training sessions.

5. *Mode:* This refers to the type of exercise used. Typically one uses whole-body exercise modes if both the upper and lower body muscles are capable of movement. Exercises such as running, jogging, stepping, cycling, swimming, cross-country skiing, aerobic dancing, and step aerobics are used to stimulate whole-body metabolism and the needed heart rate responses. When testing for fitness levels, one needs to keep in mind mode-specific testing, taking the modality that is most frequently used. For advanced athletes, using the same modality may be required, but careful variation/periodization is needed to avoid injury and overtraining.

Progression of the Aerobic Exercise Prescription

Each exercise training program should be individualized. For the fitness enthusiast, the activity should be enjoyable, especially for the average person interested in lifelong fitness and health outcomes. Cross-training using different modes of exercise can also help avoid overuse injuries and keep the exercise training fun. The exercise should start at the lower end of the prescription until physical and mental toleration is achieved. If the person is highly deconditioned, it should even start lower. A classic concept, "doing too much too soon," is a major reason for early program injuries and/or overtraining even in advanced athletes. Program variation or periodization of the intensity and volume is becoming more important in modern conditioning programs. This means that doing the same activity day in and day out is not optimal to recovery or adherence. Thus, one day one might do a higher volume at a lower intensity, the next day do a lower volume at a higher intensity, and the next day use a different modality with moderate volume and intensity.

Resistance Training Programs

Resistance training is the next major type of training program. Again, with the many possible programs that can be designed, one has to carefully determine the goals and needs of the individual and develop a resistance training program that will address those needs. Typically, the goals of a training program are for strength and power and the associated muscular hypertrophy. Local muscular endurance is also a trainable characteristic. Again, many associated adaptations occur in different tissues depending on the program design (e.g., increased bone density, improved stair-climbing ability). In addition, reduced peripheral stress on the heart and better toleration of metabolic stress due to stronger muscles and improved functional capabilities can also be observed.

Training Principles

Again, some general training principles must be kept in mind when designing a program.

1. *Specificity of training:* Only the muscles that are trained will adapt and change in response to a resistance training program. For this reason, resistance programs must target all muscles for which a training effect is desired.

2. *SAID principle: S*pecific *a*daptations to *i*mposed *d*emands relate to the fact that the adaptation will be specific to the demands that the characteristics of the workout place on the individual. If a high number of repetitions are used, the muscles will increase their ability to perform a high number of repetitions (muscular endurance).

3. *Progressive overload:* As the body adapts to a given stimulus, an increase in the stimulus is

required for further adaptations and improvements. Thus, if the load or volume is not increased over time, progress will be limited.

4. *Variation in training:* No one program should be used without changing the exercise stimulus over time. Periodized training is the major concept related to the optimal training and recovery programming.

5. *Prioritization of training:* It is difficult to train for all aspects of strength fitness. Thus, within a periodized training program, one needs to focus or prioritize the training goals for each training cycle.

The Needs Analysis

A needs analysis of the individual should be performed to design the most effective program. The major questions in a needs analysis are as follows:

- What muscle groups need to be trained?
- What are the basic energy sources (e.g., anaerobic, aerobic) that need to be trained?
- What type of muscle action (e.g., isometric, eccentric actions) should be used?
- What are the primary sites of injury for the particular sport? What is the prior injury history of the individual?

Acute Program Variables

Developed more than 20 years ago, the paradigm of acute program variables allows one to define every workout. Every resistance exercise protocol or workout is derived from the five acute program variables. The choices made for each of the variables define the exercise stimuli and, ultimately with repeated exposure, the training adaptations.

1. *Choice of exercises:* Exercises can be divided into several different categories based on their function and/or muscle involvement. Exercises can be designated as primary exercises or assistance exercises. Primary exercises train the prime movers in a particular movement and are typically major muscle group exercises (e.g., leg press, bench press, hang pulls). Assistance exercises are exercises that train predominantly a single muscle group (e.g., triceps press, biceps curls) and those that aid (synergists) in the movement produced by the prime movers. Exercises can also be classified as multijoint or single-joint exercises. Multijoint exercises require the coordinated action of several muscle groups and joints. Multijoint exercises require neural coordination among muscles and, thus, promote coordinated multijoint and multi–muscle group movements. Power cleans, power snatches, deadlifts, and squats are good examples of whole-body multijoint exercises. The bench press, which involves movement of both elbow and shoulder joints, is also a multijoint, multi–muscle group exercise, although it only involves movement in the upper body. Some other examples of multijoint exercises are the lateral pull-down, military press, and squat. Incorporating multijoint exercises in a resistance training program is important for both athletes and nonathletes. Exercises that attempt to isolate a particular muscle group's movement of a single joint are known as single-joint and/or single–muscle group exercises. Biceps curls, knee extensions, and knee curls are examples of isolated single-joint, single–muscle group exercises. Many assistance exercises may be classified as single–muscle group or single-joint exercises.

2. *Order of exercises:* The order in which the chosen exercises are performed is an important variable that affects the quality and focus of the workout. In general, the sequence of exercises for both multiple– and single–muscle group exercise sessions should be as follows:

- Large–muscle group before small–muscle group exercises
- Multijoint before single-joint exercises
- Alternating of push/pull exercises for total-body sessions
- Alternating of upper/lower body exercises for total-body sessions
- Explosive/power-type lifts (i.e., Olympic lifts) before basic strength and single-joint exercises
- Exercises for weak areas (priority) performed before exercises for strong areas
- Most intense before least intense exercises (particularly when performing several exercises consecutively for the same muscle group)

3. *Resistance and repetitions used:* The amount of resistance used for a specific exercise is one of the key variables in any resistance training program. It is the major stimulus related to changes observed in measures of strength and local muscular endurance. Typically, a repetition maximum (RM) target range (i.e., 3–5 RM) is used to prevent muscular failure due to adverse changes in blood pressure and joint compression. Performing 3 to 5 repetitions with a resistance that allows for only 3 to 5 repetitions compared with a resistance that would allow 13 or 15 repetitions produces a heavier training intensity and greater strength changes. In some exercises, one cannot use an RM zone, so one uses a percentage of the 1 RM target (e.g., 70% or 85% of 1 RM). This method requires that the maximal strength in all exercises used in the training program be evaluated regularly. In some exercises, a percentage of 1 RM needs to be used as going to failure or near failure is not optimal (e.g., power cleans, Olympic-style lifts). Without regular 1 RM testing (e.g., each week), the percentage of 1 RM actually used during training, especially at the beginning of a program, will decrease, and the training intensity will be reduced. When possible, it is recommended that the RM target range be used as it allows the trainer to alter the resistance in response to changes in the number of repetitions that can be performed at a given absolute resistance. Specific neuromuscular adaptations to resistance training depend in large part on the resistance used. These adaptations follow the SAID principle described earlier in this entry. Heavier resistances will produce lower numbers of repetitions (1–6) but have been found to lead to greater improvements in maximal strength. Thus, if maximal strength is desired, heavier loads should be used. Alternately, if muscular endurance is the goal, a lower load should be used, which will in turn allow a greater number of repetitions (12–15) to be returned.

4. *Number of sets for each exercise:* First the number of sets does not have to be the same for all exercises in a workout program. In reality, apart from training mythologies, the number of sets performed for each exercise is one variable in what is referred to as the *volume* of exercise equation (e.g., sets × reps × resistance) calculation. As such, one of the major roles of the number of sets performed is to regulate the volume performed during a particular exercise protocol or training program. These findings prompted the 2002 recommendation from the ACSM for periodized multiple-set programs when long-term progression (not maintenance) is the goal. No study has shown single-set training to be superior to multiple-set training in either trained or untrained individuals. Exercise volume is a vital concept in resistance training progression, especially for those who have already achieved a basic level of training or strength fitness. As mentioned earlier, the principle of variation in training, or more specifically "periodized training," involves the number of sets performed. Since the use of a constant-volume program can lead to staleness and lack of adherence to training, variations in training volume (i.e., both low- and high-volume exercise protocols) is important during a long-term training program to provide adequate rest and recovery periods.

5. *Duration of rest period between sets and exercises:* The rest periods play an important role in dictating the metabolic stress of the workout and influence the amount of resistance that can be used during each set or exercise. A major reason for this is that the primary energy system used during resistance exercise, the ATP-creatine phosphate system, needs to be replenished, and this process takes time. Therefore, the duration of the rest period significantly influences the metabolic, hormonal, and cardiovascular responses to an acute bout of resistance exercise, as well as the performance of subsequent sets.

For advanced training emphasizing absolute strength or power (few repetitions and maximal or near-maximal resistance), rest periods of at least 3 to 5 minutes are recommended for large–muscle mass multijoint exercises (e.g., squat, power clean, or deadlift), whereas shorter rest periods may be sufficient for smaller–muscle mass exercises or single-joint movements. For a novice-to-intermediate resistance exercise protocol, rest periods of 2 to 3 minutes may suffice for large–muscle mass multijoint exercises, since the lower absolute resistance used at this training level seems to be less stressful to the neuromuscular system. Performance of maximal resistance exercises requires maximal energy substrate availability at the onset of the exercise and a minimum fatigue level and, thus, requires relatively long rest periods between sets and exercises.

The key to rest period lengths is the observation of symptoms of loss of force production in the beginning of the workout and clinical symptoms of nausea, dizziness, and fainting, which are direct signs of the inability to tolerate the workout. When such symptoms occur, the workout should be stopped, and longer rest periods should be used in subsequent workouts. With aging, a decreased ability to tolerate decreases in muscle and blood pH underscores the need for gradual progression when cutting rest period lengths between sets and exercises. Rest periods may be as follows:

Very short rest periods: 1 minute or shorter

Short rest periods: 1 to 2 minutes

Moderate rest periods: 2 to 3 minutes

Long rest periods: 3 to 4 minutes

Very long rest periods: 5 minutes or longer

Variation and Periodization of Resistance Training

Periodization involves the use of different types of workouts over time with different resistance intensities and volumes of exercise. Periodization also includes periods of rest to allow for recovery and prevent overtraining. Understanding the “size principle” is important as heavier loads with adequate volume recruit more muscle tissue and enhance strength more than lighter resistances. The use of the “size principle” is vital for understanding variation in resistance training and, ultimately, periodized training. (See *Designing Resistance Training Programs* by Fleck and Kraemer, 2004.) Typically, periodization is applied to large–muscle group exercises, with smaller variations from moderate to light for small–muscle group exercises.

Periodization of Exercise

The use of periodized resistance training has been shown to be superior to constant training methods (*Designing Resistance Training Programs*). Periodized training involves planned variation in the intensity of exercises and in the volume of a workout. Typically, one periodizes large–muscle group exercises. However, variation schemes can be created for smaller muscle groups. One must consider the type of periodized program to use. In general, there are two basic types that have developed. Below are some of the basic differences between linear and nonlinear periodization approaches to resistance training.

Classic Linear Models

Classic periodization methods use a progressive increase in intensity, with small variations in each 2- to 4-week microcycle. For example, a classic four-cycle linear periodized program (4 weeks for each cycle) would be as follows:

Linear Periodized Program

Microcycle 1: 3 to 5 sets of 12 to 15 RM

Microcycle 2: 4 to 5 sets of 8 to 10 RM

Microcycle 3: 3 to 4 sets of 4 to 6 RM

Microcycle 4: 3 to 5 sets of 1 to 3 RM

Rest and recovery cycle

You can see that there is some variation within each microcycle due to the repetition range of each cycle. Still, the general trend for the 16-week program is a steady linear increase in the resistance intensity of the training program. Due to the straight-line increase in the intensity of the program, it has been termed *linear* periodized training. The volume of the training program will also vary, with the classic program starting with a higher initial volume and the volume gradually decreasing as the intensity of the program increases. The drop-off between the intensity and volume of exercise can become less as the training status of the athlete advances. In other words, advanced athletes can tolerate higher volumes of exercise during the heavy and very heavy microcycles. It is very important to point out here that one must be very careful not to progress too quickly to train with high volumes of heavy weights.

The increase in the intensity of the periodized program then starts to develop the needed nervous system adaptations for enhanced motor unit recruitment. This happens as the program progresses and heavier resistances are used. Heavier weights demand high-threshold motor units to become involved in the force production process. With the associated increase in muscle protein in the muscles from the early cycle training, force production of the motor units is enhanced. Here again, one sees an integration of the different parts of the 16-week training program. A 16-week program in reality is called a mesocycle, and a 1-year training program (macrocycle) is made up of several mesocycles. Each mesocycle attempts to progress the body's muscle hypertrophy and strength upward toward one's theoretical genetic maximum.

Nonlinear Periodized Programs

More recently, the concept of nonlinear periodized training programs has been developed to maintain variation in the training stimulus. However, nonlinear periodized training makes implementation of the program possible due to schedule or competitive demands. The nonlinear program allows for variation in intensity and volume within each week over the course of the training program (e.g., 16 weeks). An example of a nonlinear periodized training program over a 16-week mesocycle is as follows:

Nonlinear Periodized Program

This protocol uses a 6-day rotation with 1-day rest between workouts.

Monday: 4 sets of 12 to 15 RM

Wednesday: 4 sets of 8 to 10 RM

Friday: 3 to 4 sets of 4 to 6 RM

Monday: 4 to 5 sets of 1 to 3 RM

Wednesday: Power Day, 4 to 6 sets of 2 to 3 repetitions with 30% to 45% of 1 RM

Friday: 2 sets of 12 to 15 RM

Rest days: Used as needed to replace a training day

The variation in training is much greater within the week. One can easily see that intensity spans a maximum of a 14-RM range (possible 1-RM sets vs. 15-RM sets in the week cycle). This span in training variation appears to be as effective as linear programs. One can also add a "power" training day, where loads may be from 30% to 45% of 1 RM and release of the mass is allowed if no deceleration exists with movement of the joint(s). Medicine ball plyometrics and other lower body plyometrics are also performed here as well.

Unlike the linear programs, one trains the different components of muscle size and strength within the same week. Unlike the linear methods, nonlinear programs attempt to train both the hypertrophy and the neural aspects of strength within the same week. Thus, one is working at two different physiological adaptations together within the same 7- to 10-day period of the 16-week mesocycle. This appears possible and may be more conducive to many individuals' schedules, especially when competitions, travel, or other schedule conflicts make the traditional linear method difficult to adhere to.

In this program, one just rotates through the different protocols. The workout rotates between very heavy, heavy, moderate, and light training sessions. If one misses the Monday workout, the rotation order is just pushed forward, meaning that one just performs the rotated workout scheduled. For example, if the light 12 to 15 workout was scheduled for Monday and you miss it, you just perform it on Wednesday and continue with the rotation sequence. In this way, no workout stimulus is missed in the training program. One can also say that a mesocycle will be completed when a certain number of workouts are completed (e.g., 48) and not use training weeks to set the program length.

Again, the primary exercises are typically periodized, but one can also use a two-cycle program to vary the small–muscle group exercises. For example, in the "triceps pushdown," one could rotate between the moderate (8–10 RM) and the heavy (4–6 RM) cycle intensities. This would provide not only the hypertrophy needed for such isolated muscles of a joint but also the strength to support heavier workouts of the large muscle groups.

Conclusion

In conclusion, two different approaches can be used to periodize your training program, more specifically, linear and nonlinear program schedules. The programs appear to accomplish the same effect and are superior to constant-training programs. It appears that this is accomplished by training the hypertrophy component first and then the neural strength component in the linear method and both components within a 7- to 10-day time period in the nonlinear method. The key to workout success is variation, and different approaches can be used over the year to accomplish this training need.

Exertional Compartment Syndrome, Chronic

Chronic exertional compartment syndrome (CECS) is a condition where exercising muscles swell within a confined space, resulting in decreased blood flow, pain, and limited activity. CECS is almost always seen in the lower leg but has been reported in the thigh, gluteus, and upper extremities. It is typically seen during the third or fourth decades of life but can also be seen in adolescents, particularly young female athletes. The patient generally presents with bilateral lower leg pain (often worse in one leg), which occurs with a consistent amount of vigorous exercise and resolves with rest. CECS has been reported in 15% of competitive runners and 5% of recreational runners. Surgical treatment is indicated in patients who have a confirmed diagnosis and have failed nonoperative treatment.

Anatomy

Extremity muscles are typically grouped together and surrounded by a strong, fibrous sheet of tissue called *fascia*. Muscular groupings surrounded by fascia are called *compartments*. In the lower leg, there are four compartments: (1) the anterior (front) compartment contains the tibialis anterior, extensor digitorum longus, and extensor hallucis longus muscles; (2) the lateral (outer lower leg) compartment contains the peroneus longus and brevis muscles; (3) the superficial posterior (superficial back of lower leg) compartment contains the gastrocnemius and soleus muscles; and (4) the deep posterior (deep back) compartment contains the tibialis posterior, flexor hallucis longus, and flexor digitorum longus muscles.

Causes

With exercise, muscles can increase in volume by 20%. When muscles swell within the confines of fascia, the pressure within the muscular compartment increases. The increased pressure, in turn, places pressure on the blood vessels flowing in and out of the muscles. When the pressure gets to a critical level, the blood flow to and from the muscles is decreased, reducing oxygen delivery and metabolite removal. In this situation, the muscles produce lactic acid and other metabolites that ultimately lead to nerve irritation and pain. The pain continues until activity is stopped, muscle swelling subsides, and blood flow is restored.

Patients who develop CECS are thought to have overly thick fascia, excessive muscle bulk, and/or abnormal blood flow regulation. CECS may also be caused by defects in the fascia. About 40% of patients with CECS have a fascial defect as compared with <5% of the general population. If there is a small tear or opening in the fascia, the muscle can herniate through the defect during exercise and cause pain secondary to strangulation of the herniated muscle tissue or by placing direct pressure on the surrounding nerves.

Symptoms

CECS presents as a dull ache localized to a lower leg muscle compartment, usually brought on by a consistent period of exercise and relieved by rest. The pain usually occurs in both legs, but is often more symptomatic in one, and causes the athlete to stop training or reduce exercise intensity. The anterior and lateral leg compartments are most commonly involved. Temporary numbness and/or tingling can occur in the sensory distribution of nerves in the affected compartment. Physical exam at rest is often normal. A firm compartment may be noted if the athlete is seen immediately after exercise.

Diagnosis

The diagnosis of CECS is made using a combination of clinical presentation and objective measurements. The evaluation starts with a complete history and physical exam. If there is suspicion of CECS, measuring compartment pressures can confirm the diagnosis. Compartment pressures are recorded both at rest and immediately after a period of exercise intense enough to cause symptoms. They are measured by a doctor using a special device. Most of the commercially available devices have a needle that is connected to a pressure transducer. The tip of the needle is inserted into each compartment, and the pressure transducer reports the pressure. A positive test occurs when resting pressures are >15 mmHg and/or postexercise pressures are >30 mmHg at 1 minute or >20 mmHg at 5 minutes postexercise.

Treatment

Conservative treatments include activity modification, massage, and physical therapy; however, these typically do not result in a cure, and symptoms generally return when the patient returns to his or her previous level of activity.

Surgery

Surgery is recommended for patients who meet the diagnostic criteria and for whom conservative treatment has failed. The goal of surgery is to reduce compartment pressures. This can be done by splitting the fascia, called a fasciotomy. After surgery, when the muscles swell with exercise, the pressure does not increase because the fascia is no longer a confining space. The surgery can be performed using an incision through the skin and the fascia (open technique) or through several small incisions using an arthroscope (endoscopic technique). Care must be taken when releasing the lateral compartment, so as to avoid damaging the superficial peroneal nerve.

After Surgery

Postoperatively, patients maintain a compression dressing, ice, and elevation for the first 3 days to limit swelling. They are made to weight bear as tolerated and may discontinue crutches when able. Gentle range of motion of the knees and ankles is encouraged. Physical therapy is not routinely employed early in the postoperative period as overly vigorous massage and activity can lead to scarring of the fascial compartments. Return to running is allowed at 6 to 8 weeks postoperatively. The use of accommodative orthotics is encouraged to maximize shock absorption by the foot, and the athlete should avoid running on hard surfaces during recovery.

Extensor Mechanism Injury

The extensor mechanism of the knee includes the quadriceps muscle group, the quadriceps femoris tendon, the patella, and the patellar tendon, which inserts onto the tibial tubercle. The quadriceps group and the patella allow for extension of the knee, which is required for a proper gait.

Functional Anatomy

The quadriceps muscle group receives its nerve supply from the femoral nerve. It consists of four muscles that insert onto the tibial tubercle. The vastus lateralis, vastus medialis, and vastus intermedius originate from the femur and cross the knee joint. The rectus femoris has two heads that originate from the ilium. It inserts into the patella through a strong central tendon and extends both hip and knee joints. These muscles envelop the patella and terminate to form the patellar tendon. During normal gait, there is compressive force on the posterior aspect of the patella equal to one half of the person's body weight. Jumping produces a force greater than eight times the body weight across this joint.

As the knee is flexed, complex biomechanics occur. When the patella glides on the distal femur, it has tilt, translation, and rotation. This produces a multiplanar toroidal path, like a bobsled going around a curve. When the knee is in complete extension, only the inferior part of the patella is in contact with the femoral condyle, and the patella can easily move from a medial to a lateral direction. As the knee flexes, the patella engages the femoral groove, and lateral movement is inhibited. As the knee goes from extension to flexion, a different aspect of the patella comes in contact with the femur.

As the knee flexes, the tibia internally rotates on the femur. This occurs because the femoral condyles are not equal in size. The medial femoral condyle is longer than the lateral femoral condyle, and as the menisci come in contact with the femur during knee flexion, it forces the tibia to rotate internally.

A number of structures affect patellar position relative to the femur and tibia. The lateral retinaculum of the knee is thicker and exerts more of a pull on the patella than the medial aspect of the retinaculum. Because of the double-headed origin of the rectus femoris, it exerts a superior lateral pull on the patella. The vastus medialis has a small distal portion described as the vastus medialis obliquus, which exerts a direct medial pull to the patella. This is an important muscle because it acts in concert with the articularis genu, a small muscle that inserts onto the medial superior synovial fold of the retinaculum, described as the plica. It is possible for this synovial fold, or plica, to impinge on the inner surface of the patella, affecting the articular cartilage during knee flexion. The articularis genu pulls the plica out of the way so it does not impinge, and the vastus medialis obliquus exerts its medial pull to keep the patella in the femoral groove.

Many textbooks describe the Q angle. The Q angle requires the measurement of a line connecting the anterior superior iliac spine through the midpatella, then measuring the angle it forms from the line connecting the midpatella to the tibial tuberosity. The normal female Q angle is up to 20°, with the male Q angle being 15°. It is critical to recognize that most authors do not feel that the Q angle is a predictor of anterior knee pain or subluxation of the patella, and it is inappropriate to make surgical decisions using this measurement. It is, however, a useful concept to understand the many forces that are exerted on the patella during knee flexion.

Physiology

The posterior aspect of the patella and the distal aspect of the femur are both coated with an articulate cartilage. Through the normal wear and tear of life, the articular cartilage is gradually worn away, and a fibrocartilage is laid down to replace it. It is not as functional as the former, but it is part of the reparative process of the body.

The term *chondromalacia* should be reserved for patients in which this condition has been arthroscopically diagnosed. The term *tendinitis* is often used to describe the pathophysiology of tendon injury and is inaccurate. This condition should be referred to as *tendinopathy* as there is no inflammation histologically.

Pathophysiology

The majority of patients have symptoms caused by overuse and are not surgical candidates. During examination, they will commonly hold the affected patella and describe the pain as more global. A few maneuvers can be useful in evaluating the cause of pain. The *patellar tilt test* is done with the patient in the supine position in complete knee extension. Downward pressure is applied to the medial edge of the patella. The test is positive if the angle is less than 15°, indicating an overly tight lateral retinaculum.

The *medial and lateral patellar glide test* is accomplished by pushing the patella in a medial and lateral direction with the patient in the position described above. The test is positive if the patella can be displaced more than 75% of its width.

The *grind test* is accomplished by instructing the patient to contract the quadriceps while the examiner compresses the patella against the femur in complete knee extension. A positive test occurs when the patient complains of pain, indicating chondral injury.

The *apprehension test* is performed with the knee in 30° of flexion. Lateral pressure is applied by the examiner. A positive test indicates patellar subluxation or dislocation if the patient is apprehensive and resists.

Often the exam result is negative, indicating that the knee is the "victim" of weak gluteal muscles, excessive foot pronation, genu valgus, or excessive anterior pelvic tilt causing "dynamic" impingement of the patella during activity.

Plica syndrome is a diagnosis that is made clinically, where X-ray and magnetic resonance imaging (MRI) findings will be normal. One of the synovial folds becomes fibrotic and rubs against the posterior aspect of the patella, causing chondromalacia during flexion and extension. The medial aspect of the plica is palpated and if a thick, inflamed fold is palpated, a diagnosis of plica syndrome should be considered.

Prepubescent patients often present with anterior knee pain that is localized to the tibial tubercle. This is a *traction apophysis* and is often caused by a rapid growth spurt. If prolonged discomfort occurs, a rare condition such as fracture of the tibial tuberosity should be considered. If the same condition occurs at the distal aspect of the patella, the condition is known as *Sinding-Larsen-Johansson disease*. These conditions are best treated by ice, anti-inflammatory medications, and modification of activities.

Ruptures of the quadriceps tendon usually occur in patients older than 40 years of age, and this is approximately three times more common than patellar tendon ruptures. Most ruptures occur approximately 2 centimeters superior to the patella and are often accompanied by the patient hearing a loud pop. The usual mechanism of injury is forced knee extension with resistance. Careful examination is required to diagnose an incomplete tear as there may be no palpable tendon defect. When one of the tears is suspected, imaging with either ultrasound or MRI should be done as soon as possible, as these injuries are best treated by early surgical intervention.

If a quadriceps muscle experiences a blunt trauma, a hematoma can form quickly. This should be diagnosed acutely, and the knee should be placed in as much flexion as tolerated by the patient for 24 to 48 hours. In addition to this, ice should be applied to the quadriceps. The use of heat should be discouraged. This injury can cause various sequelae, such as chronic anterior knee pain and myositis ossificans.

Patellar tendinopathy ("jumper's knee") usually affects the proximal attachment of the patellar tendon to the distal patellar pole and often occurs in patients who participate in jumping sports. Patients in their late teen years through the mid-30s usually develop this condition from microtrauma, but a single macrotraumic event may initiate this condition. Many times, these patients respond well to the use of ice, rest, and avoidance of the offending activity. In addition to this, strengthening the core abdominal muscles, strengthening the gluteal muscles, hamstring stretching, and isometric quadriceps exercises are useful. Some clinicians advocate various supports such as the Cho-Pat® strap or knee sleeves to change the angle of the patella on the proximal patella tendon. Surgical debridement is reserved for extreme cases. Patellar tendon rupture is much less common than quadriceps rupture.

In summary, most conditions of the extensor mechanism can be treated nonsurgically, and they are the result of extensor patellar tracking problems or biomechanics of the back, hip, and foot. Quadriceps and patella tendon ruptures are best diagnosed early and treated surgically.

Extracorporeal Shock Wave Therapy

Medical technology and devices are constantly changing. Newer and better techniques are being introduced in medical practice. One such advancement is *extracorporeal shock wave therapy* (ESWT) or *orthotripsy* for the treatment of various musculoskeletal disorders. It was developed, not so long ago, in the 1990s in Europe and is a derivative of lithotripsy (the mechanical breaking up of renal stones with sound waves).

ESWT is a noninvasive treatment that involves delivering low- or high-energy shock waves through a device to a specific site within the body. These pressure waves travel through fluid and the soft tissue parts of the body and cause their effects at sites where there is a change in impedance, such as the bone/soft tissue interface.

The use of ESWT in sports-related conditions is still controversial. However, this treatment is given after failure of traditional therapies and before resorting to surgery. In sports, it is used as a means to avoid surgery. A number of sportsmen have benefited from this therapy without requiring surgery. For example, during the Olympic Games in Sydney and Atlanta, the German athletes had the opportunity to be treated with this special therapy.

Types of Extracorporeal Shock Wave Therapy

Focal Shock Wave Therapy

Focal shock wave therapy is the more commonly used form of extracorporeal shock wave therapy. The shock waves generated outside the body are focused in the precisely defined therapy zone in the deeper tissue without harming the skin or superficial tissue. Focal shock wave therapy can be of low energy or high energy.

Low-Energy Shock Wave Therapy

Low-energy shock wave therapy is applied in a series of treatments, usually three or more. Low-energy shock waves cause mild or no pain.

High-Energy Shock Wave Therapy

The treatment is given in a single session. High-energy shock waves are quite painful, and some sort of anesthesia, either regional block or general anesthesia, is required.

The relative efficacy of the two types is different for treating different conditions. Conditions such as delayed unions and pathological calcifications are more responsive to higher-energy shock waves, while low-energy shock waves are safer and more effective for tendinopathies.

Radial Shock-Wave Therapy

Pressure waves are introduced over a large area of the skin, from where the waves spread divergently through the body tissues. This is also called unfocused shock wave therapy. However, it should be more accurately called radial pressure wave therapy since no true shock waves are generated.

Mechanism of Physiological Effects

The exact mechanism of the analgesic effects and effects on osseous defects of shock waves is not known; however, there are a couple of theories that attempt to explain the mechanism. According to the most accepted one, shock waves work by inducing microtrauma to the tissues. The microtrauma initiates a healing process by the body. This response causes neo-vascularization—that is, the formation of new blood vessels—resulting in improved blood flow into the area, which increases the delivery of nutrients in the affected area, thus promoting the repair process. The second opinion is that in cases of chronic pain, the body has stopped efforts to remove the cause of pain. The shock waves start a new inflammatory process, to which the body responds by providing nutrients to the area to promote healing.

Prerequisites for Treatment

To prevent improper treatment, there are certain prerequisites for administering the treatment:

- Correct clinical diagnosis is important (radiological examination, biochemical tests, etc., may be necessary).
- Only a qualified physician may use shock wave therapy.
- A high-energy focused shock wave therapy should be used for treating bone and deep tissue diseases.
- Devices with or without focusing technology may be used for superficial soft tissue conditions.
- The therapy should only be used after failure of the standard treatments for a given condition and when surgery is the only alternative.

Applications in Sports

ESWT has been successfully used in treating various sports-related injuries. Some of the most common conditions in which the therapy is beneficial are as follows:

Tennis elbow (lateral epicondylitis): It is commonly associated with playing tennis and other racquet sports; there is tenderness and soreness in the outer part of the elbow.

Golfer's elbow (medial epicondylitis): It is also sometimes called pitcher's elbow as it is associated with making a golf swing or throwing objects such as the ball in baseball. The insertion of the common tendon at the medial epicondyle becomes inflamed.

Rotator cuff (the group of muscles and their tendons that stabilize the shoulder) *injury with or without calcification:* This is due to the wear and tear or injury to the rotator cuff frequently sustained by athletes including baseball pitchers, American football quarterbacks, volleyball players, water polo players, shot put throwers, swimmers, boxers, fast bowlers in cricket, and tennis players.

Patella tendinitis (jumper's knee and Sinding-Larsen-Johansson disease) *with or without heel spur:* There is pain in the inferior patellar region. This injury is commonly encountered in football, rugby, volleyball, American football, basketball, and gymnastics.

Achilles tendinosis: The Achilles tendon is a tendon on the posterior aspect of the lower leg. It is commonly injured due to overuse in sports such as sprinting.

Plantar fasciitis: An inflammatory condition of the foot associated with walking for long periods, especially on hard surfaces. It is sometimes seen in runners.

Pseudoarthrosis or nonunions: It can occur after fractures.

Stress fracture: It is an incomplete fracture in bone due to repeated stress and is one of the most common injuries in sports. It has been reported to occur in almost all sports.

Contraindications

Contraindications to the procedure include neurological and vascular disease of the foot, a history of rupture of the plantar ligaments, open bone growth plates, pregnancy, implanted metal in the area, and medication that interferes with blood clotting, such as Coumadin and prophylactic aspirin. Because re-inflammation is being introduced, the patient should not take anti-inflammatory medication afterward.

Possible Complications

ESWT is generally considered a safe procedure, and not many complications have been reported. However, there is a possibility of recurrence on complications such as periosteum detachments, fractures of the inner surface of the cortex, compartment syndrome, neurological symptoms, and plantar fascial rupture. Relatively more potential complications are associated with high-energy than with low-energy therapy.

Conclusion

ESWT is not being used as a first-line treatment. Available literature is not sufficient to prove the long-term safety and efficacy of the treatment, and the available literature shows contrasting evidence. Moreover, proper treatment protocols have also not been established. Even though it is in its early phases of evolution, ESWT does show promise of becoming a standard treatment in sports medicine.

Extreme Sports, Injuries in

Extreme sports is a fluid, loosely defined term applied to a variety of typically nontraditional sporting endeavors. Other descriptive terms used for these sports include *action, adventure, alternative, millenial, next generation,* and *xtreme*.

The sports grouped under these terms are characterized to some degree by the following: a countercultural attitude, a relatively high degree of risk, and a high level of physical exertion or "action." They are typically "new" sports: Whereas boxing has been extant for millennia and basketball for over a century, snowboarding, for example, is only a few decades old. The extreme sports are also characterized by being frequently solitary endeavors. Evidence, furthermore, suggests that young athletes are increasingly turning away from more traditional sports in favor of nontraditional ones, including extreme sports, despite the fact that extreme sports are usually not sanctioned by schools. It is likely that the sports medicine professional will increasingly encounter participants of these extreme sports in his or her practice.

Overview

What sports are "extreme sports"? There is no single, authoritative definition of what constitutes this grouping. One classification made in 2004 by the author Joe Tomlinson in his book *Extreme Sports* divided extreme sports into those that take place in air, land, and water:

> *Air:* BASE (building, antennas, spans, and earth) jumping, bungee jumping, gliding, hang gliding, high wire, ski jumping, sky diving, sky surfing, and sky flying.

Land: Indoor climbing, adventure racing, aggressive inline skating, bicycle motocross (BMX), caving, extreme motocross (FMX), extreme skiing, freestyle skiing, land and ice yachting, mountain biking, mountain boarding, outdoor climbing, skateboarding, snowboarding, snowmobiling, speed biking, speed skiing, and street luge.

Water: Barefoot water skiing, cliff diving, free diving, jet skiing, open-water swimming, powerboat racing, round-the-world yacht racing, scuba diving, snorkeling, speed sailing, surfing, wakeboarding, whitewater kayaking, and windsurfing.

This list is meant to be instructive more than comprehensive. Some authors might not include some of these listed sports under the descriptor of "extreme sport" (e.g., power boating, yachting); others might include sports not listed above (e.g., ultraendurance events, ice climbing, sand dune skiing, parkour). Most of the sports that would fit in anyone's grouping of extreme sports, however, are not covered elsewhere in this text.

As noted earlier, a prototypical extreme sport would have the following attributes: a countercultural attitude, a relatively high degree of risk, and high levels of exertion or "action." Basketball, a traditional sport, arguably has a high level of risk (i.e., high injury rates) and is clearly marked by its action and physical intensity; however, it is a mainstream sport and is unlikely to be seen currently as "countercultural." Big-wave surfing, however, possesses all three attributes and is typically found on most lists of extreme sports.

Lest such classifications seem clear-cut, however, it should be noted that there is considerable debate over whether an activity such as bungee jumping, included in the listing above, would constitute an extreme sport: Though relatively risky and possibly countercultural, bungee jumping is an act that dissenters might argue lacks sufficient skill or physical ability on the practitioner's part to be classified as a "sport." Moreover, some have even questioned whether snowboarding, for example, now that it is an Olympic sport and "mainstream," could still be labeled an "extreme sport." Marathon running may have made the list of extreme sports at the beginning of the running boom, but with currently more than 50,000 people at the starting line of some marathons, it arguably is no longer "extreme." That distinction may be applicable only to ultramarathoning now.

Cultural Attributes

As has been noted already, there are cultural issues to be considered when reviewing the group of extreme sports, particularly as these issues affect sports medicine. For example, youths seem to be gravitating in larger numbers toward these sports. As it is well-known that musculoskeletal injuries in a skeletally immature athlete pose different challenges for the clinician, the phenomenon of youngsters pursuing these risky sporting endeavors has obvious medical implications.

This appeal of extreme sports to youth has not gone unrecognized by certain media and marketers. Though it might still be unusual to find an article on a surf competition in a local paper, some media outlets, such as ESPN, devote an increasing amount of their coverage to extreme sports. Indeed, ESPN, in hosting the "X Games," has been instrumental not only in developing extreme sports but also in broadening their appeal. Ironically, the very recognition that successful reporting and marketing brings to a sport can be the death knell of its "countercultural chic," what for many is the very essence of an extreme sport.

The nature of risk, and the apparent willingness of devotees of extreme sports to accept higher levels of risk, directly influences, of course, sports medicine's approach to these activities. Extreme sports devotees are sometimes called "adrenaline junkies," though out of scientific correctness, it should be pointed out that the neurotransmitter that is involved in reinforcement is dopamine and not adrenaline. Anecdotally, it appears that some extreme sports participants will seek new terrain or higher-risk versions of their sport in pursuit of the "extreme" ethic. There has been a general cultural evolution in these sports toward higher levels of risk. Marathons have evolved into ultramarathons, with the Marathon des Sables being a paragon: a 6-day, 150-mile endurance race run in the deserts of Morocco. Skateboarding, originally a street version of surfing, has evolved into aggressive skating, as epitomized in the documentary *Dogtown and Z-Boys: The Birth of Extreme*. Extreme surfers seek ever bigger waves, as epitomized by the Pipeline and Mavericks contests. Many sociological studies have been conducted on this quest by subsegments of certain sports to seek extreme levels of physical endurance and/or risk. For the purposes of this entry, it is mostly important to recognize the phenomenon and understand that over time, there will evolve newer, more "extreme" sports.

Injuries

Extreme sports are characterized by a variety of injuries and other sports medicine issues, but given the broad definition of the term, it is difficult to characterize these concerns. Moreover, there does not exist a large body of medical literature investigating the sports medicine aspects of extreme sports. The reasons for this dearth of information are related to many of the issues already discussed in this entry: the relative newness of the sports, the lack of mainstream recognition, and so on. Commentary on the injuries and illnesses seen in the group of extreme sports, then, is by necessity limited to a few medical studies, plenty of popular media stories, and a large number of anecdotes. The references at the end of the entry include some of the better studies existing in the current medical literature.

Some articles have begun to characterize the epidemiology of injuries and medical risks encountered by the extreme sports practitioner. Among the various injuries, there are the usual ones that occur in endeavors that put people at risk for falls, discussed elsewhere in this text. There are also a variety of injuries that are almost unique to individual sports, including scrotal injuries in mountain bikers, "snowboarder's ankle" (a fracture of the lateral process of the talus) in snowboarders, and a disruption of the A2 pulley of the finger seen in rock climbers and known as "climber's finger."

Data from New Zealand have been helpful in assessing some of the injury patterns in extreme, or adventure, sports. New Zealand is a mecca for participants in a wide variety of these sports, and the country's Accident Compensation Corporation (ACC) database is a rich source of epidemiologic data. One study from New Zealand calculated the morbidity and mortality rates for sports activity by visitors to the country. It found that 17% of all overseas visitor injuries and 22% of fatalities during a 15-year period were attributable to "adventure sports" activity. The injury incidence rate was calculated to be approximately 8 hospitalized injuries/100,000 overseas visitors (this may be compared with a rate of 12 hospitalized injuries/100,000 overseas visitors for motor vehicle accidents).

Protective equipment exists for many of these sports, from surfing to skateboarding to inline skating; anecdotally, there appear to be significant barriers (financial and aesthetic to name two) to participants actually using the equipment.

Extreme sports are also known as adventure sports for a reason: They can take place at times in unusual and taxing environments. Parasitic infections can affect athletes traveling to and competing in the developing world. Many of the water-based extreme sports can put participants at risk for marine envenomations and infections. Tick-borne diseases, such as Lyme disease and Rocky Mountain spotted fever, are a significant risk for athletes who participate in outdoor wilderness events. Sports medicine clinicians might be involved in event coverage or postcoverage treatment of individuals who are at risk; having knowledge of local, endemic medical risks is incumbent on these clinicians.

Finally, some of the extreme sports, such as the ultramarathons or adventure racing, require a good understanding of wilderness medicine, including an ability to recognize and manage thermal injury, dehydration, and altitude sickness, as well as the usual skills required for covering an urban mass sporting event.

Eye Injuries

As participation in sports and recreational activities has become increasingly popular, so have injuries associated with them become more common. According to the American Academy of Ophthalmology, sports are responsible for causing more than 40,000 eye injuries each year. More than 90% of sports-related eye injuries are preventable through the use of appropriate protective eyewear.

Overall, most eye injuries occur in basketball and baseball, followed by water sports and racquet sports. The severity of sports-induced injuries varies from mild scrapes of the cornea to severe trauma that may even lead to loss of vision. The majority of eye injuries occur in persons under 30 years of age. Children are especially vulnerable as they often lack depth perception and may misjudge the position, speed, and/or distance of a flying ball.

In cases of ocular injury, immediate evaluation by a physician is important to ensure preservation of vision; referral to an ophthalmologist for full evaluation should be made as soon as possible.

Anatomy

The *sclera* is the opaque (usually white), fibrous, protective, outermost layer of the eye. The front sixth of this layer, called the *cornea,* is transparent and covers the iris, pupil, and anterior chamber.

Inner to the sclera is the choroid, the front part of which contains three structures:

1. The *ciliary body* is the muscular area attached to the lens. It contracts and relaxes to control the size of the lens for focusing.
2. The *iris* is the sphincter that surrounds the pupil.
3. The *retina* is the light-sensitive tissue lining the innermost surface of the eye.

Light rays enter through the pupil and are focused on the retina after being refracted through the lens. Finally, the optic nerve carries the visual images to the brain (Figure 1).

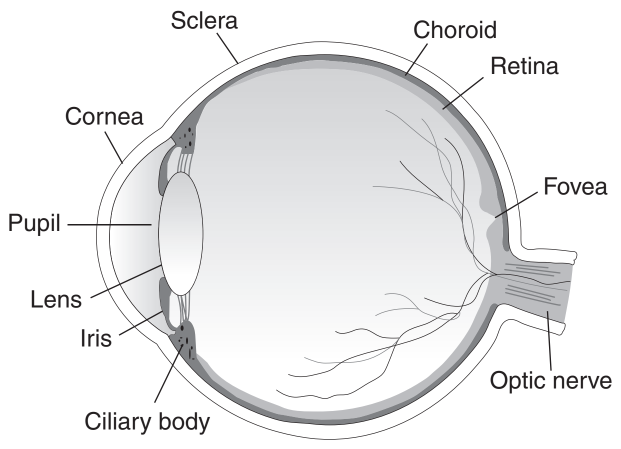

Figure 1 Sagittal Section of the Human Eye

Comparative Risk of Eye Injury, by Sport

Low Risk

There is no use of a ball, puck, bat, stick, or racquet in low-risk sports, and they do not involve body contact. Some low-risk sports are track-and-field, swimming, gymnastics, and cycling.

High Risk

A ball, puck, bat, stick, or racquet is used in high-risk sports, and they involve body contact. Examples of high-risk sports are baseball, basketball, hockey, football, lacrosse, tennis and other racquet sports, fencing, golf, and water polo.

Very High Risk

Very high risk sports involve body contact and do not use eye protectors. Some very high risk sports are boxing, wrestling, and contact martial arts.

Types of Sports-Related Eye Injuries

Types of eye trauma that can result from sports injuries include blunt trauma, corneal abrasions, penetrating trauma, and radiation injury.

Corneal Abrasion

Corneal abrasions are painful scratches on the cornea. They are not severe and eventually heal on their own. The most common cause of sports-related corneal abrasions is a scratch from a fingernail, a common event during a basketball game.

Blunt Trauma

The eye can be suddenly compressed by impact from an object, resulting in blunt injury. This is the most common form of sports-related eye injury. This can occur with player-to-player contact or when a ball or racquet strikes the eye. The severity of a blunt injury depends on the size, hardness, and velocity of the object. It can lead to a variety of injuries ranging from a black eye or hyphema (bruising of the eyelid), to a "blowout" fracture (fracture of the bone surrounding the eyeball), to a ruptured globe (rupture of the eyeball). The important structures inside the eye, such as the optic nerve, may also be damaged, resulting in permanent loss of vision.

Penetrating Injury

Penetrating injuries are relatively uncommon and occur when a foreign object pierces the eye. The object can be a BB from an air gun, a fish hook, a fingernail, or a fragment from shattered eyeglasses. Perforating BB gun injuries are the most serious type as these have the worst prognosis and often result in enucleation (removal of the eye, leaving the eye muscles and the remaining orbital contents intact).

Penetrating injuries range from mild abrasions to serious lacerations.

Radiation Injury

Radiation injury occurs as a result of exposure to UV radiation from the sun. Such an exposure is most common in sports such as snow skiing, water skiing, and other water sports.

Protective Measures

Wearing proper eye protection, although it cannot eliminate risk, greatly reduces the number and severity of ocular injuries.

Contact lenses and eyeglasses do not provide adequate protection. In fact lenses of regular eyeglasses can shatter on impact from a ball and can lead to a blunt or penetrating injury.

The American Society for Testing and Materials (ASTM) has recommended a certain type of protective eyewear for each sport.

Protective sports eyewear with polycarbonate lenses should be worn for basketball, racquet sports, soccer, and field hockey. Two-millimeter (mm) polycarbonate lenses in frames are for low-risk sports, and 3-mm lenses are recommended for moderate- to high-risk sports. Polycarbonate lenses are the thinnest and lightest lenses available. They are highly impact resistant and are available in prescription (for athletes with refractive errors) and plain forms.

Wearing goggles during a basketball game can protect against corneal abrasions. Safety goggles are also advised for children who play softball and baseball.

There is no satisfactory eye protection for boxing and full-contact martial arts, although thumbless gloves can greatly reduce the number of boxing eye injuries.

Total head and face protection is essential in collision sports; for example, a helmet with a polycarbonate face mask or wire shield should be used in football, hockey, baseball, and lacrosse.

Preparticipation Examination

A complete preparticipation eye examination of all athletes should be done. The physician should obtain the ocular history. Athletes with a high degree of myopia (near- or short-sightedness), eye surgery, injury, or infection are at increased risk.

Functionally One-Eyed Athletes

If the best corrected visual acuity in one of the eyes is less than 20/40, the athlete is considered monocular. ASTM has recommended special sports eye protectors for such persons. Eye protectors must be worn beneath a face mask in sports that require facial protection (i.e., hockey, football, and lacrosse).

An ophthalmologist should evaluate the monocular athlete before he or she is permitted to participate in a particular sport.

Warning Signs of Potentially Serious Eye Injury

- Visual loss or reduction
- Blurring of vision

- Pain on movement of the eye
- Tears in the outer ocular walls
- Presence of a foreign body inside the eye
- Bleeding on the surface or inside the eye
- Red and inflamed eye
- Photophobia
- Light flashes or floaters
- Suspected globe perforations

First Aid

Prompt first aid after eye injury greatly improves the chance of preserving vision. The recommended first aid involves a protective cover, such as taping the bottom of a paper cup over the eye or placing any other clean object there. The eye should be closed, to prevent involuntary movement of the injured eye. The athlete should be seen as soon as possible by an ophthalmologist for full evaluation of the injury.

In case of radiation injury, the victim should be removed from the source of UV light immediately.

Ocular Examination

An adequate history should be obtained to determine the force and direction of the impact. Best corrected visual acuity (clearness of vision), field of view, pupil sizes, full motility in all positions of gaze, and pupil constriction on exposure to direct light should be checked. A penlight examination of the anterior chamber should be performed to check for foreign bodies, hyphemia, abrasions, and lacerations. Occult rupture of the globe may be suspected if the red reflex (reddish-orange reflection from the eye's retina observed with an ophthalmoscope or retinoscope) is altered.

Prompt referral to an ophthalmologist is highly important in all cases as symptoms of severe injury are not always obvious.

Return to Sports

During the game, immediate return to play depends on the athlete's symptoms and the nature of the injury as determined by the team's physician. Following an eye injury and the athlete's removal from play, the athlete may return to play only after approval by an ophthalmologist.

F

Facial Injuries

Because few sports mandate facial protection or mouth guards during sports participation, faces are generally exposed and therefore at risk of injury. Between 3% and 29% of facial injuries result from sports participation. Approximately 10% to 42% of facial fractures occur in sports. The majority of these injuries occur in males aged 10 to 29 years.

Injuries to the face in sport are usually caused by direct trauma. Impact can result from equipment (goalpost, stick, ball), another player (fist, elbow, head), the ground (gym floor, wrestling mat), or the environment (tree, wall). Direct trauma can result in injuries to any of the facial components, including the facial bones, nose, eyes, teeth, and ears. Injury patterns are sport specific and are common in hockey, soccer, baseball, boxing, rugby, and skiing. Up to 95% of professional hockey players sustain some type of facial injury throughout their career.

Eye injuries can be serious but are generally preventable. Eye injuries occur most often in stick sports, such as hockey or lacrosse; racquet sports, especially squash; sports involving a ball or projectile, such as baseball, football, and soccer; and contact sports, such as basketball. It is estimated that there are more than 40,000 eye injuries from sports annually in the United States, with the majority of injuries occurring in basketball, water sports, baseball, and racquet sports. Approximately 5% of college varsity athletes sustain some type of eye injury each season.

Injuries to the teeth resulting from sports participation are common. In the United States, one third of dental injuries occur in sports-related activities. The main types of trauma include tooth fracture, avulsion, luxation, and socket injury. Often, other maxillofacial injury is associated with dental trauma, so it is important to rule out other injuries when assessing an athlete with a dental injury. Dental injuries result from collisions with opponents or direct blows from equipment such as hockey sticks and bats.

Nasal injuries are quite common in contact sports such as boxing and football. Nasal fractures are the most common midfacial fractures in athletes. Injuries to the ears are relatively uncommon. The most common injury to the ear is an auricular hematoma, seen in sports such as wrestling and judo. Injuries to the facial bones result from contact with equipment or other players.

Anatomy

Most of the bones of the face are subcutaneous, which makes examination of the face fairly straightforward. The forehead is formed by the frontal bone of the skull. The eyes are enclosed by the orbits, which are cone-shaped cavities formed by the union of seven cranial and facial bones. The orbital margin comprises the supraorbital ridge, superiorly; the infraorbital ridge, inferiorly; the zygomatic arch, laterally; and the nasal bone, medially. The resulting cavity protects the eye from blows from large objects.

The zygomatic arch of the malar bone results in the prominence of the cheek. The upper jaw consists of the maxilla. The superior surface of the maxilla forms the floor of the orbit, while the inferior surface forms the majority of the hard palate. The horseshoe-shaped mandible forms the lower jaw. The mandible comprises the body, angle, and ramus. The coronoid process is inside the mouth. The gingiva or gums overlie the alveolar ridge.

The teeth are located in individual sockets within the maxillary and alveolar bone. Each tooth is composed of a root and crown. The tooth root is attached to the socket by periodontal ligaments and is covered by cementum. The root contains the vascular pulp, the nerve, and the blood supply of the tooth. The crown consists of a tough outer shell of enamel, which protects the inner layer of dentin and the pulp extending to the crown. The gingival tissue overlying the maxilla and mandible seals the tooth in the socket.

Evaluation of Injuries

Facial injuries should be assumed to be closed-head injuries. In an unconscious athlete, a neck injury should be assumed and the athlete should be appropriately immobilized by qualified personnel. A doctor, nurse, or paramedic should evaluate the athlete's airway, breathing, and circulation. The airway may be obstructed by blood, dislodged teeth, or dental appliances or by structural injury to the bony structures, such as the mandible. If there is any airway compromise, the athlete should be intubated by a trained doctor or paramedic. Breathing should be supported as needed. Facial injuries are frequently associated with profuse bleeding. If there is significant bleeding, intravenous access should be established by trained personnel and intravenous fluids should be administered. Any unconscious or unstable athlete should be rapidly transported on a spinal board to the nearest hospital.

Details of Injury

The mechanism of facial injuries is usually direct or indirect impact. The location of the athlete's pain can help determine the nature of the injury. With some injuries, the athlete may lose consciousness or have amnesia of the events surrounding the time of the injury. The athlete may have a headache, nausea, or difficulty concentrating. If there is a history of prolonged loss of consciousness (>1 minute), significant amnesia, or symptoms of headache, nausea, or difficulty concentrating, there may also be a head injury.

Physical Findings

Facial injuries may result in bruising or active bleeding, as well as areas of asymmetry or deformity. There may be bleeding from the nose, obstruction of the nostrils, or leakage of cerebrospinal fluid (rhinorrhea). The ears may be bruised and swollen (hematoma), or there may be leakage of cerebrospinal fluid (otorrhea). There may be lacerations in the mouth or broken or misplaced teeth. Missing teeth should be located to ensure that they have not been aspirated (inhaled).

With fractures of the facial bones, tenderness to palpation will help localize the bone that is injured. There may also be crepitus (a crunching sensation to palpation), numbness, or deformities. Eye movements may be decreased because of the injury, and vision may be affected (double vision, blurred vision). The athlete may be unable to fully open his or her jaw or may have pain with jaw movement.

Investigations

Any significant eye injury should be evaluated with a slit lamp and referred to an ophthalmologist immediately.

Any suspected fractures of the facial bones should be evaluated with an X-ray or a computed tomography (CT) scan.

Dental trauma should be referred to a dentist for further evaluation. If teeth have been avulsed (knocked out) and cannot be located, a chest X-ray should be performed to rule out aspiration of the teeth. Avulsed teeth should immediately be placed in milk or saline solution to protect them until they can be replaced. Alternatively, avulsed teeth can be replaced in the socket and held in place with gum until the athlete is seen by a dentist. Avulsed teeth must be replaced within 1 hour to maintain viability.

Type of Injury

Table 1 lists a few of the common and less common facial injuries.

Table I Facial Injuries

Body Part	*Common*	*Less Common*
Facial soft tissue	Contusion	
	Laceration	
Eye	Corneal abrasion	Hyphema
	Foreign body	Retinal hemorrhage
	Subconjunctival hemorrhage	Retinal detachment
	Eyelid laceration	Lens dislocation
		Orbital blow-out fracture
Ear	Auricular hematoma (cauliflower ear)	Laceration
		Perforated tympanic membrane
Nose	Fracture	Septal hematoma
	Epistaxis	Fracture of nasal septum
Teeth	Enamel chip fracture	Crown fracture
	Luxated tooth	
	Avulsed tooth	
Facial bones	Temporomandibular joint sprain/malalignment	Fractured maxilla
		Fractured mandible

Prevention of Injury

Facial injuries can be prevented by wearing the appropriate protective equipment required by the sport or activity. Properly designed helmets, with appropriate facial protection, have reduced the incidence of facial injuries. In sports such as football, hockey, and lacrosse, protective helmets and face guards provide eye protection as well. Equipment must be properly maintained and replaced as necessary (e.g., single-impact helmets).

Protective eyewear should be worn in any sport where the risk of eye injury is high, such as squash and racquetball. Sport-appropriate eye protectors have been shown to reduce the risk of significant eye injury by 90%. Regular glasses and contact lenses do not protect the eyes from injury. Hard contact lenses should not be worn during sports activities. For most sports, 3-millimeter-thick polycarbonate lenses offer the best protection. Lenses should be treated to resist fog and should be fitted by an experienced ophthalmologist, optometrist, or optician.

An effective mouthguard can prevent or reduce the severity of dental injuries. Mouthguards should be custom-made and fitted by a dentist, kept in a plastic box, and rinsed regularly with an antiseptic mouthwash. They should be worn in collision sports, such as basketball, baseball, and soccer, as well as in contact sports, such as football, hockey, rugby, and wrestling.

Athletes participating in water sports, such as swimming and water polo, should use custom-fabricated ear plugs to maintain a dry ear canal. In athletes who experience repeated episodes of otitis externa, installation of alcohol ear drops (5% acetic acid in isopropyl alcohol) after each swimming episode may help prevent recurrence of infection.

Return to Sports
