These procedures are indicated for recurrent patellar instability with evidence of lateral patellar translation or displacement and deficient medial restraints (increased lateral glide on exam). These procedures have the advantage of avoiding contact with the femoral and tibial growth plates in the skeletally immature and may help re-create a more normal anatomy.

Distal Realignment Procedures

Several different techniques of tibial tubercle displacement have been reported. These include a posteromedial, medial, anterior, anteromedial, distal, proximal, and three-dimensional shift. Indications for these more complex operations include persistent patellofemoral pain related to malalignment, lateral facet arthritis and excessive Q angle, and a failed lateral release.

Soft Tissue Distal Realignment in the Skeletally Immature

An injury to the anterior proximal tibial physis may lead to a recurvatum deformity. Procedures such as the Galleazzi procedure or Roux-Goldwaithe are commonly performed in combination with other realignment procedures.

Surgical Treatment of Cartilage Arthrosis

The orthopedic surgeon has several intervention choices.

Cartilage debridement may help with mechanical symptoms. Intact cartilage is left alone. An intraoperative lavage alone may reduce pain.

Subchondral bone perforation, also called microfracture, encourages fibrocartilaginous ingrowth. The realignment procedures have been discussed above already.

With advanced patellofemoral arthritis, *patellar resurfacing* has not been shown to provide good results, but this may be due to the prosthesis chosen. The indications for this procedure are unclear at this time.

Patellofemoral arthroplasty has the theoretical benefit of replacing both surfaces. This intervention may have problems with component loosening. Efforts to improve this technique are continuing.

Total knee replacement may seem a drastic approach, although some studies describe its indication for isolated advanced patellofemoral arthritis. The outcome has been better than the outcome of patellofemoral replacement, isolated debridement, or patellectomy.

Patellectomy, or removal of the kneecap, is considered by many surgeons as the last resort. Some surgeons describe up to 90% excellent results. The indication for this procedure is severe patellofemoral arthritis and failed realignment procedures. Patellectomy may be combined with a distal realignment procedure to improve quadriceps efficiency.

A femoral trochlea plasty would be indicated for trochlea dysplasia. It consists of elevation of the lateral facet of the femoral trochlea and grafting.

Risk Factors for Patellofemoral Pain

The risk factors for patellofemoral pain can be classified as follows:

- Altered pH of the damaged tissues
- Avascular necrosis, patella
- Barometric pressure changes
- Bipartate/multipartate patella
- Chondromalacia
- Cytokines release
- Decreased explosive strength
- Excessive lateral pressure (syndrome)
- Fat pad impingement
- Fibroneuromatous degeneration of the lateral retinaculum
- Flexor hallucis entrapment
- Hallux rigidus
- Hypermobile patella
- Increased osseous metabolic activity
    - Loss of tissue homeostasis
- Intra-osseous hypertension
- Lateral retinacular neuromata
- Miserable malalignment (lower extremity)
    - Femoral anteversion
    - External tibial torsion
    - Pes planus/hyperpronation
- Muscle imbalance of quadriceps
    - Rectus femoris and VMO
    - Impingement of fat pad and medial retinaculum
- Neoplasm
    - Osteoid osteoma
    - Hemangiomata
- Non-RSD (Reflex Sympathetic Dystrophy) sympathetically mediated pain
- Osgood-Schlatter disease
- Overuse
- Patellar hypermobility
    - Patellar tilt
    - Patellar subluxation
- Patellar instability
- Patellar tendinitis
- Patellofemoral malalignment
- Pelvic instability
    - Core instability
- Peripatellar synovitis
- Plica syndrome
- Psychosomatic syndrome
    - Depression, anxiety, and aggression
    - Past history of physical or sexual abuse as a child
- Quadriceps tendinitis
- Referred pain from hip/spine
- Retinacular ischemia from vascular torsion
    - Secondary to patellofemoral malalignment
    - Producing neural growth factor
- RSD
- Saphenous nerve entrapment
- Sinding-Larsen-Johansson disease
- Slow VMO reaction response time
- Stress fracture patella
- Synovial impingement
- Tight gastrocnemius
- Tight hamstrings
- Tight quadriceps
- Venous engorgement

Pectoralis Strain

In recent years, pectoralis strain, once rarely seen, has become increasingly common owing to the increasing number of high-performance athletes and the greater priority given to intensive weight training. This injury occurs almost exclusively in males between the ages of 20 and 50. It usually pertains to the pectoralis major muscle, a highly visible muscle with immense strength located at the front of the chest. *Strain* means stretching the muscle too far; a severe strain can often lead to tearing of the muscle fibers (sometimes even the entire muscle from its attachment). Pectoralis strain can refer to a partial rupture of the muscle, although it is usually associated with complete rupture all the way to the bone. A pectoralis strain can be a potential threat to the career of an athlete and should be handled promptly and properly.

Anatomy

The term *pectoralis strain* most commonly means a strain or tearing of the muscle's point of insertion. The pectoralis major muscle is a fan-shaped muscle and has three heads arising from its three sites of origin:

1. *Clavicular head:* It takes origin from the medial half of the clavicle, that is, from the inner half of the collar bone.
2. *Sternal head:* It has two parts, upper and lower. The upper part arises from the manubrium, the upper body of the sternum (the central bone in the chest), and the second to fourth ribs, that is, from the upper frontal part of the chest. The lower part arises from the distal body of the sternum as well as the fifth and sixth ribs, that is, from the lower part of the chest. Basically, the pectoralis major muscle encloses the whole of the front of the chest.
3. *Abdominal head:* It arises from the lower left region of the abdomen.

The pectoralis major muscle, after taking its origin from the aforementioned places, inserts itself into the anterosuperior aspect of the humerus (the upper front portion of the upper bone of the arm). Due to its multiple origins and insertion, the pectoralis major muscle is an important player in multiple movements and a wide range of actions:

- It helps in adduction and flexion as well as internal rotation of the humerus when the thorax is fixed. It brings the arms to the front, as in a bench press maneuver.
- It serves as a climbing muscle and helps in elevation of the thorax when the humerus is fixed.
- It also serves as an accessory muscle for respiration.

Causes and Risk Factors

The injury most commonly occurs when the pectoralis muscle is put under tremendous tension or supplementary forceful tension. It occurs most often in weight lifting (more than 50% of cases), especially with the bench press maneuver. Apart from this, the strain may occur in athletes participating in racquet games, swimming, water skiing, and rowing. Traumatic injuries such as those suffered in wrestling, American football, and rugby may also lead to a pectoral strain.

The following factors predispose to the condition:

- A weak and tight pectoralis major muscle, resulting from lack of proper conditioning in the prematch period
- Fatigue
- Overexertion
- Lack of proper warming up prior to exercise (cold weather requires extra warming up)
- Steroid use, which is known to weaken the tendons and may be a contributory factor

Types of Pectoral Rupture

There are three types of pectoralis rupture:

Type 1: Rupture at the humeral insertion (tendon ruptured from the bone)

Type 2: Rupture at the musculotendinous junction (rupture in between the tendon and the muscle)

Type 3: Rupture of the muscle belly (rupture in the muscle itself)

Usually, Type 1 ruptures are full tears, while Type 2 and Type 3 are typically partial ruptures.

Signs and Symptoms

The following effects are usually encountered in a pectoralis strain:

- Pain is one of the dominant symptoms of this condition. It may be accompanied by a tearing or "pop" sound. It can take the following forms:
  - A sudden sharp pain at the front of the arm or shoulder
  - Pain in the chest
  - Pain felt when the arm is brought inward toward the chest against resistance
  - Pain felt when trying to rotate the arm inward
- Bruising may be seen in the chest and arm.
- There may be weakness when bringing the arms to the front of the body.
- A pocket (dimpling) may be formed above the armpit, indicating a tear.
- Decreased range of motion may be observed at the humerus (upper arm) as a result of the rupture.

Grading of Severity

The condition can be graded according to the severity of the pain and associated symptoms:

Grade I: This involves the tearing of a few muscle or tendon fibers. There is minimal loss of strength. It causes minor discomfort but doesn't hinder activity. Recovery occurs in a matter of days.

Grade II: This involves a greater number of torn fibers and loss of strength to a greater extent. It causes greater discomfort and can begin to limit activity. Swelling and bruising may also be seen. Recovery may take 2 to 6 weeks.

Grade III: This type of strain is very rare, painful, and incapacitating. It can have long-term implications on strength, range of motion, and sports performance. In the majority of such cases, the muscles fail to regain their original strength. Significant swelling and bruising are often present. Recovery may take 3 months or longer.

Diagnosis

The diagnosis is often apparent by history alone, but sometimes a clinical examination can show some peculiar features:

History

The patient may give a history of injury or complain of pain, weakness, or decreased movement. He or she will often report hearing a "pop" or feeling a tearing sensation at the onset of the pain.

Clinical Examination

- Maximal peculiar muscular contraction will be observed when the arm is abducted and extended.
- Tenderness, limited mobility, swelling, ecchymosis (bruising), and weakness will be manifested in the front of the shoulder or chest.
- Loss of axillary fold is also probable. The best position to observe this is when the arm is abducted to 90°; however, this can only be done after the swelling has subsided.
- The location of ecchymosis (bruising) may signify the location of the injury. If ecchymosis is observed in the front of the chest, then it is most probably a muscle belly tear. If, however, the bruising is in the axilla or arm region, then it most probably signifies a tendon rupture at its site of insertion.

Imaging

- An X-ray is taken to rule out a fracture of the upper part of the humerus.
- Ultrasound may be performed to determine the location of the tear. A tear is indicated by muscle thinning in comparison with the normal side and uneven echo generation.
- Magnetic resonance imaging (MRI) can show the exact location of the injury and evaluate partial tears. It also helps with grading the severity of the injury.

Treatment

First Aid

Athletes should be trained to recognize the symptoms and perform RICE (*r*est, *i*ce, *c*ompression, and *e*levation) immediately. They should be careful not to strain the muscle further at any cost; rest is essential. A sling may be used for immobilization and elevation. Any activity that causes chest wall pain should be limited.

Professional Treatment

Treatment depends on the severity of the injury. One or all of the following may be considered.

Initial Treatment

Rest: This is the first and foremost principle to recover from any muscle strain. Exercise should be stopped to permit the body to repair itself.

Local cold pack/ice: Ice or cold packs on the injury during the first 2 days are often very helpful in easing the pain and swelling. Ice should be applied for 15 to 20 minutes four times a day, wrapped in a towel to avoid direct contact. Ice application should be started immediately after injury and can be extended for several days if necessary; the process can be repeated after any activity involving the affected area.

Oral nonsteroidal anti-inflammatory drugs (NSAIDs): Examples are painkillers such as ibuprofen or aspirin tablets.

Subsequent Treatment

Stretching: Similar to recovering from any other muscle strain, once the pain has subsided and range of motion has returned, stretching exercises should be incorporated into the routine. Gentle stretching is advisable, although care must be taken not to overdo it as excessive stretching may be counterproductive. A gentle pulling sensation is the aim, but the stretch should not be painful. Stretching should be done in the recovery period and can be done several times a day. Cross-training activities that do not stress the pectoralis muscles, such as jogging, should also be incorporated.

Local application of heat: While cold is helpful after activity, heat is of benefit before any activity is undertaken (e.g., stretching), to soften the area and reduce any chance of further aggravation of the injury. However, use of heat should be started in the recovery period, not in the period immediately following the injury.

Physiotherapy: Ultrasound treatment, infrared treatment, specific exercises, and massage by trained physiotherapists under the supervision and guidance of sports injury specialists or rehabilitation specialists are often of great value in speeding up the recovery period and preventing complications.

Diet: Supplementary protein is advocated for repair of the torn muscle.

Strengthening exercises: The following are a few of the strengthening exercises that can be incorporated:

- ○ Active isolated pectoralis stretch: The patient stands in a comfortable position, with the arms raised and palms facing up. Then, the back muscles are contracted to bring the arms to the sides with the palms still facing up. Stretching to the point of pain should be avoided. Repeat 10 times.
- ○ Quadruped stance: The patient supports himself or herself on the hands and knees. Once the patient is comfortable, he or she extends into the push-up position and holds the body in this plank position. The duration of this exercise should be gradually increased, but the patient should not hold until the point of pain.
- ○ Resisted internal rotation: The patient starts with the arm at the side, holding an elastic tube that is tied to a stable surface. He or she then gently rotates the hand toward the belly button and then releases it. This action should be repeated 10 to 15 times. The patient should use a band that offers a moderate amount of resistance but no pain.

Surgery: This is frequently recommended for complete tears of the pectoralis muscle tendon. Patients with partial tears, elderly patients, and patients with a sedentary lifestyle can avoid surgical treatment. Surgical repair of the torn tendons gives patients a good chance of returning to high-level sports and activities. Preferably, the surgical repair is done early following injury as it minimizes muscle atrophy and scar tissue. Early surgical repair shortens the time to functional recovery and lessens the occurrence of lesions. However, there are some studies that show that late repair improves strength and cosmesis (appearance of the chest).

Prevention

The most important factor in prevention of this injury is proper conditioning of athletes, especially those who participate in sports where a pectoral strain is more likely. To ensure pectoral strength, athletes must

- warm up properly before any exercise,
- allow more time for warm-up in cold weather,
- get help from a certified strength-and-conditioning coach to learn a proper lifting technique,

- take care not to increase exercise intensity, duration, or frequency by more than 10% per week, and
- continually work out, for the stronger the muscles, the less will be the likelihood of their rupture.

Weight lifters, in particular, should be advised on the proper bench press technique. They should limit the distance that the bar is lowered and narrow the grip of the hands on the bar. Lowering the bar down to the chest or widening the grip on the bar increases stress on the pectoralis major muscle and increases the chance of pectoralis injury.

High-performance athletes who keep the cardinal principles of prevention in mind and are disciplined in their approach toward the game can usually avoid this kind of needless injury and have a rewarding career.

Pediatric Obesity, Sports, and Exercise

Over the past few decades, two problems have emerged regarding physical activity in youth. First and foremost, in the United States and many other industrialized countries, far too many youth are inactive, resulting in too little energy expenditure and contributing to the soaring rates of childhood obesity. On the flip side, some youth are engaging in extreme amounts of organized sports activity. Both scenarios result in musculoskeletal conditions that are seen daily in youth in the practice of sports medicine. Of note, the evolution of youth sports may be resulting in the exclusion of those children who could most gain from the health benefits of sports participation.

Role of Sports in Addressing the Physical Activity Needs of Children and Adolescents

It is recommended that children and adolescents participate in at least 60 minutes of moderate physical activity on most days of the week. Discussions about physical activity have focused on the need to increase the percentage of children meeting this recommendation. This is for a good reason. Epidemiological studies have found that physical activity is inversely associated with overweight status in childhood. Overweight status is clinically assessed by calculating the body mass index, or BMI, determined by weight (in kilograms) divided by height (in meters) squared. In the United States, the 2003–2006 National Health and Nutrition Survey (NHANES) found that approximately 30% of U.S. youth, from ages 2 to 19 years, are either overweight or obese as determined by a BMI that is greater than or equal to the 85th percentile as compared with the 2000 Centers for Disease Control standards. Childhood obesity has clearly become a global problem. While the rates are higher in the more industrialized countries, worldwide national surveys show that childhood obesity rates are rising in most countries. Childhood obesity is associated with poor physical and psychological health.

Participation in team or individual sports is a wonderful means for children and adolescents to be physically active. In addition to the physical health benefits of exercise, such as cardiovascular and bone health, youth sports participation is associated with a variety of psychological benefits. Many of the psychological and emotional morbidities seen in childhood obesity, such as depression and anxiety, may be decreased with participation in sports. Sports can offer youth a venue for socialization, the ability to develop moral reasoning skills in a safe environment, and the opportunity to experience either the joy of winning or the satisfaction of knowing that they have tried their best in a competition. In summary, youth sports offer a means to address both the physical activity needs of children and the psychological difficulties that arise when those needs are not met. Given the problems of obesity and inactivity among adults, it is important to note that participation in sports during childhood and adolescence is associated with a high level of physical activity in adulthood. A positive experience with sports in childhood and adolescence can be the foundation for a future reaping the health benefits of physical activity.

Youth Sports Today

Clinical experience suggests that there has been a dramatic rise in the amount of time spent by children in organized sports with formal teams, coaches, and multiple weekly practices and games. It appears that children are being channeled into single-sport specialization, often before the age of 10. In Minnesota, children participating in ice hockey are being selected for teams based on ability by age 6. Practice times in certain sports are increased steadily throughout childhood. By the age of 10, many children play on organized teams four or more times per week and often year-round. Two potential consequences of this are psychological burnout and overuse injuries.

Many youth sports clubs encourage year-round participation. Given the number of hours involved in participating in any one sport, these children, and their families, are faced with a choice: either participate in multiple sports and further increase the number of hours of sports participation or become a single-sport athlete at a very young age. It has been estimated that approximately 70% of children participating in any one sport will stop playing in their early teenage years. If a child who participates in only one sport stops playing, he or she may become a no-sport athlete, a phenomenon that likely contributes to the sharp decline in physical activity during adolescence.

Our Current System for Youth Sports Excludes Those at High Risk for Obesity

The development of our current organized sports system may not be including the demographic groups that could gain the most from the health benefits of sports participation. There seem to be fewer opportunities for play in recreational leagues for children not selected to the "traveling squads." Thus, there is less chance of sports participation for any child but those on the elite teams. The selection process for these teams tends to exclude certain groups of children. For example, pediatric obesity disproportionately affects less affluent children and adolescents. Yet organized youth club sports often require high fees for participation and significant investment by families for equipment and travel. There are decreasing opportunities for participation in school sports, and even when schools include sports, financial contributions from families are increasingly required to offset declining public investment. These financial constraints pose a barrier to sports participation by youth from less affluent families, many of whom already have too little physical activity.

There is increasing recognition that children who are not gifted with physical coordination skills participate less in physical activity and are more likely to be obese. The term *developmental coordination disorder* (DCD) has been used to describe otherwise healthy children with impairment in motor skills considered to be appropriate for their age, given normal intellectual ability and the absence of other neurologic disorders. DCD is believed to affect between 5% and 10% of youth, with higher rates in boys than in girls. There is mounting research documenting that these children participate in fewer organized and free-play physical activities, and in boys, there is an association with obesity and loneliness. Importantly, this association of poor coordination and loneliness seems to be weakened when these children participate in sports (likely due to the social aspect of sports).

Adolescents who were born with "extreme prematurity" and low birth weight but without major impairments show significantly lower rates of sports participation than do controls. Extremely low–birth weight babies are at high risk for obesity and obesity-related cardiovascular abnormalities. While their lack of sports participation is likely due to problems with coordination, which makes them prefer to avoid sports, it serves to highlight again that those who need sports the most are participating at lower rates than those who need them the least.

In summary, sports participation seems to be lowest among those at greatest risk for childhood obesity—for example, those with lesser economic means, those with coordination difficulties, and those who were born prematurely. Youth sports today aim to increase the average number of hours children spend in physical activity but may not be increasing the average number of children reaching the recommended goal for physical activity.

Pediatric Sports Medicine: A Problem of Overuse and Underuse

Youth Sports Participation and Musculoskeletal Injuries

Sports are generally safe, and the health benefits outweigh the risks. However, sports can cause either acute injuries or, with excessive training, overuse injuries. Sports are a leading cause of injury and hospital emergency room visits among adolescents. A review estimated 2.6 million emergency room visits in the United States for sports-related injuries by those between the ages of 5 and 24 years. Most of these visits are by boys between the ages of 5 and 14. Most of these are for acute injuries, such as sprains (of ligaments), strains (of muscles or tendons), contusions, and fractures. Fractures account for 20% to 30% of sports-related visits to the emergency room. There is a male predominance of 2:1, with the distal radius and ulna accounting for the most common fracture site. Anterior cruciate ligament (ACL) injuries of the knee are believed by some to be the single largest problem in orthopedic sports medicine. The most common mechanism is a noncontact deceleration injury. This mechanism is more common in female sports participants. In similar sports, consistently higher rates of ACL tears occur among female sports participants than among males. While many of those who suffer ACL tears return to sports, often after reconstructive surgery, an ACL injury itself is associated with a significant rehabilitation process and a high probability for future arthritis.

With the increased sports participation by those in organized sports, there has been a dramatic rise in musculoskeletal overuse injuries. Injuries may be attributed to overuse when there is no specific acute event and the athlete's participation is deemed excessive. Common overuse injuries include stress fractures and soft tissue injuries that are not the result of a contusion. Stress fractures in young athletes often occur in runners and often in the tibia. Especially problematic areas are the hip and the lower back (e.g., spondylolytic injuries). Additionally, excessive traction on growth plates can cause a variant of the typical stress fracture, as in the case of the proximal humerus in the throwing athlete (Little League shoulder). Among the classic soft tissue overuse injuries in youth are injuries to the apophyses, for example, at the junction of the patellar tendon with the tibial tubercle (Osgood-Schlatter syndrome) and the Achilles tendon with the calcaneus (Sever syndrome). Apophyseal injuries tend to cluster in the peripubescent years of accelerated skeletal growth.

In the treatment of youth overuse injuries, sports medicine providers must be skilled in dealing with not only the physical aspects of injury and healing but also the more subtle issues surrounding the motivations of youth athletes, their parents, and their coaches. Treatment often requires avoidance of repetitive activity for several weeks, or even months. This may seem especially problematic for athletes who are in year-round programs and who fear that any extended time away will lose them a spot on the team. It is important to recognize that adolescents often place extra importance on immediate issues (e.g., playing in the upcoming tournament) at the cost of long-term consequences (e.g., further damaging a fractured bone). When treating a minor, the sports medicine clinician must include the parents, and thus parental motivation must be evaluated. It is recommended to discuss the athletic goals for the patient/athlete with both the athlete and his or her parents. The sports medicine provider can often use the competitive nature of the athlete to increase adherence to treatment recommendations. For example, when treating the star high school freshman volleyball player with knee pain attributable to Osgood-Schlatter apophysitis a few months away from jumping, a focus on biomechanical stability training may result in a senior volleyball player who is a stronger candidate for a college scholarship.

Pediatric Obesity and Musculoskeletal Injuries

Lack of physical activity is a major cause of the childhood obesity epidemic. This underuse of the musculoskeletal system with subsequent increase in body weight may result in musculoskeletal conditions requiring the care of a sports medicine specialist. Childhood obesity is associated with a variety of biomechanical changes, especially in the lower extremities. Obesity in children is associated with changes in gait. These biomechanical changes coupled with the extra weight result in excessive forces on the lower extremity joints. Perhaps due to changes in balance, childhood obesity may be a risk factor for injuries, and studies have noted an increased risk of upper extremity fractures in overweight children. While obese children have denser bones than their nonobese counterparts, the increased bone strength is not sufficient to compensate for their increased weight. A recent study noted that children who are obese are more likely to suffer long-term morbidity after acute ankle sprains than are children with normal BMI.

For years, childhood obesity has been associated with certain rare conditions such as Blount disease (an angular deformity of the tibia causing a bowlegged appearance) and slipped capital femoral epiphysis. Recently, there is increased appreciation that obese children suffer from musculoskeletal pain due to more subtle issues. Although these pains are less acute, they may have a large impact on quality of life and the ability to perform needed physical activity. Recent studies have shown that obese children report more musculoskeletal pain than nonobese children and that among obese children, those with more body weight have a greater likelihood of experiencing pain.

As outlined in Figure 1, similar to their peers who are participating in excessive amounts of physical activity, obese and generally more sedentary children are also at high risk for musculoskeletal pains, which may lead them to the sports medicine clinician's office. Both ends of the physical activity spectrum could be improved by a balanced youth sports system. It is recommended that obese children increase their physical activity to expend energy and lose weight. However, recommendations to have overweight and obese children exercise need to be given with the understanding that once excessive weight has developed, there may be musculoskeletal issues directly limiting the ability to increase physical activity. Clinicians need to individualize their recommendations and consider exercises such as weight training, pool exercises, and bicycling, all of which may lessen the effect of body weight and the occurrence of subsequent joint pains when compared with traditional walking and running.

Certain Sports Encourage Excessive Body Weight

Sports participation is, in general, recommended for the prevention of childhood obesity. However, certain sports, where increased size confers an advantage, may be directly contributing to the rise in obesity. Increased body size is a potential benefit in many sports, most notably American football. The body weight of football players has been increasing over the past few decades. A study of a Division I football program found that from 2003 to 2005, the average BMI for the incoming freshman football players was 30 (i.e., at the cutoff line for obesity). The mean BMI of the linemen was clearly in the obese range (34 and 35 for the defensive and offensive linemen, respectively). The players in the other positions had mean BMI in the overweight range (25–30). These players are likely to gain weight during subsequent years of participation. A survey of former professional football players (mean age at the time of the survey, 54 years) conducted from 2004 to 2006 found that among the former linemen 85% were obese and 60% met the criteria for the cardiovascular risk factors known as "the metabolic syndrome." Among the nonlinemen, 50% were obese, and 30% had the metabolic syndrome.

The problem of sports increasingly selecting larger children may not be limited to football. Physical maturation seems to be the primary selection factor for many youth sports, and this criterion will only become more pronounced as children are funneled into sports at an increasingly younger age. Unlike adults, in children there is a positive association between BMI and height. Children with increased BMI are often more skeletally mature. However, early skeletal maturation is also associated with future obesity. If increased BMI and height are advantageous in a sport, then youth sports that select children who are bigger and taller (especially in prepuberty) may be encouraging development that leads to future obesity. While the energy expenditure is beneficial for a healthy body weight, encouraging increased size is not.

Conclusion

Many of today's youth fall at the two ends of the physical activity spectrum. Both ends of the spectrum are associated with musculoskeletal problems that are seen in the practice of pediatric sports medicine. From a public health perspective, the major

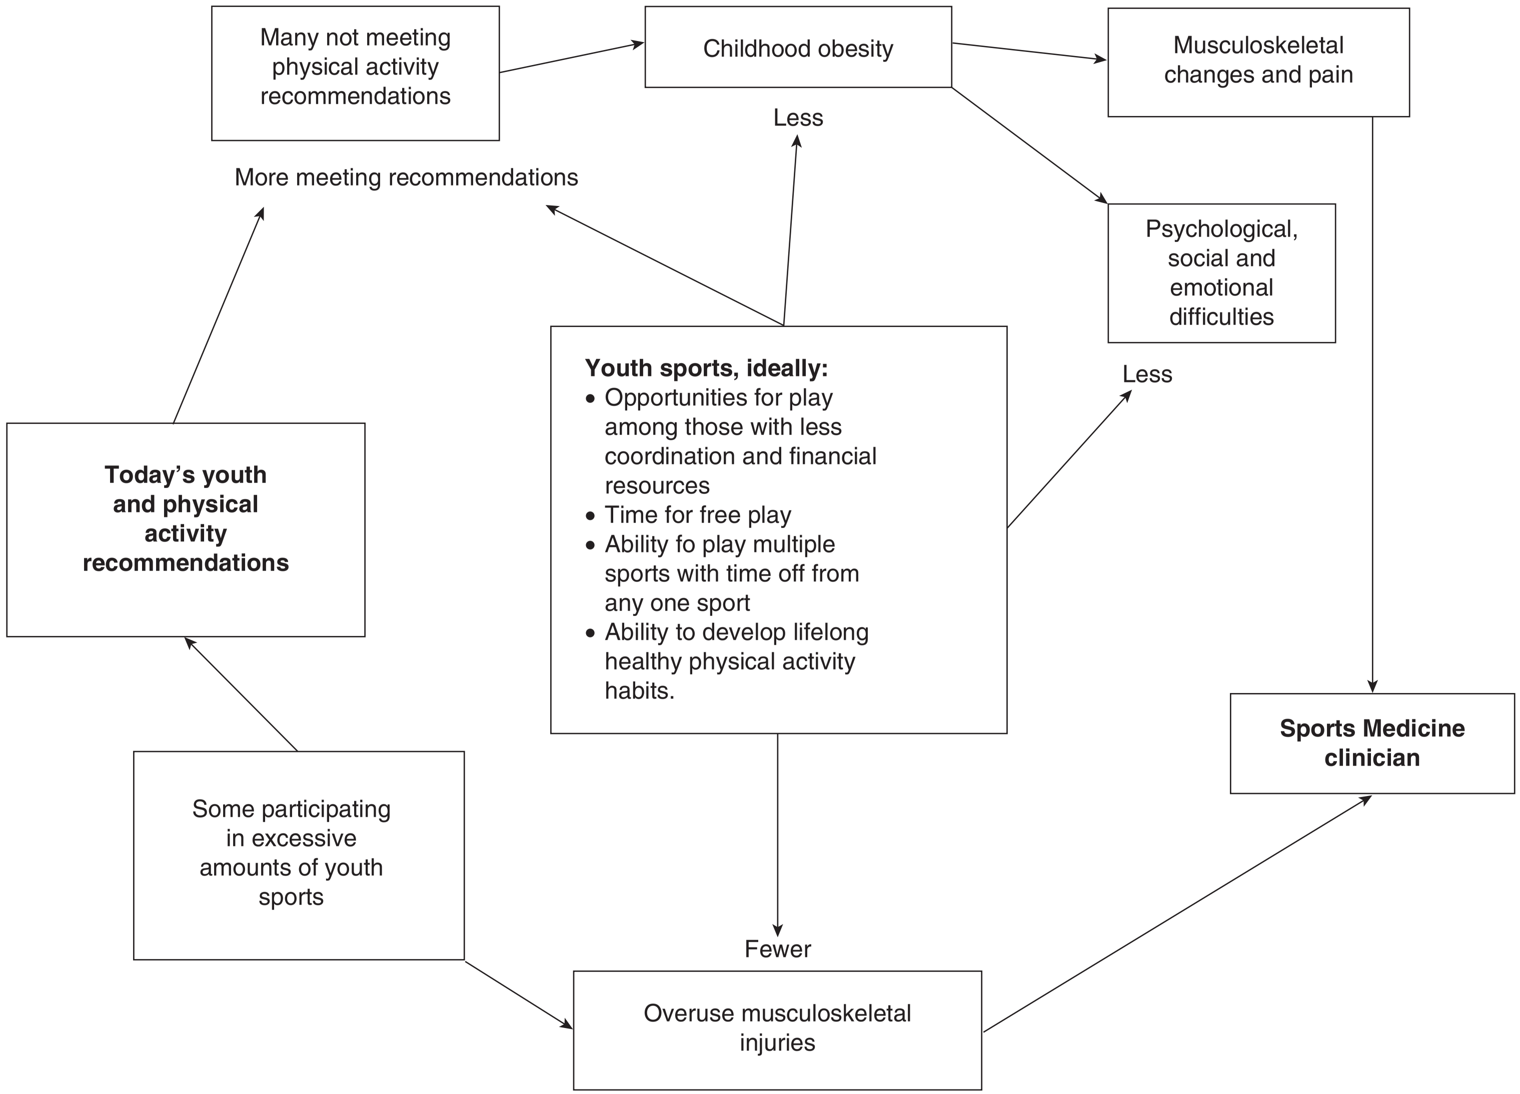

Figure 1 Interrelationships of Pediatric Obesity, Sports, and the Sports Medicine Clinician
Source: Steven D. Stovitz.

problem is that too few youth are achieving the recommended amount of physical activity. Lack of physical activity places them at risk for obesity, and obesity causes musculoskeletal changes that may result in pain and poor function. One answer to the goal of increasing physical activity in youth is youth sports. Youth sports offer a means to increase physical activity in the present and provide a foundation for a physically active future. However, recent trends in the evolution of youth sports may be hindering the attainment of these goals for those youth who need physical activity the most. Furthermore, for those in youth sports, the demands of increased physical activity may result in psychological burnout and overuse musculoskeletal injuries. It is important for the sports medicine provider to be able to individualize treatment for youth with musculoskeletal pain due to either excessive body fat or excessive body training.

Summary

- Pediatric obesity, which is partly the result of insufficient energy expenditure, is a major health problem in many parts of the world.
- Physical activity in general, and sports in particular, is recommended as a means to prevent and treat pediatric obesity
- Sports participation may be difficult for the child with extreme overweight due to changes in the musculoskeletal system and pain.
- The recent trends in childhood sports may be inadvertently excluding children at the greatest risk for obesity.
- Sports such as American football may be selecting for traits that entail increased rates of obesity.
- Sports medicine providers can be at the forefront of encouraging a healthy and physically active lifestyle for children. Some suggestions are as follows:
  - Encourage lifestyle means of increasing physical activity, such as using nonmotorized means of transportation and decreasing television watching and other "screen time," for example, surfing on the Internet.
  - Advocate for increasing the opportunities for sports participation for all children, regardless of athletic ability.
  - Counsel coaches and parents on the risk of overuse musculoskeletal injuries from excessive hours of organized sports participation, especially in a single sport with repetitive actions.
  - Recognize that obesity in children may cause musculoskeletal changes and pain that may limit their ability to perform certain activities. Individualized activity options may be indicated.

Pelvic Avulsion Fractures

Pelvic avulsion fractures are almost exclusively seen in the adolescent athletic population. The main reason for this is the relatively weak apophysis of the hip at this stage of development. An apophysis is a growing part of the bone where a large muscle group attaches. The apophysis is a secondary center of ossification that contributes to the shape or contour of the bone but not to the length of the bone. This is in contrast to the physeal growth plate, which adds to the length of the bone. This relative weak link in the chain predisposes the apophysis to avulsion fracture when coupled with a violent contraction of one of the large hip muscles that attach there.

The apophyses of the hip appear and eventually fuse at different ages and in some cases may not fuse until the third decade of life. Hence, apophyseal avulsion fractures can occur in an athlete as late as 30 years of age. The following table gives the approximate ages of appearance and fusion of the apophyses of the hip:

Apophysis	*Age of Appearance (Years)*	*Age of Fusion (Years)*
Iliac crest	13–15	15–17
Anterior superior iliac spine (ASIS)	13–15	21–25
Anterior inferior iliac spine (AIIS)	13–15	16–18
Greater trochanter (GT)	2–5	16–18
Lesser trochanter (LT)	8–12	16–18
Ischial tuberosity (IT)	16–18	19–25

The large muscle groups that attach to the pelvic apophyses are the transverus abdominus and internal and external oblique muscles, and the gluteus medius and tensor fasca lata muscles attach to the iliac crest apophysis. The anterior superior iliac spine (ASIS) apophysis is the site of origin of the sartorius muscle. The anterior inferior iliac spine (AIIS) apophysis is the site of origin of the straight head of the rectus femoris muscle. The greater trochanter (GT) apophysis is the insertion site of the gluteus medius and minimus and external rotators of the hip. The lesser trochanter (LT) apophysis is the insertion site of the iliopsoas muscle. The ischial tuberosity (IT) apophysis is the site of origin of the hamstring muscles.

Pelvic avulsion fractures are generally considered to be an uncommon injury, but their rates have been increasing over the years. Studies have reported rates of avulsion fractures between 13.4% and 40% of all pelvic and hip fractures in the adolescent population. A study by Rossi looked at 20 adolescent patients with acute pelvic avulsion fractures and found that the most common sites of injury were the ishial tuberosity, lesser trochanter, ASIS, and AIIS. The most common sports involved were gymnastics and soccer. The majority of the athletes in the study were males, but the injury is being seen more frequently in females as their rates of participation in sports are increasing. These injuries occur most commonly during Tanner Stage III, when the rate of growth is the fastest.

The most common mechanism of injury in an acute pelvic avulsion fracture is a sudden, forceful, unbalanced contraction of one of the major muscle groups that attach there. The athlete may feel a "pop" or a "snap" during activity, followed by sudden, severe pain. The athlete will usually be unable to ambulate without pain and will be forced to cease activity. Physical exam may show swelling and bony tenderness over the involved bony prominence. X-rays are needed to confirm the diagnosis. Comparison views of the opposite side are very helpful to rule in the fracture, since usually the opposite side will show the same growth stage.

Most avulsion fractures will respond adequately to a conservative treatment plan. In almost all cases, the athlete will need to walk with crutches to give rest to the joint. J. N. Metzmaker and A. M. Pappas modified a five-stage program for conservative rehabilitation of an acute apophyseal avulsion fracture. Stage 1 involves rest in a position of comfort (crutches), ice application, and anti-inflammatory medication for pain relief. Stage 2 involves a gradual increase in passive range of motion in the affected joint. Stage 3 begins when full active range of motion is achieved and involves a comprehensive resistance training program. Stage 4 begins when the athlete has gained 30% of his or her strength compared with the uninvolved side and sees the athlete incorporating the involved muscle group in rehabilitation. Stage 5 involves allowing return to play when the athlete regains full strength and pain-free integration of the involved muscle group.

Surgical intervention is considered when the avulsed fragment is displaced greater than 2 centimeters (cm), the fracture heals with symptomatic bony overgrowth, or it heals with chronic fibrous union. Surgical treatments include excision of the bony fragment or open reduction and internal fixation if the fragment is large enough to accept the hardware.

Ischial Tuberosity Avulsion Fracture

The IT is the site of origin of the hamstring muscles. The hamstring muscles function to extend the hip and flex the knee. Hence, avulsion fractures of the IT are usually caused by a sudden, forceful contraction of the hamstring muscle with the knee in extension and the hip in flexion, as occurs when an athlete jumps a hurdle or performs the splits. The IT apophysis fuses late, between 19 and 25 years of age, so the diagnosis of IT apophyseal avulsion fracture should be entertained and the appropriate X-rays ordered in the athlete in his or her third decade. This is thought to be the most common site of pelvic avulsion fracture (Figure 1).

Acutely, the athlete may find it impossible to sit due to the location of the fracture fragment and may have difficulty walking. A palpable gap may be noted, and the athlete may have pain with passive hip flexion. X-rays may show the fracture as large and crescent shaped.

An IT avulsion with less than 2 cm of displacement is usually successfully treated conservatively, including walking with crutches, rest, and slow return to activity. The IT avulsion fracture commonly heals with exuberant bony exostosis, which may lead to chronic buttock pain, difficulty sitting, and, in rare cases, sciatic nerve irritation. The exuberant bony changes can be confused with bony tumor. Treatment for chronic symptoms or a fracture fragment with greater than 2 cm displacement consists of surgical excision or open reduction and internal rotation.

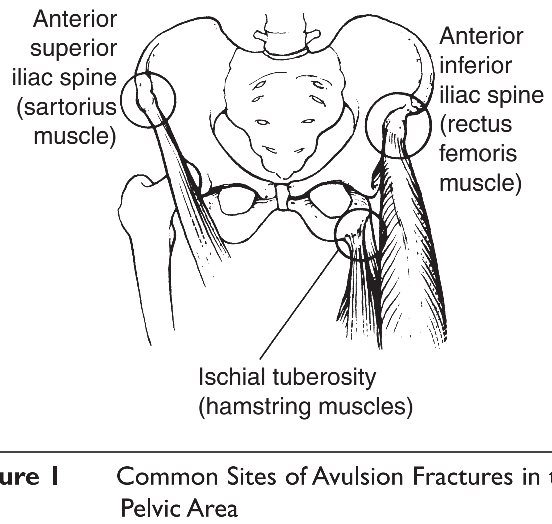

Figure 1 Common Sites of Avulsion Fractures in the Pelvic Area

Anterior Superior Iliac Spine Avulsion Fracture

The ASIS apophysis is the site of origin of the sartorius muscle, as well as several fibers of the tensor fascia lata. The sartorius muscle functions to flex the hip and is commonly avulsed during sprinting, hurdling, or running. Avulsion fracture of the ASIS is one of the more common avulsion fractures. The ASIS apophysis fuses between 21 and 25 years of age and hence can be seen in older athletes than the AIIS avulsion fracture.

At the time of injury, the athlete will usually feel or hear a "pop" and have immediate disability. Pain may be elicited by passive hip extension and with contraction of the hip flexors. In up to 90% of fractures, the avulsed fragment is palpable. As with all avulsion fractures, X-rays can confirm the diagnosis. ASIS fractures can be confused with AIIS fractures due to the inferior displacement of the ASIS fragment.

Most ASIS avulsion fractures can be treated successfully with a conservative treatment plan, including rest, walking with crutches, ice application, and analgesia. Complete recovery may take up to 10 weeks. Some authors recommend surgical treatment to allow a quicker return to sports (3–4 weeks), but generally, surgery is reserved for severe displacement, nonunion, or a rotated fragment.

Anterior Inferior Iliac Spine Avulsion Fracture

The AIIS is the site of origin of the straight head of the rectus femoris muscle, which is one of the muscles involved in hip flexion. A common mechanism of injury for the AIIS avulsion fracture is hip hyperextension and knee flexion, such as when a soccer player kicks a ball but meets the resistance of another player's foot. The injury is also seen in sprinters and hurdlers. The AIIS fracture is less commonly seen than the ASIS. It is sometimes referred to as "sprinter's fracture."

The athlete will usually complain of acute pain and be unable to bear weight. The pain may be more severe than in an ASIS fracture. The pain can be reproduced by passive extension of the hip or active flexion of the hip. The fracture fragment rarely displaces a great deal, due to the effect of the conjoined tendon. X-rays are used to confirm the diagnosis. The fracture fragment usually is crescent shaped or triangular. The injury can be confused with an os acetabuli, which is a normal finding and can be ruled out by comparison views of the opposite hip. The os acetabuli is usually bilateral, while the fracture should only be on the side of the injury.

The management of AIIS avulsion fracture is generally nonsurgical, including walking with crutches, rest, and slow return to activities. The injury may heal slowly, usually within 6 to 8 weeks. Rarely does the fracture heal with bony exostosis, but there is a report of two cases of exostosis, which required surgical excision.

Lesser Trochanter Avulsion Fracture

The LT of the femur is one of the attachment sites of the iliopsoas muscle. The iliopsoas is one of the main hip flexors, and hence, the injury is commonly seen in hurdlers, sprinters, and kickers. An LT avulsion fracture is a rare injury.

The athlete will present with acute pain and may be unable to walk. On exam, the athlete will be unable to actively flex the hip while seated, which is known as a positive Ludolph sign. The athlete will try to hold the hip in slight adduction and internal rotation to minimize the pain. X-rays can confirm the diagnosis but may need to be taken in slight external rotation to better visualize the avulsed LT fragment.

The fracture usually responds to conservative therapy consisting of a period of rest, limited activity, and protected weight bearing. The degree of displacement generally has no bearing on the prognosis, nor does it correlate with the severity or duration of the symptoms. The injury may take 10 to 12 weeks to heal completely.

Greater Trochanter Avulsion Fracture

The GT of the femur is the attachment site of multiple muscles, including the gluteus medius and minimus as well as the hip external rotators (obturator and gemelli). GT avulsion fractures are very rare but usually are caused by forceful muscle contraction of the hip abductors, such as when an athlete quickly changes direction.

As in most pelvic avulsion fractures, the athlete will present with acute onset of pain. The leg will be held in slight flexion and abduction. The patient may walk with a Trendelenburg gait, in which the involved hip doesn't elevate when walking. X-rays can confirm the diagnosis. Treatment is generally nonsurgical if the fragment is displaced less than 1 cm. Some surgeons recommend open reduction and internal fixation if the fragment is displaced more than 1 cm.

Iliac Crest Avulsion Fracture

The iliac crest is the insertion point of multiple muscle groups including the transversus abdominis muscle and the internal and external oblique muscles. An iliac crest avulsion fracture is a very rare injury and is usually caused by violent contraction of the transversus abdominis muscle, but it can also be caused by direct trauma. The mechanism of injury is usually a quick change of direction.

The management is nonsurgical, with non–weight bearing and progressive rehabilitation over 3 to 4 weeks. If the fragment is displaced more than 3 cm, surgical intervention may be considered.

Adductor Avulsion Fracture of the Symphysis Pubis

Though there is no true apophysis located at the symphysis pubis, this avulsion fracture deserves to be included in a discussion of pelvic avulsion fractures. The adductor longus, brevis, and gracilis muscles originate at this point, and an avulsion fracture may occur if there is a violent contraction of one of the adductor muscles. X-rays will show an undulated irregularity of the pubic symphysis. The treatment is conservative, with rest followed by slow return to activity.

Acetabular Rim Avulsion Fracture

A very rare example of avulsion fracture about the pelvis is an acetabular rim avulsion fracture. One case has been reported in the literature, in which the reflected head of the rectus femoris avulses a fragment from the acetabulum. The treatment is nonsurgical.

Pelvic Bursitis

Pelvic bursitis is inflammation of the bursae that lie around or within the hip/pelvis. There are three main types of pelvic bursitis: (1) greater trochanteric, (2) ischial, and (3) iliopectineal (sometimes called iliopsoas). Greater trochanteric bursitis is discussed in detail in its own entry. This entry focuses on iliopectineal and ischial bursitis, which are both relatively common causes of hip, pelvic, or groin pain.

Anatomy

Bursae are small fluid-filled sacs that are usually found around joints or bony prominences. Their purpose is to create lubrication between two uneven surfaces and provide frictionless movement, as well as serving as a pad or cushion. The pelvis is the bony structure located at the bottom of the spine. It has three components: the ilium, ischium, and pubis. The *ilium* is the large bone one feels at the outside of the waist, the *ischium* is the bone one feels when sitting on the buttocks, and the *pubis* bone, also called the pubic bone, is in the front just above the genital area (see Figure 1).

The two ischial bursa rest under the ischial bone (specifically, the ischial tuberosity) on each side of the pelvis near the attachment of the hamstring muscle. The iliopectineal bursa lies in the front of the hip and deep in the groin and results from the iliopsoas (hip flexor muscle) tendon sliding over another muscle (pectineus) and the bony prominence where the ilium and pubic bones join.

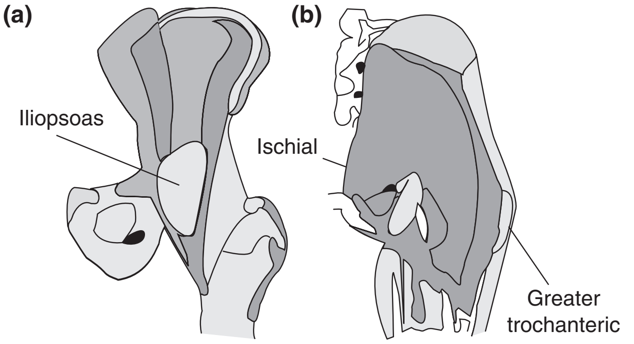

Figure 1 Bursae of the Hip and Pelvis: (a) Front and (b) Posterior View

Causes

Pelvic bursitis is caused by either overuse or direct trauma. Direct trauma such as a fall that causes the athlete to land on the buttock or a direct blow to the lower buttock or anterior hip may trigger an ischial or iliopectineal bursitis, respectively. These falls or blows will cause bleeding (hematoma) into the bursa, which then results in swelling. Usually, these hematomas are rapidly absorbed by the body, but not infrequently, they may result in scarring and thickening (calcifications), leading to a more chronic type of bursitis.

More commonly, chronic repetitive overuse is involved, which can occur from merely running or jumping. Injuries to the hamstring muscle or the hip flexor muscle can lead to ischial and iliopectineal bursitis, respectively. Other conditions that predispose athletes to this type of pelvic bursitis include postural abnormalities, which can be caused by scoliosis, degenerative spinal conditions, hip and knee arthritic conditions, leg length differences, flat feet, high-arched feet, overpronation of the feet, or even oversupination of the feet at heel strike. Improperly fitting shoes, worn-out shoes, running on uneven or hard (cement) surfaces, and sudden increases or changes in training are other causes of pelvic bursitis. At times, the bursitis develops spontaneously without any apparent cause, from infection or as a complication following hip surgery.

Symptoms

Ischial bursitis usually results from a direct blow or fall (such as in contact/collision sports), and athletes complain of pain at the ischial tuberosity that may worsen with sitting. Swelling and bruising may also be present. Pain mimicking ischial bursitis may be caused by hamstring syndrome. This syndrome also has pain around the tuberosity that gets worse with sitting, but athletes may complain of pain radiating down the back of the leg due to sciatic nerve compression within the hamstring muscle. Therefore, it is important to focus on the exact location and symptoms of this injury.

Iliopectineal bursitis is usually due to overuse and results in pain in the front of the hip that may radiate into the proximal thigh. Pain is usually worse with sports, especially stretching of the hip flexor muscle by hip extension, and may be associated with a limp. Athletes may also complain of a snapping sensation in the front of the hip due to the hip flexor tendon snapping over the bony prominence. The pain may also cause the athlete to keep the hip in a flexed and externally rotated position, such as sitting with the affected leg's foot on the opposite knee (figure-four position).

Diagnosis

Ischial and iliopectineal bursitis are both typically diagnosed by history and examination. On examination, ischial bursitis will exhibit tenderness to touch/pressure around the ischial tuberosity. Occasionally, bruising and swelling will be present. Pain is usually worse with passive stretch of the hamstring (hip flexion [forward bending] with knee extension [straightening]) or active contraction of the hamstring (hip extension [backward-bending] with knee flexion [bending]).

Iliopectineal bursitis will exhibit pain to deep touch/pressure on the front of the hip/groin, as well as pain with active hip flexion (especially while lying flat on the back and lifting the leg up about 15°) and passive hip extension. One may feel a snap in the front of the hip as the hip is actively flexed. Limping may be present, and athletes usually prefer the hip to be in the figure-four position as mentioned above.

One should also look for structural abnormalities on examination, including, but not limited to, scoliosis, leg length difference, and flat feet.

X-ray films of the hip or lower spine can be obtained to ensure that there are no bony abnormalities, such as spurs, calcifications, or arthritis, that could be contributing to the problem. Occasionally, ultrasound, magnetic resonance imaging (MRI), or a bone scan may be done if the diagnosis is unclear or if the problem does not resolve with treatment. These tests will help rule out tumor, infection, or subtle fracture of the bone.

Treatment

General treatment principles apply for both types of bursitis, including a combination of rest; heat and/or cold application; stretching and strengthening exercises; activity and shoe modification; pain medication such as acetaminophen or ibuprofen; and osteopathic manipulation along with correction of any anatomical or biomechanical asymmetry (by orthotics/heel lifts). Cross-training incorporating low-impact activity, such as biking, swimming, or using elliptical machines, can minimize the pain and allow for continued exercise. Special padding may need to be worn by those athletes involved in contact sports to minimize further irritation. Typically, resolution of symptoms occurs within 2 to 6 weeks of treatment. More advanced treatments, such as physical therapy, cortisone injections, or surgery, may be required for persistent symptoms.

Ischial bursitis. Specific treatment for ischial bursitis includes rest; ice for direct trauma followed by heat application (heat alone for overuse); stretching of the hamstrings, hip flexors, adductors, and iliotibial band; and strengthening of the gluteus muscles, hamstrings, and lower abdominals. If the pain continues, the physician can drain the fluid from the swollen bursa and inject a corticosteroid into the area to help reduce the inflammation and pain. This can be done using the same technique described in the entry Trochanteric Bursitis with or without radiologic (ultrasound) guidance. Other treatments used in physical therapy can also be employed, such as phonophoresis, which uses ultrasonic sound waves to allow for deep penetration of topical medications, or iontophoresis, which uses an electrical current to allow corticosteroids to penetrate the skin and minimize the inflammation of the bursa. Ultrasound therapy and soft tissue massage may also be helpful. Surgical excision of the bursa with removal of ischial bone spurs is reserved for the rare, nonresponsive cases.

Iliopectineal bursitis. Treatment includes rest, ice for direct trauma followed by heat application (heat alone for overuse), and hip flexor/groin/hamstring/IT band stretching and strengthening of the buttock muscles (gluteus maximus and medius), hip flexor, and lower abdominals. Phonophoresis, iontophoresis, and ultrasound may also provide some relief. Corticosteroid injections have been successfully used but are probably best administered under radiologic guidance (ultrasound) in this area to prevent damage to the surrounding nerves and/or blood vessels. Athletes should be made aware of the risks of any injection prior to the procedure and should avoid strenuous activity for several days following a cortisone injection to decrease the chance of tendon rupture. Surgery, consisting of either release or lengthening of the hip flexor muscle near its attachment on the thighbone (lesser trochanter of the femur), has been performed successfully. Surgical intervention carries the increased risk of anesthesia along with the direct surgical risks and should be considered only after appropriate nonoperative interventions have been exhausted.

Pelvic Fracture

Pelvic fractures in the athlete can range from simple avulsion injuries to pelvic ring disruptions. Avulsion fractures of the pelvis represent an injury unique to the adolescent and young adult athletic population as the result of an imbalance between the strong muscle attachments and the weaker apophysis. Fractures of the pelvic ring are often the result of high-energy injuries (cycling or skiing accidents) and may occur in isolation or in conjunction with multiple injuries, necessitating specialized treatment.

Anatomy

The bony pelvis can be thought of as a ring with the sacrum connecting the two halves of the pelvis, formed from the ilium, ischium, and pubis. There are five so-called secondary centers of ossification, also known as apophyses, around the pelvis that serve as attachment sites for muscle origins and insertions. These include the iliac crest, anterior superior iliac spine (ASIS), anterior inferior iliac spine (AIIS), ischial tuberosity, and pubic symphysis. The external abdominal obliques insert on the iliac crests and help with trunk rotation. From the ASIS, two muscles originate, the tensor fascia lata and the sartorius, the major actions of which are to flex the hip. The rectus femoris, which helps flex the hip and extend the knee, originates from the AIIS. The large group of hamstring muscles responsible for knee flexion and hip extension has a proximal attachment to the ischial tuberosity, and the hip adductors attach to the pubic symphysis.

Causes

Avulsion fractures of the apophysis are most commonly caused by participation in sports such as soccer, rugby, ice hockey, and gymnastics and activities that involve sprinting, including track, baseball, and football. These injuries are typically the result of indirect trauma caused by a sudden, strong, or unbalanced contraction of the muscle attached to the apophysis.

The three most common avulsion fractures are those that occur at the ischial tuberosity, ASIS, and AIIS. The ischial tuberosity is often fractured as the result of a forceful eccentric contracture of the hamstrings during sprinting or hurdling activities. Fractures of the ASIS commonly occur during running activities as a result of the forces generated by the sartorius muscle. Some authors have also reported that a twisting mechanism, such as swinging a baseball bat, can cause the tensor fascia lata muscle to avulse the ASIS. Injuries to the AIIS occur when the muscles of the anterior thigh are loaded in hip flexion and knee extension—such as during kicking or a forceful push-off in sprinting—and cause a large force across the weaker apophysis.

Symptoms

Avulsion fractures commonly present with a sudden onset of pain during physical activity and may be accompanied by a "pop." Walking may be difficult and uncomfortable immediately after the injury. Direct palpation over the fractured apophysis is painful, and stretching of the muscle group attached to the fractured apophyseal fragment will cause discomfort. Manual muscle testing of the affected muscle group will be painful, and the muscles will appear notably weaker.

Avulsion fractures of the ischial tuberosity present with pain in the back of the upper thigh and buttock region, and there is pain with sitting and standing and discomfort with stretching of the hamstring muscles. Avulsion fractures of the ASIS and AIIS present similarly with pain and a "pop" during activity. Palpation over the location of the apophysis is often painful, and there is pain and weakness with attempts at hip flexion or passive stretching of the hip in extension.

Sometimes these injuries are thought to be a "pulled muscle" or muscle strain, which can result in a delay in proper diagnosis.

Diagnosis

The diagnosis of an avulsion fracture is usually made from the history, physical examination, and X-ray. A plain anteroposterior radiograph of the pelvis can show the displaced apophyseal fragment and fracture, but occasionally, other oblique radiographic views such as Judet views are needed to properly see the fracture. Other imaging modalities including computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound can be used to better define the location of the injury and the amount of displacement of the fractured fragment.

Treatment

Nonsurgical Treatment

Nonoperative management with a guided rehabilitation program is the mainstay of treatment for apophyseal injuries. J. N. Metzmaker and A. M. Pappas describe a five-phase rehabilitation protocol for the treatment of such injuries. The first stage includes rest, ice application, and pain medications, with the goal of resting and avoiding stretching of the injured muscle. Usually 1 week later, after the pain has resolved, range-of-motion exercises are started. Once motion is restored to near-normal levels, resistive exercises can be added to the program. Typically around 1 to 2 months after injury, stretching and strengthening with sport-specific goals are started, with the athlete returning to activity once full strength and range of motion have been achieved.

Surgery

For most avulsion fractures of the pelvis, operative intervention is indicated when nonoperative management has failed, in cases of painful nonunions, and occasionally if the fracture is initially displaced more than 2 centimeters. Some surgeons may treat ischial avulsion fractures primarily with operative fixation, due to development of painful calluses and scarring of the sciatic nerve with nonoperative treatment. Operative techniques may include excision of the bony fragment and reattaching the muscle unit with sutures or direct fixation of the bone using screws.

After Surgery

Postoperative management of avulsion fractures typically consists of a period of non– or partial weight bearing in the first 7 to 10 days after surgery, followed by progressive weight bearing with crutches for another 4 to 6 weeks. Injury- and sport-specific physical therapy is used during this time, with the goal of return to play by 3 to 4 months after surgery.

Pelvic Stress Fracture

Stress fractures of the pelvis are a relatively uncommon injury in the general population, constituting less than 10% of reported stress fractures. Nevertheless, they represent a small but significant percentage of bone-related overuse injuries in selected populations, ranging from 10% to 20% of reported stress fractures in distance runners and soccer players to more than 22% in female military recruits. These injuries typically occur in either the pubic symphysis or the superior or inferior pubic ramus and can result in significant morbidity and loss of productivity.

Anatomy

The pelvis (from the Latin for *font*) is a bony ring at the base of the spine that forms the articulations between the axial and appendicular skeletons. It consists of two hip bones (os coxae), which are themselves composed of the ilium, the ischium, and the pubis. The ilium forms the widest and most superior portion of the pelvic girdle, while the ischium forms the inferior and posterior portion. The pubis is located anteriorly and creates the articulation between each hemipelvis. The pelvis articulates posteriorly with the axial skeleton at the sacroiliac joints.

There are significant differences in pelvic anatomy between males and females, which are mainly attributable to adaptations required for childbearing and the generally increased muscle mass of males. They include the following:

- A narrow, deep pelvis in males and a wide, shallow pelvis in females
- A heart-shaped pelvic aperture in males and a rounded or oval aperture in females
- A narrow pubic arch in males and a wide arch in females
- A large acetabulum in males, which is small and slightly anteriorly oriented in females
- A round obturator foramen in males, which is oval in females

Of these differences, perhaps the most significant in relationship to stress fractures of the pelvis is the angle of the pubic arch. The infrapubic angle tends to be around 60° in males and 90° in females. This results in a slightly flattened and elongated inferior ramus at the proximal attachments of the adductors and may explain some of the increase in pelvic stress fracture rates in females.

Causes

In general, stress fractures result from repeated stress across the bone, resulting in several small microfractures within the bony cortex. Over time, these microfractures can coalesce into a frank stress fracture. It is theorized that a disruption in usual bone homeostasis may be a primary factor in the development of stress fractures. As the exercise load increases, osteoclastic activity may outpace osteoblastic activity in the early period and result in bone injury. Additionally, intrinsic tensional forces across the bone may be a major contributor as they influence the process of bone remodeling. Factors that either accelerate the process of microfracture formation or alter the process of bony remodeling in the presence of new load requirements can contribute to the development of stress fracture.

Numerous risk factors for the development of stress fractures have been noted. Participation in activities that require a repetitive axial load to the skeleton, such as track-and-field events, marching, and long-distance running, has been shown to contribute to injury. During these types of activities, large muscle groups exert a high traction load across the bony insertion and initiate the cascade of stress-related events leading to a fracture. Poor preparticipation physical condition, especially when combined with a rapid increase in training activity, has been identified as a cause of pelvic stress fractures in military recruits. A history of a previous stress fracture also increases the risk of recurrence.

A disproportionate number of stress fractures in general, and pelvic stress fractures in particular, have been identified in females. The reasons for this are varied but may include hormonal or menstrual disturbances, nutritional deficiencies, and decreased bone density. The decreased angle of the pubic arch is posited as a significant contributor to stress fractures of the inferior pubic rami in females. The female athlete triad, a cluster of symptoms that includes amenorrhea, disordered eating patterns, and osteopenia (thinning of bone mass), perhaps due to the direct effect of decreased estrogen related to disrupted menstrual cycles, is another factor in the development of stress fractures in the female population. Stress fractures of the pelvis are rare in prepubescent individuals of either gender.

Diagnosis

As with any medical condition, a comprehensive history and physical examination are critical in diagnosing stress fractures of the pelvis. A thorough assessment of risk factors is important and should include questions related to the frequency and intensity of training, including recent changes in the training schedule; previous history of stress fractures; and other medical conditions that may predispose one to the development of stress fractures, such as nutritional, endocrine, or rheumatologic problems.

With stress fractures of the pubic rami, which are the more common of the two types, patients typically complain of chronic, diffuse pain in the groin, buttocks, or thigh that may be difficult to localize. Pain is exacerbated by activities such as running and jumping, but at least in the initial period, the pain may be of a relatively low level, and patients often continue to participate in sports activities. On physical examination, there is usually focal tenderness over the pubic ramus, but the patient may also have tenderness along the hip adductors and flexors. Examination of the hip is typically normal, although there may be some decrease in range of motion and discomfort with passive external rotation and abduction, particularly in the presence of a concomitant adductor strain.

Patients with stress fractures of the pubic symphysis present with diffuse pain throughout the lower hemipelvis and may experience radiation of pain to the groin or lower abdomen. Pain is increased with kicking, high-step marching, jumping, and running. As with stress fractures of the pubic ramus, the onset is typically insidious. Physical examination findings are similar, with tenderness at the pubic symphysis. Other areas that may produce symptoms with palpation, stretch, or resisted active motion include the hip adductors, the rectus abdominus, and the gracilis.

While treatment may be initiated on the basis of history and physical exam findings alone, initial evaluation with plain radiographs is typical. Radiographic changes may only be visible several weeks after the onset of symptoms, but attention should be paid to subtle periosteal reactions that may be seen in early films. Repeat X-rays at 2 to 4 weeks will typically show callus formation suggestive of bone healing.

In populations in which 2 weeks of relative rest while awaiting repeat radiographs is difficult, such as high-level athletes and military recruits, further imaging may be performed. Magnetic resonance imaging (MRI) offers the benefit of a clear delineation of bone and soft tissue pathology and is helpful in characterizing the nature and specific location of the fracture. MRI is also able to identify the presence or absence of a distinct fracture line. MRI is highly sensitive and specific, although it may not be as useful in identifying early lesions.

Nuclear scintigraphy (bone scan) is used to identify increased metabolic activity within the bone and, as such, can be helpful in the early diagnosis of stress fracture. Increased radionucleotide uptake is seen in any area of increased activity, such as tumors, infections, and metabolic diseases, and therefore, bone scans are not specific for stress fractures. Results should be carefully correlated with history and physical examination.

Treatment

Treatment for pelvic stress fractures includes a period of relative rest as well as a program to maintain cardiovascular fitness. The mainstay of treatment is avoidance of painful activities and may involve the use of crutches for initial management. The patient should be gradually returned to weight-bearing activities as tolerated through the use of swimming, stationary bicycling, the elliptical trainer, and other low-impact exercise regimens. A program of hip strengthening may be added to the rehabilitation program, with particular attention to the hip adductors, which often show some relative weakness and disuse atrophy.

The use of pain medications is controversial. Some practitioners feel that medicines may mask pain to such an extent that patients may participate in impact activities earlier than they should, which could result in delayed healing. Others raise concerns about data that suggest a slight delay in bone healing with the use of NSAIDs. Typical medications used include naproxen, ibuprofen, acetaminophen, tramadol, and, rarely, opioid analgesics.

Return to Sports

The final phase of rehabilitation should include sport-specific activities designed to challenge the patient in a safe and controlled environment. Total healing time for pelvic stress fractures is typically 6 to 8 weeks.

PEPTIDE HORMONES

Peptide hormones are chemicals made up of amino acid chains. They are produced naturally by various glands in the body. Synthetic forms of several peptide hormones have been created and have a wide range of medical indications. Human growth hormone (HGH), erythropoietin (EPO), and insulin are examples of peptide hormones that have been abused by athletes to achieve a competitive edge in sports.

HGH is an anabolic (tissue-building) hormone that has become very popular recently among elite athletes as a performance-enhancing drug. It is a peptide hormone that is produced in the pituitary gland throughout a person's life. The highest levels of endogenous (naturally occurring) HGH are found during puberty and early adolescence.

Growth hormone has been shown to increase lean muscle mass and strength. It assists an athlete in recovering from injuries or strenuous workouts and is of particular interest for professional athletes who endure long, grueling seasons. It is banned in all professional sports and in international competition, but it is currently almost impossible to detect. It is likely used at all levels of competition, including high school athletics, although most amateur athletes may not be able to afford this expensive drug.

Athletes who use HGH for performance enhancement may be using 10 to 20 times the normal amount, and the long-term effects of this are still unknown. Potential risks include a significantly higher rate of joint pains, carpal tunnel syndrome, and diabetes. Increased skull circumference, peripheral neuropathy, hypertension, and behavioral changes have also been noted. There are also concerns that HGH may contribute to certain types of tumors.

EPO is produced naturally in the kidney and is a hormone that stimulates the bone marrow to make more red blood cells. A synthetic form of EPO has been abused by athletes in endurance sports to increase the number of red blood cells in their bloodstream, thereby increasing oxygen-carrying capacity. EPO is a banned substance in all competitive sports and carries significant health risks. The increase in red blood cells can lead to heart attacks, strokes, and blood clots.

Insulin is a peptide hormone that regulates the body's glucose (sugar) levels. It also has some anabolic, or muscle-building, properties. Insulin is produced naturally in the pancreas. Lack of insulin production or insensitivity to insulin action is the disease known as diabetes mellitus. Athletes who don't have diabetes have used insulin as a performance-enhancing drug because of its anabolic properties and its ability to slow the degradation of muscle tissue. In addition, it assists the delivery of fuel to muscle tissue, which may improve performance and stamina in endurance athletes. Serious side effects of inappropriate use include hypoglycemia (low blood sugar), seizures, and death.

Insulin and other hormones or medications certainly have an appropriate therapeutic role for many patients and athletes. There is a way for athletes to continue use of medications such as insulin and still compete. A Therapeutic Use Exemption is filed before competition. This documents the medical necessity with the athlete's local sports governing body. Sometimes therapeutic levels of these substances are monitored in and out of competition.

Hormones exist in a very delicate balance, often in minute amounts in normal physiology. Once in the bloodstream, they influence almost all tissues in the body and can also increase or decrease the levels of other powerful hormones. Athletes using hormones for performance enhancement have to be aware of the immense power of these chemicals and the potential consequences of their action. Abuse of these hormones can have serious immediate or delayed consequences, some of which are yet to be discovered.

Performance Enhancement, Doping, Therapeutic Use Exemptions

Enhancement of athletic performance has been attempted throughout human history. People have tried to overcome the limitations of the human body through training or by using artificial substances or methods. Although proper training can improve performance, there are natural limits to the degree of improvement that can be achieved. However, with alterations in the body's own chemistry, certain substances or methods can allow athletes to perform beyond the normal physiological limits. Pharmaceuticals can be used for different purposes from those originally intended. Many common medications that are used for sick patients are unfortunately abused and taken by healthy athletes with the sole purpose of improving their athletic performance, although these medications have the potential for doing irreversible damage.

Today, there are many technologies that can enhance human performance, from medications to genetic engineering. Some people believe that we have a right to modify our bodies; others fear that performance enhancement can be dangerous and only results in short-term gains while having long-term detrimental consequences. Unequal access to such enhancements is also feared if such practices were to become commonly accepted.

Performance-enhancing drugs are typically used by athletes, including recreational athletes, to improve in their specific sport. Over time, drug use has become increasingly sophisticated and difficult to detect. Many sports organizations have developed rules and regulations for the use of performance-enhancing substances. Although there is currently no single organization that governs all sports, the World Anti-Doping Agency (WADA) monitors all Olympic athletes as well as several independent professional sports. Many countries and Olympic sports have their own antidoping organizations that are affiliated with WADA. WADA, like many antidoping organizations, provides testing, education, research, and results management in the hope of preventing athletes from using banned substances and methods.

Anabolic steroids usually come to mind when people discuss performance-enhancing drugs. There are over a hundred different types of anabolic steroids, which makes it difficult to design a test to detect their use in athletes. Although many of the athletes who use these drugs are recreational weight lifters, many professional athletes try anabolic steroids at some point in their careers.

The many types of athletic performance–enhancing drugs include lean-mass builders, stimulants, painkillers, sedatives, diuretics, and masking agents. Having additional lean body mass is directly related to improved athletic performance. Anabolic steroids, beta-2 agonists, and human growth hormone have been shown to increase the growth of muscle while improving athletic performance. Increasing an athlete's alertness and aggression and reducing fatigue can improve athletic performance. Stimulants such as caffeine and amphetamines have long been used to improve athletes' strength and speed. Many times, pain is the rate-limiting step in improved performance. Medications that reduce pain can improve performance by allowing the athlete to go beyond the normal pain threshold. Over-the-counter medications such as ibuprofen and acetaminophen as well as prescription medications such as hydrocodone are often used. Shooting sports require a steady hand and heart, and sedatives and beta blockers are used to improve aim and reduce nervousness. Drugs such as alcohol, propranolol, and even marijuana are often tried. Competition among athletes is often determined by the size of the athlete, and remaining in a narrow weight range can be difficult. Diuretics are sometimes used by athletes to reduce water weight in order to remain in a certain weight class. Sometimes these drugs are used to dilute the urine to avoid detection of a number of banned substances. These masking agents are often used, so tests have been developed to detect these chemicals.

The term *performance enhancing* can sometimes be confusing because nonbanned substances such as vitamins, carbohydrates, and proteins can also improve performance. However, these substances can only improve performance within the body's normal capacity. Most banned substances improve performance beyond the physiological norms, which can be difficult to explain and understand. The reason why there are so many different antidoping organizations is because there is no current universal agreement on which substances and methods can and cannot improve performance. Testing ability is also widely variable from test site to test site.

Some athletes even use their own blood to improve performance through a method known as "blood doping." Athletes will have several pints of their own blood removed, stored, and then transfused into their body the day of a competition. This method will often double the amount of red blood cells present in the body while improving their ability to carry oxygen and, thus, will improve performance. As with many performance enhancers, blood doping is difficult to detect.

Doping

Doping refers to the use of performance-enhancing drugs in sports that ban certain substances and methods. Athletes use doping mostly to improve performance. However, doping is also becoming increasingly popular in recreational sports such as body building.

There are many forms of doping besides blood doping (discussed in the preceding section). Other substances include erythropoietin and anabolic steroids, which can improve athletic performance. Many international sports organizations consider doping unethical because of the risk to health, the unfair advantage it gives to the user over other athletes, and the negative impact it has on public perception. Many countries followed East Germany's experiments in the 1960s with anabolic steroids. Their athletes exceeded all expectations in performance and training, but this resulted in serious long-term side effects including cancer and sometimes early death. At that time testosterone, a male hormone, was given to both male and female athletes. Testosterone increases protein production, which results in bigger and stronger muscles. Unfortunately, it also increases the vocal cord size and deepens the voice as well as increases body hair production. Anabolic steroids are used today therapeutically to treat sick patients with muscle wasting, as in cancer and AIDS. When excessive amounts are used for an extended period of time, harmful effects can occur. These include increases in cholesterol levels, acne, high blood pressure, and liver and heart damage. The nontherapeutic use of anabolic steroids has been becoming increasingly popular in competitive sports. However, all major sporting bodies have banned the use of steroids both in and out of competition. Most governments consider anabolic steroids controlled substances and regulate their use. This has resulted in a black market, and these drugs are often smuggled into countries and sold illegally. The smuggled drugs are often impure and contaminated, which makes their use even more dangerous.

Previously, athletes started using the anabolic steroid tetrahydrogestrinone (THG) because it was undetectable by the standard antidoping test. Eventually, a test was designed to determine which athletes had used the drug, based on stored urine samples. Because of its widespread use, many athletes have been banned from future competition in many sports. Because of media involvement in high-profile cases such as Olympic gold medal winners, many athletes have been vigorously persuaded in and out of court to give up use of this drug.

The International Association of Athletics Federations was the first international governing body, in 1928, to ban participants from doping. Many other organizations soon followed. Until the creation of formal antidoping organizations, many athletes had used doping methods for years without having to face the consequences. Since the creation of WADA in 1999 and the Major League Baseball Drug Policy, athletes are no longer getting away with using banned substances. Removing these athletes from competition has leveled the playing field.

Drug use in sports involves many high-profile players and championships, including the World Weightlifting Championships, Tour de France, Olympic Games, World Ski Championships, and World Track and Field Championships. Many noted athletic stars were found guilty because of their involvement with the Bay Area Laboratory Co-Operative (BALCO), a supplement lab that confirmed negative drug testing results for athletes using banned substances. The lab founder subsequently was found guilty and had to do time in prison.

Antidoping programs try to preserve "the spirit of sport." These values include the following:

- Ethics, fair play, and honesty
- Health
- Excellence in performance
- Character and education
- Fun and joy

- Teamwork
- Dedication and commitment
- Respect for rules and laws
- Respect for self and other participants
- Courage
- Community and solidarity

WADA was established in 1999 by the International Olympic Committee (IOC) with support from governmental organizations, public authorities, and private bodies. Ultimately, WADA's mission is to control doping in sports with the assistance of the IOC, national antidoping organizations (NADOs), sports federations, and athletes. The United States Anti-Doping Agency (USADA) is the independent antidoping agency for the Olympic Movement in America. Formed in 2000, USADA started providing testing, education, research, and results management for U.S. Olympic, Pan Am, and Paralympic athletes. USADA is a signatory to the World Anti-Doping Code and has implemented the requirements to meet the code, including the separate Prohibited List.

In 1999, the 1st World Conference established WADA; in 2003, the 2nd World Conference adopted the WADA Code; in 2007, the 3rd World Conference revised the WADA Code, which came into effect on January 1, 2009. The purpose of the WADA Code revision was to leverage the experience gained to date and strengthen the antidoping programs.

The definition of doping is detailed and complex, so that it can be all-inclusive and rigorous enough to stand up in courts of law. Doping involves the following:

- Presence of a Prohibited Substance or its Metabolites or Markers in an Athlete's Sample
- Use or Attempted Use by an Athlete of a Prohibited Substance or a Prohibited Method
- Refusing or failing without compelling justification to submit to Sample collection after notification as authorized in applicable anti-doping rules, or otherwise evading Sample collection
- Violation of applicable requirements regarding Athlete availability for Out-of-Competition Testing, including failure to file required whereabouts information and missed tests which are declared based on rules which comply with the International Standard for Testing. Any combination of three missed tests and/or filing failures within an eighteen-month period as determined by Anti-Doping Organizations with jurisdiction over the Athlete shall constitute an anti-doping rule violation
- Tampering or Attempted Tampering with any part of Doping Control
- Possession of Prohibited Substances and Prohibited Methods
- Trafficking or Attempted Trafficking in any Prohibited Substance or Prohibited Method
- Administration or Attempted administration to any Athlete In-Competition of any Prohibited Method or Prohibited Substance, or administration or Attempted administration to any Athlete Out-of-Competition of any Prohibited Method or any Prohibited Substance that is prohibited Out-of-Competition, or assisting, encouraging, aiding, abetting, covering up or any other type of complicity involving an anti-doping rule violation or any Attempted anti-doping rule violation. (The World Anti-Doping Code, 2009)

Criteria for placing a substance on *The 2009 Prohibited List* include the following:

- Medical or other scientific evidence, pharmacological effect, or experience that the substance or method, alone or in combination with other substances or methods, has the potential to enhance or enhances sport performance
- Medical or other scientific evidence, pharmacological effect, or experience that the use of the substance or method represents an actual or potential health risk to the athlete
- WADA's determination that the use of the substance or method violates the spirit of sport described in the Introduction to the Code
- WADA's determination that there is medical or other scientific evidence, pharmacological effect, or experience that the substance or method has the potential to mask the use of other prohibited substances or prohibited methods

With a better understanding of doping, we can appreciate the true purpose of the WADA Code.

The Code aims to protect the athlete's fundamental right to participate in doping-free sport and thus promote health, fairness, and equality for athletes worldwide. It also aims to ensure harmonized, coordinated, and effective antidoping programs at the international and national levels for the detection, deterrence, and prevention of doping.

With the development of the new WADA Code, additional groups are being considered for doping violations. When a drug trafficking violation occurs, the penalty will be a minimum of 4 years of ineligibility. When minors are involved, it will be considered a particularly serious violation, and if committed by athlete support personnel, such as a coach, physician, or trainer, it will result in a lifetime of ineligibility. Athlete support personnel should educate and counsel athletes regarding antidoping policies and rules. Athletes may often find themselves in a situation where there may be a necessity to use a prohibited substance and will need to obtain approval through a Therapeutic Use Exemption (TUE).

Therapeutic Use Exemption

The TUE process provides a method for athletes to seek permission to use a prohibited medication that is medically necessary. However, athletes seeking permission to use certain beta-2 agonists for asthma or glucocorticosteroids by inhalation and intraarticular or local injection must use the Abbreviated Therapeutic Use Exemption. Both processes must be completed and submitted prior to participation in sports.

Ultimately, it is the athlete's responsibility to know what medications he or she is taking and whether these are prohibited or not. The purpose of the TUE is to ensure that athletes get the medical care they need while harmonizing the process across sports and countries. If the medication needed to treat an illness falls in the Prohibited List, the TUE may give authorization to the athlete to use these substances. TUEs are granted if

- the athlete would experience significant health problems if the prohibited substance or method were not used,
- the therapeutic use of the substance would not produce significant enhancement of performance, and
- there is no reasonable therapeutic alternative to the use of the prohibited substance or method.

International federations (IFs) and NADOs have processes that allow athletes with documented medical conditions to request a TUE. These organizations have a panel of independent physicians who are responsible for granting or declining such applications. In the case of international-level athletes, TUEs are submitted to their sport's IF or NADO if they are registered in their country's testing pool.

Athletes can apply for a TUE as follows:

- They must contact their IF or NADO and ask for a TUE application form.
- They must have their physician fill out the TUE application form and produce the required supporting documentation and forward it to the IF or NADO. Athletes should remember that according to the International Standards, the TUE application should be submitted at least 21 days before participating in an event.

The TUE is granted for a specific medication as well as a narrowly defined dosage and period of time. Athletes taking part in a competition should mention in the doping control form that a prohibited substance is being used and that a TUE has been granted.

Perineal Numbness and Erectile Dysfunction

Pudendal nerve compression syndrome, also known as Alcock syndrome, is a cluster of symptoms most commonly described in long-distance or long-term bicyclists. It is chiefly characterized by varying degrees of decreased sensation of the perineum, decreased glandular and penile sensation, weakened/absent erections, diminished/difficult orgasms, and occasional voiding symptoms. In this entry, perineal numbness and pain syndromes from injury to the pudendal nerve are discussed, particularly as they relate to erectile dysfunction (ED).

In recent years, many advances have been made in the understanding and medical treatment of ED. Classically, male sexual function has been defined in terms of the "point-and-shoot" model, with sacral parasympathetic (point) enervation responsible for erection and sympathetic (shoot) enervation responsible for ejaculation. However, this represents an oversimplification of the complex and somewhat ill-defined sensory, psychogenic, and motor pathways and interconnections orchestrating male sexual function. Proper function requires regulation and timing of voluntary and involuntary processes such as arousal, erection, pre-ejaculatory stiffing, orgasm, and ejaculatory peristalsis. Often the somatic sensory contribution, derived mostly from the pudendal nerve, is overlooked. A degraded perineal neurovascular supply can greatly diminish or abolish response to medical therapy. Along these lines, perineal paresthesia from any of several causes is often linked to ED.

The pudendal nerve courses from the S2-S4 nerve plexus, carrying sensory and motor fibers through the pudendal canal before giving rise to the inferior rectal nerve, the perineal nerve, and the dorsal nerve of the penis. The pudendal canal, also known as the Alcock canal, features prominently in the discussion of various perineal neurological conditions. The canal is formed by a duplication of the obturator fascia and carries the pudendal nerve and accompanying vessels along the lateral wall of the ischiorectal fossa. Depending on the location of pudendal nerve involvement along its course, the type, severity, and association of symptoms can vary.

Pudendal nerve compression syndrome is believed to result from chronic compression and irritation of the dorsal nerve of the penis distal to the Alcock canal rather than truly within it. Although several small studies have shown the rate of Alcock syndrome to be higher in cyclists than in other athletes, another found the rate to be the same for bikers and nonbikers. Several studies indicate a vascular component to hypoesthesia and ED, as well as nerve compression.

Numerous studies have been conducted with the intention of optimizing bicycle seat design, handlebar-to-seat geometry, and seating configuration. The treatment for Alcock syndrome is usually conservative management and stressor avoidance, with a large percentage of patients regaining satisfactory erectile function. The recovery process time frame is variable and depends on the duration of insult and patient compliance with therapy, but usually, return of sensation occurs within several months.

Bicycle-associated acute pudendal nerve injury can present with a range of symptoms and more closely resembles pelvic trauma. There is more often a vascular injury, and one study suggests that the resultant numbness and ED are related to endothelial damage to the hypogastric and cavernosal vascular beds. This patient population more commonly encompasses a younger "daredevil" type who has sustained an acute straddle injury, and the outcome may be progressive and permanent with aging. Paresthesia may be unavoidable for some of these patients, and the success of medical ED therapy is not known.

Pudendal nerve entrapment syndrome is a separate entity from compression syndrome. It is defined by the Nantes criteria and remains a clinical diagnosis of exclusion. In addition to the five required pain symptoms defining the condition, associated symptoms may or may not include pain with defecation, fecal incontinence, urinary frequency and voiding dysfunction, pain following ejaculation, difficulty achieving orgasm, and ED. One study suggests that the configuration of the sacrotuberous ligament may congenitally predispose some individuals to pudendal nerve entrapment. Management can be coordinated with a neurologist and may include a thorough workup to exclude other diagnoses.

Severe pelvic trauma and vascular malformations/dilations can cause perineal symptoms associated with sexual dysfunction; moreover, the treatment of these conditions can also lead to the same problem. For instance, pelvic fracture is itself frequently associated with acute neurovascular injury and may be the incipient cause of paresthesia and ED. On the other hand, treatment related to acute trauma can be the cause. For instance, pelvic fracture and penetrating trauma are often accompanied by significant hemorrhage, requiring unilateral or bilateral embolization of the internal iliac artery, with resultant pelvic claudication, numbness, and ED. Likewise, patients unable to undergo open repair of an abdominal aortic aneurysm can now avail themselves of endograft placement. In many cases, unilateral or bilateral internal iliac artery embolization may be necessary for technical success of the endograft seating and function. In this patient population, the resultant perineal sequelae and ED have been mixed in several small, relatively short-term studies. In these cases, the success of medical management of the ED component is unclear and may warrant elucidation.

Male sexual function depends on sensory and motor enervation, psychological and somatic triggers, and adequate cardiac and vascular health. In many cases of dysfunction, medical therapy has made great strides in restoring erections. However, in many instances in which perineal/genital sensory input is impaired, by either neurologic or vascular insult, surgical correction may be the remaining option for correction of ED.

Periodization

Periodization is a system of training that is divided into specific periods of time each with a purpose. It is based on a scientific understanding of adaptation that requires gradually increasing repetitive stimuli with required rest to build toward peak performance. While there are various formats of periodization, the general plan includes phases of rest/transition, preparation, base, build, and taper to maximize performance.

Historical Background

In classical antiquity, the Greeks first used periodization training, with very simple plans of increasing training loads over time, in preparation for the Olympic Games.

In the 20th century, the Russians advanced periodization during the period from the 1920s to the 1940s by dividing training into different phases: general, preparatory, and specific. Previously, the training was to maintain the same constant stresses year-round. The general stage of training, often lasting for about 2 months or so, was supposed to develop the heart and lungs. The goal of preparatory training, also 2 months in duration, was to increase muscle strength and endurance. The specific phase, of about 8 months, prepared an athlete for a particular sporting event by emphasizing extensive practice of the precise movements involved in the sport. Some periods of training were made easier to rest the body and allow it to grow stronger.

Types of Periodization

While there are various models and variations of periodization training, most Western coaches have primarily focused on a model in which the volume of general preparation decreases as the intensity of and emphasis on technical training for specific preparations increase, producing peak performance during the competition phase. Tudor Bompa, considered the father of periodization, refined the ideas of Russian sports scientists in the early 1960s. His book *Theory and Methodology of Training* describes the various periodization patterns included in this classic wave cycle, starting with aerobic base, adding intensity, and building to peak.

An alternative to the wavelike periodization pattern is *step periodization,* in which training loads and intensities are changed abruptly, rather than smoothly and progressively from workout to workout, and in weekly and monthly cycles. In this plan, series of easier workouts are alternated with groups of intense efforts with very little break between the difficult sessions. Some studies have shown this method to be fairly effective in developing muscular strength for sports such as weight lifting.

In *skill strength periodization,* athletes spend an extensive amount of time perfecting their technical skills during the preparatory phase of training, prior to embarking on the development of strength and/or endurance. Once athletes become skilled (e.g., a swimmer or runner with efficient form), they can optimally use their increasing strength to boost performance. The goal is not to waste the increased strength on inefficient movements but to have it directed only toward correct patterns of motion.

Emphasis periodization is a training plan that is divided into 4- to 10-week time blocks or mesocycles, with each block having a specific emphasis or concentration. Each emphasis acts as a foundation for the following period. For example, a runner would first develop running-specific strength before power or economy prior to $\dot{V}O_2max$ (peak oxygen uptake). All the emphasis periods have to be completed prior to a targeted race.

Studies of periodization have been difficult since most studies have been limited to short periods of time. High dropout rates and lack of adherence also make it difficult to have high-quality studies to compare methods.

Basic Components of Periodization

The basic components of periodization include the following:

Microcycle: A number of training sessions form a recurrent unit, that is, a hard-easy-rest pattern, typically lasting 5 to 10 days.

Mesocycle: This refers to a block of training consisting of some number of microcycles, which emphasizes the attainment of a particular goal, for example, preparation for and completion of a very important marathon, and usually lasts 4 to 12 months.

Macrocycle: This consists of a number of different microcycles and covers a period from many months up to 1 year.

Individuality: Different athletes have different needs. Blocks may need to be devoted to muscular strength, lactate threshold, or $\dot{V}O_2max$ (peak oxygen uptake) depending on the weaknesses of a particular athlete. For example, the needs of a novice and an experienced athlete are very different. A new athlete may

Table 1 Phases of Periodization

Phase	*How Long? (Weeks)*	*Frequency*	*Duration*	*Intensity*	*Volume*
Preparatory	3–6	High	Short to medium	Very little	Low
Base	12–24	High	Medium to high	Moderate	Moderate to high
Build	4–8	Moderate to high	High	Heavy	Moderate
Peak/race	3–5	Moderate	Short	Heavy	Low

not be able to tolerate initial high volumes of training because he or she has not had the years of muscle adaptation required to tolerate such volumes. Lack of individuality in a training plan would result in soreness, impaired adaptation, possible injury, and reduced motivation. Instead, a new athlete may need more early emphasis on technique.

Periodization involves many variables, including

- frequency (how often you train),
- duration (how long you train in one session),
- volume (how much you train in a given week or cycle),
- intensity (how hard you train at any given time), and
- taper, which will help you reach your peak for the key race(s) you are targeting.

Rest or Transition Phase

The first phase of periodization, generally, is rest. The human body needs restoration periods to recover from periods of stress. This is a critical component of periodization, but it is often ignored by athletes of all ability levels. To improve performance, rest is needed.

The difficult part is how often a full recovery is needed and how long the recovery period should last. Top athletes seem to benefit from 1 month away from training each year.

Rest or the word "off" can mean different things. This is an opportunity to develop or re-aquaint oneself with other interests and hobbies and to take part in activities such as hiking or alternative sports that are not usually enjoyed during serious training. Some athletes do absolutely no training during this period, while others spend their "off" season running at a moderate pace at least a couple of times a week.

The goal, however, is to allow the body to become completely recovered and restored before resuming training. A study by Michael Warhol at Harvard Medical School found extensive damage in marathoners' leg muscles immediately after a marathon that took 4 weeks or more to recover from. Damaged muscle fibers and cell membranes, degenerated mitochondria, and damaged blood vessels were found.

Preparation Phase

The preparatory phase usually lasts 3 to 6 weeks. During this phase, the focus is on drills and on learning the technique for each sport. Strength is built to reduce the risk of injury from more intense training later in the year. The duration of workouts during this time is short and the intensity low. It is a time for the body to readjust to training. Strength training also offers benefits of improved biomechanical stability (especially if there previously were deficits), improved efficiency with improved technique (especially in sports where technique is important, such as swimming), and increased resistance to fatigue.

Base Phase

The base phase is one of the most important phases, especially for the endurance athlete. It can last from 12 to 24 weeks. The longer this phase lasts, the greater the aerobic fitness developed. This period can be shorter for endurance athletes who have trained or raced for many years and thus have had years of fitness, raising their base level of aerobic fitness. The base phase is literally the foundation of the entire year's training.

Typically, the base period itself will have blocks of 3 to 4 weeks, with each block progressively increasing in duration and distance. The training is entirely aerobic, with little to no intensity. The long workouts are gradually increased in frequency.

Build Phase

The build phase builds on the aerobic fitness developed in the base phase. This phase usually lasts 4 to 8 weeks and comes right before the targeted race. Volume will usually drop as intensity increases, although sometimes it may stay the same. But while the overall volume typically drops, the long workouts should be near all-year highs.

More workouts are focused on race pace or faster in order to prepare more for goal race conditions. Interval workouts are added to improve lactate threshold, again to simulate the intensity of racing and hard efforts with fatigue such as toward the end of a race. Intensity builds during the cycles.

Peak or Taper Phase

After all the hard work of the preparation, base, and build phases, the taper phase is physically quite easy but mentally very difficult. Many athletes never find the magic formula to make the perfect transition from their training to the race. Typically, over 2 weeks (and the duration is longer for a longer event), the volume is decreased, allowing the body to recover.

During this phase, there are still sessions of high intensities that match the pace of the race, but they are short. This phase is very individualistic. It is tempting for an athlete to continue to train during this period at a higher level than ideal due to the fear of losing fitness. To add minutes to a session or increase the number of sessions during this phase would be a mistake.

Peroneal Strain

The peroneus muscles work together to turn the foot outward (evert) and also provide stability. These muscles are necessary for side-to-side movements and are commonly injured in sports such as tennis, basketball, running, and dance. Injury to the peroneal tendons is a relatively underdiagnosed injury and not an uncommon source of lateral ankle pain. The true incidence is not known. It is often a consequence of what the patient perceives to be a lateral ankle sprain injury, although it can occur independently. As with many problems in sports medicine, injury to the peroneal tendons may be the result of an acute event, or it may occur in a chronic fashion.

Anatomy

There are generally two peroneal muscles—the peroneus longus and peroneus brevis—that originate on the outside (lateral) part of the lower leg. A small percentage of the population has an additional or accessory peroneus muscle, the peroneus quartis. The peroneus longus begins high on the fibula, while the peroneus brevis originates from the lower two thirds of the fibula. At the end of the muscle, just before the lateral ankle bone (malleolus), the muscular part becomes tendon, and the two tendons come together in a sheath. As the tendons course around the ankle bone, they enter a fibro-osseous tunnel, which helps in holding them in place as they make this turn. This tunnel is called the retromalleolar groove and is covered by connective tissue called the superior retinaculum. This is the primary restraint keeping the tendons in place in the groove. Beyond the ankle, the tendons split from their sheath and tunnel, and the peroneus brevis inserts on the outside of the midfoot (tuberosity of the fifth metatarsal), while the peroneus longus travels along the undersurface (plantar surface) of the foot and inserts onto the first metatarsal.

Causes

Tendinopathy and Tears

Peroneal tendinitis and tenosynovitis are acute inflammatory conditions that often occur in areas where the tendon comes into contact with the bony structures or the retinaculum as it turns along its course. It is usually due to repetitive activity, especially if the activity follows a period of relative inactivity. As with other overuse injuries, any change in the intensity, frequency, or duration of sports or exercise training may be a contributing factor. A single isolated traumatic event can also be the cause.

Tendinosis is a chronic condition that can develop from repetitive microtrauma. It may be characterized by degenerative changes that result from mechanical friction and shearing injury. There may be fraying, split tears, or abnormal thickening of the tendon. A complete tear or rupture can also occur, usually associated with chronic tendinosis or chronic ankle instability. A nonhealing longitudinal tear of the tendon can be a cause of persistent lateral ankle pain.

Tendon Subluxation

Subluxation of the tendon can occur when the tendon's restraining structures, especially the superior retinaculum, are disrupted. The tendon then moves or snaps out of its place behind the ankle. This may occur as a result of an acute injury when the ankle is forced into extremes of plantarflexion or dorsiflexion and the peroneal muscle reflexively contracts. A lateral ankle sprain can occur at the same time. With chronic subluxation, the tendon moves or snaps out of its place with walking or running but especially with cutting. This may occur in patients with chronic ankle instability from multiple prior ankle sprains. In some, this may not be symptomatic at all, while in others it can be very painful and cause significant dysfunction.

Diagnosis

History and Exam

Peroneal tendon disorders present with pain along the outside of the ankle (lateral side). In tendinopathy, there is often a history of repetitive overuse. On examination, there may be swelling and warmth along the course of the tendons, and pain is elicited when the foot is turned inward (inversion) and down (plantarflexion) or when the patient moves it upward and outward against resistance (dorsiflexion and eversion). With tendinosis or tears, there may be swelling but not warmth. The area along the tendon is tender on palpation, and there may or may not be weakness noted in the ability to evert the foot.

In a patient with an acute ankle injury, it may be difficult to evaluate for subluxation until the swelling improves. The area is tender, and the ankle may be unstable. Movement and location of the tendon can be seen when the patient moves the foot in dorsiflexion and eversion. With chronic subluxation, there may be a history of snapping or popping along the outside of the ankle. Pain occurs as with acute subluxation, mostly when the patient is asked to actively point the foot up and outward. The tendon may be seen moving from its place behind the ankle when observing the patient's gait. Often, and most helpfully, the subluxating tendon and its symptoms can be reproduced on exam by having the examiner place his or her fingers over the tendon as it sits just behind the lateral malleolus and then ask the patient to repeatedly dorsiflex and plantarflex the foot.

Imaging

Plain X-ray films are helpful in evaluating a possible fracture of the bone in an acute injury. If imaging is necessary for evaluating tendon injury, magnetic resonance imaging (MRI) is the test of choice. Of note, the role of dynamic ultrasound imaging looks promising for diagnosing significant tears of the peroneal tendon in the office setting.

Management

Nonoperative

Treatment of peroneal tendinitis involves rest from the offending activity, ice, and nonsteroidal anti-inflammatory drugs such as ibuprofen. This is generally successful and is followed by gradual return to activity.

Tendinosis and tears can usually be treated nonoperatively, although they may require 4 to 8 weeks of immobilization and limited weight bearing in a boot or short leg cast. Physical therapy should then be directed at strengthening, stretching, and proprioceptive work in the foot, ankle, and lower leg. Some people with peroneal tendon disorders have abnormal foot mechanics and may need specially made orthotics.

Operative

In the non–high-level athlete, a trial of nonsurgical management for a peroneal tendon tear may be reasonable; if nonoperative treatment fails after 6 to 8 weeks, surgery may be indicated. This typically involves debridement of the tendon and repair when possible. A rupture may require grafting or, rarely, a tendon transfer.

Some patients with symptomatic acute or chronic subluxation who do not respond to aggressive nonoperative management may opt for surgical repair. In acute injuries, the superior retinaculum is often lifted off the bone and must be reattached after the tendon is relocated. There are many surgical approaches to chronic subluxation, all of which attempt to not only relocate the tendon but also identify and correct anatomic variations that predispose to the subluxation. Depending on the procedure, cast immobilization for 2 to 6 weeks postoperatively may be necessary. Physical therapy is then implemented for strengthening and proprioceptive training to restore and maximize function.

Peroneal Tendinitis

Peroneal tendinitis is a source of pain in the lateral (or outer) portion of the foot and ankle. A tendon is a strong piece of fibrous, connective tissue that attaches the muscle to the bone. The peroneals are made up of two muscles—the peroneus longus and peroneus brevis. These muscles of the lower leg play an important role in moving the foot in an outward direction, known as eversion. Tendinitis refers to inflammation of the tendon, which is thought to be the source of pain. There is a common sheath that surrounds the tendon, and if this becomes inflamed, it is referred to as a tenosynovitis. When this injury becomes chronic, there are significant degenerative changes within the tendon. This condition is referred to as a tendinosis or tendinopathy. Therefore, it is common to see this injury described as such. The injury may be induced by trauma or, especially in athletes, may be the result of overuse. Runners, dancers, and skaters are especially at risk for this problem.

Anatomy

The peroneal muscles are the primary evertors of the foot. This means that they are responsible for moving the foot in an outward direction. The peroneus longus and peroneus brevis muscles both give rise to their tendons just above the lateral malleolus, the bony protuberance on the outer portion of the ankle (see Figure 1). The tendons are both contained within one common sheath, or covering. This traverses behind and then beneath the lateral malleolus and continues along the outer portion of the foot. In the area of the lateral malleolus, the common tendon sheath is anchored by fibrous attachments. The peroneus brevis tendon then inserts at the base of the fifth metatarsal, the bone that leads up to the fifth toe. The peroneus longus tendon courses along the cuboid bone in the middle of the foot and then inserts at the base of the first metatarsal, a bone on the inner half of the foot that is at the base of the big toe. Apart from eversion, the peroneals also play a role in plantarflexion (moving the foot downward) and abduction (moving the foot away from the body) of the foot.

Causes

Pain caused by the peroneal tendon may result from multiple etiologies. Overuse of the tendon leads to tendinitis because of the excessive amount of stress placed on the tendon with activity. This leads to inflammation of the tendon, which causes pain. Ongoing stress can lead to degenerative changes, resulting in chronic tendon dysfunction. Therefore, in the absence of treatment, symptoms may be commonly present for many weeks or months without resolution. Any running athlete can develop this condition, as can dancers and skaters. One study of elite mountain road racers revealed that more than 10% had symptoms of peroneal tendinitis that were present for more than 3 months. This has led to the belief that running on uneven ground can predispose one to this condition. Although it is unclear if any specific age-group is at risk, some suggest that women above 50 years have a higher incidence of peroneal tendinitis and that excessive wearing of high heels may be a risk factor. Other causes include anatomical abnormalities, peroneal tendon subluxation, ankle instability, and prior ankle surgery.

Less commonly, the tendon will undergo subluxation or a shift in position. The tendon sheath is normally tethered to a groove behind the lateral malleolus. However, underlying anatomical abnormalities or an acute injury can lead to disruption of the attachment and subsequent subluxation. The acute injury occurs when the foot is subjected to a violently forced upward motion. Downhill skiers are at risk for this often misdiagnosed injury. Complete rupture of the tendon is another uncommon presentation of peroneal tendon pain. This may occur when the foot is violently moved in a downward and inward motion that stretches the tendon(s) to the point of failure.

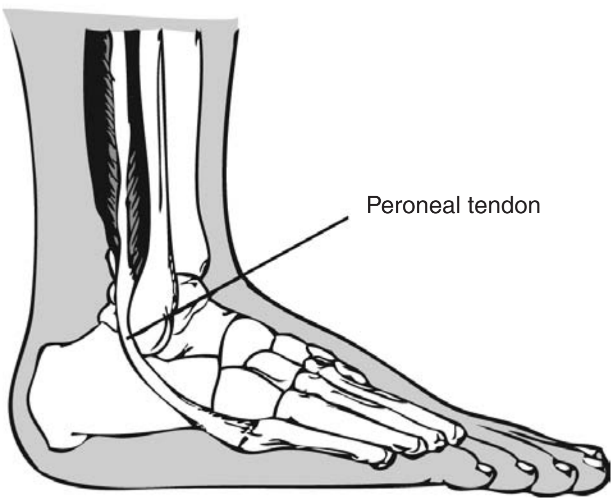

Figure 1 Peroneal Tendon

Source: Jonathan A. Becker, M.D., University of Louisville.

Note: An overview of the anatomy of the peroneal tendon showing its distribution and insertion into the fifth metatarsal.

Symptoms

The hallmark of peroneal tendinitis is the presence of lateral ankle and foot pain in the region of the peroneal tendon. Symptoms are most commonly felt in the area behind the lateral malleolus but may occur anywhere along the course of the tendon. Pain may be present for varying durations, often many months, and may or may not have been caused by a traumatic episode. Generally, the pain is related to activity and relieved by rest. Severity can be variable as well, ranging from mild to debilitating. Swelling is a common but inconsistent finding on exam. Signs of inflammation, such as warmth or redness, are less common. Certain motions, specifically moving the foot in an outward direction, can initiate the pain. In more advanced cases or those with ruptured or subluxed tendons, any weight-bearing activity can be painful. Those with peroneal subluxation may report a popping sound that precedes the pain symptoms.

Diagnosis

Typically, the diagnosis of peroneal tendinitis is made on the basis of the patient's history and physical examination. As previously mentioned, the typical history is that of lateral foot and/or ankle pain that worsens with activity. The exam will reveal tenderness in the distribution of the peroneal tendons, which may be a solitary, discrete area but can be more diffuse. Pain can be elicited with foot eversion, and the examiner can provide resistance to aid in re-creating the symptoms. Dorsiflexion of the ankle (moving the foot upward) against resistance may also elicit pain. Swelling is a common finding and may be indicative of a more severe injury. Redness and warmth are signs of acute inflammation. Signs of ankle instability are frequent as this may precipitate peroneal tendon problems.

In the case of peroneal tendon subluxation, the patient may have the ability to spontaneously move the tendon out of its normal position. The examiner may elicit subluxation by forcing the foot upward and outward. In cases of subluxation or rupture, there may be marked pain or swelling and associated weakness of the peroneal muscles. However, these findings may be rather subtle and the presentation indiscernible from more benign injuries.

X-rays are of little benefit in visualizing the peroneal tendons but may be useful in ruling out other common causes of lateral ankle pain, such as fractures of the lateral malleolus. Imaging of the foot can be used to rule out fractures of the base of the fifth metatarsal, where the peroneus brevis inserts. Magnetic resonance imaging (MRI) can be used to delineate the appearance of the tendon. Complete ruptures are well visualized, but minor longitudinal tears of the tendon, subluxation, and signs of tendinitis are often missed on an MRI scan.

Treatment

Regardless of the severity of the symptoms, initial management will be similar for most cases of peroneal tendinitis. Relative rest from the offending activity and frequent application of ice will allow for symptom control. Nonsteroidal anti-inflammatory drugs are helpful in pain reduction and may be particularly beneficial in cases of tenosynovitis. Elevation will reduce swelling. Braces or splints can be used to provide ankle support, as many patients will have concomitant ankle instability. For athletes, this can also be accomplished with taping. An exercise program that promotes stretching of the posterior calf muscles and strengthening of the foot and ankle muscles will provide rehabilitation. This not only will strengthen the peroneal muscles but also will help provide support for an unstable ankle.

In more severe cases, crutches or a short leg walking cast may be used to alleviate symptoms for those with debilitating pain or pain with routine activities of daily living. Physical therapy may be employed to provide an exercise program, and modalities such as ultrasound or iontophoresis (the introduction of pain-relieving medications through the skin) may be used. There is conflicting evidence regarding the benefits of those treatments. For cases with significant evidence of inflammation or those unresponsive to more conservative measures, a local steroid injection may be employed to relieve pain. However, these injections place the patient at risk for tendon rupture, prompting some experts to recommend against them. The time course for resolution of symptoms, especially in more severe cases, can vary from weeks to months. Generally, the longer those symptoms have been present at the time of presentation, the longer it will take for recovery. Return to activity is based on the level of discomfort. Once any deficits in strength and range of motion have been regained, patients can advance their activity level as symptoms allow.

Surgery is reserved for severe cases that are refractory to more conservative measures. The damaged portion of the tendon can be excised and the remaining free ends then sutured back together. It is recommended that even in cases of complete rupture or subluxation, patients undergo a trial of conservative treatment before surgery is employed. However, those with chronic symptoms of subluxation, especially active people, will often require surgical repair.

Peroneal Tendon Subluxation

Peroneal tendon subluxation is a relatively uncommon condition in which the peroneal tendons slip out of the retromalleolar groove during tendon loading. It was first described in 1803 in a ballet dancer, but it is also commonly associated with other sports such as skiing, ice skating, soccer, basketball, rugby, and gymnastics, and with motor vehicle accidents. The superior peroneal retinaculum is the primary restraint to peroneal tendon subluxation. Tearing or stretching out of this retinaculum makes it an incompetent restraint to subluxation of dislocation. This can occur as a result of an acute dislocation or after chronic tendon subluxation. Because of the high failure rate associated with nonoperative treatment, there has been a trend toward primary surgical management of acute peroneal tendon subluxation.

Anatomy

The peroneus longus and brevis are contained, with the superficial peroneal nerve, in the lateral compartment of the lower leg. The peroneus longus originates on the lateral aspect of the upper two thirds of the fibula and inserts onto the base of the first metatarsal and the lateral aspect of the medial cuneiform. The peroneus brevis originates on the lateral aspect of the lower one third of the fibula and inserts on the tuberosity of the base of the fifth metatarsal. Approximately 4 centimeters (cm) proximal to the distal tip of the lateral malleolus, the two tendons enter a common synovial sheath and pass posterior to the lateral malleolus in the retromalleolar groove.

The peroneal tendons are maintained within the retromalleolar groove by the superficial peroneal retinaculum (SPN). The SPN is the primary restraint to peroneal tendon subluxation. The SPN is a fibrous band of tissue, approximately 1 to 2 cm wide. It extends from the posterolateral aspect of the fibula and inserts on the lateral aspect of the calcaneus onto the peroneal tubercle. In some people, the SPN has an additional attachment onto the Achilles tendon sheath. Distal to the lateral malleolus, the tendons pass through the inferior peroneal retinaculum.

Proximal to the lateral malleolus, the peroneus brevis tendon lies deep to the peroneus longus. Distal to the lateral malleolus, the peroneus brevis tendon lies anterior to the peroneus longus. This relationship is important to understand when attempting to identify the correct tendon during surgical procedures.

The blood supply for the peroneal tendons is from the posterior peroneal artery and from the branches of the medial tarsal artery.

The peroneus brevis tendon is the primary evertor of the foot. It also assists in abducting the foot and plantarflexing the ankle. The peroneus longus everts the foot, plantarflexes the first ray, assists in ankle flexion, and helps stabilize the medial column of the foot during stance.

Certain anatomic variations are thought to predispose individuals to peroneal tendon subluxation. These include variations in the shape of the retromalleolar groove, a low-lying peroneus brevis muscle belly, or an accessory peroneus quartus muscle.

A shallow retromalleolar groove may contribute to peroneal tendon instability. A low-lying peroneus brevis muscle or an accessory peroneus quartus muscle can cause stenosis in the retromalleolar groove and can lead to attenuation of the superior peroneal retinaculum.

Etiology

Acute peroneal tendon dislocation presents following a traumatic ankle injury where the superior peroneal retinaculum has ruptured or become attenuated. Chronic peroneal tendon subluxation or dislocation may be associated with an untreated dislocation, or symptoms may have developed over a period of time with no specific traumatic event. Chronic peroneal tendon instability can be associated with lateral ankle instability, a cavovarus foot, a split in the peroneus brevis tendon, a lax superior peroneal retinaculum, or a shallow retromalleolar groove (Figure 1).

Clinical Presentation

Patients with peroneal tendon instability often localize pain to the posterior aspect of the lateral malleolus. Occasionally, they will describe a painful snapping or popping sensation within the ankle range of motion. After an acute event, the ankle is usually swollen and tender and may be ecchymotic (bruised). Tendon subluxation can occasionally be observed when the patient walks but is more commonly reproduced with active ankle dorsiflexion and eversion or circumduction of the foot.

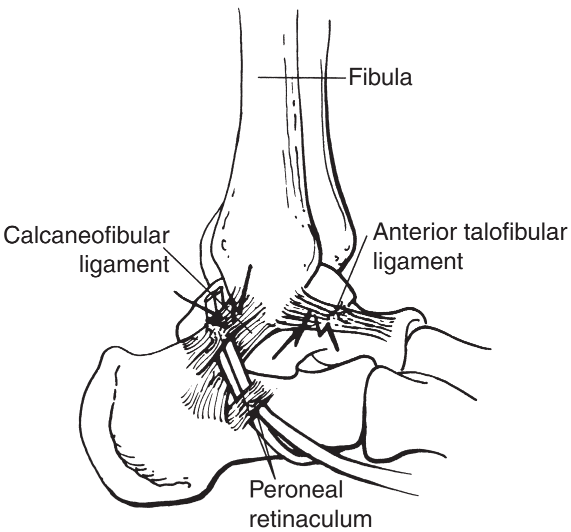

Figure 1 Peroneal Tendon Subluxation

Notes: Peroneal tendon subluxation occurs when the tendons slip forward in and out of the retromalleolar groove through which they travel. This may begin following an inversion sprain in which the peritoneal retinaculum sustains a tear.

Safran described a test to elicit tendon instability. The test is performed with the patient prone and the knee flexed to 90°. The examiner then resists the patient's attempt to dorsiflex and everts his or her ankle.

It is also important to perform an anterior drawer test and a talar tilt test to rule out lateral ankle ligamentous instability.

Imaging

Imaging studies of a patient with peroneal tendon subluxation should include weight-bearing anterior-posterior (A-P) and lateral radiographs of the foot, as well as A-P, lateral, and mortise views of the ankle. The peroneal tubercle and retromalleolar groove are best evaluated with a Harris-Beath heel view. The Harris-Beath heel view can also be used to evaluate for a cavovarus foot, which may increase the risk of peroneal tendon subluxation.

A small avulsion fracture of the lateral malleolus (fleck sign) is pathognomonic for a tear of the superior peroneal retinaculum.

Magnetic resonance imaging (MRI) is useful in evaluating the soft tissues of the foot and ankle, such as the condition of the peroneus brevis tendon. Other conditions that may be contributing to the patient's symptoms can also be ruled out. An MRI scan with the foot in dorsiflexion may demonstrate tendon displacement.

Treatment

Nonoperative

Nonoperative treatment is associated with a high rate of recurrence. It can sometimes be successful, however, in treatment after an acute dislocation. Treatment consists of immobilization in a short leg cast with the foot in neutral to slight inversion to encourage the superior peroneal retinaculum to heal to its attachment site on the posterolateral aspect of the fibula. A felt pad may be placed over the lateral malleolus prior to casting to hold the tendons within the retromalleolar groove while the retinaculum heals. After casting, aggressive physical therapy should be used to strengthen the muscles of the foot and ankle prior to return to activities.

Operative

Because of the high percentage of failure of attempted nonoperative management in high-demand individuals, there has been a trend toward primary surgical management of acute peroneal tendon dislocation.

Several approaches have been developed, including anatomic reattachment of the peroneal retinaculum, reinforcement of the retinaculum with local soft tissue, groove-deepening procedures, bone-block procedures to create a mechanical block to subluxation, and rerouting the peroneal tendons behind the calcaneofibular ligament to stabilize the ligaments within the retromalleolar groove.

With any of these procedures, it is important to address the findings that may be contributing to peroneal tendon instability, such as debriding a low-lying peroneus brevis muscle belly, excision of a peroneus quartus muscle, or correction of varus hindfoot alignment.

After Surgery

After surgery, the patient is placed in a weight-bearing cast for 4 weeks in a position of neutral dorsiflexion and slight eversion. Physical therapy is started after the cast is removed. Gradual return to sports is allowed 3 to 4 months after surgery.

Personality and Exercise

The history of personality can be traced to Hippocrates (ca. 460–377 BCE), and behaviors such as physical activity were linked to this original theorizing. Academic research on personality and exercise behavior has been sporadic for 30 years, with a recent increase in the late 1990s onward. This mimics the general upward focus on personality research as measures have improved and evidence has mounted to show that personality traits are stable and cross-cultural and display a finite taxonomy. Personality traits are considered as enduring and consistent individual-level differences in tendencies that show consistent patterns of thoughts, feelings, and actions. Many researchers further theorize that personality has a biological/genetic basis and this constitutes the focus of the personality and exercise relationship; that is, personality research is attempting to evaluate whether people have a predisposition for adhering to regular exercise behavior.

Models of Personality

Two popular frameworks (or taxonomies) dominate the extant research on personality and exercise. The first is Eysenck's three-factor model of traits: extroversion, neuroticism, and psychoticism. Extroversion represents the tendency to be social, assertive, busy, energetic, and positive in affect, while neuroticism represents the tendency to exhibit anxiety, depressed mood, self-consciousness, and vulnerability. Psychoticism, in contrast, represents a tendency toward risk taking, impulsiveness, irresponsibility, manipulativeness, and sensation seeking. The other popular taxonomy is known as the five-factor model of personality and has had considerable support as a basic structure of personality. In addition to the extroversion and neuroticism traits of Eysenck's model, this model includes the traits of agreeableness (e.g., the tendency to be perceptive, creative, reflective, and appreciative of fantasy and aesthetics), openness to experience (e.g., the tendency to be kind, cooperative, altruistic, trustworthy, and generous), and conscientiousness (e.g., the tendency to be ordered, dutiful, self-disciplined, and achievement oriented). These factors are considered orthogonal (i.e., uncorrelated), but extroversion and neuroticism are typically negatively related, while extroversion and conscientiousness are positively related.

Exercise and Personality Relationship

Overall, exercise behavior is positively correlated with extroversion and conscientiousness and negatively related to neuroticism. These are small effects; thus, the associations are reliable perhaps at a population level but contribute to only a small piece of the puzzle when attempting to explain why some people exercise while others do not. Agreeableness, openness to experience, and psychoticism are not related to exercise in a reliable way. The relationships between personality traits and exercise also depend on the mode of activity. The extroversion relationship, for example, appears to be more for vigorous or moderate-intensity exercise but does not hold for light activities or regular leisure-time walking. There is some indication that gender effects (more pronounced for females than for males) and cultural effects (North Americans seem to have a larger extroversion effect than do people from the United Kingdom) may be occurring, but this idea has not undergone enough formal testing at present. There is also some evidence that personality effects may be most influential during regular exercise transitions (e.g., adoption, resumption). Some evidence has demonstrated quite large effects for personality factors of neuroticism, extroversion, and conscientiousness when participants are organized by maintenance, adoption, or cessation exercise patterns. This suggests that personality may have both predisposition and acquisition effects on behavior change and regulation.

Current Research

Current research is now focusing on the mechanisms for how personality may influence regular exercise. There is evidence that extroversion's more specific subtrait of activity (the tendency to be busy, energetic, and talkative and have a preference for a fast pace) may be the critical link with exercise. In some cases, this trait has explained exercise behavior regardless of an individual's initial intentions. Thus, other expressed subtraits of extroversion, such as sociability and positive affect, may be less important to exercise than activity (or physical extroversion). Another line of research has focused on how personality and exercise motivation interact. Some research has indicated that personality may be linked with exercise through attitudes (i.e., the evaluation of exercise and its benefits vs. costs) and perceptions of control (i.e., the perceived capability to perform regular exercise). In this case, extroverted, conscientious, and emotionally stable people see more value in performing exercise and consider it more under their control than their introverted, less conscientious, or neurotic counterparts. This perceived value and control subsequently lead to stronger motivation and eventual performance of regular exercise.

Another interesting line of research has focused on how personality may affect the translation of exercise intentions into behavior. Exercise intention has garnered support as the proximal predictor of behavior, but a large gap between the two is still present; indeed, most of the populace has some intent to exercise regularly, but only half of these people actually follow through on these intentions. Personality research has demonstrated that conscientiousness, and sometimes extroversion, interact with this intention-behavior relationship. That is, people low in conscientiousness and extroversion have a lower intention-behavior relationship than those high on these traits. The suggested mechanism for this link is the basic premise that conscientious people are naturally more dutiful, organized, and self-disciplined, which allows them to fulfill their initial intentions. For extroversion, it has been suggested that extroverts are more likely than introverts to find themselves in situations (social, active, etc.) where they can act on their intentions.

The practical application of personality and exercise research has seen less attention. If personality is stable and not easy to change, it suggests that physical activity promotion efforts via personality may not be feasible. One possibility, however, is that exercise preferences could be matched or targeted by personality, and this successful combination could aid in improving adherence. There are some differences in exercise preferences by personality; most notable is that extroverts prefer to exercise in groups, while introverts have a preference for exercising alone. Another possibility is that personality characteristics could be used as markers of people at risk for low exercise adherence, and this could help characterize and facilitate augmented promotion initiatives. The notion of personality-based exercise programs is popular in the media, but it has not undergone extensive testing at present. Given the generally small effect that personality has on exercise behavior, however, it seems likely that interventions based on these traits should constitute a small part of a larger promotion initiative.

Pharmacology and Exercise

Exercise pharmacology is a relatively new field that studies how exercise affects drugs and how drugs affect exercise. How exercise and drugs interact is very complex, and there has not been much research done to look at these interactions. How exercise affects a drug is not a required part of the U.S. Food and Drug Administration (FDA) drug approval process or the required postmarketing surveillance. Much of the information below is based on what is known about how exercise affects the physiology of the body, followed by logical deductions on how this will affect various drugs.

The Effect of Exercise on Drugs

The study of how the body processes a drug is called *pharmacokinetics*. Pharmacokinetics is divided into four different body functions: absorption, distribution, metabolism, and excretion. How each of these is affected by exercise is detailed below. These are only general concepts, and any particular drug may be affected differently.

Absorption

Absorption is how the drug gets into the body. Drugs can be absorbed in a variety of ways, including orally, by injections, transdermally, and by inhalation.

Oral Absorption

Most drugs are absorbed orally. Generally, the drug is dissolved in the stomach and then absorbed through the lining of the small intestine. Both of these can be affected by exercise. Light exercise can decrease stomach-emptying time, while strenuous exercise can increase it. So depending on the intensity of the exercise, it may take a shorter or longer time for the drug to leave the stomach, which will then affect how quickly the drug will take effect. Exercise also decreases blood flow to the gastrointestinal tract as blood is shunted to the heart, lungs, and muscles, to deliver more oxygen to those tissues that need it during exercise. This results in less drug being absorbed in the small intestine and thus could decrease the effects of the drug.

Injections

As mentioned above, during exercise, blood is shunted to the muscles to provide more oxygen to fuel the exertion. So drugs that are injected into muscle or the surrounding tissue will be absorbed much more quickly, and more of that medication may be absorbed into the bloodstream, resulting in higher blood concentrations. One of the most commonly injected medications is insulin, used in the treatment of diabetes mellitus. Patients who use insulin are advised to avoid injecting insulin into muscles that are going to be exercised shortly. For instance, if a diabetic is going to run, it is recommended that he or she inject the insulin into the abdomen instead of the thigh, as absorption of the insulin from the thigh will be greatly affected by running.

Transdermal Absorption

Some medicines are absorbed into the bloodstream through the skin. Examples include nitroglycerin patches and creams used to treat angina, nicotine patches to help quit smoking, and female hormones for birth control. Exercise also increases blood flow to the skin so that excess heat can be released, so these medications will be absorbed as much as two to three times more during exercise than at other times.

Inhaled Absorption

The most common medicines that are absorbed through inhalation are asthma medications. Exercise increases blood flow to the lungs to facilitate better oxygen delivery to tissues, so drug absorption through this pathway is also increased. This can be helpful in the patient with asthma because asthma is often worsened by exercise, so more medicine is absorbed when the need is greater.

Distribution

Distribution refers to the parts of the body and the tissues the medication is delivered to. The most important effect exercise would have on distribution is related to dehydration. If the exercising person does not adequately hydrate during and after exercise, the body may become dehydrated, which could increase the concentration of the drug, potentially causing side effects. The other manner in which distribution could be affected by exercise is its effect on protein binding. In the bloodstream, some drugs are bound to protein, making them unavailable to act on the body. Exercise increases the levels of protein in the bloodstream, so more of a drug is bound to protein, decreasing its effects.

Metabolism

Many drugs are metabolized by the liver, which inactivates the drug. Exercise decreases blood flow to the liver, so drugs that are metabolized in the liver may have an increased duration of action before they are metabolized. However, some studies have shown that regular exercise increases the efficiency of the liver in metabolizing drugs. So while exercise decreases blood flow to the liver, it seems to make it more efficient, and thus, these two effects probably cancel out each other.

Excretion

Excretion refers to how the drug is removed from the body. Most drugs are excreted through the kidneys. During exercise, blood flow to the kidneys decreases by as much as 50%, so this can result in drugs remaining in the bloodstream longer and increasing their concentrations. Some drugs are excreted by the liver into the bile and then leave the body through the stool. Regular exercise increases bile excretion, so drugs excreted through this route are eliminated more quickly. One example of this is acetaminophen.

Summary

As can be seen, the topic of how exercise affects drugs is very complex. While there are some drugs that have been extensively studied, the effect of exercise on most drugs has not been researched. With the current lack of knowledge, it is difficult to make definitive statements about how a specific drug will be affected by exercise, but a significant impact resulting in severe side effects or toxicity is possible.

The Effect of Drugs on Exercise

Many drugs have been found to have an effect on exercise. This section discusses some commonly prescribed medications as well as common over-the-counter drugs that will change the body's ability to exercise. It is recommended that if you are taking any of these medications that may be adversely affecting your ability to exercise, you should discuss it with your physician before making any changes to your treatment plan.

Beta Blockers

Beta blockers are among the most commonly prescribed medications for hypertension and other cardiovascular diseases. Apart from decreasing the blood pressure, beta blockers decrease the resting heart rate and blunt the heart's ability to increase its rate with exercise. Because of these effects on the heart, beta blockers decrease the body's ability to exercise, commonly resulting in fatigue. For this reason, beta blockers may not be the best option for patients who exercise regularly, especially if taken for hypertension.

Diuretics

Diuretics are drugs that increase the removal of water by the kidneys and are commonly prescribed for the treatment of hypertension and congestive heart failure. Since exercise can result in loss of fluid through sweat, patients who exercise while taking diuretics are at increased risk for dehydration. Patients need to assess their hydration status closely when exercising while on these medications.

Antihistamines

Antihistamines are drugs commonly used to treat seasonal allergies or upper respiratory illnesses. They can be divided into two classes or generations. First-generation antihistamines include diphenhydramine (Benadryl), chlorpheniramine (Chlor-Trimeton), and clemastine (Tavist) and are the most common antihistamines included in over-the-counter medications for allergies and colds. Second-generation antihistamines include cetirizine (Zyrtec), loratadine (Claritin), desloratidine (Clarinex), and fexofenadine (Allegra) and are newer agents that are available over the counter (cetirizine, loratidine) or by prescription only (desloratidine, fexofenadine). First-generation antihistamines have a higher incidence of side effects than second-generation antihistamines. During exercise, first-generation antihistamines can decrease the ability of the body to sweat, thus increasing the risk of hyperthermia. They also can cause drowsiness and sedation, affecting exercise performance. For this reason, second-generation antihistamines are generally preferred for athletes.

Statins

Statin drugs are the most commonly prescribed class of drugs to treat hypercholesterolemia. Most patients can take these medications without side effects. However, this class has been linked to myopathy, a disease of muscle that can result in muscle destruction in severe cases. Strenuous exercise is thought by some to increase the risk of this side effect, so it is recommended for patients taking these medications, especially older males who are deconditioned, to avoid intense weight lifting or other strenuous exercises.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used to treat pain and inflammation, especially for musculoskeletal injuries and muscle soreness after exercise. Over-the-counter examples include aspirin, ibuprofen, and naproxen, and there are more than 20 NSAIDs available by prescription. Some studies have shown quicker recovery from muscle soreness after exercise when on these drugs, which could enable a person to exercise more frequently. While they are commonly used, there is a growing concern that these drugs may slow the healing response, especially in fractures and cartilage injuries.

Narcotic Pain Medications

Narcotic pain medications are used to treat severe pain, often from acute injuries. Narcotics include codeine, hydrocodone, and oxycodone and are available in a number of prescription formulations. A common side effect of narcotics is sedation and drowsiness, so athletes should be cautioned against exercising and competing while under the effects of narcotics.

Muscle Relaxers

Muscle relaxers are used to decrease muscle spasms, especially spasms associated with cervical and lumbar sprains and strains. They also cause sedation and drowsiness, so exercising while on these medications should probably be avoided.

Fluoroquinolone Antibiotics

Examples of fluoroquinolones include ciprofloxacin (Cipro), levofloxacin (Levaquin), norfloxacin (Noroxin), and ofloxacin (Floxin). Fluoroquinolones are one of the most commonly prescribed classes of antibiotics due to their broad spectrum of activity against many different bacteria and the low prevalence of side effects. However, the FDA has recently added a warning concerning the risk of tendon-related side effects, including an increased risk of tendon ruptures. Because of this, many sports medicine physicians avoid using this class of medications in athletes.

Physiatry and Sports Medicine

Physiatrists are physicians who are experts in the biomechanics and function of nerves, muscle, and bone. They treat injuries or illnesses that affect people's quality of performance. The goal of a physiatrist is to treat the whole person in order to restore function. Besides diagnosing and treating the condition, physiatrists work to prevent further disability. Physiatrists take a team approach with the patient and care providers to rehabilitate the patient.

A physiatrist should have completed medical school and 4 years of postdoctoral training in a physical medicine and rehabilitation (PM&R) residency. All physiatrists are trained to care for general musculoskeletal injuries. Some physicians may pursue fellowships in sports medicine, interventional spine, neuromuscular medicine, spinal cord injury, traumatic brain injury, electrodiagnostic medicine, and pediatric rehabilitation.

When seeing a patient for a sports-related injury, a physiatrist will first assess the injury using a focused and detailed history and physical exam. In some cases, further testing may be ordered or performed, including imaging studies (to visualize the structures involved) and electrodiagnostic studies (to test the muscles and nerves). The most important part of the physiatrist's treatment is to address and educate the patient about the biomechanics that may have contributed to the injury. By facilitating body awareness, the physiatrist engages patients in his or her treatment, assesses faulty habits, and prevents further injury. As head of the rehabilitation team, the physiatrist will then devise a rehabilitation program, providing direction to the physical therapists and/or occupational therapists. The physiatrist will continue to follow the patient's condition to maximize the return to the patient's pre-injury level of activity. Physiatrists also receive training in bracing and orthotics and may prescribe a device to maximize function and minimize pain.

In addition, a physiatrist is expert in treating acute pain. This may be done so that the patient can start physical therapy as soon as possible. Physiatrists are trained in many interventions, including injections of anti-inflammatory medication to relieve arthritic joints or inflamed tendons, viscosupplementation to replace the normal joint fluid, and trigger point injections to help relieve areas of focal muscle spasm. Medications may also be prescribed.

As experts in rehabilitation, physiatrists work with a wide spectrum of patients, from elite athletes to quadriplegic patients, who are unable to move on their own but would like to participate in sports. Physiatrists may develop exercise plans for athletes, overweight patients looking to get fit, elderly patients recovering from a heart attack, or patients with progressive neurological diseases. They have the expertise to prescribe exercise programs and assistive devices for athletes with new, disease-related limitations. Many physiatrists conduct research involving sports and exercise endurance, physiology, and biomechanics. They collaborate with their patients and, as needed, with their patients' families, therapists, and social workers to develop a plan to meet the patients' treatment goals. Physiatrists have a unique role in patient care; they incorporate the medical, social, emotional, and vocational effects of an injury into the treatment plan.

Physical and Occupational Therapist

Occupational therapists (OTs) and physical therapists (PTs) are key members of the sports medicine interdisciplinary team. They assist in the prevention, evaluation, diagnosis, and treatment of sports-related injuries. OTs and PTs provide guidance for a safe and early return to play.

The American Physical Therapy Association (APTA) defines physical therapy as "a health profession whose primary purpose is the promotion of optimal human health and function through the application of scientific principles to prevent, identify, access, correct, or alleviate acute or prolonged movement dysfunction." To become a physical therapist, one must earn a master's or doctorate degree from an accredited physical therapy program. This process takes approximately 5 to 7 years. PTs work with a diverse patient population, including patients with neurological, cardiopulmonary, orthopedic, and physical developmental conditions. Physical therapists can obtain a specialist certification in sports physical therapy with formal study and clinical experience through the APTA. As of 2007, 7,573 physical therapists have been certified as clinical specialists, and 640 are certified as specialists in sports medicine.

According to the American Occupational Therapy Association, occupational therapy involves the "therapeutic use of work, self-care, and play activities to increase independent function, enhance development, and prevent disability. It may include adaptation of task or environment to achieve maximum independence and to enhance the quality of life." OTs earn a master's degree from an accredited occupational therapy program. This process takes 5 to 6 years. Occupational therapists work with a wide patient population, including those with developmental delays and neurological, cardiopulmonary, orthopedic, and psychiatric conditions. Occupational therapists who work in sports medicine are typically certified hand therapists and specialize in upper extremity conditions. To become a certified hand therapist, you must have a minimum of 5 years of clinical experience working with upper extremity injuries and must have passed a board certification exam. Certified hand therapists comprise both occupational therapists and physical therapists.

Some examples of injuries that a PT would see include anterior cruciate ligament (ACL) tear, patella dislocation, low back pain, shoulder dislocation, ankle sprain, tennis elbow, plantar fasciitis, and shin splints. Examples of injuries an OT might see include hand and wrist fractures such as scaphoid fracture, hand and wrist tendon injuries such as jersey finger or skier's thumb, and elbow and wrist nerve injuries such as cubital or radial tunnel.

PTs and OTs are key in assisting sports medicine teams' efforts to prevent sports injuries. They work with athletes to increase flexibility, strength, and endurance and teach proper body mechanics and techniques specific to the athlete's sport. Examples of this include teaching in ACL injury prevention programs that focus on learning how to jump safely; providing a program for dancers that focuses on core strengthening, posture, flexibility, and proper technique to reduce injuries such as stress fractures of the spine; or providing a stretching program for tennis players to help prevent medial epicondylitis.

Despite efforts to prevent sports injuries, athletes continue to sustain injuries. PTs and OTs evaluate injuries and use many assessment and screening tools. They assess pain with visual analog scales, soft tissue edema with circumference measurements, and flexibility using tests such as popliteal angle measurements and the Thomas test. Strength is measured by performing manual muscle tests, isometric testing, and using grip dynamometers. PTs and OTs perform provocative tests such as the Lachman test, which assesses the stability of the ACL. Hand and upper extremity OTs will use provocative tests of the hand, such as palpation, the Phalen test, and the scaphoid shift test, to assess instability and fracture healing. PTs and OTs evaluate an athlete's technique, as in throwing, running, dancing, and swinging a bat or a tennis racquet. After a thorough evaluation, the PT or OT formulates a treatment plan or may refer the athlete to a physician for further clinical testing or imaging, such as an X-ray, computed tomography (CT), or magnetic resonance imaging (MRI).

A majority of sports medicine injuries will require follow-up PT or OT care. Early controlled motion or immobilization may be required. OTs/hand therapists are skilled in fabricating splints for immobilization and protection, using proper positioning of ligaments. PTs and OTs teach an athlete how to stretch properly and how to strength train safely and effectively. They use skilled techniques such as joint distraction, joint mobilization, and soft tissue mobilization. Physical agents and modalities may be an adjunct to therapy to decrease swelling, reduce pain, relax muscles, increase blood flow, and provide biofeedback to muscles. Examples of these modalities include therapeutic ultrasound, neuromuscular electrical stimulation, iontophoresis, and kinesiotaping techniques. Therapists provide recommendations regarding braces, splints, foot orthotics, and footwear.

If surgical intervention is required, sports medicine surgeons refer patients to physical and occupational therapy postoperatively. Therapists are knowledgeable in surgical procedures and guide the athlete through the postoperative stages of rehabilitation. The therapy following surgery addresses edema control, pain, wound care, dressing changes, splinting, precautions, crutch training, range of motion, strengthening, gait training, muscle reeducation, and strengthening.

The PT and OT guide the athlete back to his or her sport as safely and quickly as possible. The therapist reevaluates the athlete's flexibility, endurance, and strength. The athlete is asked to participate in functional, sport-specific tests. The therapist uses tools such as isokinetic testing, which provides an objective measurement of muscle strength, endurance, and power. Functional tests such as the hop test and agility test may be indicated. Physical and occupational therapists also provide splints, taping, or other devices that may help the athlete return earlier to sports. These tests and recommendations provide important information for the sports medicine physician as he or she determines when an athlete can return to sports safely.

PTs and OTs are a critical part of the sports medicine team, and one can appreciate how vital their role is in the management of sports-related injuries.

Physical Examination and History

Medical examinations to evaluate any health risks for people considering participation in sports are called *preparticipation examinations* (PPE). The main aim of the PPE is to establish the conditions under which people can safely participate in exercise, bearing in mind their individual medical conditions and the nature of the activities involved. An American Academy of Family Physicians (AAFP) monograph on the PPE was first published in 1992, providing guidance on the content and format of the PPE. The third edition, updated in 2005, is supported by six national medical societies: the AAFP, American Academy of Pediatrics (AAP), American College of Sports Medicine, American Medical Society for Sports Medicine (AMSSM), American Orthopaedic Society for Sports Medicine, and American Osteopathic Academy of Sports Medicine (AOASM).

The PPE is different from normal periodical health examinations and focuses on the issues likely to be encountered during exercise. Physicians vitally interested in the health care of athletes stress the importance of the PPE, which has primary and secondary goals. The primary goals are as follows:

1. To uncover relative or absolute medical contraindications to participation in particular activities: Examples include hypertrophic cardiomyopathy, aortic stenosis, hypertension, and asthma; being aware of the risk of sudden death allows the introduction of protective measures, making sports participation safer.
2. To detect the presence of physical deficiencies and/or medical conditions that predispose individuals to exercise-related disease or injury, with a view to modifying or limiting certain activities.
3. To comply with any legal or sports organization–based requirements: Health care providers should know the legal procedures of their particular countries and the sports involved.

The secondary aims of the PPE are as follows:

1. To review the general state of health of the individual and, where necessary, to introduce provisions to maintain health and safety: Sometimes the PPE is the only contact that the young athletes have with health care professionals.
2. To assess behaviors that cause health risks and evaluate suitability for undertaking exercise.
3. To identify the developmental level of young athletes whose physical development is not yet complete (e.g., the presence of epiphyseal growth plates that have not yet closed) and evaluate the effect of exercise on this development.

Types of Examination

The PPE is generally done in three types of situations: (1) office-based examinations performed by a doctor one-on-one with the athlete; (2) station-based health evaluations done by a multidisciplinary team, including physicians, sports trainers, dieticians, and physical therapists; and (3) line-up examinations. Each approach has advantages and disadvantages.

Office-based examination can be done by the athlete's personal physician. Advantages include an ongoing relationship that makes the discussion of sensitive issues easier and ready access to medical records covering previous injuries and treatment. The disadvantages are low cost-effectiveness, high cost to the athlete, and a generally low level of education about sports medicine among primary care doctors, potentially producing inconsistent advice.

Station-based PPEs can provide extensive screening, involving doctors, nurses, sports trainers, physical therapists, coaches, and/or parents who are experienced in sports medicine and covering the assessment of body composition, elasticity, muscle power, and other physical fitness parameters. They are time- and cost-effective and offer a standardized evaluation for every athlete. Other advantages include providing a database of information for research and a forum for training sports physicians and allied health professionals. However, there are usually no opportunities to discuss personal issues, sensitive medical problems, or individualized advice or to develop relationships with the athletes and, where appropriate, their parents.

Line-up PPEs are time- and cost-effective but offer no privacy and raise concerns about confidentiality. Most sports physicians would not recommend their use. Most primary care providers perform PPEs in their offices. However, it is also common for doctors to participate in school-based mass-screening examination programs. Optimum, station-based PPEs are rarely possible in this situation.

Frequency of Examination

The frequency of the PPE depends on the age of the athlete, the type of sports, the resources of any schools or organizations involved, and the requirements of the country.

The American Heart Association published a consensus proposition about cardiovascular PPE screening in 1996, recommending that this be done before beginning competitive sports in high school or college and biennially thereafter. The American Association of Pediatrics recommends a complete initial evaluation with a brief review at the beginning of each new sports season. Currently, a great many authorities recommend a PPE at the beginning of each new sports season to uncover any new problems and/or assess rehabilitation following old injuries. Other authorities suggest annual screenings.

Enough time should be set aside to diagnose new problems and assess and treat existing ones. However, this time limit for addressing problems should not be too distant from the school time or sports season, when new problems arise. Some authors recommend a PPE at least after 4 weeks and optimally 10 to 12 weeks before the sports season begins, which is enough time to assess the effectiveness of any interventions that are recommended as a result of the PPE. Others recommend PPEs 4 to 6 weeks before the season starts. Summer holidays are a convenient time for athletes attending school.

The PPE not only identifies the risk of harm but also helps individuals undertake measures to reduce this risk. It consists of a history and examination and, occasionally, investigations.

Medical History

The medical history is a very important part of the PPE because it alerts the physician to the athlete's current and past illnesses, medications, injuries, surgical interventions, and so on. A comprehensive history can define 65% to 92% of the problems that affect the athletes. The history should focus on the cardiovascular, neurologic, and musculoskeletal systems, looking for medical or orthopedic problems that could lead to life-threatening or disabling exercise-induced injury or illness. Because occult cardiac disease increases the risk of sudden death, the American Heart Association recommends asking about the following:

- Chest pain or illness with exercise
- Syncope or near syncope
- Unexplained dyspnea or exhaustion with exercise
- Heart murmurs
- Blood pressure
- A history of early and/or sudden death in the family, especially in people below 50 years of age
- Personal or family history of hypertrophic cardiomyopathy, dilated cardiomyopathy, prolonged QT syndrome, Marfan syndrome, or clinically important arrhythmias.

A thorough orthopedic history is a good screening tool, uncovering 92% of the conditions. Important points to be considered are past injuries that allow only limited participation in sports (twists, strains/sprains, dislocations, fractures, and other joint and skeletal problems) and injuries resulting in permanent functional limitation, as well as any treatments to date. It is important to check the neurologic system carefully, inquiring about injuries with loss of consciousness, hospitalization, brain surgery, and temporary paresis and/or paresthesias. Other important areas include past and current medical problems, hospitalizations, allergies, and medications. Women should be questioned about their menstrual cycles (menarche, date of last normal menstrual period, menstrual dysfunction), past pregnancies, and diet.

For all age-groups, it is important to ask about alcohol, tobacco, illicit drug use, and sexuality, and appropriate advice should be given. It is usually appropriate to make follow-up appointments to discuss any sensitive issues that arise.

Different counties may require different components in the history-taking part of the PPE. An ideal history-taking tool would be short, contain the required questions, be comprehensible to the athletes and their families, and contain adequate space to detail any positive responses. Helpful and effective screening tools for physicians have been developed by the AAFP, AAP, AMSSM, and AOASM (Forms 1 and 2 are available at http://www.aafp.org/afp/20000815/765.html). They provide guidance for the physician and the athlete. A form is filled out by the athlete before the PPE; adolescent athletes fill out the forms first, and then their parents revise them. The forms should be completed during the first assessment and updated during subsequent visits. Problem areas uncovered by the form warrant subsequent detailed physical examination.

Physical Examination

The content of the physical examination is, as with the history, primarily determined by the primary aims of the PPE: to define any medical problems that limit participation in exercise and to detect any medical conditions that would predispose an athlete to injury or disease. Therefore, the cardiopulmonary and musculoskeletal systems are key targets for the physical examination.

While physicians should examine all the systems during the physical examination, they should focus attention on any potential problems uncovered during the history. The initial physical examination should be comprehensive; subsequent regular examinations may be more restricted. Different types of exercises call for a focus on different body regions or systems.

Examination begins with measuring height, weight, visual acuity, and blood pressure. Standard height and weight charts should be used for pediatric athletes. Deviation from the norm requires further assessments. Low-weight individuals should be assessed carefully for eating disorders. Visual acuity may be checked using a Snellen chart: Individuals with visual problems are more at risk of harm from contact sports. If the blood pressure is high, the measurement should be repeated.

The cardiovascular examination should concentrate on, but should not be limited to, the following items:

- Auscultation of the precordium, with the patient supine and erect, to detect the continuous murmurs of left ventricle outlet obstruction
- Assessment of the femoral arterial pulses, to exclude coarctation of the aorta
- Looking for the features of Marfan syndrome
- Measuring the brachial blood pressure while seated
- Considering electrocardiogram (EKG), chest X-ray, echocardiogram, and/or stress echocardiogram if there are worrying features in the history or physical examination (i.e., rhythm disorders and murmurs)
- Auscultating the lungs: (If there is exercise-induced bronchospasm, the athlete should be assessed after exercise.)

During the abdominal examination, masses and organomegaly should be ruled out. Male genitourinary system examination is performed to look for cryptorchidism, testicular masses, and Tanner staging in the pediatric age-group. Female pelvic examination is not a routine part of the PPE, but if there are menstrual irregularities, the individual should be encouraged to have an examination by her own doctor.

Musculoskeletal system examination is performed to diagnose any orthopedic or rheumatologic conditions. While it is rare for musculoskeletal problems to make it impossible for an individual to participate in exercise, these are nevertheless common problems that require further evaluation. Previous injuries require repeated assessment. During the musculoskeletal examination, check for symmetry of the upper and lower extremities and trunk, cervical spine mobility, muscle strength and joint flexibility in the areas that are important for the exercise program being considered, and the curvature of the thoracic and lumbosacral spine and the range of spinal movements. Anatomical anomalies and decreased ranges of movement require further examination. Neurological examination is a part of the PPE.

Routine Screening Tests

Routine laboratory tests are not recommended for young athletes. However, abnormalities uncovered during the history or physical examination may require laboratory, radiography, or other diagnostic tests. If athletes request a simultaneous general screening examination, appropriate screening tests will be dictated by their age, sex, family history, and general health.

Cardiovascular tests are not recommended unless there are clinical indications. If there is a family history of early atherosclerotic heart disease, athletes should have a lipid profile taken. A family history of sudden cardiac death should prompt assessment for conditions such as congenital prolonged QT syndrome and Brugada syndrome. Some authors recommend pulmonary and cardiovascular screening with chest X-ray, EKG, and echocardiogram to look for anomalies that can lead to sudden death. Others claim that such screening is unnecessary unless there are worrying features in the history and physical examination.

Consent for Participation

At the end of the PPE, physicians must make a decision about participation in exercise, taking into account the type(s) of sports, findings of the history and examination, and results of any investigations. Consent for participation can be granted if the answer is "no" to all the following questions:

- Is there an increased risk of mortality or morbidity?
- Is there a risk to other athletes?
- Is further evaluation, treatment, and/or rehabilitation required?

If problems prohibit full participation, consider whether the athlete could participate in restricted activities.

Physically and Mentally Challenged Athletes

Individuals with physical and intellectual disabilities regularly compete in sports alongside athletes with and without similar disabilities. This entry outlines the benefits of sports and exercise for individuals with disabilities and provides information on participation levels, barriers, special considerations, and program design. The discussion is intentionally broad because individuals with disabilities represent a heterogeneous population and each individual has his or her own unique needs. This entry provides general guidelines that could assist coaches, fitness instructors, health professionals, and teachers in implementing and/or supporting a program that would include individuals of all abilities. This entry also focuses on both sports *and* exercise for individuals with disabilities, with an emphasis on participation in community programs for recreation and health.

Defining Disability

The World Health Organization states that

> disabilities is an umbrella term, covering impairments, activity limitations, and participation restrictions. Impairment is a problem in body function or structure; an activity limitation is a difficulty encountered by an individual in executing a task or action; while a participation restriction is a problem experienced by an individual in involvement in life situations. Thus disability is a complex phenomenon, reflecting an interaction between features of a person's body and features of the society in which he or she lives. (http://www.who.int/topics/disabilities/en)

There is no universal agreement on the definition of the term *disability,* but the shift from a medical model of disability to the social model has been widely accepted. This means that people's physical, cognitive, or sensory limitations are no longer the center point of disability; rather, it is the interaction of their functional status with their environment. If an environment is free of physical and attitudinal barriers and offers appropriate support to accommodate people of all abilities, then a person with a disability can fully participate in all aspects of society. This includes involvement in competitive and recreational sport.

Prevalence rates of disability vary radically around the world, in part because surveys and data collection methods differ. The lack of a standard definition of disability as well as comorbidities and multiple pathologies contribute to the uncertainty of current prevalence estimates. Rates have ranged from less than 1% to 20% of a nation's population, and the United Nations estimates that disabilities are prevalent in 10% of the world's population.

Participation in Sports and Exercise

Sports for People With Disabilities

Individuals with physical and intellectual disabilities have excelled in competitive and recreational sports for many years. An athlete with a disability may elect to engage in inclusive sports alongside nondisabled individuals (i.e., regular sports) or in adapted sports alongside other individuals with similar disabilities (i.e., disability sports). Opportunities for athletes with disabilities to compete at an elite level and to achieve athletic excellence are often within disability sports, such as the Paralympics. However, athletes with disabilities have also competed at the highest level of regular sports. Jim Abbot (Major League Baseball pitcher from 1989 to 1998) and Casey Martin (former golfer on the PGA tour and member of the 1994 National Collegiate Athletic Association Championship golf team) are just two examples of high-performance athletes with disabilities.

There are a number of international organizations that govern sports programming for athletes with disabilities, including Cerebral Palsy–International Sports and Recreation Association, International Blind Sports Association, International Committee on Silent Sports, and Stoke Mandeville Wheelchair Sports Federation. The International Paralympic Committee is the governing body of the Paralympic Movement, which was initiated by Sir Ludwig Guttman. Guttman was the first to recognize the therapeutic benefit of competitive sport in the lives of people with physical disabilities, and he organized the Stoke Mandeville Games for World War II veterans with a spinal cord injury in 1948. The first organized Olympic-style games for individuals with disabilities followed in Rome in 1960, where 400 athletes competed. A total of 3,951 athletes from 146 countries competed in the 2008 Paralympic Games in Beijing, a notable increase from 3,806 athletes in Athens just 4 years earlier. The Paralympics are elite sports events for athletes from six different disability groups: amputee, cerebral palsy, visual impairment, spinal cord injuries, intellectual disability, and les autres ("the others"). There are 27 summer and winter sports in the Paralympics, some of which are sports designed specifically for athletes with disabilities, such as goalball, wheelchair basketball, wheelchair rugby, ice sledge hockey, and sitting volleyball. Each sport has a classification system, and athletes are allotted a class defined by the degree of function presented by their disability.

Special Olympics is an international organization that offers sports training and competition to

2.5 million athletes with intellectual disabilities around the world. The movement was initiated by Eunice Kennedy Shriver, who believed that people with intellectual disabilities should be afforded the same opportunities as others and that sports could be an avenue for self-actualization. In 1968, the first International Special Olympics Games took place in Chicago, with 1,000 athletes from the United States and Canada. According to its Mission Statement, Special Olympics aims to give children and adults with intellectual disabilities the opportunity to "develop physical fitness, demonstrate courage, experience joy and participate in a sharing of gifts, skills and friendship." There are training and competition opportunities in 30 Olympic-type sports, and athletes participate in local, regional, national, and international events. Athletes are classified according to age, gender, and ability and compete against others of similar ability in equitable divisions. The 2007 Special Olympics World Summer Games were held in Shanghai, where approximately 7,500 athletes representing 165 countries competed in 25 sports. The most recent Winter Games were held in Nagano, where more than 1,800 athletes from 80 countries competed in 7 sports.

Exercise/Physical Activity for People With Disabilities

As is true with the general population, most individuals with physical and intellectual disabilities do not possess the skills required to compete at an elite level. However, all are able to benefit from participation in exercise and sports programs. Recreational opportunities including intramural programs, community sports teams, fitness classes, and physical education can generally accommodate people of all abilities and should be emphasized in health promotion efforts. Research indicates that children and adults with disabilities do not engage in adequate physical activity and spend considerable time in sedentary pursuits such as watching television. In the United States, for example, 37.7% of adults with a disability reported meeting the recommended levels of physical activity in 2005 versus 49.4% of adults without a disability. The prevalence of persons with a disability who met the recommendations ranged from 23.2% to 53.3%. Significantly more adults with a disability (25.6%) also reported being physically inactive during a typical week than nondisabled adults (12.8%). Low levels of physical activity contribute to the higher incidence of overweight and obesity, coronary heart disease, and poor fitness levels observed in people with physical and intellectual disabilities.

Benefits of Involvement in Sports and Exercise

The benefits of regular exercise for health and functioning in general populations are well established and include reduced risk of coronary heart disease, hypertension, obesity, osteoporosis, and different types of cancer. Benefits also include increased emotional well-being, self-confidence, body awareness, and reduced levels of stress and depression. Participation in sports offers additional benefits such as developing sportsmanship, as well as opportunities for team building, competition, and socialization. Individuals with physical and intellectual disabilities derive these same benefits from exercise and sports, and their participation may be even more important. Regular exercise reduces the risk for some secondary disabling conditions, such as obesity, joint contractures, and diabetes, which could exacerbate the problems of a primary disability. Furthermore, regular exercise improves function, which can increase independence in activities of daily living, recreational pursuits, and professional tasks and reduce the need for assistance. Sports provide children and adults with disabilities an outlet for "normalization" and are an excellent means to facilitate inclusion. Sports programs for individuals with disabilities can be for the purpose of education, leisure, health and wellness, elite competition, and/or therapy, but an important objective is to maximize self-actualization.

Correlates of Sports and Exercise

The factors associated with exercise participation by people without disabilities have been studied extensively and are generally consistent. However, little is known about why people with disabilities do, or do not, engage in regular exercise and sports. There is a need to better understand the factors that support and impede the ability of people with disabilities to exercise and to participate in sports.

Barriers

The barriers to exercise participation faced by people with physical disabilities include a variety of personal and environmental variables. Cost of programs and services, no means of transportation, no knowledge of where to exercise, and no knowledge of how to exercise are frequently reported barriers to participation among people with physical disabilities. Low exercise self-efficacy, lack of time, low energy/motivation, and concerns associated with health are also common. The barriers encountered by people with physical disabilities that are unique and do not typically apply to the general population include inaccessible exercise facilities, lack of adapted equipment, untrained coaches/instructors, and overprotection by care providers and health professionals.

Individuals with intellectual disabilities have reported that the cost of programs, the weather, time limitations, and limited transportation restrict opportunities to participate in exercise and sports. Lack of energy, feeling that exercise is boring, concerns about health, and having no one to teach them to exercise are also barriers faced by people with intellectual disabilities. Unlike the general population, inaccessible facilities, lack of guidance, fear of injury, and negative influences by care providers are obstacles reported by this group.

Facilitators

Information about the factors that promote exercise participation among individuals with disabilities is scarce. Most of the work in this area has focused on athletes and their motivations for competing in sports. For example, athletes with intellectual disabilities who participate in Special Olympics training and competition report being motivated by winning ribbons, having fun, and making new friends. Adults with physical disabilities have noted that an accessible built environment (e.g., parking spaces, ramps, automatic doors), availability of adapted equipment, trained and motivated coaches/instructors, and opportunities to try programs to determine their comfort level would facilitate engagement in exercise and sports.

Special Considerations for Participation

Individuals with disabilities respond to exercise and sports training with improved performance and capacity. They are equally able to adapt to increased levels of intensity through enhanced fitness and progressive development of motor skills. That being said, it may be necessary to modify the components of a sport or exercise to accommodate functional limitations such as low strength, balance, speed, endurance, or range of motion. The cognitive, behavioral, motor, and/or communication deficits associated specifically with intellectual disabilities may also require that an activity be adapted so that an individual can be successful and a training effect achieved. A few considerations for coaches and fitness professionals to promote safe participation of people with disabilities in sports and exercise are highlighted below. These examples are not meant to be exhaustive but only provide insight into some exercise-related conditions. Practitioners are encouraged to get to know each person individually and to understand his or her strengths and limitations in order to meet his or her unique needs.

Individuals With Physical Disabilities

Individuals with spinal cord injuries often have impairment in the autonomic and sensory nervous systems. As a result, normal thermoregulatory function is altered, leading to problems with hyper- and hypothermia. This is particularly true for individuals with injuries above T6 (i.e., the sixth thoracic segment). Hypotension (low blood pressure) may also be a consequence of disruption in the sympathetic nervous system and results from blood pooling in the legs and reduced venous return. Autonomic dysreflexia, a dangerously rapid increase in heart rate and blood pressure with associated anxiety, headache, and profuse sweating, is also a risk for individuals with spinal cord injuries above T6. This can arise from bowel or bladder distension, skin irritation, urinary tract infection, and other pain stimuli. Some of these conditions are seen in people with spina bifida and cerebral palsy, who can also experience seizures, spasticity, contractures, hydrocephalus (spina bifida), and obesity. Taking care to include appropriate warm-up and cooldown, avoiding exercise in extreme temperatures, encouraging proper clothing to retain or dissipate heat, and exercising in a reclined position (e.g., the recumbent bicycle) are appropriate precautions for some of these conditions.

The incidence of injury in wheelchair athletes is low, and injuries are generally minor. Abrasions, skin lacerations, and soft tissue contusions make up the majority of injuries, although fractures and dislocations in the upper body are also reported. Overuse injuries such as tendinitis in the shoulder, wrist, and hands may occur in wheelchair athletes and should be taken into account by coaches/instructors.

Individuals With Intellectual Disabilities

There is no evidence that athletes with intellectual disabilities are at greater risk for injury during sports than those without disabilities. As long as coaches/instructors offer precise instruction, planned opportunities for practice, and additional supervision as needed, children and adults with intellectual disabilities can safely engage in exercise and sports. However, individuals with intellectual disabilities may have limited attention, reduced ability to retain information, impulsivity, and limited motivation, which will have to be considered in programming to ensure that athletes understand safe practices. Overweight and obesity, diabetes, seizure disorders, and vision problems also need to be managed in order to reduce the risk of sports-related injuries.

Down syndrome is a genetic condition associated with intellectual disabilities that requires special consideration for exercise and sports. There are several medical problems commonly associated with Down syndrome that may warrant medical clearance prior to participation, as well as careful programming. Specifically, muscle hypotonia (low tone) and associated hypermobility of the joints often cause orthopedic impairments such as atlantoaxial instability, lordosis, and dislocation of the joints. Individuals with Down syndrome also may have poor vision and hearing and impaired balance, which must be taken into account. Approximately 40% of individuals with Down syndrome develop congenital heart disease. Heart rate monitoring to estimate exercise intensity in people with Down syndrome may be misleading since resting heart rate is unusually low and heart rate often rises quickly at the onset of exercise.

Program Design and Organization

It is important to emphasize that people with disabilities can safely participate in vigorous exercise and sports. It may be necessary to adapt an activity to accommodate a person's functional limitations, but this can easily be accomplished through creativity and simple problem solving. Variations to rules, equipment, playing area, scoring, or organization, for example, can level the playing field for an individual with a disability without fundamentally altering the competitive nature of an activity. The steps involved in planning, implementing, and sustaining community sports programs for children and adults with disabilities are similar to those for general programs, although there are some additional factors that warrant consideration. In particular, many of the barriers to participation can be eliminated with good decision making at each step.

An important consideration for sports participation among individuals with disabilities is whether they will compete in regular sports or disability sports. The inclusion of people with disabilities in community sports programs (i.e., regular sports) should be a priority since the benefits of inclusion are clear. That being said, athletes with disabilities should have a continuum of opportunities available to them and should exercise their right to choose the environment that allows for optimal performance. An awareness of policies and legislation that promote inclusion and prevent discrimination of people with disabilities is important in community sports programming. For example, the Americans with Disabilities Act and the Canadian Charter of Rights and Freedoms have implications that encourage participation by individuals of all abilities and restrict prejudice. Some key components of community sports programs (not elite sports) for athletes with disabilities that can be useful either for inclusive opportunities or for disability sports are outlined below.

Program Planning

Accessibility of the Environment. The facility selected for a sports program should be physically accessible (e.g., ramps, automatic doors), which also includes availability of adapted equipment as well as access to transportation (accessible parking spots and/or public transportation).

Knowledge of the Athlete. Getting to know the individual athlete is critical since functional level varies significantly even within the same diagnosis. Understanding an athlete's strengths, limitations, previous experience, and motivation is a good place to start.

Coach/Instructor Training. Personnel should be educated about disabilities as well as inclusion strategies, activity/sport modifications, and safety procedures. This training can be provided by people with varied expertise, including athletes with disabilities, adapted physical activity specialists, families, physicians, and physical therapists.

Preparticipation Screening. Athletes with disabilities should be encouraged to undergo a general medical examination prior to participation in vigorous exercise or sports. This screening will help ensure that athletes are not at risk and may also reduce potential overprotection by families and coaches. Consent and/or waiver forms may also be important, with adjustments made to ensure understanding by athletes with intellectual disabilities.

Establish Trust. For full participation, it is important that trust be established between an athlete and a coach/instructor. Trust can be achieved in several ways, including providing opportunities to observe an activity prior to participation, creating a welcoming and nonthreatening environment, and giving a person control over his or her own participation through offering choices (e.g., on type of activity, the nature of modification to an activity, the extent and type of assistance needed, and equipment).

Program Implementation

Modify Sports. Be prepared to adapt the elements of a sport in order to promote success. Elements that can be easily modified include equipment, playing area, rules, players and positions, game speed, scoring, and organization. When including athletes with disabilities in regular sports, the aim is not to give them an unfair advantage but to level the playing field. One of the best examples of accommodating people of all abilities in sports is the handicap in golf.

Support. Participation in a sports program often partly depends on social support from peers, families, and/or care providers; physical support in the form of adapted equipment and accessible facilities; and instructional support from trained professionals. Providing the appropriate type and amount of support can improve self-efficacy, which is directly related to participation.

Health Limitations. Ensure that coaches/instructors are educated about the health limitations of athletes and any activities that are contraindicative. Coaches should also be trained on general safety procedures.

Program Sustainability

Evaluation. Ongoing evaluation of program priorities, skill development, and fitness is important to ensure that goals are being met. There are valid test batteries to objectively measure health-related fitness in athletes with physical and intellectual disabilities. The biomechanics of sports performance can also be examined, although this may be appropriate for high-performance athletes, where precise form is critical.

Independence. Independent participation in sports and exercise over the life span is generally the goal of community programs. It is important to involve these athletes in decisions about their participation and to teach them mastery of the functional skills that will allow for their inclusion in community-based and home-based activities with family and friends.

Continued Training. Ongoing training of coaches/instructors is important to ensure that they have up-to-date information on instructional strategies, activity/sport modification techniques, health issues, and assessment methods.

Conclusion

Participation in exercise and sports is highly beneficial for individuals with disabilities and should be encouraged. People with disabilities may face additional barriers to participation in exercise and sports because of limitations in physical, cognitive, and/or behavioral functioning, but the impact of barriers can be easily mitigated through good program design. As long as coaches/instructors, administrators, families, and health professionals are well-informed and are prepared to meet the unique needs of people with disabilities, their successful inclusion in exercise and sports programs can be realized.

Physiological Effects of Exercise on Cardiopulmonary System

In exercise physiology, it is a long-held belief that cardiopulmonary fitness is the foundation of an individual's exercise capacity. Indeed, improved fitness and performance with training are in part the product of an increased capacity to supply exercising muscle with oxygen and nutrients owing to adaptations of the cardiorespiratory system. However, other significant changes in exercising muscle can result in a reduction of required cardiorespiratory effort at a given level of exercise. These adaptations are discussed in the following sections of this entry.

Cardiovascular Effects

At the onset of exercise, heart rate and stroke volume both increase, resulting in an increase in cardiac output (the amount of blood pumped through the heart in 1 minute, usually expressed in units of liters [L] per minute) and increased systemic blood supply. Over time, the body accommodates to the stress of chronic exercise by improving stroke volume (the volume of blood pumped with each contraction of the heart), which translates into improved cardiac output. Several factors combine to produce this increased stroke volume.

1. *Lower resting heart rate as well lower heart rate at a given exercise workload:* This allows increased time for the heart to fill with blood, thus increasing the amount of blood that can be pumped back out of the heart. For endurance athletes, the heart rate is often bradycardic, or less than the 50 to 55 beats/minute (bpm) considered the lower limit of "normal." The mechanism of the observed heart rate reduction appears to be reduced sympathoadrenal system activation as well as a decline in the withdrawal of vagal nerve activity during the same level of exercise in the trained versus untrained subject. The mechanistic pathway for these changes in neural stimulation remains unclear.
2. *Increased blood volume:* Blood volume in a trained individual is about 15% higher than in an untrained individual. Interestingly, this adaptation occurs very rapidly, resulting in improved exercise capacity after only a week of training. Unfortunately, it also disappears quickly, after only days of inactivity.
3. *Cardiovascular hypertrophy:* Hypertrophy is the increase in *size* of the heart muscle fibers, not an increase in the *number* of fibers. This change is evident on electrocardiogram (EKG) as well as imaging (chest X-ray, echocardiography, etc.). With exercise, hypertrophy is eccentric. This means that the volume of the ventricle increases substantially, resulting in an increase in the volume of the lumen of the chambers of the heart, while the increase in the thickness of the wall of the heart chambers is relatively minor. Hypertrophy is most evident in the left ventricle. The consequence of a larger pump is the ability to pump more blood. The eccentric hypertrophy that occurs with chronic exercise is in contrast to the concentric hypertrophy seen when the heart does more work in the setting of systemic hypertension. In hypertension, although the heart works harder, the lumen does not increase in size and the heart rate does not drop.
4. *Of note, when the heart hypertrophies, the number of capillaries and mitochondria in the heart muscle increases.* However, the *density* of the mitochondria and capillaries in the heart remains unchanged. This is in contrast to the skeletal muscle adaptations in which the density of both capillaries and mitochondria is increased. There is also no change in an individual's maximal heart rate with training. In fact, it tends to decrease slightly.

The net effect of these changes is a reduction in cardiac work over time. During exercise, clearly the heart is working harder than at rest; however, this increased work is relatively short term. For example, let's assume that an individual's untrained pre-exercise resting heart rate is 70 bpm. This individual then begins a fitness program and exercises daily with a heart rate of 140 (roughly 70% of the maximum heart rate for a 30-year-old) for 1 hour, and with training, the individual's baseline heart rate drops to 55 bpm. Over the course of a day, this will reduce the number of times the trained heart beats by 16,500 beats (see the calculations below). Thus, over time, the trained heart will work much less than the sedentary heart.

Pulmonary Effects

Respiratory output increases with exercise due to increased tidal volume and increased respiratory rate. There is also recruitment of areas of lung that are underperfused and/or underventilated at rest. These changes combine to allow the greater volume of blood moving through the lungs to continue to undergo efficient gas exchange.

Most sources suggest that there is no fundamental change in pulmonary function following a period of fitness training. For example, total lung capacity, FEV_1 (forced expiratory volume in the first second after full inspiration), and tidal volume all remain unchanged despite improved fitness. It is notable, however, that respiratory muscles undergo significant fatigue during both brief intense exercise and prolonged endurance events. While general exercise training improves respiratory muscle strength, specific focused strength training of the respiratory muscles with a respiratory trainer results in significant further gains in respiratory muscle strength. This in turn is associated with reduced dyspnea (the perception of shortness of breath) and has been linked with improved performance, even in highly trained athletes. Although at the end of the exercise most athletes have a breathing reserve by physiological measurements, these measurements do not capture the impaired ability to move air in and out of the lung that develops with respiratory muscle fatigue, and thus respiratory limitations likely remain an underappreciated cause of reduced exercise performance.

Peripheral Adaptations

As mentioned above, some of the apparent improvement in cardiopulmonary capacity is not a result of changes *within* the heart and lungs but instead is the consequence of peripheral, systemic adaptations that allow for more efficient supply and utilization of oxygen and nutrients. Single-leg training studies are very interesting in this regard. There are numerous studies in which fitness is determined in each leg pretraining using objective parameters such as anaerobic threshold, $\dot{V}O_2max$ (peak oxygen uptake), or heart rate at a given work rate as well as metabolic data and even muscle biopsy evaluation. Then a single leg is trained, usually through unilateral cycling, and postexercise parameters are compared. These data suggest that *some* but *not all* of the training effects seen in the trained leg are "transferred" and also seen in the untrained leg. There are several noncardiac systemic explanations for this transference, including the following:

1. *Increased blood volume:* As noted above, increased blood volume is an important factor in increasing stroke volume.
2. *Increased red blood cells:* The increase in red cells does not quite keep pace with the increase in blood volume; consequently, hematocrit (the volume of red cells per volume of whole blood) will be slightly reduced with training.

A component of exercise adaptation also occurs at the level of exercising muscle and is unique to the muscle trained. With training, peripheral changes include the following:

1. Increased numbers of mitochondria in the exercising muscle
2. Increased size of mitochondria in the exercising muscle
3. Formation of new capillaries within muscle (more and larger mitochondria coupled with increased capillary density, resulting in less distance for diffusion of oxygen and nutrients into the exercising muscle)
4. Increase in anaerobic work capacity by increasing the enzymes of anabolic metabolism
5. Increased ability to metabolize fatty acids for energy, which results in sparing of glycogen stores
6. Increased muscle glycogen stores
7. Enhanced local vascular control, allowing for increased blood supply to the exercising muscle
8. Reduced lactic acid production for a given level of exercise and tolerance for higher blood lactate level at the end of exercise

The net effect of these noncardiac adaptations is to spare glucose/glycogen through increased fatty acid utilization and improved anaerobic metabolic capacity, as well as to enhance oxygen delivery to and uptake by the exercising muscle. By maximizing the metabolism of alternate energy sources, aerobic metabolism is spared, and both the anaerobic threshold and the maximal oxygen uptake are enhanced. This reduces the cardiopulmonary work required to maintain a given level of exercise in the trained individual.

The calculation is as follows:

Untrained heartbeats = 70 bpm × 24 hours/day × 60 minutes/hour = 100,800 beats/day

Trained heartbeats = 55 bpm × 23 hours/day × 60 minutes/hour + 140 bpm × 1 hour × 60 minutes/hour = 84,300 beats/day

Untrained heartbeats – Trained heartbeats = 100,800 – 84,300 = 16,500 beats/day.

Clearly, this calculation is just an estimate for the purpose of illustration, since heart rate is not a constant but vacillates throughout the day in response to various stimuli. However, given that the trained heart rate will not climb as high with activities of daily living, this calculation likely underestimates the overall reduction in daily heartbeats.

Piriformis Syndrome

Piriformis syndrome is one of the many causes of leg and buttock pain. In piriformis syndrome, the symptoms result from irritation of the sciatic nerve as it passes over, under, or through the piriformis muscle. Pressure on the nerve can lead to pain in the low back, buttock, groin, or posterior thigh, and it can be a cause of *sciatica,* with pain, tingling, or numbness along the course of the sciatic nerve. Other nerves and structures in the area may also be impinged (compressed), leading to similar symptoms.

Anatomy

The piriformis is a triangle-shaped gluteal (buttock) muscle. The base of the triangle attaches to the tail bone (sacrum). At the opposite end, the muscle attaches to the side of the upper thighbone (femur). The muscle also passes through an area of the pelvic bone called the greater sciatic foramen. The piriformis muscle is important in turning the hip out and moving the leg away from the center of the body.

The sciatic nerve is a very large nerve, important for both movement and sensation. The sciatic nerve supplies much of the skin of the leg, as well as the muscles of the back of the thigh, the leg, and the foot. It is formed from branches of the lumbar and sacral nerve roots (L4, L5, S1, S2, and S3). The nerve travels from the lower back, out of the pelvis, into the buttock, and down the back of the thigh, where it divides at the knee into the tibial and common peroneal nerves.

Because of the close proximity of the piriformis muscle and sciatic nerve, irritation and pain can develop. In some individuals, the exact location of the sciatic nerve and the structure of the piriformis muscle increase the risk of piriformis syndrome, and activities that require repeated hip motion also increase the risk. In up to 15% of cases, the sciatic nerve travels through the piriformis muscle.

Causes

Piriformis syndrome is due to entrapment and irritation of the sciatic nerve. Depending on the individual anatomy, the sciatic nerve can be compressed as it passes between the piriformis muscle and the bone of the sciatic notch, or through the muscle itself. Irritation of the nerve is more likely to occur if there is an abnormality of the piriformis, such as hypertrophy (enlargement of the muscle), inflammation, scarring, or spasm. These abnormalities can result from overuse, trauma to the area, or excessive pressure (e.g., prolonged sitting on a large wallet, or constriction by a tight, low-fitting waistband). In athletes, piriformis syndrome can also be seen following activities that cause repetitive hip rotation and extension, such as running and climbing.

Symptoms

Piriformis syndrome most commonly leads to dull aching pain in the buttock with or without radiation to the back of the thigh, knee, and calf. Numbness is rare, but tingling has been described in all five toes rather than along the path of an individual nerve. The symptoms tend to worsen with prolonged sitting or lying on the back and improve with standing and walking. Walking upstairs or uphill can be particularly painful. Activities that stretch the piriformis, such as rotating the hip and moving the upper leg, can also make the symptoms worse. Both bending and extending the hip may increase the symptoms. Also, because of the position of the piriformis close to the pelvic wall, some patients may develop pelvic pain.

Diagnosis

On physical exam, patients often have tenderness when pressure is placed on the piriformis muscle, either in the belly of the muscle or at the attachment to bone. Patients may also have tenderness to palpation of the sciatic notch and at the greater trochanter of the femur, where the muscle attaches.

A positive piriformis sign has been described in which the patient tries to avoid discomfort by keeping the leg in a slightly raised and externally rotated position when lying on the back. Other clinical tests include the Freiberg sign, which involves reproduction of the pain with passive internal rotation of the hip with the leg in an extended position, and the Pace sign, which is pain with resisted abduction and external rotation of the hip in a flexed position.

Gluteal muscle wasting (atrophy) may also be seen with long-standing nerve entrapment, especially of the peritoneal branch of the sciatic nerve.

Because the symptoms of piriformis syndrome overlap with those of many other conditions, it may be difficult to make the diagnosis. Other, more common causes of buttock pain and leg pain—such as muscle strain, sacroiliac joint irritation, and hip pathology—as well as other causes of sciatica—such as disk pathology and spinal stenosis—must be ruled out. Patients with lumbosacral radiculopathy—pain that radiates into the buttock and leg due to problems at the spine—often have pain with a straight leg raise test, whereas in piriformis syndrome, this test is typically negative. In addition, if tingling into the toes is noted with piriformis syndrome, it tends to be in all five toes rather than along the course of any one particular nerve.

Imaging studies can be useful in making the diagnosis of piriformis syndrome. Plain X-rays are typically normal. Magnetic resonance imaging (MRI) can be used to rule out other possible causes of the symptoms and can show anatomical variation or changes in the piriformis muscle that increase the risk of piriformis syndrome. Magnetic resonance neurography, which can be used to obtain images of nerves, can demonstrate swelling or other changes around the sciatic nerve to support the diagnosis. Electromyography, which records the electrical activity of muscles, may be helpful, but a negative test does not rule out the diagnosis.

Treatment

Many cases of piriformis syndrome can be successfully treated with conservative measures, which include rest from those activities that exacerbate the symptoms, oral anti-inflammatories, muscle relaxants, and physical therapy for gradual piriformis stretching. Strengthening of the piriformis and other gluteal muscles can also be beneficial. Additional treatment with ultrasound, electrical stimulation, heat, and ice has also been used with success.

If symptoms persist, trigger point injections or steroid injections, generally performed with imaging guidance, may provide relief. Use of Botox (botulinum toxin A) has also been described for treating persistent piriformis syndrome. Acupuncture can help reduce symptoms in some patients. These act to reduce pain, swelling, and/or spasm in the area of nerve compression.

If nonoperative treatment fails, surgical exploration and decompression of the nerve can address the problem. Several surgical options are available, including resection of portions of the piriformis muscle, release of muscular bands or scar tissue, and sciatic neuroplasty (surgical repair of the nerve).

Plantar Fasciitis and Heel Spurs

Plantar fasciitis is an injury to the plantar fascia (the fibrous membrane on the bottom of the foot) that causes heel pain. It is the most common cause of heel pain in adults. The pain is usually at its worst when taking the first few steps in the morning or after prolonged periods of activity. Plantar fasciitis is sometimes referred to as having a heel spur (deposit of bone off the calcaneus). A heel spur is a deposit of calcium in the plantar fascia that can be seen on radiographs. The presence of a heel spur does not have diagnostic value, as there is no correlation between a heel spur and heel pain. Plantar fasciitis is commonly seen in middle-aged women, young male runners, and military personnel.

Anatomy

The plantar fascia is a sheetlike membrane that helps form the arch of the foot. It originates at the medial tubercle of the calcaneus (heel bone) and forms the longitudinal arch of the foot, before attaching to the plantar aspect of the metatarsals (toes). It functions to support the arch of the foot and acts as a shock absorber during running and walking.

Causes

When the plantar fascia is overstressed, microtears can develop. Plantar fasciitis occurs when microtear formation exceeds the body's ability to repair the damage. These microtears cause a degradation of the collagen structure of the plantar fascia. The plantar fascia is put under stress and stretched with every step, therefore making it difficult for the body to repair the tear before the injury recurs. Many who suffer from plantar fasciitis do not have any evidence of bony spurs on radiographs; however, in some people, a heel spur forms as a reaction to the inflammation. The spur is not the source of the pain felt in plantar fasciitis. In fact, 15% to 25% of the population has an asymptomatic heel spur (Figure 1).

Commonly, plantar fasciitis is seen, as noted earlier, in middle-aged women, young male runners, and military personnel, but can it develop in anyone, especially those who spend a lot of time on their feet, walking on hard surfaces. Risk factors for developing plantar fasciitis include obesity, overtraining, a tight Achilles tendon, wearing shoes that lack support, overpronating when walking, pes planus (flat feet), pes cavus (high arches), ankylosing spondylitis, psoriatic arthritis, or Reiter syndrome.

Symptoms

Plantar fasciitis causes heel pain on the bottom of the foot while standing, walking, or running. Many will report having their worst pain with their first steps out of bed in the morning. The pain is usually severe at the beginning of activity but decreases after warming up. The pain then returns with prolonged activity or standing, and one may experience a throbbing or burning pain for a period of time immediately after activity has ended. Plantar fasciitis typically does not cause pain at rest but can be painful if someone applies pressure or presses firmly on the heel.

Diagnosis

History and physical exam are the best tools to diagnose plantar fasciitis. On examination, the area of maximal tenderness is usually the anterior-medial portion of the calcaneus (heel bone). A tight Achilles tendon, pes cavus, or pes planus are also diagnostic clues. Nocturnal pain is generally not a symptom of plantar fasciitis and should prompt further investigation as it could be a sign of something more serious, such as infection or a tumor. Radiographs generally are not necessary unless there is a concerning symptom from the history, such as night pain.

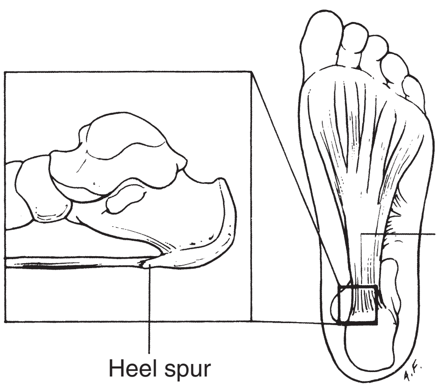

Figure 1 Plantar Fasciitis

Note: Persistent inflammation increases the possibility that a bone spur will develop where the plantar fascia attaches to the calcaneus.

Treatment

In general, plantar fasciitis improves without surgical intervention. Most see resolution of their symptoms in 6 to 8 weeks; however, plantar fasciitis can linger for up to 6 to 18 months or longer. It is especially difficult to cure those who are unable or unwilling to take time off to rest. Treatment started within the first 6 weeks from the onset of symptoms will hasten recovery.

The majority diagnosed with plantar fasciitis will find relief from very basic treatments, including rest, appropriate shoes, avoiding barefoot walking, ice application, nonsteroidal anti-inflammatory drugs (NSAIDs), and stretching. Stopping all activities that involve impact (or cause pain) is sometimes difficult to enforce in athletic patients. Not listening to this recommendation will slow recovery. Decreasing the amount of activity (i.e., the number of miles run per day) to allow symptoms to resolve and then increasing by approximately 10% per week will help avoid re-aggravating the injury once healed.

Proper support for the foot is very important, and shoes with proper fit and an adequate amount of heel cushioning should be worn at all times. Avoid wearing sandals or other shoes where the foot is not adequately supported. For serious athletes, it is recommended to get new shoes every 3 months or 500 miles (mi; 1 mi = 1.61 kilometers). Orthotics can be used for additional cushioning and support. Prefabricated orthotics are as effective as custom-made orthotics and are much cheaper. Three-quarter length or full-length orthotics are more effective than heel cups in treating plantar fasciitis.

Applying ice to the heel at the end of a long day or after exercise can be helpful for pain relief. Place the heel of the foot in an ice bath for 10 to 15 minutes or on a bag of ice for 20 minutes, or roll the heel over a frozen water bottle for 10 to 15 minutes. It is recommended to use ice two to three times per day. NSAIDs can be used acutely to help relieve pain. There is an associated risk of gastrointestinal bleeding or renal damage with chronic use of NSAIDs; thus, this class of medications is not an ideal long-term solution.

Poor flexibility in the Achilles, gastrocnemius (calf), and foot muscles can contribute to plantar fasciitis. Performing stretching exercises can help correct this problem. Stretching the calf and Achilles (by leaning against a wall or using a step) and pulling the toes back toward the shin until a stretch is felt in the plantar fascia are two of the more common stretches prescribed. Stretching before getting out of bed in the morning can help decrease the pain felt with the first steps each day.

Night splints are traditionally reserved for those who fail to obtain relief from conservative treatments. Using them involves placing the foot in a flexed position overnight by wearing a splint or a brace, in the hope that the microtears will heal at their maximum length instead of being restretched (and retorn) each morning. The disadvantages of night splints include discomfort and interference with sleep.

Injection of steroids into the heel can be done to reduce inflammation and has been shown to provide some relief. It is reserved for those who fail conservative treatments, because there are associated risks with this procedure, it can be very painful, and the pain relief may only last 4 weeks. Complications of steroid injection include fat pad atrophy, osteomyelitis (infection of the bone), nerve damage, and rupture of the plantar fascia. Some physicians will use ultrasound guidance to help reduce the risk of these complications. Giving multiple injections increases the risk of these side effects.

Extracorporeal shock wave therapy (ESWT) is generally reserved for cases of plantar fasciitis that have failed other treatment options. ESWT is one of the final treatment options before having to resort to surgery. ESWT uses a probe to focus high-energy shock waves at the area of pain. The shock waves have approximately 1,000 times the potency of an ultrasound wave. The treatment is very painful; however, it has been shown to have good long-term results in some studies.

Surgical intervention is only recommended when symptoms are not relieved after 12 months or more of treatment. A plantar fasciotomy or release of the plantar fascia can be performed through an incision or with the help of an arthroscopic camera. Up to 30% of people who undergo surgery will still have pain or activity restrictions after the surgery. Generally, the time taken for return to normal activity after the surgery is approximately 4 to 8 months. Risks include arch flattening and the general risks of surgery (infection, death).

Plyometrics

The term *plyometrics* derives from the Greek roots *plio,* meaning "more," and *metr,* meaning "measure." Plyometrics, also known as the stretch-shortening cycle (SSC), is a form of conditioning for athletic improvement as well as for activities of daily living where quick and explosive movement is used in a progressive, sequenced manner to increase the acceleration and deceleration of an object or oneself. The fundamental necessity to increase jumping and/or throwing height, distance, or quickness is to increase power. The formula of power is

$$\text{Power} = \text{Force} \times \text{Velocity}.$$

To increase power, two variables may be improved: force or acceleration. Force may be improved by performing resistance or strength training. However, performing high-volume resistance training can adversely affect the ability to obtain full range of motion of any one joint in the body due to excessive muscular hypertrophy.

To increase power through plyometric training, two models of adaptation must be understood: mechanical and neuromuscular models of plyometric exercise.

In the mechanical model, the series elastic component (SEC) is the primary force-producing component in the SSC. Like a spring, the muscle is stretched, thus storing potential energy. For that potential energy to be converted to kinetic energy, a concentric muscle action must ensue immediately, otherwise the potential energy will be lost as heat.

The neuromuscular component of the SSC contributes through the stretch reflex, which is an involuntary reaction to the rate and magnitude of the stretch that occurs in a muscle. This rate and magnitude of stretch are sensed in the intrafusal muscle fibers, called *muscle spindles*. The quicker the rate of stretch felt in the muscle, the quicker the response to the stretch by the antagonist muscles, which co-contract as a protective mechanism to prevent musculotendonious damage to the stretched muscle. The stretch reflex is lost in a similar manner as it is in the SEC if there is a long delay between the stretch on the agonist muscle and a concentric muscle contraction. The potential energy in the form of the stretch reflex will be lost as heat.

The SSC embodies the stretch reflex as well as the SEC and has three very distinct and equally important phases to improve and manipulate plyometric training: eccentric, amortization, and concentric.

Eccentric Phase

The eccentric phase of the SSC sets up the second and third phases. This is where the agonist muscle gets the potential energy through the SEC and the stretch reflex begins, through the muscle spindle being activated and sending a signal to the spinal cord from the muscle that is being stretched. This is also called the *countermovement,* as when a person attempts to perform a vertical jump starting from a squatting position (see photos a through f).

Amortization Phase

The second phase of the stretch-shortening cycle is the amortization phase. This is the brief pause between the eccentric phase and the last phase, the concentric phase. The longer the amortization phase is, the more of the elastic energy that is lost. Therefore, it is essential to get a training response in plyometric training so that the pause is as brief as possible.

Concentric Phase

The last phase is the concentric phase. This is where the potential energy produced in the eccentric phase of the SSC is turned into kinetic energy. The signal that was sent to the spinal cord has now returned, and the SEC is now recoiling, to produce a powerful explosive movement. This is the takeoff of a vertical jump.

Without plyometric training interspersed throughout the training cycle, athletic development would be minimal at best, and the tendency to injury would be high in noncontact situations. Research supports the conclusion that plyometric training increases power production in anaerobic compared with aerobic athletes. Similar relative improvements may be seen in general populations in the activities of daily living as well as at the workplace. From getting out of a chair to climbing stairs quickly, the use adaptations from plyometrics for all ages and populations are positive. Conservative, low-intensity and low-volume plyometric training is best for prepubescent and osteoarthritic populations due to the lack of epiphyseal plate closure in long bones and low bone mineral density, respectively.

Prerequisites of Plyometric Training

When implementing plyometrics into a training program, it is important to know the training age of the individual who will be executing the exercise(s). If the participant has little or no training experience, then the use of plyometrics should be delayed to allow for the skeletal muscles and their tendons to adapt to the stress of resistance/strength training. General anatomical adaptation exercises must be implemented for 4 to 6 weeks prior to the execution of plyometrics to decrease the risk of injury.

Types of Plyometric Training

With sufficient anatomical adaptations, plyometrics may be executed for both the upper and the and lower body. Upper body plyometrics include, but are not limited to, exercises such as medicine ball overhead throws, plyometric push-ups (see photos g–i and j–l), and soccer throws. Essentially, any type of throwing pattern will elicit a plyometric adaptation. Lower body plyometric exercises are those that can be performed at very young ages, such as hopping, skipping, and jumping.

Although hopping, skipping, and jumping seem to be simple, unassuming activities, the intensity of their execution is what determines whether overuse or acute injury will result. High intensity and high volume in plyometric training often result in injury if not carefully monitored. In a properly designed nonlinear undulating training program, the propensity for injury due to plyometrics training is low. The frequency, intensity, type, duration, and age of training are important factors in deciding on the most appropriate plyometric training. With careful program design, the result will be increased performance in activities of daily living for general populations and greater athletic performance for both aerobic and anaerobic athletes.

Podiatric Sports Medicine

Podiatric sports medicine is the branch of podiatric medicine devoted to the study and practice of sports medicine; its practitioners are podiatrists with expertise in the foot and ankle areas. Important areas of understanding for the podiatric sports medicine practitioner include biomechanics, the physiology of sports and exercise, and surgery. Podiatric physicians are integral members of the sports medicine team at all levels of competition, including high school and college sports, youth sports, club sports, and professional athletic teams.

Podiatric sports medicine often assists those who are just beginning to undertake fitness as part of the treatment plan for systemic disorders such as postcoronary events, diabetes mellitus, obesity, and others. These new exercisers often need significant care to be able to continue to exercise. Foot and lower limb disorders are among the most common areas of injury for many athletes, especially runners.

The practice of podiatric sports medicine is exemplified by the American Academy of Podiatric Sports Medicine (AAPSM). The AAPSM defines its mission as advancing the understanding, prevention, and management of lower extremity sports and fitness injuries. The AAPSM sets out to accomplish its mission by supporting research in sports medicine and also in biomechanics, student education, and postgraduate education. The AAPSM began in 1970 with a founding core of podiatrists and the cardiologist George Sheehan, M.D. Sheehan was one of the first running gurus to appear on the scene. Shortly after beginning running, he developed foot and leg problems, which were treated by the sports podiatrist Richard Schuster, DPM. This relationship blossomed into a long association, focused on running, sports medicine, and sports podiatry. Sheehan championed podiatric sports medicine as having a large role to play in the understanding and treatment of lower limb disorders, especially in the treatment of patellofemoral pain syndrome (at that time one of the most common running injuries and commonly called *runner's knee*). In the 1970s, the primary focus of podiatric sports medicine was running, and the discipline grew right along with the running boom.

In the United States, there was no national sports medicine organization with physician participation until the 1950s, when the American College of Sports Medicine (ACSM) was founded. The AAPSM, founded some years later, ultimately forged bonds with the ACSM. The AAPSM has also forged close bonds with the National Athletic Trainers Association and the Special Olympics. The AAPSM is a participating member organization of the Joint Commission on Sports Medicine and Sports Science.

Prior to the founding of the AAPSM, and predating the foundation of the ACSM, there were a number of individuals who promoted the importance of care of the athlete and of those participating in athletic endeavors, including the soldier. One of the earliest uses of the X-ray was to define the "march" fracture, also known as a stress fracture. Although this was published by an orthopedist, the importance of the foot in sports was noted by Alfred Joseph, K. Burnett, and R. Gross as far back as 1918 in their textbook *Practical Podiatry*. This textbook included walking as a form of exercise. It included significant details on the treatment of the soldier. Foot hygiene, the importance of shoe fit, and the use of socks were key issues. Although it has been said that an army marches on its stomach, it won't march far with ill-fitting shoes and sore, blistered feet. Environmental issues were considered important, with trench foot being a problem at the time. Avoidance of infection and the treatment of skin problems were of paramount importance in the days before antibiotics. Some of these simple problems are a major issue for ultramarathoners. The authors noted that the foot had not received special attention prior to the 1900s and felt that it was about time.

The Boston Marathon, which began in 1897, is the oldest continuing marathon in the United States. The podiatrist Joseph Lelyveld began assisting with foot care issues in the first part of the 1900s and continued volunteering for 30 years. The podiatry tent at many marathons is one of the busiest places in the middle of the marathon course, and podiatrists have historically assisted at many of the nation's marathons.

Podiatric sports medicine physicians are active not only with many professional sports teams but also with athletes who face challenges and must overcome handicaps. The FitFeet program of the Special Olympics, begun by the podiatrist Patrick Nunan, DPM, screens the participants of the Special Olympics events. It has a presence at local, state, and international competitions. The AAPSM assisted in the foundation of FitFeet and supports its undertakings.

Other sports in which podiatric sports medicine plays an important role include skiing, hockey, figure skating, cycling, ultrarunning, and extreme survival running. Podiatrists are valued participants at the global desert ultraraces that take place in deserts on different continents, including the Gobi (China), Antarctica, Atacama (Chile), and Sahara (Egypt) deserts.

Podiatrists play a significant role in the development and advancement of athletic shoe technology and have worked with most major athletic shoe manufacturers. Bringing knowledge to the public and educating peers on sports injuries have always been of utmost importance to the leaders in sports medicine. Starting with the first educational meetings put on by the founders of the AAPSM, the educational push has been ongoing. Books directed at both the professional and the lay public have been published by many authors. Their impact on runners, running, and the view of the causes and treatment of injury was enormous. The AAPSM has developed a website that houses its popular athletic shoe lists. The AAPSM uses the Internet and multimedia to continue fulfilling its mission to educate the public.

While the historical basis of podiatric sports medicine has been biomechanics, there has been a trend toward increasing qualification in surgical skills. The sports medicine team is a diverse one. The increasing interest in genomics, applied physiology, and many other disciplines contributes to our advancement in the knowledge, understanding, and treatment of the athlete. However, the special understanding of foot and lower limb function, biomechanics, training regimens, shoe structure and function, and foot and ankle structure, function, and injury makes the podiatric sports physician a valued member of the team.

Posterior Cruciate Ligament Injuries

Posterior cruciate ligament (PCL) injuries are less common than anterior cruciate ligament (ACL) injuries and generally are not as debilitating. The PCL is important for stability of the knee and for maintaining the tibia in its correct position anterior to the femur.

Anatomy

The PCL is one ligament that consists of two distinct bundles, one bundle working in flexion and the other working more in extension. The ligament originates from the femur and inserts on the back of the tibia.

Biomechanics

The PCL is the primary restraint to posterior tibial translation. The lateral collateral ligament and the posterolateral knee structures, including the popliteus tendon and capsule, are the secondary restraints, with the medial collateral ligament playing a lesser role.

Epidemology

PCL injuries often remain undetected. A 2% to 5% incidence of undetected PCL injuries has been noted in elite college athletes. Fanelli and Edson conducted a prospective analysis in 1995 of the incidence of PCL injuries in patients presenting with an acute hemarthrosis (swelling) of the knee. In this cohort, PCL injuries were present in 38% of cases. Trauma patients represented 56.5% of these injuries, and 32.9% were related to sports. Isolated PCL injuries were rare (3.5%), whereas 96.5% of PCL injuries occurred in combination with other ligament injuries. The activity most frequently associated with PCL injury is football, followed by baseball, skiing, and soccer.

Mechanism

Damage to the PCL may occur by any of several different mechanisms, including both low- and high-energy injuries in which a posteriorly directed force is applied to the proximal tibia of a flexed knee. This may happen when an athlete falls with the foot in a flexed position or as a result of a "dashboard injury" (when a flexed knee hits the dashboard) during a motor vehicle accident.

The mechanisms underlying combined ligament injuries involving the PCL are usually a combination of a posteriorly directed force applied to the tibia in conjunction with a sideward or a torsional force. These combined forces may result in injury to the ACL, collateral ligaments, posterior capsule, or posterolateral corner/structures (PLC).

Assessment

History

The details of the initial injury should be obtained to determine the magnitude of energy exchange during the event and, consequently, the potential extent of injury to the stabilizing structures of the knee. The majority of injuries to the PCL involve other ligamentous injuries, and higher-velocity trauma may be more likely to result in combined injury.

Symptoms of PCL deficiency include pain, stiffness, and swelling in the knee. Instability is occasionally noted but with less frequency than in ACL deficiency.

The first presentation of a chronic injury may be with symptoms of osteoarthritis.

Examination

The posterior drawer test is the most accurate test for a PCL injury and is performed with the patient lying on his or her back with the knee at 90°. The examiner places his or her hands on the proximal tibia and applies a posterior force. The degree of posterior translation of the tibia is noted relative to the femur.

Grade I PCL laxity is consistent with translation of 0 to 5 millimeters (mm) (the tibial condyle remains anterior to the femoral condyle). Grade II is classified by posterior translation of 6 to 10 mm (the tibial is flush with the femoral condyle). Grade III injuries measure >10 mm of posterior translation (the tibia plateau is posterior to the femoral condyle).

As a patient with an acute knee injury suffers a lot of discomfort, the posterior Lachman test is more often advised. It is carried out in a similar manner to the draw test, but the knee is only bent to 30°.

The posterior sag test is a static test and looks for posterior sag of the tibia relative to the femur with the knee bent to 90°. Generally, comparing the injured knee with the uninjured side is helpful.

To identify combined injuries, the integrity of the other ligaments around the knee should be tested.

Imaging Studies

Plain X-rays may reveal a bony avulsion of the ligament off the back of the tibia, posterior translation of the tibia relative to the femur, or signs of injury to other ligaments. In patients who have a chronic tear of the PCL, there may be changes consistent with osteoarthritis of the tibiofemoral compartment or the patellofemoral joint.

Stress radiography is a useful testing method for objectively determining the amount of posterior tibial translation of the knee. A machine places a posterior force on the tibia, and a lateral X-ray is taken simultaneously. The position of the tibia relative to the femur can then be measured.

Magnetic resonance imaging (MRI) has been proven to be 99% accurate in diagnosing acute injuries of the PCL. Information regarding the integrity of the other ligaments around the knee can also be obtained. MR images can also provide useful information of prognostic value in predicting the capacity for healing. It has been shown that rupture of a single PCL bundle is more likely to result in a satisfactory outcome than complete rupture involving both bundles.

Treatment

Nonoperative Treatment

Unlike the ACL, the PCL can heal after injury. Shelbourne and colleagues found that only 2 weeks after injury, patients often have no pain and also demonstrate a firm end point on posterior drawer testing. Continuity of the PCL was found in 37 of 40 patients who had an MRI evaluation at a mean of 3.2 years after injury. The actual time it takes to obtain PCL continuity after acute injury is not yet known.

Shelbourne and colleagues evaluated 271 patients at a mean follow-up of 7.8 years after acute isolated Grade 2 PCL injuries. All patients were treated nonoperatively. The patients were allowed to return to their previous activities and sports as tolerated after attaining a good range of movement and strength. The authors found little change in the PCL laxity grade from the initial injury to the final examination. There was no correlation between objective and subjective knee function and the PCL laxity grade. No correlation was found between radiographic evidence of arthritis and the grade of laxity. The presence or absence of degenerative changes on radiographs did not significantly affect the total scores. Regardless of the amount of the laxity, 50% of the patients were able to resume sports at the same level or higher.

Conservative treatment of acute PCL injuries emphasizes reducing swelling and regaining full knee range of motion, leg strength, and control. Immobilization is rarely required for an isolated PCL injury, although some patients feel more comfortable with an immobilizer and crutches during the first week. As the swelling and pain subside, range-of-motion exercises and leg-strengthening exercises are instituted, with an emphasis on the quadriceps.

During physical therapy, it is important to minimize posterior tibial translation by protecting against gravity-induced posterior tibial sag and by avoiding open–kinetic chain hamstring exercises. Closed–kinetic chain exercises, such as the squat between 0° and 70°, in which the foot is fixed, produce less force on the knee.

In some patients, use of a higher-heeled boot or shoe to increase the activity of the quadriceps muscle during walking may help alleviate symptoms. Patients who have symptomatic instability may benefit from use of a four-point brace, but objective data and long-term follow-up studies on this mode of treatment are lacking.

Patients with greater quadriceps muscle strength show better results after a PCL injury. Return to sports is often achieved by 3 months.

Operative Treatment

Bony Avulsion Injuries

Patients in whom the PCL is avulsed from the back of the tibia with a bone fragment can have an excellent result with primary operative management if the fragment can be anatomically restored to its bed. If the fragment is large enough, a single screw is usually sufficient for effective fixation. For smaller fragments of bone or cartilage, sutures pulled through drill holes have been used effectively.

Isolated Injuries of the PCL

For those patients with acute or chronic Grade III injuries and symptomatic instability, single-bundle, PCL reconstruction seems to improve both subjective knee function and posterior tibial translation in the short term. However, some patients may continue to demonstrate residual laxity, and there is no definitive evidence to suggest that PCL reconstruction significantly alters the natural history of the PCL-deficient knee.

There are two main methods of reconstructing the ligament. One is an arthroscopic technique performed by drilling tunnels in the tibia and femur from the front of the knee, through which a graft is passed. Alternatively, reconstruction can be carried out via a combined open and arthroscopic surgical approach from behind and in front of the knee. No differences in outcomes have been reported for the different methods of reconstruction, and it is currently not known which tendon graft is optimal. Recent interest in reconstructing both bundles of the PCL has failed to provide any further benefit.

Posterior Impingement Syndrome

This disorder is caused by anything that creates compression of the shoulder anatomy (e.g., muscles, tendons, nerves, or blood vessels). Other potential causes include imbalances between the muscles that permit shoulder motion and those that provide stability to the joint. These include the rotator cuff muscles, such as the infraspinatus and supraspinatus, which may cause friction against the posterior-superior part of the glenoid and glenoid labrum.

The wing bone (scapula) and collar bone (clavicle) create an arch at the tip of the shoulder, through which tendons and nerves pass, usually with ease. The posterior border of the arch is the head of the humerus.

Understanding the mechanism of the injury is important, requiring familiarity with the basic related anatomy. The shoulder is a ball-and-socket joint. The glenoid fossa (cavity) of the scapula (shoulder blade) is the socket and is composed of bone at the base and lined with cartilage. This is surrounded with additional lining at the circular rim by the glenoid labrum (from the Latin meaning "upper lip"), which is composed of cartilage. This makes the socket deeper, affords more stability to the joint, and provides easier movement to the ball part of the joint, with minimal friction. The ball of the joint is the proximal part of the humerus (upper arm bone) that is embedded in the glenoid fossa and surrounded by the glenoid labrum.

Several muscles and ligaments help in joint stability, serving to either initiate or maintain motion and providing a balance of forces, which permits the ball to remain in the socket. Major involved muscles include the deltoid, biceps, and supraspinatus.

The synchronous action of the ligaments and muscles provides stability and strength to the shoulder and permits a wide range of motion, including abduction (away from the body), adduction (toward the body), and internal and external rotation. The main shoulder muscles are as follows:

1. The deltoid, which covers the shoulder joint and provides a smooth contour of the shoulder, originates from the humerus and inserts into the shoulder joint, thus covering it from three surfaces.
2. The supraspinatus (part of the rotator cuff muscles, along with the infraspinatus, teres minor, and subscapularis) originates at the wing bone, passing under the acromion, and inserts into the ball of the humerus. It causes abduction of the arm and is the most commonly injured rotator cuff muscle.
3. The infraspinatus originates at the shoulder blade and inserts at the humerus head (ball) and is encapsulated by the shoulder joint under the coracoacromial arch, which laterally rotates the arm.

The fact that the passage of these structures occurs through a narrow area places them at a high risk of injury. Overuse of the shoulder muscles and ligaments as well as the underlying bursae (fluid-filled sacks that serve as shock absorbers) also contributes to the risk of injury. Anything else that decreases the space in the shoulder joints, such as calcification or bony spurs, may cause potential problems. Individuals who use their arms frequently, such as swimmers and baseball pitchers, are primary candidates for shoulder impingement syndrome.

Tendons connect bone to muscle and transmit force when muscles contract. Repeated use of a tendon may cause tendinitis (inflammation of the tendons). Other injuries may occur from excessive strain on the tendon. For example, if a person attempts to lift a heavy box, force will be exerted on the tendon and the area of insertion, which in this case is the glenoid labrum. A possible injury could occur. The tendon could get inflamed and begin to tear from the area of insertion of the glenoid fossa (cavity). The shoulder has two sets of muscles and ligaments, with differing functions. One set holds the joint in place, while the other permits free motion of the shoulder and upper arm in all directions with ease.

Many factors come into play to ensure good shoulder movement.

1. Sufficient subacromial arch outlet space
2. Smooth synchronization and proper balance (pull and push) around and inside the shoulder joint
3. A firm, but not too tight, coupling between the wing bone and the ball of the humerus
4. The labrum in good condition
5. No bony spurs or calcification in the space under the coracoacromial arch

The most common type of impingement syndrome is posterior-superior impingement syndrome. This is directly associated with the rotator cuff muscles and tendons and causes posterior shoulder pain. The primary cause of this impingement is the compression of the supraspinatus and infraspinatus tendons under the coracoacromial arch. Posterior shoulder pain is often elicited by elevation of the arm.

Causes and Etiology

There are several pathological changes that occur in the area of the subacromial arch (especially in the very active population) due to age, such as bony spurs and bursitis. Other contributory factors include compromising the depth of the subacromial space, degenerative joint disease, arthritis, and rotator cuff muscle atrophy and weakness. Even external factors, such as a severe kyphosis (bending forward) of the upper and midback, can apply tension to the scapula, leading to pressure in the area of the origin of the rotator cuff muscles. Poor form during weight lifting and repetitive overhead motion in athletes, especially baseball players and swimmers, cause excessive external rotation of the humeral head and eventually lead to decreased internal rotation.

The key to diagnosing this syndrome lies in knowing the mechanism of injury. Typically, it is caused by overuse and repetitive movements that cause stress of the shoulder, especially those that cause the arm to be elevated. One must keep in mind that the stability of the shoulder depends on the strength of the rotator cuff muscles and glenohumeral ligaments—stresses may cause instability, which in turn predisposes to injury.

Medical History and Patient Presentation (Symptoms and Signs)

Patients may complain of posterior shoulder pain that gets progressively worse, especially with activities. Patients may also have a feeling of weakness when trying to lift a box overhead or with activities such as swimming. Patients generally present without any history of trauma or surgery and state an insidious onset of symptoms.

Physical exam should include the following:

1. Inspect the shoulder for any signs of trauma/swelling, and compare the affected side with the uninvolved side for asymmetry.
2. Evaluate range of motion in all directions, both actively and passively.
3. Evaluate muscle strength of the rotator cuff muscles and deltoid.
4. Conduct sensory testing for the nerves that pass under the coracoacromial arch to rule out any nerve injuries.
5. Evaluate blood circulation to rule out any compromise in the affected arm.
6. Palpate the shoulder joint for localization of tenderness.
7. Perform appropriate special screening tests based on the clinical presentation, including the following:
    - *Infraspinatus stress test:* Force is placed on this muscle to elicit pain.
    - *Supraspinatus stress test:* The patient's arm is supported until it is above his or her shoulder level, and then the examiner lets the arm drop while the patient tries to hold it up. (A positive test is one in which the patient cannot hold the arm up.)

- *Stress testing of ranges of motion of the joint:* Apley scratch test is used to determine all ranges of motion of the shoulder.
- *Impingement test:* A slight passive (by moving the arm) elevation motion with slight internal arm rotation will either reproduce the pain or worsen it.
- *Jobe relocation test:* This test is used to check for anterior instability of the shoulder. The arm is held at 90° by the examiner. Then, a posterior (back) force is applied on the humerus head as the patient tries to return the arm to its normal position. The pain actually is reduced because the pressure on the head of the humerus is relieved. Thus, easing of pain signifies a positive test.

In addition to the above tests, radiologic studies, such as shoulder X-rays and/or magnetic resonance imaging (MRI), may be appropriate if needed for definitive diagnosis.

Coupling the history, severity of symptoms, and physical exam with radiologic studies will provide the stage of the diagnosis of the impingement, which allows for management of the condition.

Stage I: In this stage, some feeling of stiffness with activity is noticed, and a slow warm-up for activities may be essential.

- The athlete should stop activity for at least 2 to 4 weeks to evaluate and strengthen the rotator cuff muscles, in addition to taking anti-inflammatory medications.

Stage II: In this stage, mild posterior shoulder pain that worsens with overhead activity is noticed. Anterior shoulder instability is examined by the Jobe relocation test.

- The athlete should stop activities for at least 4 to 12 weeks and needs a very detailed and appropriate rehabilitation program based on the presentation and physical exam.

Stage III: This stage consists of moderate to severe shoulder pain that worsens with any movement in any direction. Anterior shoulder instability is examined by the Jobe relocation test. If the condition does not improve in 12 weeks' time, then a rehab program is advised.

- The athlete, in addition to the above interventions, will consider surgical procedures such as anterior-capsulo-labral reconstruction and thermal capsulorrhaphy (which basically shrinks the capsule so that it will be decompressed on the head [ball] of the humerus), so that there will be more space for the tendon to pass easily to prevent rubbing on the bones. Another surgical intervention is acromioplasty, which is the removal of a part of the acromion, which in turn would decrease the pressure on the tendon and finally enlist an appropriate rehabilitation program with more detailed monitoring, evaluation, and reevaluation of the progress. The patient should have minimal activity for 1 month.

The key to avoiding such an injury from occurring is prevention. Proper warm-up and strengthening of the shoulder muscles and ligaments are crucial. In addition, starting slow, increasing activity gradually, and avoiding excessive repetitive motion will certainly decrease the likelihood and severity of injury.

Posterior Tibial Tendinitis

Posterior tibial tendinitis is a source of pain in the medial (or inner) portion of the foot and ankle. A tendon is a strong piece of fibrous, connective tissue that attaches muscle to bone. The tendon arises from the posterior tibial muscle. This is a muscle in the lower leg, which plays an important role in moving the foot in inward and downward directions. These motions are known as inversion and plantarflexion, respectively. Tendinitis refers to inflammation of the tendon, which is thought to be the source of pain. The injury may be induced by trauma or, especially in athletes, may be the result of overuse due to the excessive mechanical stress placed on the tendon. There is a sheath that surrounds the tendon, and if this becomes inflamed, it is referred to as a *tenosynovitis*. When this injury becomes chronic, there are significant degenerative changes within the tendon. This condition is referred to as *tendinosis* or *tendinopathy*. Therefore, it is common to see this injury described as such. This condition is most commonly seen among those above 40 years of age but is also frequently encountered in younger athletes.

Anatomy

The posterior tibial muscle is a large muscle of the lower leg that is the primary invertor of the foot and plays a key role in plantarflexion. It gives rise to the posterior tibial tendon in the lower one third of the leg, in an area just above the medial malleolus, a bony protuberance on the inner half of the ankle (Figure 1). Within its sheath, or covering, the tendon traverses behind the medial malleolus and then inserts into the medial arch of the foot. Specifically, it mainly inserts into the navicular bone on the inner half of the foot. From there, it splays into smaller attachments that connect the midfoot with the bones closer to the toes. It also has insertions that play an important role in supporting the medial arch of the foot. Additionally, the tendon also serves as a shock absorber to prevent excessive motion of the foot while running. All these different forces cause the posterior tibial tendon to be placed under a great deal of mechanical stress. Athletes who participate in activities that emphasize running, cutting, or jumping are prone to such injuries.

Causes

As previously stated, the posterior tibial tendon is under significant stress and plays a key role in a number of foot movements. Therefore, posterior tibial tendinitis is usually the result of repetitive stress on the tendon. This injury is generally thought to be due to overuse, as it is not commonly seen in younger people unless they engage in sports that warrant rapid changes in direction, such as basketball and soccer. It is also common among skaters and dancers as they place excessive stresses on their feet. It is a frequent injury in runners, with 2% to 4% of all participants estimated to be affected. They may have excessive motion of the foot, which is described as *overpronation*. Those who have occupations that necessitate extended periods of standing are also at risk. Obesity, pes planus (flat feet), and various types of arthritis are all felt to predispose people to posterior tibial tendinitis.

Although the majority of cases are the result of overuse, some cases of posterior tibial tendinitis

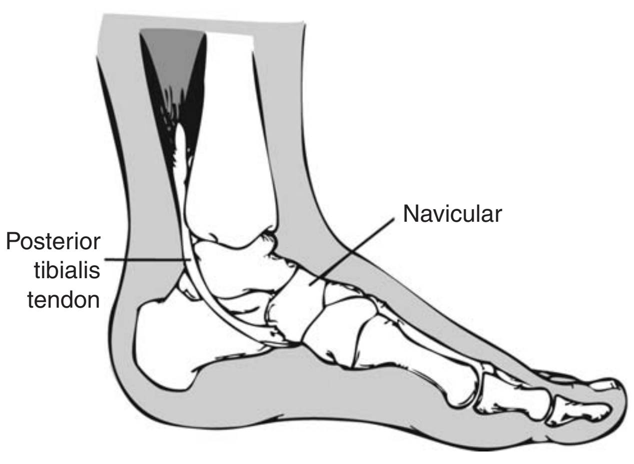

Figure 1 Posterior Tibial Tendon

Source: Jonathan A. Becker, M.D., University of Louisville.

Note: An overview of the anatomy of the posterior tibial tendon, showing its insertion into the navicular bone.

are due to acute trauma. The tendon becomes vulnerable when the foot is rapidly moved outward and upward. This can stretch the tendon, leading to acute injury or, at its worst, a complete tear or rupture.

Symptoms

The most common symptom of posterior tibial tendinitis is pain over the medial portion of the foot. This pain is generally seen near the insertion of the tendon into the midfoot or the area just below the medial malleolus. However, pain can be located over any portion of the tendon and is often not confined to a discrete area. A minority of patients may report a traumatic episode as their etiology. Pain will generally increase with activity or sports participation and resolve with rest; it can present with severity that ranges from mild to debilitating. Most often, the patient will have had symptoms for a number of weeks or months at the time of presentation. In cases where there is acute inflammation or a tenosynovitis, there may also be redness and swelling. Certain motions, such as moving the foot inward or standing on one's toes, may be reported as particularly painful. In advanced cases, there may be a loss of the arch, or flattening of the foot. Posterior tibial tendon problems are one of the most common reasons for a person to develop flat feet.

Diagnosis

Posterior tibial diagnosis is usually done on the basis of the patient's history and physical exam. Most frequently, the patient participates in an activity that places excessive stress on the feet, such as running, skating, or dancing. A recent increase in activity or alteration in footwear or cleats may be noted as well. There will be tenderness over some portion of the posterior tibial tendon. Having the patient plantarflex and invert the foot will induce pain. The examiner may provide resistance to help provoke the symptoms. Discomfort can also be elicited by having the patient attempt to bear weight on his or her toes. In settings of acute inflammation or tenosynovitis, there may be redness or swelling. Weakness may also be noted on any of these provocative movements. Acute rupture of the tendon will often present not only with pain but also with significant swelling and marked weakness, especially when the patient tries to stand on his or her toes.

Anatomical changes may be noteworthy on exam. These may have been acquired secondary to incompetence of the tendon or may be anatomical abnormalities that predisposed the patient to the problem. These include pes planus or the appearance of a "too many toes" sign. The latter refers to the appearance of the feet when examined from behind with the patient standing. The inner part of the foot will sag with loss of the arch, and more of the outer toes of the foot will be visible from behind the heel. The foot will be in an everted, or outward pointing, position. The gait should be observed closely for evidence of flattening of the arch or overpronation.

Generally, imaging is not necessary to diagnose posterior tibial tendinits. X-rays will not visualize the tendon but may be useful in ruling out other sources of pain such as arthritis or fracture. Magnetic resonance imaging (MRI) will visualize the tendon and can be useful in delineating the extent of tendinitis or tendinopathy. It is also useful for determining if the tendon has been ruptured.

Treatment

Regardless of the severity of symptoms, initial management will be similar for most cases. Relative rest from the offending activity and frequent application of ice will allow for symptom control. Nonsteroidal anti-inflammatory drugs (NSAIDs) are helpful for treating the pain and may be particularly beneficial in cases of tenosynovitis. Elevation will reduce swelling. Improved shoe fit and arch supports are helpful even in cases where there is no evidence of pes planus, as they may assist in the supportive role of the posterior tibial tendon. For athletes, this can also be accomplished with taping. Participants who use cleats may consider wearing alternative shoes for conditioning and practice and reserving the use of cleats for competition, as this may play a role in the etiology. An exercise program that promotes stretching of the posterior calf muscles and strengthening of the foot muscles will provide rehabilitation. The goal is to improve muscle and tendon strength and mobility.

In more severe cases, crutches or a short leg walking cast may be used to alleviate symptoms for those with debilitating pain or for those who have pain with routine activities of daily living. Physical therapy may be employed to provide an exercise program, as well as modalities such as ultrasound or iontophoresis (introduction of pain-relieving medications through the skin). There is conflicting evidence regarding the benefits of those treatments. Also, consideration ought to be given to fitting the patient with a custom-made orthotic. For cases with advanced inflammation of the tendon sheath, a local steroid injection may be employed to relieve pain. However, these injections place the patient at risk for tendon rupture, prompting some experts not to recommend them. The time course for resolution of symptoms, especially in more severe cases, can vary from weeks to months. Generally, the longer those symptoms are present at the time of presentation, the longer it will take for recovery. Return to activity is based on the level of discomfort. Once any lost strength or range of motion has been regained, patients can advance their activity level as their symptoms allow.

Surgery is reserved for severe cases that are refractory to more conservative measures or those with complete rupture of the tendon. Surgical techniques may include repair of the tendon and reinsertion into the navicular bone. After surgery, it will be approximately 3 months before return to normal activity.

Posterolateral Rotatory Instability

Posterolateral rotatory instability (PLRI) is the most common type of chronic lateral elbow instability. It has been well-defined in the literature by O'Driscoll and others since 1991, yet our understanding of the pathophysiology and biomechanical abnormalities associated with this injury is still evolving. PLRI is part of a spectrum of injury to the soft tissues of the lateral elbow, primarily the lateral ulnar collateral ligament, usually following a traumatic elbow injury, such as an elbow dislocation. There are three stages of PLRI: (1) posterolateral subluxation, (2) incomplete dislocation with the coronoid lodged beneath the trochlea, and (3) complete dislocation of the elbow joint with the coronoid located behind the humerus.

In children, the elbow is the most commonly dislocated major joint, whereas in adults, the elbow is the second most commonly dislocated joint, after the shoulder. Dislocations represent about 10% to 25% of all elbow injuries. Like other upper extremity injuries, elbow dislocations can occur from direct trauma, a FOOSH (fall on an outstretched hand) injury, or a strong directional or levering force on the elbow. Elbow dislocations typically occur in children older than 13 years, after the physes around the elbow are closed. However, it is not uncommon to sustain a combined elbow fracture and dislocation. The highest incidence of elbow dislocations is in the under-20 age-group, and the majority are associated with sports activity. In general, prompt closed reduction of simple elbow dislocations results in favorable outcomes; however, when residual instability persists despite a period of proper immobilization, then significant dysfunction can develop. Complications include loss of range of motion (ROM), structural instability, nerve palsies, and muscular weakness.

Other causes of PLRI include apparent "elbow sprains," prior tennis elbow release, radial head excision, and multiple corticosteroid injections in the lateral elbow. Finally, PLRI has been associated with congenital or acquired cubitus varus deformities, which can develop secondary to supracondylar fractures in children.

Anatomy

The elbow is one of the most complex joints in the body, consisting of three articulations: (1) ulnotrochlear, (2) radiocapitellar, and (3) proximal radioulnar. Ulnotrochlear (ulnohumeral) joint instability results in PLRI due to lateral ulnar collateral ligament (LUCL) complex injury. The LUCL complex consists of four structures: (1) the LUCL itself, (2) the annular ligament, (3) the radial collateral ligament, and (4) the accessory lateral collateral ligament (LCL). The posterolateral joint capsule, capsular insertion of the annual ligament, and common extensor origin function as secondary soft tissue restraints to the lateral elbow.

Elbow flexion/extension occurs mainly at the ulnohumeral and radiocapitellar articulation, whereas forearm pronation/supination involves the radiocapitellar and proximal radioulnar articulation. Normal ROM of the elbow is approximately 150° of flexion to 0° of extension, 90° of forearm pronation, and 90° of forearm supination. The elbow provides attachment sites for various muscle groups and ligaments. The primary stabilizers of the elbow are the ulnotrochlear articulation, medial collateral ligament (MCL), and LCL. The radial head and the surrounding muscle bundles make up the secondary stabilizers of the elbow. Supination of the ulna results in a posterolateral displacement away from the trochlea in PLRI.

Clinical Evaluation

Elbow dislocations on physical examination may have an obvious deformity, diffuse joint pain and swelling, decreased or painful ROM, and crepitus. The normal anatomic triangle that is formed by the radial head, lateral epicondyle, and distal lateral tip of the olecranon process is disrupted with elbow dislocations. Any athlete who sustains trauma to the upper extremity and presents with any of these signs or symptoms should be evaluated for the possibility of an elbow fracture or dislocation. With such injuries, the examining physician must also assess the entire upper extremity for associated injuries; however, the instability associated with PLRI is not usually immediately evident due to the severity of pain present acutely; thus, physicians must have a high index of suspicion and monitor the patient for signs of instability during the recovery period.

The presenting history of PLRI patients varies from chronic elbow pain, clicking, catching, or snapping to a spectrum of giving way/subluxation with extension/supination or even a compensatory flexion forearm pronation contracture. The most reliable maneuver to reproduce instability symptoms is to have the patient push off on armrests as he or she rises from a chair. Physical examination for PLRI includes palpation for tenderness along the LUCL followed by provocative testing. The lateral pivot-shift test is the most sensitive examination technique described. The patient is placed in a supine position with the shoulder in external rotation and the arm overhead. The elbow starts fully extended and supinated. A valgus supination and axial compression force is generated as the elbow is flexed. Rotary subluxation of the ulnohumeral joint may be reproduced at approximately 40° of flexion, with pain and prominence of the radial head noted. Further flexion actually reduces the joint. Patients often experience significant apprehension during this maneuver.

The push-up sign occurs when apprehension, subluxation, or dislocation occurs on terminal elbow extension from a flexed position in a wide-shoulder push-up position. The chair sign is when the patient arises from a seated position by pushing the arms of the chair with the elbows flexed 90°, with the forearms supinated and arms abducted. This test yields a positive result when apprehension, subluxation, or dislocation occurs.

Radiographs

Standard anteroposterior and lateral views of the elbow should be sufficient to diagnose most elbow dislocations. Radiographs of the forearm may be necessary to evaluate for associated fractures. Computed tomography (CT) with three-dimensional reconstructions can be helpful in assessing for intraarticular fragments and the congruity of the articular surfaces. Approximately 10% to 20% of elbow dislocations have an associated fracture.

Typical fractures associated with elbow dislocations are radial head, olecranon, medial/lateral epicondylar, and coronoid process fractures. Elbow dislocations, specifically dislocation of the ulnohumeral joint, are described based on the position of the olecranon with regard to the humerus (posterior, anterior, lateral, and/or medial). The posterolateral elbow dislocation is the most common. It is rare to have a divergent dislocation where the radius and ulna are separated from one another and the humerus.

Continuous fluoroscopy during the pivot-shift test and stress radiographs may be useful to confirm the diagnosis of recurrent elbow instability. Widening of the ulnohumeral joint or posterior subluxation of the radial head demonstrates PLRI. Magnetic resonance imaging (MRI) has a limited role in demonstrating PLRI, as it is difficult to assess the true extent of LUCL complex injuries.

Treatment

Immediate treatment consists of using a hinged elbow brace and keeping the forearm in full pronation for a period of 4 to 6 weeks to maintain the reduction. Prolonged immobilization can adversely affect outcome and time to recovery for simple dislocations, but longer immobilization times are indicated in the setting of LUCL injury and instability. Surgical stabilization is indicated in active patients who are symptomatic with recurrent instability, pain, and functional limitations. Primary LUCL repair is difficult unless it is performed within days to weeks of the initial injury; thus, the vast majority of surgical treatments involve reconstruction of the LUCL complex. A typical recovery period ranges from 3 to 6 months and involves extensive physical therapy, progressing with joint stability exercises, strengthening, ROM, and progressing to sport-specific multiplanar exercise, such as throwing.

Urgent orthopedic referral is indicated for any elbow that remains unstable, has redislocated, or has entrapment of either fractured fragments or soft tissue within the joint. Long-term complications include stiffness, recurrent pain, arthritis, myositis ossificans, recurrent instability, ligament damage, contractures, and nerve injury.

Postgame Meal

Recovery from training is the period when one achieves the maximum results. Postworkout nutrition has gained significant attention. A postworkout meal is intended to help the body in increasing protein synthesis, creating more of an anabolic state, and making the most of the body's desire to repair itself.

The meal after an athletic event, be it practice, workout, or competition, is a deciding factor in the potential gain that is being achieved and in the recovery process. Gaining strength and muscle does not occur during a workout, but after, during the recovery stage. After the event, it is important to have a meal that fulfills several needs. It should help provide the energy needed for rapid replenishment of glycogen stores, stop protein breakdown, compensate for loss of fluid and salts, and increase protein synthesis. Ideally, the postevent meal occurs within 30 minutes and again within 2 hours.

Goals

Replenishing Glycogen Stores. A postgame meal delivers energy to the muscles as quickly as possible (within 30 minutes and again within 2 hours) to help rebuild muscle energy stores for the next workout.

Rehydration. Drink 16 ounces (oz; 1 oz = 28.35 grams [g]) of water for each pound (lb; 1 lb = 0.45 kilograms [kg]) lost. One half of the fluid loss should be replaced in the first 4 hours, the other half over the subsequent 8 hours.

Timing

Many inexperienced athletes do not understand that gaining strength and muscle occurs after a workout, during the recovery stage. The timing of a postevent meal is crucial.

It is important to consume a portion of the postevent meal immediately after exercise. During this time, the muscles are biochemically "primed" for nutrient uptake. The muscles are depleted and require an abundance of protein and carbohydrate. This phenomenon is commonly known as the "window of opportunity." This window gradually closes as time passes. Failing to eat immediately after exercise diminishes the chances for promoting optimal recovery. A postexercise meal taken immediately after working out is superior to a meal consumed just 1 hour later. A meal taken 1 hour after the event is superior to the same meal consumed 3 hours later.

Immediately after physical activity, it is advised to consume a liquid meal that is quickly absorbed.

Two hours after the competition or workout, a well-balanced meal with complex carbohydrates and protein is recommended.

When a prolonged period of recovery is scheduled (e.g., a bye week or weekend), a slower-releasing casein protein drink, such as milk, would be better.

If athletes are going to take a few days off between intense training sessions, the timing of the postevent meal becomes less important. As long as sufficient carbohydrates are provided throughout the day, the timing of carbohydrate ingestion does not affect the amount of glycogen stored.

- Take 100g carbohydrates in the first hour, then every 2 to 4 hours
- Consume high–glycemic index (GI) carbohydrates immediately, low-GI carbs as tolerated
- Replace fluid at 16 oz per pound lost
- Take 1 g of salt and 16 oz of fluid for each pound of weight loss over 5 lb
- Maintain the ratio of carbohydrate to protein as 3:1

Carbohydrates

Successful athletes, regardless of their chosen sport, take their postexercise nutrition seriously. All forms of exercise use carbohydrates for energy, resulting in muscle glycogen depletion. The post-workout meal should be high in carbohydrates to replenish the muscle energy stores.

The rate of glycogen synthesis peaks immediately following exercise. The athlete should consume about 100 g of high-GI carbohydrates in the first hour and every 2 to 4 hours thereafter. The addition of complex solid carbohydrates can be as tolerated over time.

Consumption of 1 g of glucose per kilogram of body weight after exercise and every 2 hours for 6 hours afterward improves the muscle glycogen stores. The same amount of fructose increases the liver glycogen stores. The addition of protein raises the insulin response, which may further increase the glycogen stores.

The carbohydrates that work best are dextrose and maltodextrin (taken in a 50:50 balance). These two carbohydrates also create an insulin spike. When simple sugars such as maltodextrin and dextrose are ingested, insulin is released into the bloodstream, making sure that blood sugar does reach dangerous levels.

Insulin is highly anabolic at rest, which means that it helps build muscle and stops protein breakdown after exercise. Consuming a large amount of carbohydrates leads to a large insulin release, increased glycogen storage, and increased protein repair. A carbohydrate intake of 0.8 to 1.2 g/kg of body weight maximizes glycogen synthesis and accelerates protein repair. Additional carbohydrates that exceed the storage capacity are converted to body fat. Creating an insulin spike too frequently decreases insulin sensitivity.

Protein

Protein is a key "building" nutrient for a variety of bodily tissues, many of which support muscle growth (enzymes, skin, hair, nails, bones, and connective tissue are all constructed from protein). Protein constitutes 15% to 20% of the body weight and follows water as the body's second most abundant substance.

The current U.S. recommended dietary allowance (RDA) for protein is 0.8 g kg^{-1} day^{-1}. Athletes participating in different sports have different needs. A strength athlete requires about 2 g kg^{-1} day^{-1} of protein, whereas an endurance athlete needs only 1.5 g kg^{-1} day^{-1}. The daily caloric intake from protein should be 150 to 250 g/day.

Since muscle protein is degraded during exercise, the addition of a relatively large amount of protein to the postexercise meal is important to help rebuild the structural aspects of the muscle. After exercise, the body decreases its rate of protein synthesis and increases its rate of protein breakdown. The provision of protein and amino acid solutions has been shown to reverse this trend, increasing protein synthesis and decreasing protein breakdown. Stopping protein breakdown is achieved with the help of insulin.

Nonessential amino acids can be produced by the liver. However, essential amino acids must be provided through the diet before any muscle can be synthesized. The correct ratios of essential and nonessential amino acids should be made available in sufficient quantities before any muscle can be produced.

Essential Amino Acids

Histidine	Methionine
Isoleucine	Phenylalanine
Leucine	Threonine
Valine	Tryptophan
Lysine	

Nonessential Amino Acids

Alanine	Glutamine
Arginine	Glycine
Asparagine	Proline
Aspartic acid	Serine
Cysteine	Tyrosine
Glutamic acid	

Nitrogen Balance

All the tissues in the body are composed of carbon, hydrogen, and oxygen. Only protein has the additional nitrogen molecule. Therefore, nitrogen excretion (meaning the amount of protein being eliminated from the body) can be measured to determine the amount of protein present in the body. Since 70% of protein is found in muscle tissue, nitrogen balance gives an excellent indication of the body's muscle-building potential.

There are three states of nitrogen balance:

1. *Positive:* This is the best situation for muscle growth. The protein (nitrogen) intake is greater than the nitrogen output. It shows that the body has sufficiently recovered from its last workout. The greater the nitrogen balance, the faster the workout recovery. This is the body's anabolic state.

2. *Negative:* This is the worst state an athlete can find himself or herself in. Nitrogen loss is greater than nitrogen intake. Not only is nitrogen drawn away from muscle, where it is needed for growth, but it is also taken from the vital organs, where serious damage can occur. A negative nitrogen balance also destroys muscle and is consequently considered a catabolic state. A negative nitrogen balance may result from consuming an insufficient amount of high–biological value proteins, poor-quality proteins (e.g., lunch meats, fatty meats, and vegetables), or protein sources lacking an optimal balance of the essential amino acids. A severe lack of protein equates to fewer antibodies to fight infection, and more frequent bacterial infections may be the result. To support protein synthesis, good-quality fats and carbohydrates should be available for energy purposes. If one consumes primarily protein, without considering the importance of other macronutrients, the body may metabolize the protein for energy purposes, thus lowering the nitrogen balance, in which case valuable amino acids will be shuttled to the vital organs, thus depriving the muscles of exactly what they need for growth. Training involves breaking down muscle tissue. Protein and rest help regenerate these tissues. Too much training, coupled with insufficient protein consumption, will hasten a negative nitrogen balance. In case of a negative nitrogen balance, all training should be

ceased, and protein intake should be increased significantly. If training is continued, the muscles might continue to deteriorate.

3. *Equilibrium:* This state should be what anyone might achieve at the very minimum. Nitrogen intake and loss are equal. The performance in this state is not regressing, nor are there any appreciable muscle gains.

Carbohydrate-Protein Mix

The postexercise ingestion of protein with carbohydrate accelerates recovery. In a recent study, a carbohydrate-protein combination maintained a positive nitrogen balance during and after a 6-hour endurance training session, while a straight carbohydrate drink did not.

The consensus of current scientific opinion is that following intense exercise, athletes should ingest a carbohydrate and protein mix (around 1 g of carbohydrate per kilogram of body mass and 0.5 g/kg of protein) within 30 minutes of completing exercise, as well as consuming a high-carbohydrate meal within 2 hours. This nutritional strategy accelerates glycogen synthesis and allows for a more anabolic situation that may hasten recovery.

Fat

The postworkout meal should be rich in protein and carbohydrate, but it should be fatfree. The consumption of essential fats is one of the most overlooked areas of daily nutritional intake. However, in the postevent situation, fat consumption can actually be counterproductive. Fat slows the transit of food through the intestines. Ingesting fat during the postworkout period may slow down the digestion and absorption of carbohydrates and proteins.

The postworkout meal should promote the fastest delivery of carbohydrates and protein to the depleted muscles, so fats should be avoided during this time.

Liquid Versus Complex

Liquid meals take better advantage of "the window of opportunity," where whole foods may miss this opportunity. Similar to the problems with a pre-event meal, eating a big meal can be difficult after an intense competition. Liquid supplemental formulas are palatable and easy to consume, and they can be quite nutrient dense, providing all the nutrition needed at this time.

Liquid supplemental formulas containing fast-digesting protein (whey hydrolysates and isolates) and carbohydrates (dextrose and maltodextrin) can be absorbed more quickly than whole-food meals. A liquid postexercise formula may be fully absorbed within 30 to 60 minutes, providing much-needed muscle nourishment during this time. However, a slower-digesting solid meal may take 2 to 3 hours to fully reach the muscle.

During the postexercise period, specific nutrients maximize recovery. These include an abundance of water, high-GI carbohydrates, and certain amino acids (in specific ratios). It is also best to avoid fat during this time. The only way to ensure that these nutrients are present in the correct amounts is to formulate a specific liquid blend. Whole foods may miss the mark.

Water

Fluid losses during an event can be calculated from the pre- and postevent weights. Athletes are encouraged to drink 16 oz of water for each pound lost. One half of the fluid loss should be replaced in the first 4 hours and the remaining half during the subsequent 8 hours. There is no one ideal postevent replacement fluid for all athletes.

Salt

Consider salt supplementation with 5 lb of weight loss or greater. Give 1 g of salt and 16 oz of fluid for each pound of weight loss over 5 lb.

Carbohydrate Loading

The "classic" regimen requires 3 days of intense, exhaustive exercise on an extremely low-carbohydrate (less than 10%), high-fat, high-protein diet to deplete the muscle glycogen stores. Days 4, 5, and 6 are spent resting and consuming a high-carbohydrate (greater than 80%) diet. The endurance event is held on Day 7, when the athlete consumes a normal, high-carbohydrate pre-event meal.

The "modified" carbohydrate regimen involves a moderate-carbohydrate (50%) diet on Days 1, 2, and 3 and a high-carbohydrate (>80%) diet on Days 4, 5, and 6. The endurance event is held on Day 7, when the athlete consumes a normal, high-carbohydrate pre-event meal as in the classic regimen.

Does this actually improve performance?

A 3-day, high-carbohydrate load (9 g kg^{-1} day^{-1} compared with 6 g kg^{-1} day^{-1}) increased muscle glycogen levels in cyclists, but there was *no* improvement in 100-km race time. Carbohydrate loading shows best results in runners with lower aerobic capacities in events lasting 1.5 to 2 hours.

Rest

Sufficient resting of the muscles following intense training is essential if protein synthesis is to take place. If training sessions are too frequent, even a protein surplus might be useless to fuel training efforts.

Pregame Meal

The goals of pregame, or pre-event, meals are to ensure adequate carbohydrates, prevent dehydration, provide a relatively empty stomach, and avoid gastrointestinal disturbance and hunger pangs. The meal should be pleasant and satisfying, contain 60% to 70% carbohydrates, and be consumed 2 to 5 hours before competition. The meal before an endurance event should be individualized but should consist primarily of higher–glycemic index (GI) foods consumed 2 to 5 hours before exercise, with adequate fluid and electrolytes; shorter-duration events at higher intensity are less likely to be affected by the pre-event meal.

No last-minute food will make up for a poor diet in previous weeks. Supplements do not balance a poor diet. If an insufficient diet is supplemented, then you have an insufficient supplemented diet!

The Basics

Exercising muscles leads to burning of fat and glucose. Glucose is obtained from the glycogen stores in both the muscles and the liver and from the glucose circulating in the blood. The liver controls blood glucose levels to ensure that the blood sugar does not drop too low (causing weakness, dizziness, and nausea). If it detects low blood sugar levels, it can release glucose into the blood from its own glycogen store. Glycogen is the stored form of glucose in the body. If blood glucose levels rise (e.g., after eating food containing carbohydrates), insulin is released, which forces glucose out of the bloodstream and into storage.

The relevance of pre-exercise nutrition is as follows. During a fasting period (such as overnight), liver glycogen stores will be lowered. If the athlete competes in a morning event without having eaten anything since the night before, he or she is starting at a disadvantage. Although muscle glycogen will still start off high, once it is used up (after about 60 minutes), a limited amount of blood sugar supplied by the liver is available.

Glycemic Index

Some carbohydrates create a faster surge in blood glucose than other carbohydrates. A food's GI gives an indication of the expected degree of blood glucose.

High-GI foods (e.g., glucose, white bread, bananas) produce a substantial and immediate rush of glucose into the bloodstream. Low-GI foods (e.g., beans, lentils, full-grain products) release glucose at a slow and steady rate over a much longer time period. One potential problem with high-GI foods is that the high insulin response can actually lead to an increased storing of blood glucose, creating a net drop in blood sugar and its undesired effects.

For some time, a dogma that existed in sports nutrition was that sugar should not be consumed 60 to 15 minutes prior to exercise for fear of a hypoglycemic backlash. Several early studies found that the time to exhaustion was shorter, 20% to 25%, after athletes consumed 2 to 3 ounces (oz; 1 oz = 28.35 grams [g]) of glucose during the hour preceding an endurance event. More recent studies have failed to demonstrate this effect. Individual variability in athletes may explain the apparent contradictions in the current nutritional literature.

International studies have shown that large numbers of players eat foods that contain carbohydrates far below the optimal level of 2,400 to 3,000 calories (cal; 1 cal = 4.19 joules). As a result, athletes enter their competitions with insufficient glycogen levels. Players who start a match with low glycogen stores have few carbohydrates left in their muscles as the event progresses. This leads to poor performance, especially during the latter part of the competition. Glycogen-deficient athletes run sometimes as much as 50% slower during the latter part of events than in the earlier parts. Compared with competitors who have normal glycogen levels, low-glycogen athletes spend more time walking and less time sprinting as the competition proceeds.

Loading additional carbohydrates before an athletic event has a minimal effect if the event lasts less than 60 minutes. By analogy, adding an extra gallon of petrol to a car with a full tank before a short journey is not beneficial. However, if initial glycogen levels are low (e.g., when participating in a prolonged tournament) and/or the exercise lasts 90 minutes or longer, pre-exercise carbohydrate may improve performance.

Goals of a Pre-Event Meal

A good and balanced diet is as important for performance as proper training. Pre-event meals are a major factor. Before an athletic event or even before highly physical activities in general, certain aspects need to be considered. The meal before an event should ensure adequate carbohydrate intake, prevent dehydration, and avoid gastrointestinal upset. It should provide an empty stomach but prevent hunger pangs and should be pleasant and satisfying. The goal is to maximize the energy available to fuel the muscles and prevent hypoglycemia.

Timing

The timing of the pre-event meal determines whether the meal is helpful or counterproductive. In general, athletes have a meal 2 to 5 hours before the event. Liquid meals may be consumed up to 1 hour before the event. Fructose may be consumed until the time of the event with caution, because fructose-containing solutions are associated with gastrointestinal upset. High-GI carbohydrates taken immediately before high-intensity exercise may improve performance.

Hydration

Adequate fluid intake is paramount, especially when the event takes place in hot weather. Often, athletes hydrate 2 to 3 hours before practices, games, and events. Athletes should aim for at least 16 oz (2 cups) of fluid at this time. Generally, 10 to 30 minutes before competition, 250 to 1,000 milliliters (ml) of liquids should be ingested. A 2% loss of body weight from fluid deficit can impair endurance performance by 22%.

Food

An ideal pre-event meal should consist of 70% carbohydrates or more. It should produce only minimal bulk. The salt content depends on the athlete's cramping tendency (high crampers should use more salt). Experiments with new food before an event should be avoided. High-protein diets do not improve performance. Carbohydrate intake should be 1 to 4 g/kilogram (kg) body weight 1 to 4 hours prior to activity.

Sometimes, the pre-event time is marked with anxiety or excitement, which may preclude the intake of a regular meal. If the athlete cannot consume a solid meal because of anxiety or other causes, a liquid carbohydrate meal may be consumed up to

60 minutes before competition. A carbohydrate meal taken 3 hours before a running exercise at 70% $\dot{V}O_2max$ (peak oxygen uptake) increases insulin levels, but improved exercise time leads to exhaustion. Carbohydrate meals taken before and during high-intensity activity improved lap times, glucose levels, and insulin levels and decreased free fatty acid levels. A comparison between high- and low-GI pre-exercise meals showed no difference in endurance time; however, the low-GI meal resulted in increased fat metabolism. Pre-exercise high-GI foods decreased blood sugar levels, but they had no effect on 10-kilometer (km) running time. Low-GI foods consumed within 1 hour before endurance competition may provide carbohydrates without an associated insulin surge but are associated with a feeling of fullness.

High-fat (61% of calories) meals increased fat oxidation and decreased carbohydrate oxidation but did not change endurance cycling time compared with low-fat (31% of calories) meals. Extra fluid or electrolyte solutions, which may guard against dehydration, hyponatremia, and hyperthermia, may be consumed as tolerated up to the time of the event.

Alcohol

Consumption of alcohol adversely affects the performance of athletes. Five or more alcoholic beverages in one night can affect brain and body activity for up to 3 days. Two consecutive nights of five or more drinks can affect the athlete for up to 5 days. What many athletes do not realize is that five drinks each on Friday and Saturday nights will affect Thursday's performance. A hangover reduces performance by 11%. Alcohol also influences fluid homeostasis. Within 4 hours of drinking alcohol, there is an increased loss of urine. Fluid losses can reach 3% of body weight, but there is already a significant drop in performance when fluid losses reach 2% of body weight.

Salt

Cramping can be devastating to an athlete's performance. Frequently, the cramping is due to high salt losses from sweating. Athletes should salt their food to replace the sodium they lose during sweating, especially if they are heavy crampers. Athletes have varying degrees of salt concentration in their sweat. Those with high salt concentrations may need more salt than the average sweating athlete.

Carbohydrate Loading

Athletes are constantly looking for an "edge" to gain an advantage. Carbohydrate loading is a dietary technique that has been used for quite some time.

Carbohydrate loading (also known as glycogen supercompensation) may improve performance in endurance competition by allowing the muscles to store two to three times more glycogen than normal.

The "classic" regimen requires 3 days of intense, exhaustive exercise on an extremely low-carbohydrate (<10%), high-fat, high-protein diet, to deplete the muscle glycogen stores. Days 4, 5, and 6 are spent resting and consuming a high-carbohydrate (greater than 80%) diet. The endurance event is held on Day 7, when the athlete consumes a normal, high-carbohydrate pre-event meal.

The "modified" carbohydrate regimen involves a moderate carbohydrate (50%) diet on Days 1, 2, and 3 and a high-carbohydrate (>80%) diet on Days 4, 5, and 6. The endurance event is held on Day 7, when the athlete consumes a normal, high-carbohydrate pre-event meal, as in the classic regimen.

Does this actually improve performance?

A 3-day, high-carbohydrate load (9 g kg^{-1} day^{-1} compared with 6 g kg^{-1} day^{-1}) increased muscle glycogen levels in cyclists, but *no* improvement in 100-km race time was observed. Carbohydrate loading demonstrated better results in runners with lower aerobic capacities in events lasting 1.5 to 2 hours.

Preparticipation Cardiovascular Screening

The preparticipation physical exam (PPE) is a well-entrenched part of our sports culture. The purpose of this exam is to review the general health of athletes and make sure that it is safe for them to participate in organized sports. At this point, approximately 30 to 40 million athletes participate in organized sports each year.

Sports-associated sudden cardiac death (SCD) is defined as the death of an athlete from cardiovascular causes during or within 1 hour of completing a sports activity. The death of an athlete, often regarded as a model of physical fitness, is a devastating loss to both the family and the community in which the athlete lives. Many athletes who have experienced such an outcome were considered to have been previously asymptomatic; for this reason, an ongoing debate has arisen regarding screening methods to detect the potentially lethal disorders that lead to SCD in athletes.

Any of a variety of disorders may result in the death of an athlete. For athletes younger than 35 years of age, undetected coronary artery disease is the most common cause, and there are a variety of congenital causes that are thought to contribute to this adverse outcome.

The most common cause of SCD is hypertrophic cardiomyopathy (HCM), which accounts for approximately 40% of deaths in the United States. This disease may have prevalence as high as 1 out of 500 individuals. This disorder results in asymmetric hypertrophy of the intraventricular septum of the heart, which may result in obstruction of blood flow at near-maximum levels of exercise. Also, this hypertrophy and potential obstruction may cause the initiation of an arrhythmia, which then leads to a failure of the electrical conduction system of the heart.

Abnormal development of the coronary arteries, otherwise known as anomalous coronary arteries, is also a common cause of SCD. Typically, during embryogenic development, the coronary arteries arise from and are located in the center of the left and right anterior sinuses of the aortic valve. However, in some individuals, these arteries arise in another fashion. There are multiple variations of this anomalous origin, which is beyond the review of this entry. Of particular interest in SCD is the origin of the left coronary artery from the right sinus of Valsalva, where the right coronary artery also arises. In this instance, the left coronary artery then courses between the aorta and the pulmonary artery, where during periods of intense activity, this artery may become obstructed, resulting in decreased blood flow to a significant portion of the heart, leading to ischemia and cardiac death.

Another common cause of SCD is arrhythmogenic right ventricular dysphasia (ARVD), which is also sometimes referred to as arrhythmogenic right ventricular cardiomyopathy (ARVC). This disorder is thought to result in abnormal growth and development of the myocytes of the heart, leading to myocyte disarray; this disarray also leads to the development of a fibrous fatty deposit that develops in the myocardium. It is thought that this fibrous tissue may lead to the development of an arrhythmia, which could often prove to be fatal.

There are multiple other cardiac abnormalities that may result in SCD, including, but not limited to, the following: myocarditis, severe mitral valve prolapse, long QT syndrome, Brugada syndrome, Marfan syndrome, and sarcoidosis.

Any effective screening test to look for cardiovascular abnormalities such as those noted above should have several key characteristics. It should be able to detect such abnormalities with an appropriate level of sensitivity. This allows for identification of those athletes with the abnormalities that may result in SCD (the true positives). It should also have a high specificity, which would mean that those who test negative truly do not have the disease (true negatives). It would be preferable for the screening tests to approach both 100% sensitivity and 100% specificity in order to prevent a large number of false-positive and false-negative results. In actuality, no test truly reaches such percentages, but the best tests do have values upward of 90% for both specificity and sensitivity. In addition, the test should be able to accurately predict all causes of SCD. Finally, there should be a set point in the course of athletics when the test should be offered to effectively screen everyone while avoiding duplication of services. The following section examines several cardiovascular screening methods that could be used at present.

Cardiovascular Screening Methods

The most commonly touted method of cardiovascular screening is the electrocardiogram, commonly known as the EKG. This test measures the electrical activity of the heart through the use of electrodes spread across the body. The placement of the electrodes and the resulting electrical potentials measured by such electrodes result in a "tracing" of the heart's electrical activity. Several of the diagnoses discussed above may result in abnormal electrical tracings (i.e., evidence of left ventricular hypertrophy and inverted T waves in the percordial leads in HCM). However, even for HCM, EKG sensitivity may only be as high as 50%, with at least a 4% false-negative rate. This is due, in part, to the normal physiologic changes that develop with participation in athletics, known as the "athletic heart"; many of these changes may mimic cardiac abnormalities and will often lead to further, often unnecessary, testing. Additionally, several of the diagnoses associated with SCD will have no electrocardiographic abnormalities even in the best of circumstances (e.g., anomalous coronary arteries).

Another test that could be used is the echocardiogram, which uses ultrasound waves to form an image of the heart. This would be beneficial in looking for abnormalities such as asymmetric septal hypertrophy, which may be noted in conditions such as HCM. The use of echocardiography also allows for visualization of the origin of both coronary arteries. However, this test is much more expensive than electrocardiography, is more time intensive, and requires specialized training to administer and to interpret.

At present, it is recommended that athletes have brachial blood pressures recorded, with auscultation of the heart in both supine and standing positions, along with palpation of the radial and femoral pulses for the cardiovascular exam of the PPE. There has also been some consideration given to providing a more thorough history and physical examination during the PPE to screen for cardiovascular abnormalities. This concern has been raised by several studies that have demonstrated that perhaps several of the athletes who had SCD may have indeed exhibited symptoms such as syncope, chest pain, or dyspnea on exertion prior to succumbing to SCD. The PPE portion requires special attention to be given to the cardiovascular screening questions often present on the PPE form, and the physical examination includes provocative maneuvers such as a Valsalva maneuver to try to elicit findings, such as a murmur, that otherwise may not be appreciated. This would not require any further equipment besides that currently employed at PPE screening; it would, however, require education of those performing PPEs as well as the probable formation of standardized guidelines beyond those currently available. However, to date no published studies have concluded that screenings such as these are any more accurate than the traditional PPE.

There are other tests that, in the future, may become applicable to cardiovascular screening. These could include imaging studies (coronary CT [computed tomography] or cardiac MRI [magnetic resonance imaging]), or they may be perturbations of currently accepted techniques (two-lead EKGs, a handheld limited echocardiogram). At present, these technologies are either too limited in availability or still considered experimental.

Other countries do require some form of screening for cardiovascular abnormalities prior to athletic participation. In Italy, for example, a screening EKG is required as part of the PPE process. A review of the data of the past 20 years reveals a decrease in the rate of SCD in Italy. However, at this time, the current rate of SCD is equal to the best estimate of the currently observed rate found in the United States, along with a disqualification rate that would probably not be acceptable in the United States. Also, there appears to be a dominance of ARVC as a cause of SCD in

Italy, probably secondary to genetic differences in the population of each country. Finally, the cost of EKG is much cheaper in Italy (approximately equal to US$10), and the country itself is much smaller, with fewer athletes than in the United States. Based in part on the evidence from Italy, the International Olympic Committee now requires screening EKGs in all its athletes prior to Olympic competition. Also, partly in response to recent SCD events in its athletes, the National Basketball Association now requires screening electrocardiograms (EKGs) on all its rookie athletes prior to competition. In both these instances, however, there are a much smaller number of athletes competing at much higher levels of competition and/or compensation when compared with the rest of the athletic population as a whole.

Finally, the costs of mandatory cardiovascular screening must be factored in as well. At present, EKG screening seems to be the most commonly considered and, if screening were to be employed, the most practical as well as the most cost-effective. However, even when using a conservative estimate of $30 per EKG as well as a screening of only 10% of the athletic population per year, this would result in a cost to the U.S. health care system of $90 million/year.

Conclusion

In summary, there is still considerable debate regarding preparticipation cardiovascular screening. Given the current limitations in testing abilities and in the availability of screening, as well as the cost-prohibitive nature of such screening, the application of such screening will continue to be limited to specific populations; however, there will continue to be research and discussion on the best methods with which to conduct such screening so as to attempt to eliminate SCD in the young athlete.

Presports Physical Examination

When we look at the preparticipation physical exam (PPE) in sports, we see that the overall objective is to promote the health and safety of the athlete in training and competition. This can be divided further into several basic objectives:

1. To determine the general health of the athlete
2. To detect any conditions that might limit participation, such as hypertrophic cardiomyopathy or aortic stenosis, or any catastrophic event that may place the athlete at risk
3. To detect conditions that might predispose the athlete to injury, such as illness or injuries, lack of conditioning or flexibility, overuse injuries, inadequately rehabilitated injuries, and congenital or developmental problems
4. To evaluate the fitness level of the athlete, and perhaps to improve performance and prevent injury
5. To afford an opportunity for physician-athlete discussion regarding adolescent health care and issues such as testicular and breast self-examination, drug use, alcohol, smoking,

smokeless tobacco, obesity, safe sexual practices, use of seat belts, disordered eating, and nutrition (a correlation between athletes and "risk-taking" behaviors has been reported)

6. To meet legal and insurance requirements

Consistency, Timing, and Frequency of Examination

Minimum requirements for the preparticipation athletic screening are published and clearly outlined but may vary widely in content, length, and comprehensiveness. A licensed practitioner who has the medical skills, background, and training to take the recommended history and physical examination should perform the examination.

Six weeks prior to the season would be an ideal time for the PPE, as this would allow for correction and/or rehabilitation of problems prior to activity. However, the timing of the examination will ultimately depend on the resources of the community, the schools, and the patients. It is recommended that high school athletes get a complete PPE (a) every 2 years with an interim history in the intervening years, (b) when transitioning from junior high school to senior high school, and (c) if switching from one school to another. College student-athletes should undergo a complete PPE initially on entry to college, with a limited annual history afterward that addresses vital signs and any significant changes that may constitute evidence that another examination and further testing are warranted. Many schools require PPE examinations more often than recommended based on local and state requirements.

Type of Examination

PPEs can be accomplished by office-based evaluations or mass-screening, "station" evaluations. Primary care office-based PPEs have the advantages of (a) physician-patient familiarity, (b) continuity of care, and (c) an opportunity for counseling, while the disadvantages include (a) many athletes not having a primary care physician, (b) limited time for appointments, (c) varying knowledge and interest in sports medicine problems, (d) greater cost, and (e) lack of communication with the school athletic staff. Station-type mass examinations have the advantages of (a) specialized personnel, (b) being efficient and cost-effective, (c) good communication with the school athletic staff, and (d) the opportunity for performance testing, while the disadvantages include (a) a noisy environment, (b) lack of privacy, (c) difficulty following up on medical problems and concerns, and (d) lack of communication with parents. It should be recognized that the type of physical examination provided to the athletes may vary according to the needs of the athletes and the resources of the community. If not performed by one's family practitioner, the PPE is meant as a screening tool only and should not be considered to take the place of a comprehensive health maintenance visit.

Athletes should be provided in advance with information about the detailed nature of the examination and the appropriate attire to wear so as to deal with privacy concerns and increase efficiency. Male and female athletes should have separate examination areas. Private individual counseling should be available for discussion of sensitive issues to maintain confidentiality and facilitate better communication. A clear protocol should be established for referral and rehabilitation if needed. Athletes from low-income families may need assistance in arranging and completing follow-up evaluations. If the athlete is not cleared for the desired sport, the evaluating physician should counsel the athlete concerning alternate permissible activities.

History

The medical history is the cornerstone of this evaluation. A complete history will identify most problems affecting the athletes. The history should focus primarily on the cardiovascular, musculoskeletal, and neurological systems, as well as questions regarding general health. A standard PPE form should be used that is brief, easy to read, and understandable by athletes and parents and that allows adequate space for elaboration of positive findings. A copy of a standard PPE form that follows national guidelines in content and structure can be found at http://www.newamssm.org/ppe history.pdf and may be reproduced as needed.

Personal and family histories reveal approximately 75% of the conditions that may prohibit or alter sports participation; therefore, the history is a more sensitive screening tool than the physical examination. Parents and athletes should fill out the form together, and signed parental consent for emergency treatment should be obtained. Reported histories filled out by athletes often do not agree with the information provided by parents, so parental verification of history is recommended.

- Has your doctor ever denied or restricted your participation in sports for any reason?
- Do you have any medical conditions (e.g., asthma, heart disease, or diabetes)?
- Have you ever spent a night in a hospital?
- Have you ever had surgery?

You may discover information regarding past or recent hospitalizations that may affect participation. You may also determine whether a medical illness is under proper control. Frequent admissions for asthma, seizures, and diabetes may require better control before athletic clearance. A history of recent surgery may necessitate a more directed examination to ensure adequate healing time and recovery.

- Are you currently taking any prescription or nonprescription (over-the-counter) medications or pills?

Knowledge of the prescription and over-the-counter medications that athletes take is important. Intermittent medications such as inhalers and antihistamines may affect performance. The proper use of the inhaler should be discussed. The use of nutritional supplements and/or oral contraceptives should be noted. Finally, any history of illicit drug use, such as steroids, cigarettes, marijuana, cocaine, alcohol, smokeless tobacco, or human growth hormone, should be discussed if appropriate. Insulin-dependent diabetics are predisposed to hypoglycemia, and injection sites may need to differ with each sport. Because exercise enhances absorption of insulin from the injection site, nonexercised injection sites should be used. Some athletes do better on a more frequent insulin injection schedule with glucose monitoring while in competition. With diabetes, exercise should preferably be done after meals and daily rather than occasionally and sporadically. Exercise will enable the youth to adjust his or her dietary and insulin requirements, as physical activity appears to increase an individual's sensitivity or responsiveness to insulin. The use of insulin pumps and contact sports should be discussed.

- Do you have any allergies to medicines, pollens, foods, or stinging insects?

A history of allergy to medicines, foods, and insects may necessitate prescription epinephrine kits on the sidelines. Seasonal allergies may be clues to chronic use of over-the-counter drugs. A history of exercise-induced anaphylaxis may necessitate prophylactic antihistamines.

- Have you ever passed out during or after exercise?
- Have you ever had discomfort, pain, or pressure in your chest during exercise?
- Has a doctor ever told you that you have high blood pressure, high cholesterol, heart murmur, or a heart infection?
- Does your heart race or skip beats during exercise?
- Has a doctor ever ordered a test for your heart, that is, EKG or echocardiogram?
- Has anyone in your family died for no apparent reason?
- Does anyone in your family have a heart problem?
- Has any family member or relative died of heart problems or of sudden death before 50 years of age?

Because the majority of sudden death cases in athletes under 35 years of age involve the cardiovascular system, careful attention to cardiac history is paramount. Certain symptoms can identify at-risk individuals with underlying cardiac abnormalities. Strict guidelines have been published regarding the cardiovascular preparticipation screening of athletes. The most common cause of sudden death in young athletes in the United States remains hypertrophic cardiomyopathy. Syncope and near-syncope are "red flags" that should make you consider hypertrophic cardiomyopathy, conduction abnormalities, valvular problems, or congenital coronary artery abnormalities. Advanced atherosclerosis is a rare cause of coronary artery disease in the younger age-group, unless it is associated with a lipid abnormality, but it may be a factor in the older athlete. Congenital abnormality of the coronary arteries (the absence or underdevelopment of coronary arteries; anomalous artery) may be a cause of chest pain and sudden death, but it is difficult to identify without invasive testing.

The medical history should address prior heart murmurs, rheumatic fever, or cardiac surgery. Approximately one third of all adolescents will have audible murmurs, and if these are considered to be normal and functional, the athlete should be reassured that there is no problem. Otherwise, further workup or referral to a cardiologist is recommended. Although no studies are available documenting the prevalence of mitral valve prolapse (MVP) in athletes, screening tests of apparently healthy women have revealed that approximately 5% have auscultatory or echocardiographic evidence of MVP. Sudden death has rarely been associated with MVP, and its finding in the absence of any serious symptomatic ventricular arrhythmias or other symptoms should be considered benign. A more conservative approach should be followed for the occasional athlete with MVP and other symptoms or arrhythmias. Any history of recent severe viral infection that may indicate a risk of myocarditis should be investigated. Palpitations may suggest Wolfe-Parkinson-White syndrome, Lown-Ganong-Levine syndrome, arrhythmias, and other conduction abnormalities. Paroxysmal supraventricular tachycardia is not a reason for restriction from full, competitive participation if the arrhythmia can be controlled; an exercise EKG should be obtained to observe what happens to the cardiac rhythm during intense activity. When in doubt, consult a cardiologist! A family history of sudden death should alert you to some of the common hereditary causes of sudden death. Hypertrophic cardiomyopathy, Marfan syndrome, and some of the prolonged QT syndromes are autosomal dominant (transmission of Romano-Ward syndrome [no deafness] is autosomal-dominant; transmission of Jervell and Lange-Neilson syndrome [QT prolongation, (+) deafness] is autosomal-recessive). EKG changes may be manifested only after exercise. These are rare diseases; however, the risk of sudden death in these patients may be as high as 1% per year. A family history of hypercholesterolemia should also be discussed.

The sensitivity of tests detecting diseases leading to sudden death increases in proportion to the financial resources that can be applied to the screening program. Although at times debated in the literature, the relative high cost of screening and low yield of a positive test in this relatively healthy population of athletes make mandatory noninvasive screening procedures unfeasible. The routine use of EKG has not been demonstrated to effectively enhance the present screening guidelines and is not presently recommended as a routine screening tool for PPE. EKG, echocardiogram, and exercise stress testing are indicated only when findings on history and physical examination warrant further testing. Cardiac consultation should be sought in cases of indecision.

- Does anyone in your family have Marfan syndrome?

Marfan syndrome is an autosomal-dominant disorder caused by a defective gene for the production of fibrillin. Athletes with Marfan syndrome are at risk for cystic medial necrosis with resultant aortic dissection and cardiac valve malformations. Physical stigmata of Marfan syndrome include kyphosis, a high-arched palate, pectus excavatum, arachnodactyly, arm span greater than height, MVP, aortic insufficiency, myopia, lenticular dislocation, “thumb sign,” and “wrist sign.”

- Do you tire more quickly than your friends during exercise?

Dyspnea on exertion could signify chronic lung disease, reactive airway disease, or valvular disease.

- Have you ever had an injury, such as a sprain, muscle or ligament tear, or tendinitis that caused you to miss a practice or game?
- Have you had any broken or fractured bones or dislocated joints?
- Have you had a bone or joint injury that required X-rays, magnetic resonance imaging (MRI), computed tomography (CT), surgery, injection, rehabilitation, physical therapy, a cast, or crutches?

Orthopedic review of systems is obviously important. Focus on any history of injuries to bones, joints, and muscles. Previous history of fractures, dislocations, subluxations, sprains, strains, and tendinitis should be discussed, as well as a review of treatments and rehabilitation modalities that have occurred.

- Have you ever had a stress fracture?

Repetitive stress, poor training technique, menstrual irregularity, poor dietary intake, and/or disordered eating patterns may predispose the athlete to stress fractures.

- Do you regularly use a brace, assistive device, or any special equipment?

Document any pads, braces, neck rolls, sleeves, mouthguards, eye guards, athletic supportive cups, and so on that are used by the athlete during activity.

- Have you ever been told that you have asthma or allergies?
- Do you cough, wheeze, or have difficulty breathing during or after activity?
- Is there anyone in your family who has asthma?
- Have you ever used an inhaler or taken asthma medications?

Athletes with asthma and/or exercise-induced bronchospasm (EIB) should be identified. Find out what treatments have been used in the past and how successful those treatments have been. Remember, EIB is often undiagnosed, and some patients may have only a cough as their asthma variant. The examiner should inquire about difficulty in breathing or wheezing during or after exercise, cough, easy fatigability, chest pain, or tightness in the chest. Make sure that those on inhalers are using them correctly, and consider inhaler spacer devices when appropriate. Children with asthma and EIB should not be restricted but rather encouraged to participate in a full range of exercise activities. Those athletes who are resistant to a challenge of bronchodilators may be followed with pulmonary function studies and/or pulmonary consultation.

- Were you born without or do you have a missing kidney, an eye, a testicle, or any other organ?

Certain restrictions and protective wear may be required for competition.

- Have you had infectious mononucleosis (mono) within the last 3 months?

Full clearance after a bout of infectious mononucleosis is required before activity.

- Do you have any rashes, pressure sores, or other skin problems?
- Have you had a herpes skin infection?

Review of the athlete's dermatological history may reveal sexually transmitted diseases, herpes simplex, scabies, pubic lice, molluscum contagiosum, furunculosis, carbunculosis, and impetigo. A history of itching skin and/or acne should also be reviewed, as equipment and perspiration may exacerbate skin conditions.

- Have you ever had a head injury or concussion?
- Have you ever been hit in the head and been confused or lost your memory?

The number of previous concussions is an important factor when determining preparticipation clearance. Even more important is whether each of those previous concussions resolved completely before return to play. The use of preparticipation neuropsychological testing may be of benefit in some cases.

- Have you ever had a seizure?
- Do you have headaches with activity?

The guidelines regarding epilepsy and participation must be individualized; in athletes with poorly controlled seizures, clearance should be deferred until therapeutic drug levels are reached, the neurological examination becomes normal, and a 1-month seizure-free interval is achieved. Skiing, scuba diving, rope and rock climbing, gymnastics on the high apparatus, parachuting, hang gliding, horseback riding, and high diving are contraindicated in athletes with a history of uncontrolled seizures. Athletes with well-controlled seizures can be cleared to participate in contact and collision sports, provided these activities do not precipitate the seizure activity. Relative contraindicated sports include swimming without the presence of a person qualified in lifesaving techniques, weight lifting, javelin, shot put, discus, archery, and shooting sports such as pistol and rifle shooting.

- Have you ever had a stinger or burner or pinched nerve?
- Have you ever had numbness, tingling, or weakness in your arms or legs after being hit or falling?
- Have you ever been unable to move your arms or legs after being hit or falling?

A thorough review of the athlete's history of any neurological conditions or injuries is required. Burners/stingers and pinched nerves are traumatic neuropraxias secondary to pinching or stretching of the cervical nerve roots or brachial plexus. Signs and symptoms include numbness and tingling in the upper extremity, with occasional weakness in the *absence* of neck pain or stiffness. Burners/stingers do not preclude participation if no neck pain or radicular pain is present, the cervical spine has full range of motion, and no preexisting cervical spine abnoorities and evidence of permanent neurological damage are present (cervical spine instability or degenerative changes). Athletes with a history of recurrent burners/stingers should be counseled regarding neck and upper extremity strengthening, proper technique, and use of protective equipment (neck roll, proper shoulder pad fit). Cervical spinal cord neuropraxia with transient quadriplegia is a rare entity and may occur as a result of trauma. It is found in individuals with cervical spinal stenosis, congenital fusions, cervical instability, and intervertebral disk protrusions. It may also occur in individuals without predisposing abnormalities. Symptoms manifest themselves as burning pain, numbness or tingling, and weakness or paralysis of all four extremities. Episodes are transient, and recovery is usually complete within 10 to 15 minutes, although some cases gradually resolve over 36 to 48 hours. There is no evidence that transient quadriplegia predisposes an athlete to permanent neurological injury, but further consultation is necessary to evaluate the athlete for other underlying cervical spine abnormalities; these patients should be treated on an individual basis, with clearance from a neurosurgeon before return to activity.

- When exercising in the heat, do you have severe muscle cramps or become ill?

Review of an athlete's history of heat-related disorders is important, especially for those training or competing in hot or humid environments. Because athletes with previous heat issues are at increased risk for recurrence, any history of problems with activity in the heat should be documented. Extrinsic factors related to heat illness may include the sporting activity, the environment, geography, clothing and equipment, and certain medications and supplements; intrinsic factors may include dehydration, previous history of heat illness, inadequate acclimatization, poor aerobic fitness, excess body fat, large body size, fever, overexertion, and younger age. Athletes with this condition are usually allowed to participate, but temperature extremes must be avoided and hydration maintained throughout training.

- Has a doctor told you that you or someone in your family has sickle cell trait or sickle cell disease?

Athletes with sickle cell trait are at increased risk of complication when exposed to extreme environmental conditions, such as physical exertion at high altitude or at high temperatures. These athletes should be counseled on appropriate hydration and acclimatization to reduce risks.

- Do you have any problems with your eyes or vision?
- Do you wear glasses, contact lenses, or protective eye wear?

The examiner is specifically looking for the athlete who is single eyed due to complete blindness or has best-corrected vision poorer than 20/40 in one eye. Document what type of contact lens the athlete uses. Obtain any history of previous eye injury or surgery. In those with best-corrected vision poorer than 20/40 in one eye, protective eye gear approved by the American Society for Testing and Materials is required for competition if eye trauma is a possibility. For the one-eyed athlete, sports in which no eye protection can be worn are contraindicated. A detached retina requires clearance by an ophthalmologist. High-risk sports include sports with hard projectiles, sticks, and close contact, such as baseball/softball, basketball, cricket, fencing, field and ice hockey, lacrosse, racquetball, and squash. Sports that put the eyes at risk also include boxing, martial arts, and sports with small, fast projectiles, such as paintball.

- Are you satisfied with your eating patterns?
- Are you unhappy with your weight, trying to gain or lose weight?
- Has anyone recommended you to change your weight or eating habits?
- Do you limit or carefully control what you eat?

Screening for disordered eating patterns is recommended.

- Have you ever had a menstrual period? What was the age of your first period?
- Are your periods regular? How many periods have you had in the past 12 months?
- Have you missed any periods? Any chance that you might be pregnant?

Female athletes should be aware of the importance of a normal menstrual cycle during training. Consideration for estrogen replacement may be appropriate in these athletes. No restrictions are necessary for women with one ovary. Gender-specific aspects of the PPE have been discussed.

- Do you have any concerns that you would like to discuss with a doctor?

This question gives the athlete a chance to discuss issues of interest or concern in private.

Physical Examination

The physical examination can be relatively brief and can focus on areas that are more pertinent to safe participation, particularly the cardiovascular, pulmonary, and musculoskeletal examinations. More detailed examination may be warranted if suggested by the history given previously. The examination should be performed with awareness of the requirements of the particular sport(s) being played by the athlete in question.

Athletes should dress properly for the examination. Height, weight, and body mass index (BMI) are documented and compared with standard growth curves when growth abnormalities are suspected. Thinness may be suggestive of eating disorders, while large increases in body mass over a short period may suggest steroid use. Body fat composition may be required for gymnastics and wrestling. Extremes of thinness and obesity should be addressed.

Blood pressure, heart rate, and respiratory rate should be documented. Although blood pressure measurement is rarely an indication for disqualification from sports, abnormalities are often first noted during the sports physical examination. Hypertension in the adolescent can be a marker of endocrinologic, renal, cardiac, or central nervous system abnormalities or substance abuse. Blood pressure should be compared with age-adjusted tables, as well as interpreted on the basis of the person's gender and height. Standards have been developed by the Task Force on Blood Pressure Control in Children; National Heart, Lung, and Blood Institute; and National Institutes of Health. Proper-sized sphygmomanometer bladder cuffs should be used on all patients. Athletes with blood pressure changes can be referred for follow-up care with a primary care provider. Certain sports, such as weight lifting, may cause significant blood pressure elevations. If hypertension is identified on serial readings, exercise stress testing to determine blood pressure response to maximum exercise may be recommended as part of the workup prior to clearance. Despite recommendations, no findings have been published regarding morbidity/mortality attributable to hypertension in the student athlete, and a relatively liberal position has been taken in allowing participation. In these patients, recommendations of reduction in weight, moderate use of salt in foods, and aerobic exercise are prudent. A history of caffeine, nicotine, or supplements such as ephedra should be elicited.

The oral cavity, ears, nose, and throat should be examined. An eye examination (papillary exam, visual acuity) should be performed. Visual acuity, measured with a Snellen eye chart, should be correctable to better than 20/50. In those with best-corrected vision poorer than 20/40 in either eye, protective eye gear approved by the American Society for Testing and Materials is required for competition. Screening for baseline anisocoria should be done. Use of glasses or contacts, as well as use of approved protective eye wear, needs to be documented. Scar formation or perforation of the tympanic membrane (TM), septal nasal deviation or polyps, oral ulcers, gingival atrophy, enamel erosion, leukoplakia, a high-arched palate, braces, and lymph node enlargement also need to be documented. Poor dentition may be a sign of an eating disorder.

Heart and lung examination should be performed. Document symmetric diaphragmatic excursion, clear breath sounds (no rales, wheezing, rubs), and the absence or stability of any asthma or chronic lung disease. Remember that a normal lung examination does not preclude the possibility of exercise-induced bronchospasm. Palpation of peripheral pulses (radial and femoral simultaneously) may pick up a previously missed coarctation of the aorta. Cardiac auscultation with provocative maneuvers can differentiate a benign, innocent heart murmur from a pathological murmur. Auscultate the chest with the athlete supine and standing, and using the Valsalva maneuver, and listen for murmurs. Be familiar with the murmur of hypertrophic cardiomyopathy (increases with standing, the Valsalva maneuver). The murmur of hypertrophic cardiomyopathy is not sensitive but very specific. Unifocal ectopic beats of atrial or ventricular origin have been considered benign and of little risk to the young athlete if they are fewer than 6 to 8 per minute and decrease with low-intensity exercise (10 sit-ups or deep knee bends). Youths who are symptomatic or in whom ectopic beats do not disappear, or in whom there is an increase in premature ventricular contractions (PVCs) at low intensity, should undergo exercise electrocardiography. If the PVCs disappear when the cardiac rate reaches 140 to 150 beats/minute, the ectopic beats are likely to be benign and do not preclude full competitive activity (monitor the EKG for 10 minutes postexercise to observe malignant arrhythmias during the recovery period). Frequent sporadic ectopic beats of fixed coupling may rarely be associated with myocarditis.

Check the abdominal exam for masses, tenderness, and organomegaly. An athlete with hepatomegaly or splenomegaly should be disqualified and referred for evaluation. The male genital examination should rule out testicular pathology; document a single or undescended testicle, testicular mass, hernia, and varicoceles. Instruct the athlete on the proper technique for the self-testicular examination. The female genital and breast examination is not usually a basic part of the preparticipation examination, but any athlete with menstrual irregularities or breast complaints requires referral. Those in need of a Pap test as per the guidelines of the American Academy of Family Practice should also be referred or rescheduled.

Skin rashes, lesions, and tattoos should be documented. Any dermatological conditions, such as acne, rashes, or skin infections (furuncle, carbuncle, herpes, scabies, lice, molluscum contagiosum) should be treated. Any suspicious nevi or lesions should be excised for identification. Increased acne on the back may be a sign of steroid use. Some athletes may attempt to hide skin conditions that may limit their clearance, so be sure to have the athlete wearing appropriate clothing that will allow for skin visualization. Also, make a point to examine any lesions that are covered with adhesive strips (such as Band-Aids) or bandages at the time of examination.

A neurologic examination should be performed only if the musculoskeletal examination is abnormal, the history is suggestive of a neurologic condition, or the patient has a history of concussions with symptoms.

A standard screening musculoskeletal examination is performed, looking at the contour, range of motion, stability, and symmetry of the neck, back, shoulder/arm, elbow/forearm, wrist/hand, knee, leg/ankle, and foot. A more detailed examination should be undertaken if indicated by the history and physical exam. The following maneuvers should be performed:

- Inspection
- Forward flexion, extension, and lateral flexion of the neck
- Resisted shoulder shrug
- Internal and external rotation of the shoulders
- Resisted shoulder abduction
- Extension and flexion of the elbows
- Fist clench and finger spread
- Back flexion and extension

- Standing/walking on toes and heels
- Duck walk

Special Olympics

Physically challenged athletes can often safely enjoy the thrill of competition. Because physically challenged athletes are many times more likely than most athletes to have a sport-specific impediment, preparticipation examinations must be tailored to meet their special needs. In Down syndrome, the incidence of atlantoaxial instability is 10% to 20%; therefore, all athletes who have Down syndrome should have initial cervical spine radiographs taken to rule out atlantoaxial instability as part of the preparticipation examination. If atlantoaxial subluxation or dislocation and neurologic signs or symptoms are present, all strenuous activities are contraindicated. The athlete should not participate in any contact/collision or limited contact/impact sports, or sports that place undue repetitive flexion or extension stress on the cervical spine, such as butterfly stroke and breaststroke in swimming.

Clearance for Participation

When considering clearance for participation in a particular sport or activity, the practitioner must understand the demands of the sport to evaluate and make recommendations. Does the problem place the athlete at increased risk of injury? Are any other athletes at risk due to the problem? Can the athlete safely participate with treatment (medications, rehabilitation, bracing)? Is limited participation allowed during treatment? If clearance is denied, what limited activities can the athlete safely participate in? After the PPE, the athlete is typically assigned into one of three categories: (1) cleared to play with no restrictions; (2) cleared to play following further evaluation, treatment, rehabilitation, or documentation; and (3) not cleared to play certain types of sports. Lists of conditions that can limit participation and recommendations on who can and cannot compete are available.

In general, it is rare that athletes are not eventually cleared. One study showed that the majority of PPE disqualifications involved the following seven findings: (1) dizziness with exercise, (2) asthma, (3) unfavorable BMI, (4) blood pressure, (5) visual acuity defect, (6) heart murmurs, and (7) musculoskeletal abnormality. Many of these conditions were further evaluated and deemed low risk, and clearance was eventually granted.

The role of the preparticipation sports examination is not to exclude from participation but to make athletics safer for participants. For a screening tool to be effective, it should identify the conditions that will affect the athlete, be both sensitive and accurate, and be practical and affordable. The practice of providing preparticipation medical screening for athletes is neither supported nor refuted by the current medical literature, but while acknowledging these concerns, an organized academic approach to this examination, when thoroughly and consistently performed and supervised by qualified licensed providers, can be an effective tool in identifying medical and orthopedic conditions that may affect the athlete's ability to safely participate in sports.

Pressure Injuries to the Skin

There are several dermatologic entities that are a result of trauma, specifically of friction and pressure during athletic activities. Blisters are a common acute friction injury, and they are seen in almost all athletes. Blisters form when an intraepidermal split occurs from a shearing force within the level of the stratum spinosum (see Figure 1). The stratum spinosum is the deepest layer of the epidermis before the dermis and contains the rete pegs and hair follicles. The split that occurs in blisters rapidly fills with fluid, the composition of which is similar to plasma but with a lower protein content. They may also fill with blood, creating a hemorrhagic or "blood" blister. Blisters typically occur on the hands and feet. On the feet, most commonly, blisters affect the tips of the toes, the balls of the feet, and the back of heels. Heat, moisture, ill-fitting shoes, and unusual exercises all predispose to blisters. If excessive blisters are noted on the body, the physician should keep in mind the potential diagnosis of epidermolysis bullosa. Nail deformities, thin-appearing skin, scalp blistering and alopecia, dysphagia, and dental abnormalities are all characteristics of epidermolysis bullosa.

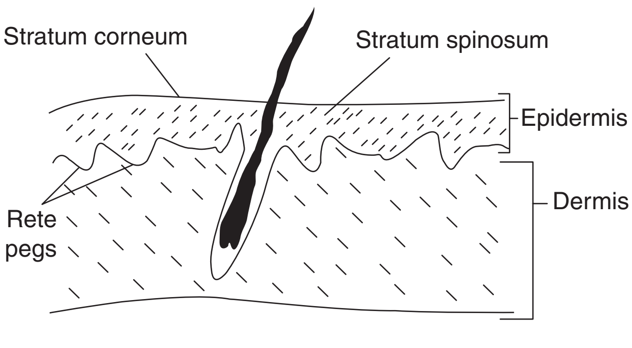

Figure 1 Diagram of the Skin

Source: Elizabeth Rothe, M.D.

Note: The epidermis, showing the top layer (stratum corneum) and the lower layer (stratum spinosum), which contains rete pegs, and the dermis layer of the skin.

Blisters may be left alone if they are not bothering the patient, but if they are causing pain, they are treated by first draining the fluid. This prevents additional intralesional pressure and pain, which might potentially worsen the original injury. This is done by lancing the blister at one of the edges with a sterile blade. The blister roof should be maintained to prevent infection, reduce pain, and provide a natural dressing for the wound. Hydrocolloid dressings may be helpful in promoting re-epithelialization and can also provide protection.

Prevention of blisters can be accomplished by taking steps to decrease the points of friction. Moisture can be decreased by using moisture-wicking socks, using drying powders such as talcum or alum, or using antiperspirants on the feet. In addition, using two pairs of socks composed of different materials, applying petroleum for lubrication, using neoprene insoles, and soaking the feet in 10% tannic acid solution to thicken the skin have been suggested as methods to prevent blisters.

Calluses result from long-term, repetitive friction. They consist of hypertrophied skin and are most often seen on the hands and feet. They are typically painless and often confer a competitive advantage to the athletes for their particular sport. They may be pared down with a surgical blade if desired. The differential diagnosis of calluses includes warts and corns. A careful clinical exam is warranted, as warts can occur within calluses and can therefore be well disguised. Calluses may be prevented by wearing synthetic socks and properly fitted athletic clothing and equipment. Petroleum jelly may also help prevent calluses.

The toenails are particularly susceptible to pressure injuries. *Jogger's toe* occurs on the longest (most often, the first) toe. It is a result of the toe hitting the end of the toebox repeatedly. Jogger's toe is exacerbated by running downhill. The toenail becomes thickened and darkens, and develops horizontal ridges. These are the result of an initial subungual hematoma and hyperkeratosis in response to the continued trauma. A related entity is *tennis toe,* which results from the quick stops and starts in racquet sports and basketball. Soccer players can also develop this in response to repetitive kicking. Jogger's toe will often resolve on its own. Evacuation of the hematoma by puncturing the nail is controversial, but if the hematoma is large, it may prevent loss of the nail. This is best accomplished with electrocautery to prevent infection. Rest and warm soaks are more helpful for chronic injuries. Some runners will paint their toenails with a dark color to hide the trauma. The differential diagnosis includes fungal infection and melanoma. A potassium hydroxide (KOH) preparation slide and culture will rule out the former diagnosis. If melanoma is suspected, as when discoloration occurs in the periungual region, a biopsy should be taken. Jogger's toe can be prevented by wearing a properly fitted shoe with a tight midfoot, to prevent too much anterior movement of the foot, and a long and tall toe box. Furthermore, nails should be cut straight across, not rounded, to distribute forces more evenly across the width of the toe.

Jogger's nipples are a chafing injury that can occur in distance runners. They typically occur in men who wear coarse shirts or women who don't wear a properly fitted bra and are more common in cold weather, when the nipples are erect. Jogger's nipples consist of painful, erythematous, crusted erosions over the nipple and areola. They can fissure and bleed, resulting in streaks of blood running down the shirt. They should be treated with petroleum jelly with or without an antibiotic ointment. Those who have had them in the past should try to prevent their occurrence by using soft-fiber bras or shirts, applying petroleum, taping the nipple or using commercially available patches prior to running, or keeping the skin dry with talcum or alum powders.

Piezogenic pedal papules are herniations of fat through the reticular dermis on the posterolateral heel. They can be painful or asymptomatic, but if they are painful, they may sideline an athlete. They are often not visible if the athlete is seated or supine, so diagnosis requires the athlete to stand and apply pressure to the heel. They are often 2 to 5 millimeters (mm) in diameter and yellow-white in color. There is no cure, but heel pads have been reported to alleviate the discomfort.

Talon noir and *mogul's palm* result from intra-epidermal bleeding from shearing forces of the epidermis sliding across the rete pegs, causing intra-epidermal hemorrhage (see Figure 1). Talon noir consists of blue or black macules, most commonly seen on the posterior, lateral, or medial heels of basketball players (see photo, this page), while mogul's palm affects the hands of skiers who repeatedly plant their poles. They can be diagnosed with removal of the hemorrhage with a surgical blade. The differential may include melanoma, and if this is suspected, a biopsy should be performed. Both entities resolve on their own in 2 to 3 weeks. Talon noir can be prevented by wearing two pairs of socks, applying lubrication, and using heel pads.

Talon noir in the heels. Observe the hyper-pigmented appearance.

Source: William W. Dexter, M.D.

Runner's rump consists of hyperpigmentation from ecchymoses at the superior gluteal cleft. It results from contact of the buttocks during each stride. It resolves at times of decreased training. It is of little clinical significance.

Preventing Sports Injuries

A common pronouncement on sports injuries is that they are "part of the game" and that little can be done to prevent their incidence and severity. Studies have dispelled this myth. By addressing the risk factors associated with sports injuries, especially those seen in young athletes, reductions in both *acute* and *overuse* injury rates of between 15% and 50% have been demonstrated.

Preventing Acute Sports Injuries

Preseason Fitness Preparation

Athletes should participate in a directed preseason physical conditioning program focusing on heart and lung endurance, strength, and flexibility. The conditioning program should also include sport-specific exercises to prevent injury: Swimmers and tennis players should focus on shoulder and arm conditioning, soccer players should emphasize strength and flexibility exercises for the groin and legs, and so on.

The team physician should use the off-season to help the athlete, where appropriate, address a previous injury with an exercise program. For example, the football player who has sustained a sprained ankle the previous season should be encouraged to work on a program to build strength and flexibility in the ankle dorsiflexors and evertors.

Wherever possible, teams should be encouraged to employ the services of athletic trainers or physical therapists, who can assist the team physician in instituting and monitoring this preparticipation fitness program.

Proper Warm-up and Cooldown

The benefits of warming up and cooling down (sometimes called "warming down") are well established: improved performance, psychological preparation, creating a comfort zone for the activity itself, and relieving the aches and pains of vigorous athletic activity.

Most important, though, the warm-ups and cooldowns prevent injuries from occurring.

Acute injuries are much more likely to occur when the muscles, tendons, and ligaments are "tight" or "cold." Tissues that have not been warmed by increased blood flow and then lengthened with gradual stretches are less pliable. Thus, they are at a greater risk of being torn during the normal twists, turns, and stretches of sports. Less pliable tissues are also more susceptible to overuse injuries.

Another important reason to properly prepare for exercise is that warm-ups improve coordination/proprioception and minimize the risk of accidents—a slip, fall, or trip.

Additionally, studies have shown that beginning vigorous exercise without a gradual warm-up—sudden strenuous exercise (SSE)—puts athletes at risk of cardiovascular difficulties. Remember too that good preparation improves performance.

The intensity and duration of the warm-up and cooldown vary with each athlete. To achieve optimal elevation in body temperature and heart rate, the well-conditioned athlete probably requires a longer, more intense warm-up than a less well-conditioned person.

Irrespective of the conditioning level of the athlete, every workout should include five stages: (1) limbering up (5 minutes), (2) stretching (5–10 minutes), (3) warm-up (5 minutes), (4) primary activity, and (5) cooling-down and cooldown stretching (10 minutes). For more on the five stages of a workout schedule, see below.

A team whose players experience a disproportionate number of acute injuries such as sprains and strains may not be doing enough pre- or post-activity preparation, and if so, the team physician should address this issue with the person responsible for this area.

The Five Stages of a Workout

Limbering Up (5 minutes)

One of the most common mistakes athletes make is not limbering up before stretching. Muscles need to be warmed before they can be safely and effectively lengthened during the stretch session.

In the limbering-up stage, athletes should raise their body temperature by 1.5° or 2° above normal before stretching. When the body temperature is raised by a couple of degrees, the athlete is making his or her muscles and tendons more lubricated and elastic. The joints increase their secretions, and so there is less friction. The transmission of nerve impulses into the muscle fibers is more efficient, and the reflexes also improve.

The limbering-up phase is complete when the athlete breaks into a sweat.

The kinds of exercise that are ideal for the limbering-up session include the following: stationary bike riding, a light jog, a brisk walk, rope skipping, using a rowing machine, or using a stair-climbing machine.

It is not necessary to become tired during the limbering-up period. The goal is simply to warm the muscles in preparation for stretching.

Stretching (5–10 minutes)

After limbering up, do between 5 and 10 minutes of stretching exercises. As the athlete gets older, flexibility decreases. The older the athlete, the more important it is that he or she take the time to stretch. Also, athletes who have specific trouble with injuries should focus on the appropriate areas, both before and after the activity.

Stretching improves flexibility. As seen in the section on flexibility conditioning, stretching should not be painful. During each exercise, stretch to the point of tension, known as the "action point," and hold it for between 30 and 60 seconds, depending on preexisting flexibility. By not overstretching, the exerciser can relax and hold each position longer.

"Ballistic" stretching, when the exerciser bounces up and down to create the stretch, is not recommended because of potential injury to muscles resulting from stretching and contracting them too quickly.

In addition to stretching all the major muscle groups before exercising, the athlete may need to pay special attention to specific stretches for different sports demands. For example, tennis players need to devote extra time to stretching out their upper backs, shoulders, and necks, as well as their calves, Achilles tendons, and ankles. Runners need to focus on their lower backs, quadriceps, hamstrings, calves, and groin muscles.

It may also be necessary to spend additional time stretching areas that are naturally tight or ones that have been previously injured.

Remember not to overstretch and to hold each stretch for between 30 and 60 seconds. Do each stretch between one and three times, depending on preexisting levels of flexibility, area-specific tightness, previous injuries, and the chosen sport or fitness activity.

Warm-Up Prior to Vigorous Activity

The warm-up session should ideally last 10 minutes.

The activity selected for the warm-up should mimic the primary workout activity. This is to maximize coordination for the sport and in so doing minimize the risk of accidental injury. For instance, joggers should perform a walk-jog, then slowly increase to a run. Swimmers should start with a few slow laps. Players of racquet sports should rally with their partners or by themselves (including service), and golfers should take practice strokes.

When warming up for an endurance health fitness activity such as running, swimming, aerobics, or biking, the heart rate during the warm-up should be 50% of the maximum heart rate.

Primary Activity of Workout

Cooling Down (5 minutes) and Cooldown Stretches (5 minutes)

Never end any vigorous physical activity suddenly. A 5-minute cooling down period helps prevent sudden changes in the cardiovascular system that can cause light-headedness or even fainting.

Gradually slowing down is as important as gradually warming up. Cooldown should be done in the same way as the warm-up—with gentle, easy movements that return the heart rate to normal. Joggers should gradually slow down to where they are walking. Swimmers should take their last few laps slowly. Even racquet sports players need a period during which their heart rate slows gradually; squash and racquetball players who work out in fitness facilities may have the opportunity to jog, then walk on a treadmill, cycle slowly on a stationary bike, or gently use a rowing machine.

Stretching for 5 minutes after exercise prevents the muscles from tightening too quickly. It may minimize muscle discomfort and may also be helpful in maintaining flexibility. Perform an abbreviated version of the exercises in the prestretch portion of the workout. Again, pay special attention to those specific areas that the sport has stressed.

Safe Playing Conditions

Sports injuries are less likely to occur if the athlete is using proper facilities. Examples include the following:

- Playing fields free of potholes, glass, or other debris and with padded posts
- Basketball/volleyball courts free of any debris or potentially dangerous objects (discarded sweatpants, water bottles, etc.) and without any wet spots from sweat, spillage, or roof leaks (If any occur during games or practice, they should be immediately wiped up.)

Coaches and team physicians should involve themselves in inspecting the playing conditions before the sports event.

Addressing Extreme Temperatures

The safety of sports participation can be directly affected by the ambient climate at the time of participation. A dramatic example of this is the Massachusetts Commonwealth Games of 1999, when a number of athletes were inadequately prepared for the extreme heat and humidity during the competition. Heat and cold acclimatization as well as altitude acclimatization are known physiological processes that can be facilitated by a proper progression in training in these environments. Both the International Federation of Sports Medicine and the American College of Sports Medicine have published position stands and recommendations on athletic participation in extreme heat.

Athletes who exercise outside in hot and humid or cold and wet conditions can suffer from a variety of ailments. Injuries due to overheating and overcooling are especially prevalent among runners. In fun runs, for instance, the most serious injuries are related to the inability to keep the body temperature from rising too high. This increase in temperature occurs when the body produces heat at a faster rate than it can disperse heat. In short races of 10 kilometers (km; 6.2 miles) or less, increased body temperature (*hyperthermia*) occurs in conjunction with the tiredness caused by the heat; fainting and dizziness can occur, even on relatively cool days. In longer races on warm days, these heat problems are common. On cool or cold days, especially when it is wet and windy, the risk to participants in running races is related to low body temperature (*hypothermia*).

Athletes may become too hot or too cold, depending on the prevailing temperature, humidity, wind conditions, and clothing.

Overheating: Hyperthermia

During vigorous exercise, the amount of heat produced by the working muscles is 15 to 20 times what they produce at rest. This elevated rate of heat production can raise the body temperature rapidly. As body temperature rises, the brain senses this and increases the amount of blood sent to the skin and stimulates sweating. The skin is then cooled by sweat evaporation. If the cooling effect is inadequate, the body will overheat. Injury will occur when the person becomes too hot, that is, when body temperature goes higher than 104 °F (40 °C).

During long training sessions or athletic events, the amount of body fluid lost through sweat can cause runners to lose a lot of weight. The loss of weight is directly related to how much fluid the athlete has lost and can be equal to 6% to 10% of total body weight. This water loss is medically known as dehydration. Severe dehydration will cause a reduction in the athlete's capacity to sweat and, therefore, increases the risk of getting too hot, which may lead to heat stroke, heat exhaustion, and muscle cramps. Children are much more likely to get overheated and overcooled than adults and should be watched carefully during training sessions and games in hot conditions.

The risk of heat injuries can be reduced by dressing appropriately for the weather. It is also possible to reduce dehydration during long training sessions by drinking plenty of fluids, mainly cool water. Sometimes during shorter exercise sessions, the participant's body may heat up without the person seeming to lose weight; therefore, athletes should always be alert to the problems of heat stress. Athletes should always avoid drinking liquids containing high amounts of sugar (e.g., soft drinks) immediately before or during runs. Many sports drinks contain high concentrations of glucose, which delay the water's absorption into the system. Also, sports drinks' much-touted extra electrolytes are not necessary because electrolyte loss from sweating is minimal in the trained athlete who performs relatively short-term exercise. Most of the sugar and electrolytes can be replaced through a balanced meal after the exercise. Athletes who prefer the flavor of sports drinks should dilute them with water by half.

Athletes who do vigorous exercise frequently—especially during extremely hot temperatures—should make sure that their diets contain plenty of salt, potassium, and calcium. These are the essential minerals lost through sweat. Salt tablets are not a good idea. They are difficult to digest, and consequently, the salt doesn't get into the system where it can provide any benefit. Salt tablets may also upset the chemical and electrolyte balance of the body.

Alcohol should never be used to replace lost fluids.

In hot climates, athletes should avoid exercising outside at midday, when the temperature is at its peak. It is best to exercise in the early morning or late evening. Avoid strenuous workouts when the humidity is high.

Overcooling: Hypothermia

The body can lose too much heat when the rate at which a person loses heat is greater than the rate at which he or she produces heat. Even on moderately cool days, if a runner's pace becomes too slow and/or if the weather conditions become cooler during the run, the runner can become too cold. Several deaths have been reported due to cold conditions during fun runs, especially in the mountains. Being too cold is common for inexperienced marathon runners, who frequently run more slowly in the second half of the race, but as they slow down during the race, especially on cool, wet, or windy days, they can suddenly become too cold. Early signs and symptoms of being too cold are shivering, a false sense of well-being, and an appearance of intoxication. As the body temperature drops further, the shivering may stop, and excessive drowsiness and muscle weakness may occur, with disorientation, hallucinations, often a belligerent attitude, and finally unconsciousness or death.

Injuries caused by cold temperatures are preventable largely through appropriate use of protective clothing. The appropriately clothed athlete can withstand a wide range of temperatures. Obviously, wearing the appropriate clothes to help keep the body cool will be very helpful in hot temperatures. For example, light-colored clothing made of cotton is much better than dark-colored clothing made of synthetic fibers such as nylon. In cold weather, insufficient clothing will not provide the protection necessary for a runner to keep warm, especially near the end of the race, when he or she slows down and the heat production of the body is less than that necessary to keep warm. On a cool day, the clothing worn should consist of multiple thin layers of cotton fibers. A polypropylene fabric may be worn near the skin. This clothing should be covered with an easily removed Windbreaker (preferably human-made nylon). As the athlete gets warm, clothing can be removed to allow sweat to evaporate or dry. However, when the pace gets too slow for the runner to keep warm, the clothes can be put back on. In addition to being more effective at retaining body heat, *multilayering* allows athletes to remove layers when they get warm. When the clothing is nonconstricting, multilayering helps prevent sweat freezing on the body. Appropriate headgear should not be neglected during cold weather, as the body loses most of its heat through the head. In very cold weather, the face, nose, and ears should also be covered, as these areas are the ones most likely to become frostbitten. During wet weather, waterproof clothing is essential.

It is also advisable to wear sweatsuits while warming up during cool or cold weather. The insulation provided helps muscles, ligaments, and tendons get warmer and more flexible, which contributes to preventing both acute and overuse injuries.

Appropriate Safety Equipment

Protective safety equipment has been developed and recommended for many different sports. The purpose of such equipment is to help prevent and reduce the severity of injuries. The use of safety equipment is usually an outcome of research by health professionals who have identified a high risk of injury in a particular sport or recreational activity. The use of safety equipment may be advocated by the government, national medical organizations, public health professionals, safety groups, national governing bodies of sports, or sports associations to prevent many different types of injuries, especially catastrophic injuries. It is the job of the coach and the team physician to oversee the equipment personnel in making sure that athletes wear safety equipment appropriate for their sport and that the safety equipment worn be sized correctly for the athlete.

Preventing Overuse Sports Injuries

After studying millions of overuse injuries, sports medicine physicians have identified risk factors that are either *intrinsic* or *extrinsic.*

Intrinsic Risk Factors

- Previous injury
- Poor conditioning/muscle imbalances
- Anatomical abnormalities
- Nutritional factors
- Growth (in children)

Extrinsic Risk Factors

- Training errors, including abrupt increases in the intensity, duration, or frequency of training
- Inappropriate workout structure, including improper footwear

Risk factors are the key not only to preventing sports injuries but also for diagnosis, treatment, and rehabilitation. They often explain why some athletes sustain overuse injuries while others do not. Of the risk factors associated with overuse sports injuries, the ones most to blame are *previous injury, poor conditioning/muscle imbalances, anatomical abnormalities,* and *training errors.*

Often, two or more risk factors can cause an overuse injury to occur. For example, an athlete may have dramatically increased the amount of training over a relatively short period of time while training in worn-out footwear and on training surfaces that have become harder because of climatic changes such as lack of rain.

An understanding of all the risk factors associated with overuse injuries is a crucial first step toward taking a comprehensive approach to injury management.

Intrinsic Risk Factors

Previous Injury

The most reliable predictor of injury is previous injury. Most athletes who get injured are destined to reinjure themselves. This underlines the inadequacy of injury management, especially rehabilitation. Unless rehabilitation is done, tissues weakened by injury do not fully regain their strength, which puts them at risk of getting damaged again.

Proper rehabilitation may break the injury-reinjury cycle, but only when the program emphasizes return to *full function,* not just symptom relief.

Poor Conditioning

Unfit athletes are much more likely to get injured than those who are in shape. Studies have shown that injuries tend to occur early on in the sports season, when athletes are generally less conditioned than later in the season. This applies to overuse injuries, too, because an unfit athlete's body is less able to cope with the repetitive stresses of his or her chosen activity. It is extremely important that athletes do not go from being relatively inactive for an extended period straight into rigorous training, such as going directly into the football season after a summer "off." Athletes should be given off-season strength and flexibility programs by their coaches. These programs should address "weak" areas that have been the site of previous injury.

It is also important to keep in mind that being fit for one sport does not mean that an athlete is necessarily fit for another. For example, long-distance runners may not be immediately fit for intensive swimming training—and vice versa—so it is important if they switch over that they do exercises to condition their bodies and work themselves slowly into the training.

Muscle Imbalances

Imbalances between muscle groups near one another are common in athletes, and the team physician should be aware of their significance. Muscle imbalances may be due to asymmetry of muscle use reflecting the special demands of the sport itself. For example, ballet dancers often have excessive strength and tightness in the abductors of the hip and relative weakness of the adductors of the hip. Additionally, adolescent athletes may have muscle imbalances induced by the growth process. About the anterior thigh, there is a tendency for the lateral muscles to become stronger and tighter and the medial muscles to be relatively weaker. Usually, these muscle imbalances are seen in the lower back and legs.

The consequence of these imbalances is threefold. First, they can cause stresses to the underlying tissues; second, they can pull certain parts of the anatomy out of alignment; and third, they may interfere with proper running form. All three can lead to overuse injuries.

Stresses Caused by Muscle Imbalances. Tight muscles can cause any number of overuse injuries, especially in running sports. Excessive tightness in the muscles that run along the outside of the thigh, the iliotibial band, can create pressure on the outer side of the hip (*trochanteric bursitis*) and the outside of the knee (*iliotibial band friction syndrome*). Tight muscles and tendons in the back of the lower leg (gastroc-soleus/Achilles tendon unit) can cause Achilles tendinitis, an inflammation of the thick cord of tissue that connects the calf muscles to the back of the heel, and *plantar fasciitis,* an inflammation of the connective tissue underneath the foot that connects the toes to the heel (*plantar fascia*).

Alignment Problems Caused by Muscle Imbalances. The most frequent sites of alignment problems caused by muscle imbalances are the back and the knee.

Low back pain is common in athletes. Often, it is caused by tightness in the muscles in the front of the hip (*psoas*) and behind the thigh (hamstrings) relative to tightness in the stomach muscles (abdominals) and the muscles in the front of the thigh (quadriceps). The spinal postural stabilizing muscles may also be relatively weak. Such an imbalance can cause a posture problem called "swayback" (*lordosis*), in which there is excessive front-to-back curve in the lower spine. This in turn predisposes the athlete to serious overuse injuries of the lower back, such as a herniated disk and spondylolysis.

Patellofemoral pain is another frequent problem in athletes, especially those who have to do a lot of running during training or competition. The most common patellofemoral problem is the patellofemoral pain syndrome, which is usually caused by maltracking of the patella in the *trochlea,* the anterior groove of the femur. A number of factors may contribute to the imbalance of forces at the patella that result in pain, including anatomic factors and muscle imbalances. The patellofemoral pain is caused by an imbalance between the muscles on the inner and outer sides of the quadriceps, the *vastus medialis* and *vastus lateralis,* respectively. The end result of this imbalance is a tendency toward lateral tracking and posturing of the patella in its trochlear groove. With early institution of appropriate exercises to strengthen the vastus medialis and stretch the vastus lateralis, this imbalance can often be corrected and the pain relieved.

Foot Strike Problems Caused by Muscle Imbalances. The third problem associated with muscle imbalances is their effect on the biomechanics of running. This generally affects athletes engaged in sports that involve a lot of running.

Running causes tightness in certain areas, most often the psoas muscles in front of the hip, the hamstring muscles in the back of the thigh, and the gastroc-soleus/Achilles tendon unit in the back of the lower leg.

Athletes with this pattern of tightness tend to have a much briefer than normal foot strike when running, because their muscles are so tight that they cannot perform the optimal relaxed heel-to-toe foot strike. With each step, the time taken for each foot to touch the ground is less, and thus the feet absorb more stress every time they hit the ground. Although the time differential may seem relatively minor, when one considers that a runner may take 10,000 steps every hour, the consequences may be dramatic.

Anatomical Abnormalities

One of the most common reasons some athletes sustain overuse injuries while others do not is that they have anatomical abnormalities that place additional stress on the surrounding structures. In daily activities, these anatomical abnormalities do not cause problems, but when they are subjected to the repetitive stresses of running, overuse injuries may occur. The most common anatomical abnormalities of the lower extremities are flat feet, feet that excessively *pronate* (roll inward when the athlete runs), high arches, knock-knees, bowlegs, and turned-in thighbones (*femoral anteversion*).

Flat Feet/Excessive Pronation (Pes Planus). Some people have naturally flat feet that excessively turn inward ("pronate") when they run (Figure 1). A certain amount of natural pronation occurs during the "running cycle" with each step any athlete takes. Excessive pronation, however, can be harmful. It causes increased stress throughout the lower extremities. In such cases, overuse injuries may occur. In the foot itself, the most common overuse injuries associated with flat feet and feet that excessively pronate are stress fractures and posterior tibial tendinitis.

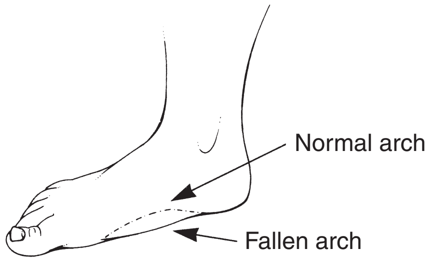

Figure 1 Flat Feet (Pes Planus)

Flat feet and feet that excessively pronate not only cause problems in the foot but may also affect the entire lower extremities, including the knee and hip, because both these conditions cause inward rotation of the legs.

Other lower extremity problems thought to be caused in part by flat feet or feet that excessively pronate are compartment syndrome in the lower leg, patellofemoral pain in the knee, and trochanteric bursitis in the hip.

High Arches (Pes Cavus). High arches, or "claw foot" as this condition is sometimes known, make the feet inflexible (Figure 2). The rigidity of this kind of foot makes it susceptible to overuse injuries.

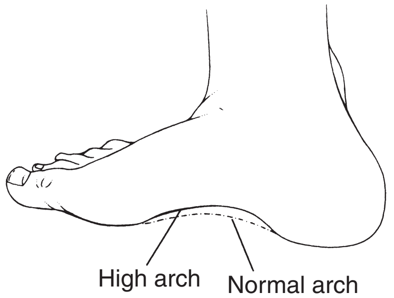

Figure 2 High Arches (Pes Cavus)

It also results in overuse injuries in the lower leg because its inflexibility causes the force to be transmitted to the structures above.

Athletes with high arches are susceptible to stress fractures in the foot, lower leg, upper thigh, and pelvis; plantar fasciitis (heel spurs); and Achilles tendinitis.

A person with high arches may also develop a *hammer toe,* in which the second toe becomes buckled and cannot be straightened. A high arch causes the big toe to slide under the second toe when the athlete runs, causing the hammer toe condition to develop.

Knock-Knees (Genu Valgum). Knock-knees create serious problems for the knee joint. Excessive inward angling at the point where the thigh and lower leg meet (*Q angle*) causes the athlete's weight to be borne on the inside of the knee (Figures 3 and 4). A Q angle greater than 10° in men and 15° in women is said to predispose that person to knee problems if he or she participates in a sports program that involves extensive running. Knock-knees are a common cause of patellofemoral pain syndrome, the most common diagnosis seen in the sports clinic.

Bowlegs (Genu Varum). Bowlegs are the opposite of knock-knees—they bend outward instead of angling inward. Athletes with bowlegs are at greater risk for sustaining problems on the outer side of the knee, especially iliotibial band friction syndrome. Having bowlegs creates a longer distance over which the iliotibial band must stretch, making it tighter over the outer side of the knee joint, where the symptoms develop. However, it should be noted that many athletes with bowlegs participate in distance running without any problems (Figure 5).

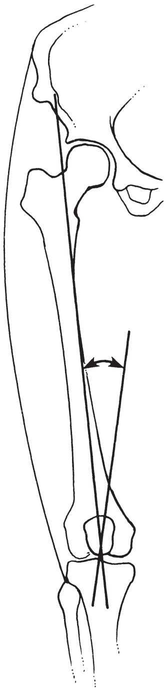

Figure 4 Q Angle

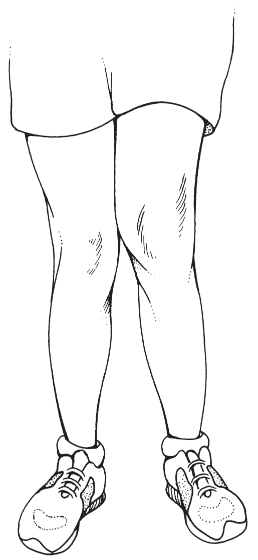

Figure 3 Knock-Knees (Genu Valgum)

Turned-In Thighbones (Femoral Anteversion). At birth, almost all infants have anterior rotation of the femoral neck with respect to the distal femur (anteversion). There is a progressive tendency with growth and maturation for the degree of femoral anteversion to decrease. However, in certain cases, anteversion does not decrease or was initially so excessive that the end result is an inward facing of the entire femur when the athlete stands with feet together. Often, femoral anteversion, when combined with a compensatory external tibial torsion, can increase the lateral torque at the patellofemoral groove and contribute to the onset of patellofemoral pain. Because it so often results in overuse sports injuries, the combination of femoral anteversion, genu valgum, external tibial

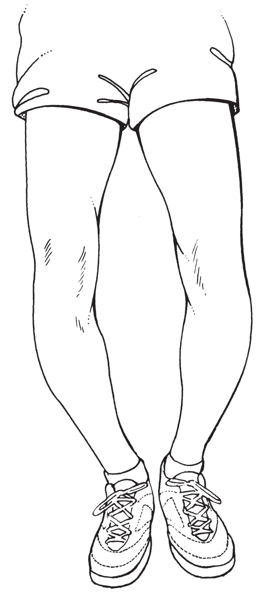

Figure 5 Bowlegs (Genu Varum)

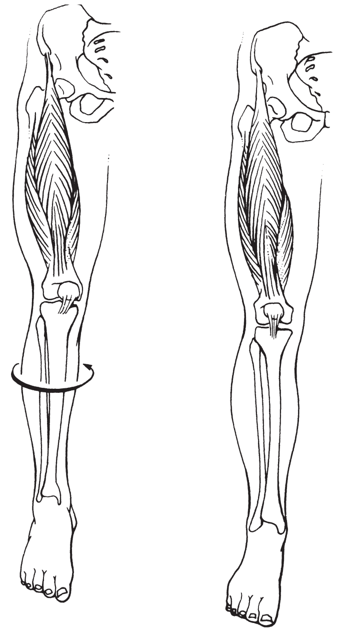

Figure 6 Femoral Anteversion

torsion, and pes planus has been dubbed *miserable malalignment syndrome* (Figure 6).

Unequal Leg Length. It is not uncommon for people to have one leg longer than the other. This can create problems, especially in the longer leg. For instance, in the longer leg, the iliotibial band (the thick swathe of tissue that runs down the side of the leg from the hip to just below the knee) must stretch over a longer distance, which may cause inflammation of this tissue where it passes over the side of the knee joint. Also, a person with one leg longer than the other tends to run with his or her spine curved slightly sideways. As a result, wear and tear can occur on the concave side of the spine.

Nutritional Factors

The relationship between three distinct but interrelated conditions—eating disorders, menstrual irregularities, and stress fractures—is known as the *female athlete triad.* Those responsible for the health of female athletes should familiarize themselves with this phenomenon.

Female athletes have more eating disorders than sedentary women. The combination of poor eating habits and high activity level can cause a woman's fat level to drop below the level necessary for normal menstrual function. When women of reproductive age stop having their periods (amenorrhea) or have periods irregularly (oligomenorrhea), they lose much of the estrogen necessary for the bone rebuilding that normal bodies perform on a continuous basis. This causes premature osteoporosis, a disease that causes the bones to become thinner and more brittle, which in turn predisposes the athlete to stress fractures. Among female athletes with menstrual irregularities, there is an almost tripled incidence of stress fractures. The most common sites of stress fractures in female athletes are the back, hip, pelvis, lower leg, and foot.

The Growth Factor

Until quite recently, overuse injuries were seen only in adults, most often highly trained elite athletes and "weekend warriors"—sedentary adults who do no athletic activity during the week and then play three sets of tennis on Sunday. Because of this pattern, physicians thought that overuse injuries such as tennis elbow resulted from too much stress on aging bones, muscles, tendons, and ligaments in a short period of time. However, with the rise of rigorous, repetitive sports training regimens for children, it has been discovered that children are even more likely than adults to sustain these overuse syndromes.

Children are more susceptible than adults to overuse injury because growth is the fundamental feature of childhood. Growth makes children vulnerable to overuse injuries for two reasons: (1) the presence of growth cartilage and (2) the growth process itself.

The team physician who is responsible for the sports health of young athletes must be aware of the significance of these two components of the growth factor.

Growth Cartilage. Growth cartilage is found at three main sites in the growing child's body: (1) the growth plates near the ends of the long bones, (2) the cartilage lining the joint surfaces (articular cartilage), and (3) the points at which the major tendons attach to the bones. Until a child stops growing, growth cartilage is present, and it is more easily damaged by repetitive microtrauma than thin, hard, fully formed adult bone cartilage. This is of particular concern at the joint surface. And because this cartilage is "prebone," injuring it may have serious consequences in later life.

The Growth Process. The major role of growth cartilage in predisposing children to overuse injury is now well-known in the medical community. What is not as well recognized is that overuse injuries are exacerbated by the growth process itself. In the past decade, pediatric sports medicine experts have devoted an enormous amount of research time to unraveling the mysteries of growth and to discovering how and why it increases the risk of overuse injuries in children.

Research has identified the chief culprit: the tightness in growing muscles and tendons. The muscles and tendons do not grow at the same rate as the bones but instead must stretch to keep pace with the growth of bone. During the adolescent growth spurt, the bones in children's legs grow so quickly that a height increase of 2 centimeters in a month is not uncommon. But because the muscles and tendons spanning these rapidly growing bones do not elongate as quickly, they get much tighter. This tightness is particularly noticeable in muscles that cross two joints. The loss of flexibility, although temporary, increases the likelihood of overuse injuries, particularly in the knee and back.

Extrinsic Risk Factors

Errors in Training

Training error—usually "too much too soon"—is the primary cause of injury, especially overuse injury. Injuries can develop when athletes suddenly increase the *frequency, duration,* or *intensity* of their workouts.

Frequency refers to *how often* the athlete trains.

Duration refers to *how long* the athlete trains.

Intensity refers to *how hard* the athlete trains. Not only does intensity encompass factors such as how far or how fast a person jogs or how heavy a weight he or she lifts; it also refers to less obvious aspects of the exercise regimen, such as the hardness of the training surface on which the athlete is exercising. Track athletes can consider that they have significantly increased the intensity of their workout if they switch from running on grass or clay to road running or from running primarily on flat surfaces to running on hills. The same applies to football players who switch from natural to artificial surfaces. Playing on a softer surface is not always less stressful; for instance, running on sand stresses the Achilles tendons and predisposes the athlete to tendinitis in that area. Sometimes "intensity" is subtle: A more tightly strung tennis racquet provides a more intense workout for the player's arm. In general, it is recommended that careful medical monitoring should be done for any athlete training more than 18 hours/week. Furthermore, it is recommended that increases in training volume should not exceed 10% per week.

Inappropriate Footwear

In sports that involve a lot of running and jumping activity, athletes exert forces of 3 to 10 times their body weight with each step. That force is absorbed by the running surface, the shoe, and the foot and leg. The less force the limb absorbs, the less risk there is of overuse injury. That explains why it is better to train on slightly softer surfaces such as clay or grass than on cement or asphalt, which have less "give." It also explains why shoes are the most important item in most athletes' wardrobes.

Shoes are especially important for track athletes. The right footwear makes for an enjoyable, injury-free running experience, while the wrong footwear can cause discomfort and ailments ranging from ankle sprains to heel spurs to knee cartilage tears.

Basketball players also need to wear shoes with adequate, appropriate shock absorption properties.

Technological improvements in footwear in the past decade have contributed to a decline in many footwear-related overuse injuries.

Improper Workout Structure

One of the most common reasons why athletes get injured is because they do not prepare their bodies for the immediate demands of exercise with a structured workout that includes warm-up and cooldown periods.

Less pliable tissues are also more susceptible to overuse injuries: Tiny tears may occur due to repetitive, low-intensity stretching of inflexible tissues. Overuse injuries of a joint can develop because the surrounding tissues are not warmed up and stretched, which restricts the joint's range of motion and may cause grinding of the cartilage against bone or cartilage against other cartilage.

The intensity and duration of the warm-up and cooldown vary with each athlete. A well-conditioned athlete probably requires a longer, more intense warm-up—compared with a less well-conditioned person—to achieve optimal elevation in body temperature and heart rate.

Irrespective of the conditioning level of the athlete, every workout should include five stages: limbering up (5 minutes), stretching (5–10 minutes), warm-up (5 minutes), primary activity, and cooling-down and cooldown stretching (10 minutes). Refer to the box on pages 113 through 115 for more details on the five stages of a workout schedule.

Conclusion

A major obstacle to developing injury prevention strategies is the lack of epidemiological data on injury rates in most sports. Without sound baseline data, the effect of measures to enhance sports safety cannot be gauged.

In 1998, the International Federation of Sports Medicine (FIMS) and the World Health Organization (WHO) released a joint consensus statement on children and sports. One of the central themes of the document was injury prevention. This consensus statement called for a number of initiatives to be adopted by sports governing bodies, including the collection of statistics on sports injuries.

This statement also called on health professionals to take steps to improve their knowledge and understanding of the organized sports environment as well as the risk factors associated with organized sports participation.

PRICE/MICE

PRICE/MICE is a therapeutic modality that uses *p*rotection, *r*est/*m*odified activity, *i*ce, *c*ompression, and *e*levation to improve healing after an acute injury. The physical therapist traditionally applies this modality to improve the impairments and functional limitations that can be caused by an injury. A successful outcome in the management of any acute injury depends on immediate intervention. PRICE/MICE is one example of immediate injury care.

PRICE/MICE is used in the treatment of acute injuries such as fractures, sprained joints, and/or strained muscles. PRICE/MICE can decrease pain, reduce swelling, protect the injured area, and promote healing. When an injury occurs, there is swelling and pain, with difficulty moving the affected area. Immediate application of PRICE/MICE within 15 to 20 minutes after an injury can reduce the duration of healing by several days or weeks, depending on the injury.

Protect/Rest/Modified Activity

Protect, rest, or modified activity is recommended for the first 24 to 72 hours after an injury. This will allow time for the injury to heal. As soon as possible, the athlete should be evaluated by a physician, who will determine the appropriate level of activity depending on the severity of the injury. Protect/rest may include stopping the activity or modifying the activity. For example, a splint, orthotic, and/or crutches may be prescribed to protect and rest a severely sprained ankle. An athlete who sustains a mild injury may be allowed to participate in sports provided the injured area is supported and/or the activity is modified.

Ice

Ice should be applied as soon as possible after the injury to decrease pain, swelling, and bleeding. Ice will effect a decrease in tissue temperature, therefore slowing down the inflammatory process. Ice should never be applied directly to the skin but should have a thin protective layer, such as a moist towel. Ice could be applied in the form of a cold pack, or it could be as simple as a package of frozen vegetables. In the acute management of soft tissue injuries, applying ice immediately after an injury can reduce tissue temperature by 10 to 15 °C. Intermittent application of ice at 10-minute intervals has been shown to be more effective in cooling human tissues. Ice application may be most effective when combined with exercises. The cooling effect reduces pain, spasm, and neural inhibition, which makes it possible to begin exercises earlier.

Compression

Compression is a gentle pressure or force that will reduce swelling and pain. Compression can be achieved by applying a bandage with gentle pressure to reduce swelling. The bandage should not be applied too tightly or in a circular fashion around the extremity, to avoid circulatory impairment.

Elevation

Elevation of the injured part is necessary to prevent pooling of blood. The rationale of raising the injured extremity above the heart is to decrease the hydrostatic pressure and reduce the accumulation of interstitial fluid.

Prickly Heat

Athletes are particularly susceptible to prickly heat, otherwise known as heat rash, or milaria rubra. Prickly heat is a superficial skin irritation characterized by red skin, small bumps, and a feeling of itchiness or discomfort. Prickly heat occurs when heat and sweating are excessive. It is most often found on the body in areas where the clothing is tight or occlusive. Because most athletes are predisposed to heavy sweating and often need to wear tight clothing for uniforms or to reduce air friction, they are afflicted by prickly heat quite frequently.

Prickly heat is named for the "prickly" sensation present on appearance of the rash. The rash appears as a pink or red discoloration to the skin, often with bumps or small blisters. It may itch or feel prickly and is mildly to moderately irritating to the athlete. The rash is associated with exposure to heat or heavy sweating. It occurs when the sweat glands become blocked. The glands rupture, and the sweat they contain irritates the surrounding skin, causing a red, inflammatory reaction. It can also occur with overdressing or if ointments are applied to the skin, as these may block the sweat glands in a similar manner.

There are a few techniques to treat prickly heat that focus on cooling the skin. Using cool baths without soap, applying a cool and wet washcloth to a local rash, dressing in fewer layers, and lowering the temperature of the skin by moving into an air-conditioned location may be helpful. Wearing clothing that is not occlusive or has the ability to wick away the sweat ("allowing the skin to breathe") will be less likely to produce a prickly heat reaction. In more extensive or uncomfortable cases, using an anti-inflammatory cream, such as over-the-counter hydrocortisone 1%, may be helpful to reduce the nuisance. It is recommended to avoid ointments because they are thicker than creams and may occlude the sweat glands.

Principles of Rehabilitation and Physical Therapy

Rehabilitation is the process of restoring function after sustaining an injury and/or illness. The major goal of a rehabilitation program is to attain maximal independence in all activities of daily living (ADL), including independence in recreation and sports activity. In some cases, if this is not possible, the secondary goal is to achieve functional independence within the limits of the disability.

Principles of Rehabilitation

The major principle of rehabilitation is to safely enhance the athlete's abilities despite an existing or a developing impairment. The goals of rehabilitation include the following: to control inflammation, decrease pain, promote healing, restore function, gain independence in ADL, facilitate safe return to recreational and/or sports activities, and prevent future injury.

Definition of Physical Therapy

Physical therapy provides treatment to athletes who have sustained impairments, functional limitations, and/or disabilities resulting from an illness or injury. According to the *Guide to Physical Therapist Practice,* second edition (2001), by the American Physical Therapy Association, *impairment* is defined as a loss or abnormality of anatomical, physiological, mental, or psychological structure or function. *Functional limitation* is defined as restriction of the ability to perform, at the level of the whole person, physical actions, tasks, or activities in an efficient, typically expected, or competent manner. Disability is defined as the inability to perform the actions, tasks, and activities usually expected in specific social roles.

The Physical Therapist

Physical therapists are educated at a collegiate level and are required to be licensed in the state or states in which they practice. To obtain a valid license, the physical therapist must pass a written examination; the license to practice is issued through the Board of Registration and Medicine in that particular state.

The physical therapist performs a comprehensive examination of the athlete and designs and implements a plan of care based on the results of the examination. It is essential for patients receiving physical therapy to have a clear understanding of the role of physical therapy in their rehabilitation program. The plan of care is modified or changed as indicated by the athlete's responses to treatment.

Physical Therapy Management

Physical therapy management in the rehabilitation program includes, but is not limited to, athlete history, review of systems, comprehensive assessments of posture, muscle performance, joint integrity and mobility, pain, function, and communication. The goal of a successful rehabilitation program is not only to restore optimal functional outcomes but also to educate the athlete in health and wellness in order to prevent future injuries. The following elements are essential in the development of a comprehensive rehabilitation program.

History

A detailed history must be obtained prior to establishing a rehabilitation program. Information should be gathered from the athlete, the physician, diagnostic tests, and hospital records if indicated. The following elements should be included in the history: demographics, current medical diagnoses as well as any previous diagnoses and/or injuries, surgical intervention(s), and date(s), including outcomes, complications, and treatments. Family history, if pertinent, pain level, and current concerns, especially as they relate to activity and function, are also reviewed. The athlete's desired outcomes and goals should also be included in the assessment.

Review of Systems

Collecting baseline information prior to treatment intervention is necessary to establish goals, to monitor the effects of both therapeutic and conditioning exercises, and to identify risks for future injury. The following systems are reviewed. Cardiovascular/pulmonary review measures respiratory and heart rates and blood pressure. Integumentary (skin) review inspects skin integrity, skin color, and scar formation. Blistering, skin temperature, scar tissue pliability, texture, and sensation are also documented. If the athlete has had surgery, assessment of activities or movements that aggravate the incision sight should be noted. Musculoskeletal review evaluates gross symmetry, muscle performance, joint integrity and mobility, height, and weight. Neuromuscular review assesses balance, locomotion, transfers, and transitions. Communication review evaluates language, learning style, and cognition.

Physical Therapy Examination

Posture

According to the *Guide to Physical Therapist Practice,* posture is the alignment and the positioning of the body in relation to gravity, center of mass, or base of support. The physical therapist uses various tests and measurements to examine structural alignment. Good posture is a state of musculoskeletal balance that protects the supporting structures of the body against injury or progressive deformity. Postural deviations and/or malalignment can have a serious, negative impact on body mechanics, function, ADL, and sport-specific techniques. Identifying postural deviations leads the physical therapist to further investigate joint and muscle impairments.

Muscle Performance

The *Guide* defines *muscle performance* as the capacity of a muscle or a group of muscles to generate forces. *Strength* is the muscle force exerted by a muscle or a group of muscles to overcome a resistance under a specific set of circumstances. *Power* is the work produced per unit of time or the product of strength and speed. *Endurance* is the ability of muscles to sustain forces repeatedly or to generate forces over a period of time. The physical therapist uses standardized testing procedures to assess strength, power, and endurance in order to establish a baseline for the plan of care. Deficits in muscle performance can lead to weakness, fatigue, and functional impairment. Furthermore, athletic performance is dramatically affected if there are any deficits in muscle strength, power, or endurance.

Joint Integrity and Mobility

The *Guide* defines *joint integrity* as the intactness of the structure and shape of the joint, whereas joint mobility is the capacity of the joint to be moved passively taking into account the structure and shape of the joint surface in addition to the characteristics of the tissues surrounding the joint. The physical therapist administers standardized tests and measurements to assess both joint integrity and mobility. Abnormal integrity and mobility can place undue stress not only to the joint but also on the surrounding structures. Biomechanical limitations often cause an increase in pain and may also lead to loss of function, which can affect athletic performance.

Pain

The *Guide* defines *pain* as a disturbed sensation that causes suffering and distress. The physical therapist assesses the intensity, quality, and temporal and physical characteristics of pain that may result in impairment, functional limitations, and/or disability. Although many serious athletes perform with varying amounts of pain, prolonged chronic pain may not only inhibit the athlete's performance but also end a potential career.

Function

In physical therapy, *function* is defined as independence in all activities with maximal efficiency and effectiveness. The physical therapist assesses functional limitations with a variety of standardized tests that include balance, locomotion, transfers, transitions, and the athlete's self-report. Functional limitations in any of these areas not only lead to disability but also may lead to undue psychosocial stresses. This is especially true in the athlete.

Communication

The physical therapist is responsible for accurate communication and appropriate documentation. Clear and concise communication to the athlete, to health care providers, and to coaches and trainers with a need to know is an essential component of a successful rehabilitation program with the goal of safe return to sports.

Physical Therapy Plan of Care

The physical therapy plan of care is based on the information gathered from the examination. The rehabilitation program is based on the diagnosis, the goals of treatment, the athlete's expectations, and the anticipated course of healing. Acute injuries require early medical attention, especially if the injury affects mechanics and performance. An accurate diagnosis is necessary so that appropriate management can be planned. The goals of rehabilitation are to control inflammation, decrease pain, promote healing, and restore function. Essential components of the rehabilitation program include maintaining the athlete's physical fitness during recovery, education on preventing future injury, and specialized training to improve performance. Full recovery is independence in ADL and safe return to recreational and/or sports activities.

Treatment Intervention

Modalities

A successful treatment program depends on reducing pain, decreasing inflammation, and promoting healing. The physical therapist uses a variety of the following modalities to achieve this effect:

Superficial heat or cold is applied to increase or decrease tissue temperature, at a depth of up to 5 centimeters (cm), depending on the method of delivery. The physiological response to heat causes expansion in the blood flow, with erythema (redness), while the application of cold causes restriction in the blood flow, followed by expansion of blood flow. Both heat and cold can reduce conduction along fast and slow nerve fibers, thus decreasing pain and promoting relaxation of the tissues. In addition, applying pressure along with an ice pack reduces posttraumatic swelling. It is essential to have a proper barrier between the skin and the hot or cold pack in order to prevent skin irritation and/or damage.

Hydrotherapy is the immersion of body segments in water, for example, in a whirlpool. Water immersion promotes an increase or decrease in superficial tissue temperature in a large body part. The main goal of hydrotherapy is to decrease swelling, relieve joint pain and stiffness, and promote relaxation.

Therapeutic ultrasound is a form of deep heat that is produced by a transducer that converts electrical energy into sound energy. Ultrasound produces a thermal effect by increasing tissue temperature by 1 to 2 °C at a depth of 5 cm. The main goal is to increase tissue extensibility and to decrease inflammation, swelling, pain, and muscle spasm. In addition, ultrasound can help reduce joint contractures and scar tissue. Ultrasound should never be applied over an open growth plate.

Massage is the manipulation of soft tissues by the hands. Pressure and stretching are applied to compress soft tissue, causing an increase in circulation and, thus, promoting better muscle nutrition and relaxation. Massage prior to performing a series of exercises can enhance mobility, reduce pain, facilitate relaxation, and also reduce stress.

Transcutaneous Electrical Nerve Stimulation (TENS) is the procedure of applying controlled, low-voltage electrical impulses to the nervous system by passing electricity through the skin. TENS is often effective in the treatment of acute and chronic pain. TENS is based on the theory that the peripheral stimulation of large-diameter cutaneous afferent nerve fibers blocks pain sensation at the spinal cord through the gate control mechanism.

Neuromuscular Electrical Stimulation (NMES) is the application of electrical current to the skin to activate motor units, causing an involuntary skeletal muscle contraction. The main goal is to provide biofeedback and muscle re-education to the involved muscles. NMES has been shown to enhance muscle function postoperatively.

Iontophoresis is the transfer of topical medications in the form of applied active ions into the skin by direct current. Topical steroids are commonly administered using iontophoresis. The goals of iontophoresis are to decrease inflammation and edema, soften scar tissue, and reduce pain.

Orthotic (braces) and assistive devices are prescribed to support or immobilize a body part, to correct or prevent deformity, and/or to assist function. Devices include braces, foot orthotics, shoulder slings, splints, prosthetics, crutches, and many others. Devices such as braces restrict, control, or eliminate joint movement, while others assist movement, such as prosthetics. Some orthotic devices can help reduce pain, decrease swelling, control and enhance movement, and improve body awareness. Proper selection, evaluation, and fit of the orthoses are critical to ensure both function and safety.

Therapeutic Exercise

The *Guide* defines *therapeutic exercise* as the systematic performance or execution of planned physical movement. An exercise program enables the patient to remediate or prevent impairments and enhance function, fitness, and well-being. Therapeutic exercise may include any or all of the following: muscle strengthening and joint range of motion, aerobic and endurance conditioning, agility, balance training, body mechanics, coordination exercises, gait, and locomotion training. The selection of an appropriate therapeutic exercise program depends on the diagnosis, the surgical procedure, the stage of healing, and the degree of inflammation, pain, and patient cognition, readiness, and compliance. Teaching the patient a realistic exercise program that can be performed daily either at home or at a medical or physical fitness facility will ensure a successful functional outcome and safe return to recreational and/or sports activity. It is important to individualize the exercise program in order to meet the athlete's physical and emotional needs. Attitude, motivation, and time availability will have a significant effect on the success of the program. The overall focus of the exercise program should be to regain full, painfree, and safe independent function and return to sports.

Therapeutic exercises may be active-assistive, active, and/or resistive. The aim of resistance exercises is to regain the strength, joint stability, and neuromuscular control to perform functional and/or sports activities. Therapeutic exercise programs should be designed to apply controlled but not excessive stress to healing structures, based on the underlying pathology. The amount of resistance, repetitions, frequency, speed, and rest intervals can be varied during exercises to promote optimal loading of the muscles and joints. Simple exercises are started first, followed by more complex activities involving more than one joint. In athletes, special attention must be paid to their sport. Sport-specific exercises are introduced for safe return to sports activity.

Conclusion

An effective rehabilitation program will not only promote total functional independence with safe return to sports but also help educate the athlete on healthy lifestyle changes. Instructing the athletes in the proper care of their bodies is the responsibility of all who are involved with their care. A proper, well-designed program will not only help the athlete recover from a current injury but also help prevent future injuries.

Principles of Training

Training is the method that athletes use to improve performance in their sport. Training methods have been studied extensively over the years, and some common themes can be traced through the myriad sports and events.

From a holistic point of view, athletes should be considered as living psycho-social-physiologic systems. This holistic can be expanded into five areas, which when combined, culminate in an integrated view of performance: (1) physiology, (2) biomechanics, (3) psychology, (4) tactics, and (5) health/lifestyle. All these components need to be functioning at near-optimal levels for the athlete to achieve a successful performance or a maximum training adaptation.

Stimulus

The first component of successful training is a sufficient amount of exercise to stimulate the musculoskeletal and other body systems. Only when a system is suitably stressed will it be stimulated to adapt to future recurrences of such stress. Exercise stress can be conceptualized in terms of frequency, volume, and intensity of training.

Duration

Athletes training for a marathon must incorporate "long runs" (10 miles [mi; 1 mi = 1.61 kilometers] or longer; longer than 90 minutes) into their preparation for the marathon event. By doing so, their muscles and cardiovascular system, in particular, are better prepared for the rigors of running for more than 3 hours, the time required by most of them to finish 26+ mi on the marathon course. Thus, the duration of training is a quantitative component referring to the length in time of such a long-run training session.

Frequency

Training frequency refers to the number of training sessions within a given time frame, such as a day or a week. In general, maximum aerobic adaptation is achieved from completing a long run only once a week.

Volume

Athletes and coaches often refer to combinations of these variables. Training volume refers to the product of duration and frequency of training (usually in a week).

Intensity

Intensity of effort is a qualitative component, and in endurance activities (e.g., a marathon), where distance and time are the factors to be considered, absolute intensity can be recorded as running speed. Relative intensity can be quantified as a proportion of an athlete's maximum speed or by a physiologic variable such as the percentage of maximum heart rate an athlete is training at. Intensity is generally considered the most critical factor of training. Within the training process, the correct balance of low-, medium-, and high-intensity training is critical to the adaptation process, and if too much moderate- or high-intensity training is undertaken, there is a significant risk of fatigue, which may lead to "overtraining."

Load

Training load refers to the product of all three fundamental components: (1) frequency, (2) duration, and (3) intensity. The correct sequencing of changes in volume and load throughout a training year is critical to the adaptation process.

Specificity

A second major component of training is *specificity*. Even though swimming and biking for 3 hours would provide a similar aerobic stimulus to running, the act of swimming lacks specificity; simply put, you need to practice what you wish to perform. The benefits of cross-training may be covered elsewhere; however, for maximal efficiency of training, you get the biggest benefit to eventual performance by training in the mode of exercise you will eventually compete in. Furthermore, while training in the same mode as the competition, an athlete will also attempt to mimic the speed, range of motion, and typical resistance likely to be attempted on a race day. For example, training for a mountain bike race by spending time riding easy trails will be beneficial for performance; however, if the race is over challenging terrain with obstacles, steep climbs, and fast descents, there would be greater performance gains in general if the athlete had trained at least to some extent on similar terrain. Adaptations in muscle strength, speed, and coordination are partly peripheral at the myocyte cellular level, but they are also central, with "motor memory" developed for the activities the brain, spinal cord, and neurons would otherwise be unaccustomed to.

Progressive Overload

Having chosen the appropriate mode and stimulus, the next component of successful training is that of *overload*. Systems stressed by exercise in a training schedule operate in a balance between damage and repair. For example, after a strenuous 90-minute soccer practice, players' leg muscles will show microscopic evidence of cellular damage, manifested as muscle soreness 24 to 48 hours later. This damage is limited and corrected by the immune system and local muscle factors, and if sufficient recovery time is allowed, there are microstructural improvements made such that the muscles will be better able to cope with this training stimulus. Hence, subsequent practices need to be of greater intensity or in longer sessions to achieve a sufficient stimulus to challenge those muscles. This is the principle of progressive overload: Body systems adapt when a consecutively greater stimulus is provided during the training program.

Periodization

Periodization is the organization of training into large, medium, and small training blocks, referred to as macro-, meso-, and microcycles, respectively. When the sequencing of training is correctly applied, athletes can achieve a high state of competition readiness, and during the months of hard training, they can avoid the "overtraining syndrome." A microcycle refers to a structure of separate training sessions or a small grouping of several sessions; mesocycles (3–5 weeks) are groupings of several microcycles with a predetermined training objective or performance goal, and macrocycles (12–16 weeks) reflect groupings of mesocycles within a semiannual or annual plan. Periodization provides a framework that allows a coach to formulate a specific program to achieve improvements in the physiologic, technical, or psychologic components of performance. Hence, during periods after high physiological demands have been experienced, a coach may choose to focus on technical and psychological improvements while allowing for relative physiological rest.

The researcher David Pyne (1996) listed the common features of periodized training programs as follows:

- The long-term performance goal for the season forms the basis for the training program.
- There is a progressive and cyclical increase in training loads.
- There is a logical sequence to the order of the training phases.
- There is scientific monitoring in physiology, biomechanics, psychology, and physical therapy.
- There is intensive use of recovery or regenerative techniques throughout the training program.
- Emphasis on skill development and refinement is maintained throughout the training program.
- There is an underlying improvement and maintenance of general athletic abilities.

- Each part of the training program builds on the preceding phase.

Individualization

Individualization implies that individual athletes will react and adapt differently when presented with identical training regimes. On a spectrum, there are two broad categories of athletes, with the genetically talented at one end and those with a highly developed work ethic, and perhaps a system guiding their effort, at the other. Individualized training programs with monitoring systems available to evaluate individual responses to a training load are a necessity.

Structural Tolerance

Structural tolerance implies that the body needs time to adapt to a training load. Structural tolerance is the ability to withstand weeks or months of high-volume training without the incidence of injury, illness, or fatigue, which may lead to overtraining. Through years of general and specific training, structural tolerance can be greatly improved. From a lay perspective, team sports athletes, such as soccer or football players, may be pushed beyond their individual structural tolerance during vigorous preseason training camps and may then be perceived as “injury prone” for the remainder of the season as their bodies attempt to recuperate.

Reversibility

Reversibility highlights the requirement for consistent training. As suggested by the fitness-fatigue model of Dr. Eric Bannister, fitness and fatigue are never constant, and interruptions to training caused by injury, illness, or social needs break the consistency of training that is required to achieve improvements. Loss of fitness can occur through inconsistent training, and fatigue may occur through nontraining stress factors and inadequate recovery.

All-Round Development

All-round development suggests the need for an underlying general athletic ability that is supported by a strong psychologic platform and technical ability in the various activities in which an athlete engages. Personality type plays an important role in athletic success. Unless an athlete is gifted with the personality and inherent coordination and skills fundamental to his or her sport, training may not achieve the success of others more fortunate. Within the training process, overcoming training and competition stresses promotes willpower, self-confidence, and tolerance for higher training and competition demands.

Protective Equipment in Sports

Sports injuries are common in professional sports, but the amateur is equally at risk. While many people sustain injury due to overexertion or lack of correct technique, many others sustain injuries that could have been prevented or at the very least minimized by the use of the correct protective sports equipment. Using the correct equipment can increase the career life of professional sportspersons and have a significant impact on their earning potential. For others, it may mean the chance to safely continue to enjoy their favorite sport and ensure a good quality of life.

Most sports have documented standards for protective equipment. Some athletic organizations have rules that require athletes to use protective equipment; failure to do so may result in fines or disqualification. Many organizations have established quality control standards for the manufacture of protective equipment. Compliance with these standards is voluntary, however, and cannot be enforced on the manufacturers. The onus lies on the purchaser to choose the protective equipment that will perform its function under field conditions reliably.

Protective Eyewear

The American Academy of Ophthalmology has stated that more than 90% of eye injuries can be prevented by using protective eye equipment. The most common types of eye injuries are as follows:

- *Blunt trauma:* for example, getting hit in the eye by a racquet
- *Penetrating eye injuries:* for example, from glass shards or an arrow
- *Radiation injuries:* for example, burn injuries caused by the sun's radiation to the retina of athletes who perform in the snow or on water

All these can lead to serious visual defects and possibly eye-threatening infections. Protective eyewear is thus a must for all those at risk of eye injury. However, the eyewear must follow standard specifications. The following types of eyewear do not provide adequate eye protection during sports; in fact, some of them may even be hazardous.

- Fashion sunglasses
- Regular eyeglasses
- Contact lenses
- Industrial safety glasses

The American Academy of Ophthalmology recommends that eyeglasses or goggles have lenses made of 3-millmeter (mm) polycarbonate, which is very thin, light, and impact resistant, with a 100% ultraviolet (UV) light filter to prevent radiation injuries. Neutral gray or amber lenses are good colors to filter out bright light, and polarized lenses are useful in avoiding glare on water or snow. Different sports have different requirements, as elaborated below:

- Full face protection with attached polycarbonate eyeshade: football, baseball, and the batter in softball
- *Full face protection:* field hockey goalie, ice hockey, men's and women's lacrosse, paintball
- *Goggles with polycarbonate lenses:* racquet sports, field hockey, basketball, soccer, baseball, softball, women's lacrosse, and tennis
- High-impact resistant sports goggles with polycarbonate lenses with filter for UV and excessive sunlight: skiing

Helmets

A direct hit to the skull can lead to concussion, intracranial bleeding, or skull fracture. A proper helmet can absorb blows to the skull and protect the brain. It does not, however, protect the neck.

Selecting a Helmet

- It should fit comfortably and have a firm grip. Less than 1 inch (in.; 1 in. = 2.5 centimeters) of head movement should be possible inside the helmet. Vision should not be obscured, but the forehead should be covered; however, the side and back length can vary.
- Stretching the lower jaw should be accompanied by a stretch on the chin strap, and the top of the helmet should move downward.
- There should be room for goggles or a hat under the helmet, if required. The helmet should be tried on with the additional gear.
- Helmets with vents are also available for air circulation.
- A previously damaged helmet (especially if it is cracked or if the foam lining is crushed) must not be used.

For particular sports, the following points should be kept in mind:

Bike helmets: They should be in bright colors to make the wearer easily visible.

Skiing/snowboarding helmets: They should be insulated against the cold. Head coverage should be complete, and they must have space for ski goggles.

Football and hockey helmets: They should be able to withstand multiple impacts.

Baseball helmets: The batter needs to wear a helmet to protect his or her head from a possible hit by the ball; however, the catcher must wear full-face protection.

Skateboarding/skating helmets: While bike helmets can be used, it is better to wear a helmet that can protect the back and sides of the head.

Safety Pads and Guards

There are multiple types of safety pads and guards meant for different sports. They serve to protect the skin and prevent sprains and sometimes even fractures.

Safety Pads

The shape is meant to fit the body part it is supposed to protect. It has soft padding on the inside and a harder shell on the outside. There are numerous types of pads:

Knee pads: recommended for football, hockey, inline skating, volleyball, and wrestling

Shoulder pads: recommended for football, hockey, and lacrosse

Elbow pads: recommended for football, hockey, inline skating, skateboarding, volleyball, and wrestling

Hip pads: recommended for football, hockey, inline skating, and skateboarding (they slide into the uniform easily and protect the hips)

Thigh pads: recommended for football, hockey, and cricket (they also slide into the uniform and protect the front of the thigh)

Safety Guards

A guard is a rigid structure that covers the vulnerable areas of the body, for example, the groin. Unlike safety pads, guards do not usually have padding. They are specific for different body areas:

Shin guards: They usually slide into the socks; they are recommended for football, soccer, hockey, baseball, and cricket.

Wrist guards: They are recommended for football, inline skating, skateboarding, and snowboarding.

Knee guards: They are recommended for football, soccer, hockey, inline skating, snowboarding, skateboarding, and cricket.

Elbow guards: They are recommended for football, soccer, hockey, inline skating, snowboarding, and wrestling.

Mouthguards: They fit over and are molded to the shape of the upper teeth. They are essential in some sports, such as boxing, to protect not only the teeth but also the lip, tongue, and jaw. The American Dental Association recommends mouth protection for hockey, football, basketball, volleyball, and gymnastics. Athletes who wear braces should also consider using these guards. The guard should be secure and not fall off during activity; however, it should not hinder breathing or talking.

Some Types of Mouthguards

- *Off the shelf:* ready-made, inexpensive; usually does not provide a perfect fit
- *Boil and bite:* ensures a better fit
- *Custom made:* made by the dentist and ensures the best possible fit; obviously more expensive

Care of the Mouthguard

- Brush after each use. Wash with soap once a week.
- Store in a case that allows air to flow, in a cool place. Never leave it in the sun or near a heat source.
- Replace at the first sign of any damage—for example, frayed edges, tears.

Footwear

There are different types of shoes for different sports, and these should be selected on the basis of foot type and running style.

Foot Type

The foot type can be determined by checking the footprint. Modern stores can also check the foot type using a computer, with the athlete running on the treadmill. The following foot types are usually observed (see Figure 1):

Flat feet: There is no visible arch. The footprint is visible in its entirety, and there is no inward curve between the heel and the big toe (Footprint 3).

High arches: The arch is very prominent. The footprint curve is large, and the outer edge is skinny. Sometimes there is a complete gap in the footprint between the big toe and the heel (Footprints 0 and 1).

Neutral foot type: There is a small curve inward (Footprint 2).

Running Style

One can observe the soles of current running shoes: The location that is most worn can tell you if one has a neutral strike, rolls in or out, or lands on the heels. Another method is to observe the shoes: If the wear is more on the inside of the heels, the feet are rolling inward as one runs, and vice versa. Common running styles are as follows:

- *Overpronators:* These athletes tend to roll inward with heel strike. They need more stable shoes.
- *Supinators:* They tend to roll outward during heel strike. These people need a flexible, cushioned shoe.
- *Neutral.*

Shoe Types

There are five basic shoe types that should be selected according to the foot type, running style, and game requirements.

Figure 1 Foot Type

Motion control shoes: rigid and stable shoes that control movement; recommended for pronators and also for those with flat feet

Stability shoes: for those with neutral foot types who just need support and cushioning

Cushioned shoes: for those with high arches; also for underpronators

Lightweight training shoes: fast and efficient shoes; recommended for those who don't have any feet problems

Trail shoes: offer the most traction, are hardy, and have a thick sole; for those who run on rough ground or in extreme weather

Exercising in worn-out shoes can cause problems. It makes sense to own two pairs of shoes that can be used alternately and to buy a new pair before the old ones run out. The usual recommendation is to replace running shoes between 350 and 550 miles (mi; 1 mi = 1.61 kilometers) and for heavier athletes to replace them earlier.

The following points should be kept in mind when buying a running shoe:

- Feet swell at the end of the day, so shoes should be bought in the evening.
- The shoe should be tried while standing and walking, not sitting.
- Both shoes should be tried with the socks that are commonly used.
- If the feet are unequal in size, the larger size should be bought.
- A thumbnail-width space should be left between the edge of the shoe and the big toe.
- Shoes that hurt or are not immediately comfortable should be rejected.
- Shoes should be bought according to the foot type and running style.
- The shoes should be worn around the house before starting to run in them. Even then, a short run should be done first. Any hot spot may be the forerunner of a blister.

Bracing and Taping

These can provide limited protection against injury. Bracing, however, is better as taping becomes ineffective after 20 minutes. For further information, see specific entries in this encyclopedia.

Protein in the Athlete's Diet

Protein is an essential part of our daily diet; however, the dietary requirements of athletes constitute a controversial topic. There are two major schools of thought: (1) that exercise participation increases the nutritional protein requirement and (2) that protein requirements are relatively similar between sedentary persons and active athletes. Part of this controversy arises from the differences in the definition of protein requirements. Scientifically, protein needs are based on nitrogen balance. Protein metabolism is affected by the athlete's age, sex, energy intake, and carbohydrate availability, as well as the intensity, type, and duration of exercise. The functions of proteins are the building and maintenance of muscle, hair, skin, and nails, as well as nutrient transportation and enzyme production. In fact, more than 10,000 different proteins are found in the body. Protein use increases during exercise as it is broken down via gluconeogenesis in the liver to maintain the blood glucose.

Daily Requirements

The current recommended dietary allowance (RDA) is 0.8 gram/kilogram (g/kg) of body weight daily, accounting for 10% to 35% of the total energy. In the athletic population, an attempt is made to calculate the potential increases in protein requirements based on increased metabolic demand. Endurance and resistance exercise are most likely to potentially result in increased protein requirements, and many endurance athletes increase protein intake to 1.2 to 1.4 g kg^{-1} day^{-1} to support nitrogen balance. Branched-chain amino acids (BCAA), including leucine, isoleucine, and valine, are the primary protein energy source for endurance athletes. High-intensity strength training may increase protein requirements by up to 1.7 g kg^{-1} day^{-1}.

Protein as a Source of Energy

One gram of protein supplies 4 kilocalories (kcal; 1 kcal = 4,184 joules [J]) of energy, similar to carbohydrates. However, protein generally provides less than 5% of the energy expended during light exercise and activities of daily living. Basic energy requirements (BER) include the basal metabolic rate (BMR) and general activities of daily living. BER is approximately 1.3 cal/kg (1 cal = 4.18 J) of total body weight per hour. Extra energy requirements (EER) are the calories required above the BER to maintain a neutral energy balance. An average of 8.5 cal/kg of total body weight per hour of training is a gross estimation. Actual EER calories can vary greatly, depending on the individual

BMR and the intensity of the exercise. Opinions differ widely with regard to the recommended amount of EER calories that should come from protein, and they likely should vary among individual athletes. If the amount of protein is controlled in the diet, then much of the EER calories will likely come from a carbohydrate source, which is better used as an energy substrate during prolonged and strenuous exercise.

Effects on Sports Performance

Studies have shown that protein and amino acids consumed around the time strength and endurance exercises are performed can both maintain and potentially increase skeletal muscle mass. However, protein and amino acid supplementations have not proven to enhance overall athletic performance. It is also known that high-quality proteins such as soy, casein, and whey are effective in skeletal muscle synthesis and repair. Protein quality is determined by amino acid composition and digestibility. Amino acid composition in plant versus animal proteins is quite different, primarily based on the concentration of essential amino acids, which are necessary for growth and repair. Animal protein foods are called complete, high-quality proteins because they contain all the nine essential amino acids. Plant-based foods are incomplete proteins because they lack one or more of these essential amino acids. Soybean products are essentially equivalent to animal protein and only lack methionine. They are an important dietary protein source, especially in a restrictive vegetarian.

Optimum Timing of Protein Intake

The timing of protein intake has been studied in an attempt to optimize training and recovery from exercise. Protein intake should be spread throughout the day. This allows the body an opportunity to use the necessary amino acids throughout the day rather than convert them to fat. Protein ingested shortly before workouts may lead to gastric upset in some individuals. It also may serve as exercise fuel and in small amounts may have a muscle-sparing effect pre-exercise when added to carbohydrates in small amounts, similar to postexercise recovery recommendations.

Dietary Sources of Protein

There are a wide variety of natural dietary sources of protein, some of which can be used to supplement other dietary foods to increase the overall protein intake for athletes. There are four forms in which amino acids may be introduced into circulation: (1) whole-food proteins, (2) intact protein supplements, (3) free-form amino acids, and (4) protein hydrolysates. Protein can be hydrolyzed, producing small amino acid chains called peptides, which are protein forms that are easily digested. Several studies have shown that protein hydrolysates, containing mostly di- and tripeptides, are absorbed more rapidly than free-form amino acids or intact proteins. There is also recent evidence that protein hydrolysate ingestion has a strong insulinotropic effect. Thus, sports drinks containing protein hydrolysates may be beneficial in postexercise muscle recovery but cannot be consumed in unlimited amounts even in the setting of exercise-related dehydration. The American Academy of Pediatrics (AAP) recommends that health care providers strongly discourage commercial protein supplementation in adolescent and young athletes. These commercial protein supplements are largely unregulated and may contain widely varied amounts of the reported ingredients. They may also contain potentially harmful impurities. In all athletes, regardless of age, commercial protein supplementation is not better than increasing the dietary sources of protein (see Table 1). One example of increasing dietary protein is to add ¼ cup of nonfat dry milk (11 g of protein) to milk, fruit smoothies, cereal, pasta, soup, or sauce. Protein shakes can be made using milk and instant breakfast packets.

Isn't More Protein Better Than Less?

Excessive protein intake is unnecessary and even potentially harmful to an athlete's health. This is of particular importance in athletes who seek to consume protein supplements as ergogenic aids. High-protein dietary intake can compromise carbohydrate status and contribute to dehydration, weight gain, kidney and liver stress, and urinary loss of calcium due to the need for up to seven times more water to metabolize the protein. Furthermore, protein taken in excess of the daily requirement does not significantly enhance muscle gains or improve sports performance. Instead,

Table 1 Common Sources of Dietary Protein

Food	*Amount*	*Protein (g)*
Fish	3 oz	21
Chicken	3 oz	21
Turkey	3 oz	21
Red/white meat	3 oz	21
Milk	8 oz	8
Eggs	2 large	13
Tofu	3 oz	21
Peanut butter	2 tbsp	8
Yogurt	8 oz	8
Cheese	3 oz	21

Note: 1 ounce (oz) = 28.35 grams (g).

excess protein is likely to be metabolized into fat stores. Protein synthesis, even in weight lifters, seems to be most effective when protein consumption is 1.4 g kg^{-1} day^{-1}. Therefore, a calculation based on grams per kilogram per day is better than calculating percentages of protein, carbohydrate, and fat for athletes whose total caloric intake exceeds 2,000 to 2,500 kcal/day.

Table 2 provides a sample protein calculation for a 70-kg male.

Carbohydrate Plus Protein Speeds Recovery

Combining protein (AA) with carbohydrate (CHO) in the postexercise meal consumed within 2 hours of cessation of exercise nearly doubles the insulin response. As a result, a significantly larger amount of glycogen stores are replenished. The ideal carbohydrate to protein ratio is 4:1 g. Excessive protein intake postexercise can slow glycogen replacement and rehydration. Protein intake provides the necessary amino acids to rebuild the muscle broken down during intense exercise and improves muscle hydration. Consumption of CHO + AA postexercise improves postexercise recovery, thus preventing a decline in endurance performance during the heavy bouts of exercise on the following day. What research has failed to demonstrate is an actual improvement in exercise performance in endurance athletes following protein or CHO + AA supplementation. Thus, the optimal intake of carbohydrate/protein quantities is likely to be individual and is affected by personal tolerance, dietary practices, metabolism, and exercise type as well as duration. Further research is needed to establish optimal carbohydrate/protein types, amounts, and timing with regard to specific types of exercise.

Conclusion

Protein is an essential part of an athlete's diet. However, it is not a primary energy source. Even for strength and endurance athletes, limits on daily

Table 2 Sample Protein Calculation for a 70-kg Male

Daily kcal	*Protein (%)*	*kcal/day*	*Protein (g/day)*	*Protein ($g\ kg^{-1}\ day^{-1}$)*
2,000	10	200	50	0.7
2,000	15	300	75	1.1
2,000	30	600	125	1.8
4,000	10–15	400–600	100–125	1.4–1.8
5,000	10–15	500–750	125–187.5	1.8–2.7[a]
5,000	30	1,500	375	5.35[a]

Note: 1 calorie (cal) = 4.186 joules. g = gram; kcal = kilocalorie; kg = kilogram.

a. Exceeds the daily maximum of 1.7 g kg^{-1} day^{-1}.

dietary protein intake are necessary and should be calculated as percentages of total caloric intake. Protein ingestion should be spread throughout the day. A wide variety of natural protein sources exist. Commercial protein supplementation should be used with caution and strictly avoided in adolescent athletes. Consumption of CHO + AA postexercise improves postexercise recovery and is likely to be of particular benefit to endurance athletes. Further research is needed to evaluate the effects of protein intake on exercise performance, recovery, and overall health in the athletic population.

Proximal Hamstring Syndrome

Proximal hamstring syndrome is a nerve entrapment disorder that occurs just below the origin of the hamstring muscles on the ischial tuberosity (the lowest part of the bony pelvis). It is characterized by pain in the buttock and the back of the thigh that typically radiates toward the back of the knee. The cause is usually fibrous bands of scar tissue around the upper hamstring muscles, which constrict and irritate the sciatic nerve. In many patients, proximal hamstring syndrome improves on its own without surgery. In patients who continue to have pain, surgical release of the fibrous bands can often resolve the problem.

Anatomy

The term *hamstrings* refers to a group of muscles in the back of the thigh that perform the same function—bending the knee and, to a lesser extent, extending the hip. The hamstrings are usually considered to include three muscles: (1) the semitendinosus, (2) the semimembranosus, and (3) the biceps femoris. Two other muscles—the sartorius and gracilis—are also technically considered hamstrings because their actions include bending the knee. They have a different action at the hip joint, however, and they are much weaker than the three primary hamstring muscles.

The ischial tuberosity is the bony part of the pelvis that you sit on. The semitendinosus and biceps femoris share a common origin on the pelvis at the ischial tuberosity. In other words, the two muscles begin as a single tendon (a ropelike connection of muscle to bone). They then split into two separate muscles as they progress down the back of the thigh. The semitendinosus travels to the inner (medial) aspect of the tibia (leg bone), while the biceps femoris travels to the outer (lateral) aspect of the tibia and fibula. The semimembranosus runs deep to the semitendinosus from its origin on the ischial tuberosity to its multiple insertions at the back of the knee. The sciatic nerve is the nerve that innervates the muscles of the lower leg. The sciatic nerve exits the pelvis and passes just lateral to the origin of the semitendinosus and biceps femoris muscles. The nerve then passes beneath the biceps femoris muscle as it runs to its connection at the back of the knee. The gluteus maximus is the large buttock muscle that covers the upper part of all these structures. The hamstrings emerge from under the gluteus maximus about 3 inches (in.; 1 in. = 2.54 centimeters) below the ischial tuberosity.

Etiology

Proximal hamstring syndrome most commonly occurs in high-level athletes, especially sprinters and hurdlers. It is relatively rare, and there are few published reports describing its symptoms. Proximal hamstring syndrome is thought to be associated with prior hamstring strains. A strain occurs when a muscle overstretches, which tears some of the muscle fibers. These strains can range from minor injuries to complete ruptures of the entire muscle. As the muscle attempts to repair the strain, it can form thick, fibrous bands of scar tissue.

Hamstring strains in particular are extremely common sports-related injuries at all levels of participation. The most commonly injured muscle is the biceps femoris, and the most common location of injury is the upper junction between the muscle and the single tendon. This location is exactly where the sciatic nerve dives underneath the biceps femoris muscle to travel down the rest of the posterior thigh. It is thought that scarring in this area from prior hamstring strain injuries can entrap and compress the sciatic nerve. This leads to pain in the buttock area and can cause referred pain to other sites innervated by the sciatic nerve.

Symptoms

Patients typically complain of pain in the buttock region that radiates down the back of the thigh or even lower into the leg. It is usually exacerbated by activities that put pressure on that area, such as sitting or driving, or activities that stretch the nerve, such as performing hamstring stretches. Athletes will often complain of pain when fully using the hamstrings for rigorous activity, such as speeding up to a sprint or kicking a ball forcefully. Changing the position or stopping the offending activity usually relieves the pain.

Physical Exam

Generally, there is localized tenderness over the ischial tuberosity. It may be possible to palpate the tight bands of scar tissue in the biceps femoris muscle, although this is not a reliable finding. Having the patient perform a hamstring stretch will usually reproduce the symptoms. However, the typical straight leg raise test, which is helpful for diagnosing sciatica, is usually negative in proximal hamstring syndrome. The patient's neurologic exam is usually normal, and electrical nerve and muscle studies can be normal as well.

Diagnosis

Proximal hamstring syndrome is a clinical diagnosis. However, after seeing a patient with signs and symptoms of proximal hamstring syndrome, several other diagnoses should be considered. Plain X-rays of the area should be taken to rule out a growth plate avulsion fracture of the pelvis, especially in adolescents. In addition, a magnetic resonance imaging (MRI) scan of the lumbar spine should be obtained to rule out a herniated disk or lumbar spinal stenosis (narrowing of the spine causing nerve impingement). Another important diagnosis to exclude is piriformis syndrome, in which the sciatic nerve is compressed under the piriformis muscle (see the entry Piriformis Syndrome). In this condition, the patient's pain is usually located more proximal (higher up) than the buttock pain of proximal hamstring syndrome. Helpful physical exam maneuvers to diagnose piriformis syndrome include the *Pace sign* (pain with resisted hip abduction and thigh external rotation) and the *Freiberg sign* (pain with forced internal rotation of the extended thigh). Other diagnoses to consider are *ischiogluteal bursitis* (pain in the buttock that is usually constant and does not change with activity or position) and *chronic exertional compartment syndrome* (pain occurs only when exercising; stretching or sitting usually does not elicit pain).

Nonoperative Treatment

As with most hamstring problems, the first-line treatment for proximal hamstring syndrome does not involve surgery. The mainstay of conservative treatment for most muscle injuries remains the RICE protocol (*r*est, *i*ce, *c*ompress, and *e*levate). However, given the long healing times for most hamstring strains (3 to 6 weeks or more), many other treatment protocols have been devised. These range from stretching programs and posture and trunk control training to other modalities such as electrical stimulation and deep tissue massage. There are no published randomized control trials comparing any of these treatment modalities with rest, so their efficacy is unclear. In addition, there are no published data of any kind evaluating the nonoperative treatment of proximal hamstring syndrome. Theoretically, the treatments designed to help muscle strains should also help heal the scarring in proximal hamstring syndrome. Therefore, most sports medicine physicians recommend an extensive trial of some or all of the above conservative measures before resorting to surgery.

Operative Treatment

Once the diagnosis is established and the patient has failed a prolonged course of conservative measures, it is reasonable to consider operative intervention. Patients should be counseled that this involves a large incision, typically over the buttock region. The sciatic nerve is identified deep in the buttock, and any scar tissue around it is released. Some surgeons will then cover the nerve with a special, skin-derived tissue to try to prevent the scar from re-forming. The primary risk of the operation is injury to the sciatic nerve as it is dissected free from the fibrous bands of scar tissue. Any minor injury to the nerve generally resolves after 6 to 12 months, but more severe injuries can result in permanent severe leg weakness, numbness, muscle wasting, and foot drop. In the only published operative case series, 52 of 59 patients had resolution of their symptoms after surgery. Seven failed to improve well enough to return to sports. Two patients had wound complications, and 2 patients had numbness on the thigh from cutaneous nerve damage. Five patients took more than 6 months to improve but ultimately did have resolution of their symptoms.

After Surgery

Crutches are typically used until the patient is able to walk comfortably on the affected leg. As soon as the skin incision heals (in about 2 weeks), physical therapy is begun. At first, this usually consists of gentle hamstring stretching, which then advances to more rigorous motion. The principle behind physical therapy is to use motion to prevent the formation of more scar tissue, while avoiding being overaggressive to prevent reinjury to the muscle or nerve.

Proximal Interphalangeal Joint Dislocation

The most frequently injured joint in sports is the proximal interphalangeal (PIP) joint, with dislocations at this site being more common than in any other joint in the body. PIP joint dislocations can be anatomically divided into dorsal, volar, or lateral. Dorsal dislocations are the most common. Athletes participating in sports involving manual ball contact, such as football and basketball, experience the highest rates of PIP injuries.

The hinge joint configuration allows flexion and extension only. Each finger joint consists of a fibrous capsule lined by a synovial membrane, two collateral ligaments, and a volar plate. Both the volar plate and the collateral ligaments protect against hyperextension; the latter also resists lateral dislocation, while the former hinders dorsal dislocation. Hyperflexion and volar displacement are prevented by the stabilizing extensor hood complex.

Dorsal dislocations are the most common and refer to dorsal displacement of the middle phalanx relative to the proximal phalanx. The more rare volar dislocation signifies an anterolateral displacement of the middle phalanx relative to the proximal phalanx head. Lateral dislocations involve a partial or complete tear of the collateral ligament complex.

History and Physical Exam

Because injuries to the hand are common, athletes may initially disregard PIP trauma as simply a "jammed" finger and delay seeking medical attention. A thorough assessment and accurate diagnosis are important first steps to avoid chronic defects and disability. The history of injury should include the setting of injury, specifically the sports, position, and mechanism. Next, a typical pain assessment should uncover both the immediate and the persistent symptoms, including any change in this pattern over time. Typically, the athlete will describe pain, swelling, and paresthesias over the affected joint. Ultimately, the information most likely to lead to diagnosis is a description of dysfunction, what the player can and cannot do since the injury occurred.

A thorough physical exam of the entire upper extremity on both the injured and the uninjured side is ideal. When focusing on the PIP joint, inspection of the hand in the relaxed and clenched positions may help reveal any deformity. Certain acute PIP dislocations may result in characteristic phalanx deformities, such as swan-neck and boutonniere. The swan-neck deformity occurs when the PIP joint is hyperextended and the distal interphalangeal (DIP) joint is flexed, while the boutonniere deformity is the opposite, occurring with flexion of the PIP and extension of the DIP, a result of avulsion at the extensor digitorum communis tendon.

Normal range of motion at the PIP joint is 100° of flexion and 0° of extension. Accurate assessment relies on isolating the joint by holding the DIP just distal to the site being examined. Tenderness, swelling, and weakness over the affected PIP joint are common. Rupture of a tendon, ligament, or intraarticular fragment can manifest as limitation in active and resisted flexion and extension. Perform passive hyperextension to determine volar plate integrity, and apply varus and valgus stress to assess the collateral ligaments. The Elson test evaluates for rupture of the extensor tendon central slip at the base of the proximal phalanx, which leads to the boutonniere deformity mentioned above. With the finger over the edge of a table and the PIP joint at 90°, a positive test yields weakness against resisted extension and hyperextension of the DIP. A neurovascular exam of the finger is an essential part of the complete exam.

Imaging Tests

Anteroposterior, lateral, and oblique radiographs of the entire finger should be obtained prior to and after treatment to both confirm the diagnosis and exclude a related fracture. A true lateral view causes the condyles of the proximal phalanx head to be superimposed and allows for detection of otherwise subtle irregularities. Stress views may be used to determine joint stability. One caution when interpreting radiographs is that the nutrient arteries of the proximal phalanx distal condyles can appear as undisplaced fractures.

Dorsal Dislocation

Mechanism

Dorsal PIP joint dislocations typically occur when an act of hyperextension stress is combined with axial loading. This action disrupts the volar plate from its distal attachment, along with at least one collateral ligament. The resulting volar plate rupture may occur with or without an avulsion fracture of the base of the middle phalanx. The volar plate remains attached proximally to the proximal phalanx and laterally to the accessory collateral ligament. Injuries can be categorized as hyperextension injury (Type I), dorsal dislocations (Type II), and fracture dislocations (Type III).

Treatment

The goals of treatment are to promote healing of the volar plate, joint capsule, and collateral ligaments with the goal of restoring normal joint function.

However, in practice, reduction often occurs immediately on the playing field or sideline. In fact, dorsal dislocations are often referred to as "coaches' finger" because of the tendency of coaches, or the athletes themselves, to perform the reduction.

Reduction involves first freeing the middle phalanx by gently hyperextending the PIP. Then, while exerting gentle axial traction, flex the middle phalanx until it reduces. Following reduction, examine the joint for local tenderness, range of motion, and tendon function. Also examine to detect instability in the dorsal-volar and medial-lateral directions. Radiographs must be obtained after reduction to confirm proper alignment.

Most dislocations are stable and can then be immobilized by splinting with 20° to 30° of flexion for 2 to 3 weeks in a dorsal block splint. Following this period of immobilization, an active flexion program with buddy tapping can be initiated. Supplementary therapy with ice, nonsteroidal anti-inflammatory drugs (NSAIDs), and elevation can treat the accompanying pain and inflammation.

Dorsal dislocations involving fracture are considered stable if less than 40% of the joint surface is affected and unstable if the fracture fragment is greater. Injuries with fracture can be treated with a trial of closed reduction by placing the joint in 75° of flexion and reducing the amount over 4 to 5 weeks. In some cases, open reduction and internal fixation are required.

Complications

An untreated dorsal dislocation may result in hyperextension deformity and chronic instability from laxity of the volar plate. Compensatory changes in a chronically dislocated PIP joint can lead to a swan-neck deformity. The ultimate function and appearance of the joint can also be compromised by nonunion of a fracture at this site.

Despite early reduction, pain and swelling often persist for weeks to months following the injury. Other complications following appropriate treatment include recurrent dislocation, resulting from inadequate immobilization, and muscle contraction following prolonged splinting.

Return to Sports

The issue of return to play (RTP) must take into account the individual athlete, the dominant hand, the degree of injury, and the specific sport or position played. In general, athletes with simple dorsal dislocations may return to sports as tolerated only with protective immobilization. When fractures are involved or open reduction is required, RTP will be more prolonged and may take up to 8 weeks before activity with buddy taping is permitted. Complete resolution of symptoms may not occur for 6 to 8 months.

Volar Dislocation

Mechanism

Volar PIP joint dislocations result from the combination of either valgus or varus force with an action of volar thrust to the middle phalanx. This compressive and rotatory motion can cause injury to the central slip, collateral ligaments, and volar plate. The resulting dislocation can be either a volar dislocation or a volar rotatory subluxation, involving rotation about one intact collateral ligament. A rare volar fracture dislocation can also occur from a similar mechanism.

Imaging Tests

As with dorsal dislocations, radiographs (anterior-posterior, lateral, and oblique) ideally should be obtained prior to and following an attempted reduction.

Treatment

Although volar PIP joint dislocations are uncommon, they often require more involved intervention because of instability and resistance to closed reduction. The inability to reduce can result from soft tissue or bone interposing the joint. The recommendation is to attempt reduction by holding the metacarpophalangeal (MP) and proximal interphalangeal (PIP) joints in flexed position while applying gentle traction with the idea of relaxing the displaced lateral band and allowing the intraarticular portion to be disengaged. However, some cases will require orthopedic referral for possible open reduction and internal fixation.

Depending on the method of reduction and the specific type of injury, immobilization in extension may be required for 6 weeks.

Complications

Chronic volar dislocations can lead to boutonniere deformity as described above. Obtaining full function is difficult with delayed surgery.

Return to Sports

The PIP needs to remain in extension with this dislocation for 6 weeks. Because surgical correction may be required, the time period before RTP will be longer (up to 12 weeks) in volar dislocations.

Psychological Aspects of Injury and Rehabilitation

Athletes, whether world class or sandlot, incur psychological trauma when they sustain physical injury. While this might seem obvious if there is a financial concern, as with a professional ballplayer or high school prospect aiming for a scholarship, the issue is no less real for recreational athletes, including *senior* or *masters athletes*. Importantly, how one responds to this psychological stress can determine one's commitment to therapy and, thus, the possible return to pre-injury or presurgical fitness. Moreover, it is important for older patients to remain active for optimal long-term physical and mental health. Most doctors, therapists, and athletic trainers excel at the physical aspects of treating injuries, but it is also important for these caregivers to appreciate the psychological influence of injury and rehabilitation.

The American Orthopaedic Society for Sports Medicine (AOSSM) released a Consensus Statement in 2006 describing what they believed was important sport psychology knowledge for team doctors, many of whom are orthopedic surgeons. Included in this statement was language indicating that the team doctor should have knowledge regarding the psychological aspects of the antecedents of athletic injury. Additionally, the team physician should be well versed in the psychological issues accompanying injury, rehabilitation, and return to play. Finally, they recommended that team doctors be aware of the mental health resources in their area. These conclusions were seconded in an article describing the results of a survey taken with a range of sports medicine providers, including orthopedic surgeons, physiatrists, osteopaths, and primary care sports medicine doctors. Unfortunately, and consistent with long-held stereotypes, the results of this survey noted that orthopedic surgeons, the doctors who are most often designated team physicians, were comparatively the worst specialty for discussing emotional and behavioral issues with their patient-athletes. This section will attempt to serve as an introduction toward a remedy for these deficiencies.

Response to Injury

A large segment of sport psychology is devoted to the concept of harnessing the brain for performance enhancement, most famously in athletes. When injury is thrown into this cauldron of athletic performance, the psychological stress added to the physical stress often marks the end of an athletic career, or at least a diminution in effectiveness. In one recent study from the National Football League, only two out of three running and defensive backs returned to a similar level of play after an anterior cruciate ligament (ACL) injury. While one knee cannot be compared exactly with another knee, this study begs the question of why, once an ACL is reconstructed, there is such a discrepancy in this group's recovery. One question that might be considered when returning from injury is, Are we rehabilitating a limb injury or a "brain" injury? In other words, is the athlete struggling with achieving his or her rehab goals because of physical issues, or is he or she limited due to (often appropriate) psychological issues?

It is perfectly reasonable for an athlete to feel trepidation when returning to a dangerous sport; in fact, it is hardwired in our sympathetic nervous system. When competing on the athletic field in most sports, we are putting ourselves in harm's way and must fight our primitive brain on some level to accomplish this task effectively. Those who can "sacrifice their bodies" and "play through pain" are coveted by teammates and coaches. This fight with our primitive (and cognitive) brain is especially heightened when returning from the recent pain and disability of injury or surgery. The athlete now must wrestle with his or her brain's awareness of the "bad knee" or surgically reconstructed shoulder. This presents a significant challenge of confidence for any patient, especially for those competing in high-risk sports.

As caregivers, by addressing the "whole athlete," we will gain insight into how athletes appraise their injury, how motivated they will be in the recovery process, how they will deal with setbacks, and how they might negotiate the fear of possible reinjury. While the recovery from physical injury generally follows a physiologic path,

Injury → Healing → Rehabilitation →
Gradual Return to Sports,

psychological recovery might not proceed in such a stepwise fashion. Those with athletic backgrounds, however, tend to do better with rehab and coping postinjury than do nonathletes. Having each patient assessed by a sports psychologist is ideal but not especially practical. A baseline sport psychology evaluation should be the norm, however, for high-level athletes. Similar to neurocognitive studies, which are now administered to assess return from head injury, sport psychology data should be obtained in serious athletes pre-injury to establish a baseline and, subsequently, postinjury to assess any potential issues.

One parameter that can help assess how an athlete responds psychologically to an injury is the importance of athletics in that person's life. This is often referred to as *athletic identity,* or the degree to which an individual identifies with the athlete's role, which can remain throughout a lifetime. Such evaluations are influenced by past achievements, family, friends, and no doubt certain intrinsic motivations. Having a strong athletic identity is thought to help patients continue to participate in some type of physical activity in old age. Those patients with high athletic identities, however, will be more prone to depression after sustaining a significant injury. Also important to note for those of us treating masters athletes is that simply getting old does not change this attitude! After injury and illness, along with the blow to athletic identity comes possible mood disturbance, lowered self-esteem, diminished self-efficacy, and, in some cases, the first inklings of mortality.

Psychological Injury Models

A number of models have been developed that discuss both the response to and the prediction of athletic injury. This includes the death-and-dying model of Elisabeth Kübler-Ross as it might pertain to athletic trauma. Though these models can be interesting from a research standpoint and for their long-term implications, they can be difficult to relate to in a busy sports medicine practice. Gould and colleagues, in their article "Coping With Season-Ending Injuries" (1997), describe various stress sources that athletes might have to deal with when recovering from injury. They describe three major aspects of this stress, including (1) a "major life event change," referring to the loss of one's career and paycheck; (2) "chronic stress," both physical and psychological, due to one's injury; and (3) "daily hassles" due to physical immobility. All these stress sources, barring the monetary issue, are a huge part of the psychology of everyone who identifies himself or herself as an athlete on any level. Thus, in addition to the professional athlete, the stresses of injury are also true for older athletes who are retired from work and whose children have left home. For elderly patients, their activities, whether they are competitive, social, or simply hiking in the woods with their dog, are a major part of their health situation, and for many, they treat them essentially as a second career. They cannot (and should not) give them up easily. Active elders are often one significant injury or illness away from true disability. This fact is not lost on these patients and will often add to the psychological stress.

Heil, in his article "Sport Psychology, the Athlete at Risk, and the Sports Medicine Team" (1993), describes a cyclical response to injury as opposed to progressive acceptance through stages. He breaks down the response to injury as *distress, denial,* and *determined coping*. Distress is the effect the injury has on one's emotional equilibrium, denial is unacknowledged distress, and determined coping involves using knowledge, skills, and energy to move beyond and recover from the injury. Of course, not all athletes respond to injury in a similar fashion, as this will depend on many factors, such as maturity level and what career stage they are in. As noted by Britton W. Brewer, it is not necessarily how the injury occurs but how it is perceived and appraised. Brewer includes in his model personal variables such as psychological involvement in sports, self-esteem, and age.

Andersen and Williams, in their article "A Model of Stress and Athletic Injury: Prediction and Prevention" (1988), based on a seminal study conducted more than two decades ago, discuss the connection between stress and injury and offer possible interventions to decrease these connections. Their interactional, theoretical model takes into account aspects of life that could lead to injury, including cognitive, attentional, behavioral, intrapersonal, social, and general stress factors. Problems with any of these factors could potentially result in changing focus, muscle tension, distractibility, and so on. These concepts have been supported by other studies in collegiate athletes engaged in multiple sports. The article by Hanson et al. titled "The Relationship of Personality Characteristics, Life Stress, and Coping Resources to Athletic Injury" (1992) equates the severity of injury with the amount of negative life stress. While many of these models are individualized, they are still too cumbersome for routine use. Sports psychologists must develop quantitative/user-friendly tools that general sports medicine providers can employ to help their patients return from injury.

One such program that attempts to simplify and combine physical and psychological rehab is that of O'Neill. He asks athletes to equate their "rehabilitation program" with their pre-injury "training program" by quantifying activities into a "three-pronged attack" of exercise, sport-specific movement patterns, and aerobic training. By involving the athlete in a program he or she can understand in a physiologic sense, as well as introducing simple sport psychology principles immediately, this program attempts to bring the mind and body together in recovery. The patient is asked not to think of rehabilitation in stages that only focus on the injury but to begin working on specific doable sports skills that need improvement, as well as other possible physiologic and psychological weaknesses. The period of rehabilitation from injury can be a time for coaching that can effect positive changes in certain skills and muscle qualities in areas away from the injury. Physiologic issues such as core strength and flexibility or very specific skills, such as serve toss, putting, foul shooting, and so on, can be evaluated, and bad habits can potentially be eliminated while recovering from, for example, a meniscus tear. A positive cycle of improvements in physiology, followed by improvements in psychology, followed by improvements in physiology, and so on, can then be developed.

Quantifying Sport Psychology

Yogi Berra famously said, "Baseball is 90% mental, and the other half is physical." Although this was said more than 50 years ago, the elusive "mind-body connection" has proven difficult to achieve consistently, except in the most remarkable of athletes. Is avoiding undue risk and injury a skill that can be taught? Are we able to teach self-awareness? Do both the primitive and the cognitive brain shut down to risk in certain athletes? Sport psychology is still in its infancy in attempting to answer these questions and to help make the mind-body connection available to everyone.

While patients will often respond to injury with mood disturbances and decreased self-esteem, it is difficult to know to what extent they will do so. In addition to those involved with the care of patients having "their antenna up" for adjustment issues, psychometric testing is another way to quantify how the patient is doing psychologically. Psychometric testing is attempting to measure emotions and feelings by having the patient complete questionnaires. Due to this individualized method of eliciting information, these tools are subjective evaluations and are thus often weakened by reporter bias. Despite the potential weaknesses, many sports psychologists will obtain baseline psychometric data and repeat testing on a periodic basis. There are many tests available depending on the population being cared for. In the orthopedic literature, SF-36 is presently the most commonly sited health survey for adult patients as it includes both general and psychological health information.

In addition to psychometric testing, another way to make psychological issues more quantitative and get answers to these questions is through biofeedback. Biofeedback can be thought of as teaching people to improve health and performance by observing the physiologic signals generated from their bodies in "real time." Physiologic signals such as the electroencephalogram (EEG), electromyogram (EMG), skin conductance (sweating), respiration, blood pressure, temperature, and the like can all be measured and "fed back" to the subject. Using this information, the athlete can more rapidly improve on problematic issues, including stress response, arousal, relaxation, exercise tolerance, and so on. With new computer technology and mobile monitoring, biofeedback is not limited to the laboratory but can be taken onto the field, the golf course, and the ski jump hill. One of the more exciting aspects of biofeedback is its use to quantify coping and recovery, and thus, it may have a role in injury prevention (see the entry Biofeedback).

Sports Psychology Skills

When we discuss sport psychology with noninjured players, we often speak of a litany of techniques now familiar to most athletes, including goal setting, coping, self-talk, arousal, relaxation, and so on. This same skill set should be employed by athletes (or nonathletes) returning from injury. Athletes tend to do better in rehab as they can use such skills, their natural determination, and physical muscle memory to get better faster. In addition to these extrinsic factors, intrinsic factors such as optimism, hardiness, and global self-esteem will play a role in recovering from injury.

It is normal and often functional to have fear after injury, and in fact the patient will often show symptoms similar to posttraumatic stress disorder. Some coaches famously ignore injured athletes, because they see the attention as a sign of weakness or because of concerns about a possible "injury contagion" phenomenon. While this might be acceptable in professional sports, it should not be the rule at the lower levels. We should try to have the athlete returning from injury in full view of the coaches and teammates, for the purposes of both coaching and other social aspects of team participation. Parents, coaches, trainers, doctors, friends, and teammates are all important components of the support system for a healthy psychological response in the face of a physical setback.

The Role of the Sports Medicine Doctor

There are huge differences between professional and recreational athletes on the field, but when it comes to injuries, there are many similarities. No matter what the patient-athletes' age or competition level, once an injury occurs, numerous questions should be asked that will be important to their recovery. What are their coping mechanisms? How is their time structured regarding work, family, and athletics? What kind of social support do they have? What do they see as alternatives to their previous activities while they are recovering or, in the worst case scenario, if they never recover? For professional athletes returning from injury, coping mechanisms, time management, and social support are very important. Conversely, many nonprofessionals are using athletics *for* coping, time management, and social support. When nonprofessionals are injured and cannot attend ski races, triathlons, or lawn bowling matches, it can create an equally significant void in their lives. Coping can be defined on many fronts, but the most common definition used by sports psychologists is that of "a process of constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands or conflicts appraised as taxing or exceeding one's resources." Sports medicine doctors should be a part of the coping mechanism to help patients through these potentially difficult periods. Part of this approach would be to recommend new outlets for the athlete's competitive and emotional needs, as well as suggesting safe physical venues for training and rehab. Many of these folks will not respond to psychological support without a physical outlet. A well-functioning sports medicine clinic will employ like-minded physical therapists, trainers, and ideally a sports psychologist to create a true rehab *team* to participate in the patient's care.

Of the psychological skills listed above, apart from coping, perhaps the next most important skill while recovering from injury is the use of goal setting. Major injuries will lead to the loss of many "ego" goals, such as the scoring record, the picture in the newspaper, perhaps even a scholarship. As a result, we try to focus the patient on "task-oriented" goals—goals that are concerned with daily and weekly improvement, moving toward full recovery. By establishing specific task goals, not only will the athletes improve physically, but also the quantitative improvement they see (though it might seem glacial) will lead to improved rehab adherence. Getting the athlete on board with a systematic program will give him or her confidence in rehabilitation and, subsequently, confidence in returning to competition. Such goals must be realistic and should build daily toward the long-term goal of full athletic involvement.

Perhaps one problem with asking medical and surgical doctors to address the psychological needs of their patients is not only time but also background. Athletic trainers, physical therapists, coaches, and friends have all been deemed more important outlets and confidants for athletes' emotional issues while recovering from injury than the team physician. This is despite the fact that these other caregivers often have equally little formal training to help with such problems. Ideally, the physician or other members of the medical rehab team will recognize the patient who needs extra support after an injury and can designate time to address such issues. Again, everyone involved with the care of patient-athletes should have some understanding of their psychological traumas, if for no other reason than to know when to refer them to a mental health provider. Signs of such psychological trauma and possible problematic adjustment to injury include, but of course are not limited to, depression, mood swings, apathy, obsession with playing again, denial of the significance of the injury, guilt for "letting the team down," dependence on caregivers, and quitting. Remember, many recreational athletes use athletics for coping—when this outlet is no longer available, they will sometimes use socially unacceptable or unhealthy mechanisms for stress relief. In an unpublished study, we found that Division III athletes had a decrease in grades after a season-ending injury—contrary to what one might expect with the increased time thus available for study.

In conclusion, our goal as sports medicine providers is to return athletes to the field after appropriate rehabilitation, both physical and mental. While we might not be able to guarantee a new, improved body, we might be able to achieve a new, improved mentality. What we should attempt as sports medicine providers who treat the whole athlete is to help make the athletes *smarter* even in light of potentially less than perfect physiology. Try to get the brain involved to appreciate what the athletes can and cannot do physically, as well as what they had done previously and also what they might do better. This should be thought of as *physical* sport psychology. In the sport psychology of returning from injury, we are dealing not just with the emotional issues related to the injury but with the actual physiologic changes that must be accounted for to allow complete recovery. To be most effective, this approach requires assessing not just the strength of the injured limb but the full spectrum of physical, mental, and emotional trauma. By using a rehab team, we believe, full recovery can be accomplished in an efficient manner and, ultimately, the athlete can be readied for a safer return to the field of play.

Psychological Assessment in Sports

Psychological assessment in sports involves the use of information sources, including psychological tests, personal and medical history, current symptoms and problems reported by either the athlete or professionals, and persons related to the athletes. Whenever an athlete seeks help from a psychologist, the first task of the sports psychologist is to determine the problem precisely. A nomothetic approach is expected in the traditional psychological assessment, which emphasizes group experimental designs, diagnosis, or classification and the use of standardized interview and psychometrics.

Assessment and intervention are phases within a psychological process in which intervention (treatment) evolves from assessment. Assessment refers to the explorative part, and intervention refers to modifying part of this integrated action sequence. Assessment includes sports psychological interviews, systematic observation of athletes, coaches' and team behavior, and sports psychological tests (questionnaires as well as computerized testing of, e.g., attention skills). It also may help identify problems.

Sports psychologists are aware of the different psychological processes of athletes. Most of the assessment instruments in sport psychology focus on individual differences (i.e., achievement orientation, concentration skills, or anxiety). An intervention in sport psychology might be useful in identifying the individual differences within a team, helping the coach better understand his or her athletes' individual behavior, and placing certain events or positions in teams.

It may be difficult to understand or distinguish all the causes and effects of the attitudes, beliefs, and behaviors of athletes during training and competition that lead to excellence of performance or the lack of it. Not only do people naturally have different personal preferences from a general psychological viewpoint (strong vs. weak personality characteristics, temperament, attributions, or ways of coping with stress and adversity), but in sports, other (sports psychological) factors may be involved as well (i.e., achievement goal orientations, sources of confidence in sports, optimal levels of arousal, competitive anxiety, or basic mental skills for control and adaptation in the sports context).

A sports psychological assessment aims to provide more clarity about the athletes' sports psychological makeup. Self-awareness is the first step to decide if appropriate follow-up is needed. The results of the assessment could help deal with future situations more effectively. Opportunities for improvement and development, thereby empowering the athlete for increasing personal well-being and the potential for performance excellence, may evolve.

For different reasons, the athlete, coach, or sports psychologist may want to assess various personal and sports psychological preferences, characteristics, or skills that may co-influence the athlete's performances or preparations for performances.

For each assessment, the sports psychologist will discuss the need with the athlete, explain the assessment process, and come to a mutual agreement through an informed consent for administration of the chosen sport's psychological assessment tool(s).

The use of appropriate assessment instruments requires clarification of the following questions:

1. What is the level of the assessment?
2. Should the assessment instrument be a general psychological measure or domain specific, or even sport specific?
3. What type of assessment data should or can be obtained? (Questionnaire data are usually the most simple and the cheapest method of obtaining information. Other types are interviews, observations, and physiological measures.)

In sport psychology practice and research, traditional forms of assessment have included the use of self-report questionnaires or inventories. Psychological assessment can be successfully integrated into competitive sports if important elements are considered and appropriately applied. Up to three fourths of sports psychological consultants are believed to use psychological inventories or survey questionnaires in their applied work with athletes.

The most formal assessment instruments are standardized tests. The more formal and standardized the assessment is, the easier it is to make interindividual comparisons and to relate the given situation to more general, theoretical knowledge in sport psychology, which might derive appropriate interventions that have proven to be successful. Formal tests are highly reliable and valid instruments. Standardized questionnaires rely on the main psychometric criteria of objectivity (the results of the test are independent from the person who provides the test), reliability (determining the level of accuracy of the measurement tool), and validity (how precisely the test can measure what it aims at measuring). The side criteria of economics (the cost of the procedure, evaluation, and general handling of the test should be as low as possible) and norms (standardized test for an economical comparison of the test scores) are important when standardized instruments are evaluated.

The testing principle needs to be understood before administering and interpreting psychological inventories. Furthermore, recognition of measurement errors and having well-designed and validated measures are important. Not all psychological tests have been systematically developed and made reliable. A prediction about the behavior and personality structure of an athlete or coach according to such tests would be misleading and unethical.

After completion of the actual assessment, all information gathered must be interpreted and translated in an understandable language. A personal, individualized report is completed, including explanations about the results and conclusions. During a feedback session, the results of the sports psychological assessment and the concluding report are discussed. The athletes' own beliefs and suggestions may be recorded and added to the report. Finally, informed consent will be established and for each (combination of) sports psychological assessment(s), an individualized and confidential report is generated and offered to the participating athlete. In the follow-up session, the results are discussed and explained.

Psychology of the Young Athlete

Sport psychology not only addresses the mental skill needs of elite athletes; it also makes a significant contribution to the understanding of children in youth sports. In the United States, it is estimated that 45 million children under the age of 18 participate in school and extracurricular physical activity programs. Researchers have found that children on average spend 11 hours weekly in youth sports programs and have seasons that extend for about 18 weeks per year. For most children, sports participation peaks around the age of 12. Developmental psychology outlines in detail the periods of development leading up to this age that are critical for children's growth in self-esteem and social development through sports.

Milestone Development

Early Childhood (6–8 Years)

Sports activities for this age-group need to be tailored to the physical, cognitive, and emotional abilities of this group. These children make slow gains in height and weight until their adolescent growth spurt. Kids in this age-group start to play games with rules, and dominance in hierarchies becomes more stable and self-organizing. The cognitive markers for this age-group include thinking, becoming more logical, and a beginning of understanding of spatial concepts. Attention becomes more selective and adaptable. Children in this age-group also begin to use memory strategies of rehearsal and organization. The emotional and social characteristics of this age are marked by the beginning of the development of self-concept. This includes the ability to identify personality traits and make social comparisons. Self-esteem starts to differentiate and becomes hierarchically organized. The child starts to become realistic, and emotions of pride and guilt start to be governed by personal responsibility. Children in this age-group begin to develop the awareness that individuals can have more than one emotion and start to understand that access to different information often causes people to have different perspectives.

Middle Childhood (9–11 Years)

Organized sports activities for this age-group will build on the skills acquired in early childhood and integrate the child's growing abilities to meet the physical, cognitive, and emotional challenges presented through sports experience. Adolescent growth spurts begin on average 2 years earlier for girls than for boys. Gross motor skills of running, jumping, throwing, catching, kicking, batting, and dribbling are executed more quickly and with better coordination. Reaction time improves, contributing to overall motor skill development. Logical thought remains tied to the concrete situation until the end of middle childhood. Planning improves, and memory strategies of rehearsal and organization become more effective. Self-esteem becomes more durable, and children in this age-group begin to distinguish between ability and effort, as well as their attributions for success and failure. Child athletes in this age-group also begin to form strategies for regulating emotion, and the beginning of mental skill training in sports is possible.

Early Adolescence (11–14 Years)

Girls may have reached the peak of their growth spurt, including the beginning of menses and potential changes in body composition (adding more body fat than muscle). Boys are usually beginning their growth spurt, and changes in athletic ability as well as proneness to injury are related to change in muscle composition as rapid growth occurs. This phase of development includes the ability to become more capable cognitively of formal operation reasoning. Adolescent athletes are better able to coordinate theory with evidence, argue more effectively, and become more self-conscious and self-focused. The emotional swings of this age are well-known and understood. Moodiness and parent-child conflict increase. Adolescents define their identities through peer relationships, spend time with kids who share similar values, and organize into cliques.

Late Adolescence (14–16 Years)

Girls have mostly completed their growth spurts and may or may not have reached menses. Early competitive sports that require low body fat and composition ratios (e.g., gymnastics and figure skating) can delay growth as well as full development. Boys are still growing furiously during this age and are adding muscle while body fat declines. For most boys, this age range includes rapid increases in motor performances and sharpened athletic abilities. The cognitive gains made in early adolescence are being refined through early adulthood. Adolescents become better at planning and decision making, and there is a trailing off of self-consciousness and self-preoccupation. The emotional/social characteristics of this age-group consist of forming the self into an organized self-concept. Athletes in this age-group experience better differentiation in self-esteem. Big-picture thinking and relating become more consistent, and the ability to view things from a societal perspective increases.

Psychological Growth and Development

When exploring the psychology of the young athlete, several components of youth experience are taken into account. There are developmental considerations of both motor and cognitive abilities, motivation issues, and competitive considerations. Research shows that the main reason why young athletes participate in nonschool and school sports is "to have fun." Several gender differences emerge after the primary motivation, with boys emphasizing skill development and girls emphasizing "staying in shape." Both girls and boys rate the "challenge of competition" and "skill acquisition" among the first seven reasons. It is significant that the ongoing reasons why child athletes continue to compete in sports is because learning new skills keeps them engaged and having fun.

Before age 9, most children do not have the ability to make a distinction between effort and ability. With this inability to differentiate between the two, children do not draw conclusions that effectiveness in sports participation is related to their own abilities. If they lose, they are likely to believe that they can win if they work harder, rather than drawing a conclusion that they are not "as good" as another player. Between the ages of 9 and 11, the concepts of ability and effort begin to be distinguished. Children can start to make their own assessment of their ability and the abilities of others. By age 11 or 12, this distinction is rather clear in most children's minds. This awareness has a significant impact on their experience, participation, and drive to pursue sports activities after age 12. Understanding this awareness in children can help provide the right level of sports experience to encourage more young athletes to stay active and remain in youth sports instead of drawing conclusions about not being good enough and quitting.

Implications for Practice and Training

Maureen Weiss, a leading researcher in youth sports, concluded that the children who continue to participate in youth sports continue to perceive that they are competent in their sport. That is, children who start to develop low perceptions of their athletic abilities start to drop out. There are six important needs of young athletes that should be addressed by the structure in sports situations, by providing settings that

1. improve new skills,
2. encourage kids to have fun,
3. provide opportunities for developing friendships and positive peer experiences,
4. provide excitement and novelty in training,
5. teach young athletes how to monitor their own fitness, and
6. allow children to compete and develop goals that define winning not just as beating others but as achieving one's own standard.

Gould and Petlichkoff, demonstrating why children participate in and withdraw from sports, have published a motivational model of youth sports participation. According to their model, the chief reason for children to prematurely withdraw from sports is perceived competence, goal orientations, and stress response.

Character Development

There is a long-standing relationship between good sportsmanship and character development. Youth sports is a ripe forum for cultivating good sportsmanship behaviors on the part of coaches, parents, and athletes, leading to longer-term character development. Weinberg and Gould define character as an array of characteristics (usually referring to a positive moral overtone) that can be developed in sports. They describe athletes of good character as being able to overcome obstacles, cooperate with teammates, develop self-control, and persist in the face of defeat. They connote that character in sports consists of four interrelated virtues: (1) compassion, (2) fairness, (3) sportsmanship, and (4) integrity. Compassion is a form of empathy that is the ability to take on and appreciate the feelings of others. Integrity is the ability to maintain one's morality and fairness, along with the belief that the athlete can remain moral in his or her actions.

The Johnston Alliance for Character Development notes five common core principles associated with fostering good sportsmanship and character development:

1. *Trustworthiness:* Pursue victory with honor and fair play.
2. *Respect:* Engage within the boundaries of the guidelines of the sport. Win and lose with dignity.
3. *Responsibility:* Be a responsible role model on and off the field.
4. *Fairness:* Adhere to standards of fair play.
5. *Caring:* Understand that emotional, physical, and moral well-being are always placed above desires and pressures to win.

Talent Development of the Young Athlete

There are a number of ways to look at the development of young athletes. Jon H. Hellstedt looks at the parallel processes of the development of young athletes and the correlated changes in the family system supporting the training of young athletes. He has identified three main stages of development that must be completed for a child athlete to become successful in his or her sport.

Phase 1: Exploration

The first phase is exploration; this phase usually occurs between the ages of 4 and 12. Shane Murphy termed this Phase 1 and noted that it nicely emphasizes the sense of trying different sports and the excitement of exploring one's skills. Hellstedt describes that parents negotiate several objects within each phase for the child athlete to develop successfully. In this first phase, parents and coaches need to emphasize fun and skill development while minimizing competitive success.

Phase 2: Commitment

As skill, success, and fulfillment emerge through a sport, the young athlete makes an increasing commitment to the chosen sport. This phase is marked by the athlete taking responsibility for the skill development process. This is often a time when a talented athlete starts to make choices between sports and other activities to make a primary commitment to skill development in one sport. Murphy describes a potential deterrent during this phase, what he calls the "externalization" of sports. It is during this phase that the outcomes of games and performance or working to make a team or not being cut from a team start to shape the young athlete's experience. When sports experience is more heavily weighed as externally driven, the athlete may lose his or her passion for the sport or may experience burnout. Programs, coaches, and parents need to remain mindful through all phases of sports development that the critical elements that brought the young athlete to the sport remain a vital component of his or her experience.

Phase 3: Proficiency

This phase of athletic training maximizes the commitment phase and takes training to a new level. This phase is marked by long hours of training, expert coaching, and participation in very competitive situations and events. As referenced earlier, the phases of proficiency vary by sport. In gymnastics and figure skating, for example, proficiency needs to be accomplished by the midteen years, and executing training with this level of commitment starts at a very young age. The development impact on younger athletes is different from the proficiency that may be required of a soccer player who is expecting to start peaking in his or her late teens and college years. Most Division I college athletes are living the life of a proficient athlete, being required to make the compromises necessary to maintain a high-level commitment to sports while remaining strong in academics. The conflict between pleasure and external demands has an impact on the athlete's experience of the sport.

Young Athletes and Competition

As youth sports promote competition and specialization in a sport at younger and younger ages, the developmental appropriateness of these experiences for developing athletes becomes a matter of concern. Important questions are raised about the enhancing aspects of competition as well as how competitiveness at an early age can lead to loss of interest in the sport and premature termination of sports participation. The themes that emerge surrounding the value of competition include building teamwork and leadership skills as well as personal discipline and following through on commitments. Others are concerned that premature exposure to competition can lead to injuries to self-esteem and premature termination of sports participation.

Sport psychology research on this issue has demonstrated that it is the attitude of the athlete that determines the strength or weakness associated with the experience of competition. It has also been demonstrated that by adolescence, athletes have formed a stable set of attitudes regarding competition—termed *competitive orientation.* There are two dimensions that characterize competitive orientation. The ego orientation is characterized by the athlete's concern to "look good." This orientation is marked by social comparison, and athletes value their own expertise based on how it compares with the skills or competence of their peers. The mastery orientation toward competition values excellence in one's sport. This dimension of the athlete's experience values skill acquisition and becoming an expert in the chosen sport.

Murphy holds that the strength of an athlete's orientation between the ego and mastery orientation will have significant implications. The four styles are (1) high ego, high mastery; (2) high ego, low mastery; (3) low ego, high mastery; and (4) low ego, low mastery. An athlete with high ego, high mastery is often considered "competitive." This athlete enjoys competition as an environment to test out his or her own skills and works hard to reach higher levels in his or her sport. This athlete measures progress according to his or her own standards and pushes to improve skill level based on external and internal comparisons. In contrast, the low ego, low mastery style has low levels of both types of goal orientations. This athlete is not driven by internal standards but instead is participating in sports to please parents, be with friends, or please some other external motivator. This athlete does not value skill acquisition and is unlikely to remain in competitive sports for very long because the demands of training will prove to be taxing or frustrating.

This concept of competitive orientation sheds light on how parents and coaches can encourage the "right fit" for levels of competition for the young athletes participating in youth sports.

Pulmonary and Cardiac Infections in Athletes

Pulmonary and cardiac infections in the athlete can have a wide range of presentations and complications.

Such infections may present few problems for the training athlete, but they also have the potential to become a life-threatening condition. The team physician must be able to recognize the diagnosis, give the appropriate treatment, understand the potential complications, and ensure proper follow-up and return-to-play protocols.

Pneumonia

Pneumonia is defined as an acute infection or inflammation of the pulmonary parenchyma. The term *community-acquired pneumonia* (CAP) is used when a patient is not hospitalized or in a long-term facility for at least 14 days prior to the onset of symptoms. Typical pneumonias are most commonly caused by *Streptococcus pneumoniae* and are found in patients very young or older. Atypical pneumonias are usually caused by legionella, chlamydia, or influenza organisms; are found most often in young adults; and account for 20% to 40% of cases of CAP. CAP generally is a more serious illness with considerable morbidity and mortality and requires increased recovery time for the athlete.

Clinical Presentation

Cough is the most common symptom in CAP. Symptoms may also include sputum production, shortness of breath, and chest pain. Patients may present with nonspecific symptoms such as malaise, anorexia, headache, myalgias, fever, and chills.

It is imperative to document the vital signs (temperature, pulse, respiratory rate, blood pressure, and oxygen saturation) of any athlete who presents with a respiratory complaint. The vital signs on physical exam may reveal fever, tachycardia, tachypnea, hypoxemia, or hypotension. The most common sign associated with CAP is fever. Vital signs are important elements in the decision-making process on the appropriate management of CAP.

The examination may demonstrate crackles, rales, or bronchial breath sounds on auscultation. It is also important to document the patient's appearance and neurological status.

Diagnosis

An infiltrate on chest radiograph is considered the "gold standard" for the diagnosis of pneumonia in the appropriate clinical scenario.

Treatment

Once the diagnosis of CAP has been made, physicians must choose between inpatient treatment and outpatient treatment for the athlete. In the training room setting, the most useful indicators are vital signs and physical exam findings.

The most common contraindications to outpatient treatment are inability to maintain oral intake, unstable vital signs, history of substance abuse, mental/cognitive impairment, or the presence of comorbid conditions.

Antibiotics that provide coverage against the most common organisms known to cause CAP (*S. pneumoniae, Mycoplasma pneumoniae, Chlamydia pneumonia, Legionella*) should be selected.

Generally, most cases of CAP should be treated for 7 to 10 days. The severity of the clinical presentation and the presence of coexisting illnesses should be considered in the decision on duration of antibiotic treatment.

Complications

Most patients recover from CAP without complications. One of the most common complications for the athlete is reactive airway disease. This abnormality typically resolves after 3 weeks but may last up to 2 months. This potential complication could inhibit the athlete's ability to fully return to play. If clinically indicated, the athlete may respond to short-term inhaled bronchodilator therapy.

Return to Sports

Athletes treated with an effective drug regimen usually show improvement of symptoms within 72 hours. The athlete should be afebrile prior to returning to training and competition. The athlete also should be reevaluated by the team physician prior to clearance to ensure normalcy of the vital signs and respiratory status. Once the athlete is able, we recommend restarting exercise and training slowly.

Acute Bronchitis

Bronchitis is defined as inflammation of the bronchial mucous membranes. Acute bronchitis is a clinical syndrome characterized by cough (with or without sputum production) lasting up to 3 weeks, with evidence of concurrent upper airway infection.

Causes

Respiratory viral infections are the most common causes of acute bronchitis. The most common viruses associated with acute bronchitis include influenzas A and B, adenovirus, rhinovirus, parainfluenza, coronavirus, and respiratory synctial virus (RSV). When contemplating treatment options, it is important for the physician to understand the limited role of bacterial agents in acute bronchitis. Acute bronchitis is one of the most common examples of the misuse of antibiotics by the primary care physician.

Clinical Evaluation

Cough is the most common symptom in acute bronchitis. The patient may or may not have sputum production. Fever is unusual in acute bronchitis. The patient may also complain of concurrent or prodromal symptoms of an upper respiratory infection (URI), including pharyngitis, coryza, and fatigue. Most URI symptoms improve within 5 to 7 days. In acute bronchitis, the cough can last up to 3 weeks.

It is imperative to document vital signs (temperature, pulse, respiratory rate, blood pressure, and oxygen saturation) on any athlete who presents with a respiratory complaint. The exam will often reveal similar findings as in URIs—pharyngeal erythema, anterior cervical lymphadenopathy, and rhinorrhea.

Diagnosis

The diagnosis of acute bronchitis is considered a clinical diagnosis and should be suspected in cases of acute respiratory disease with prolonged cough that continues after other signs and symptoms of acute infection have resolved. It is likely not necessary to obtain any further studies in the appropriate clinical situation.

Treatment

Once the clinical diagnosis of acute bronchitis has been established, the recommended therapy is symptomatic. The physician may choose to use acetaminophen, ibuprofen, and nasal decongestants if appropriate.

Return to Sports

There are few data regarding appropriate return-to-play issues for athletes with acute bronchitis. It is important for proper follow-up with the team physician to ensure resolution of symptoms and to guarantee a nonworsening clinical situation.

Pertussis

Bordetella pertussis, a gram-negative coccobacillus, is a commonly undiagnosed cause of acute bronchitis. *Pertussis*, also known as "whooping cough," is an acute, highly contagious infection of the respiratory airways. Pertussis is transmitted from person to person by contact with aerosolized droplets. Due to the amount of time that athletes spend training together and the high infectivity of pertussis, this is a diagnosis that must not be missed in the training room.

Clinical Presentation

The classic clinical course of pertussis is divided into three stages: (1) catarrhal phase, (2) paroxysmal phase, and (3) convalescent phase. Table 1 describes each stage of pertussis. Athletes may report a cough lasting more than 2 weeks with a paroxysmal quality, posttussive emesis, or inspiratory whooping cough.

Diagnosis

The most reliable diagnostic test for pertussis is detection of the organism from nasopharynx secretions. The Centers for Disease Control and Prevention (CDC) recommends that physicians report and treat pertussis once there is clinical suspicion and not wait for laboratory confirmation.

Treatment

In the case of proven or presumed infection, therapy should be started as soon as pertussis is suspected. The recommended treatment is erythromycin for 14 days. Athletes with confirmed or

Table 1 Stages of Pertussis

Catarrhal Phase	*Paroxysmal Phase*	*Convalescent Phase*
Lasts 1 to 2 weeks	Lasts 3 to 6 weeks	May last 2 to 12 weeks
Most contagious phase	Clinically, spells of coughing with characteristic inspiratory whooping	Cough still present
Clinically resembles upper respiratory tract infection	Posttussive vomiting, cyanosis, and apnea	Paroxysms may recur with respiratory infection
Cough increases in severity and frequency		

probable pertussis should be isolated for 5 days from the start of treatment.

Prophylaxis

Athletes known to be in close contact with a known or suspected case of pertussis should be given prophylactic antibiotic treatment. The recommended regimen is full dosing of erythromycin for 14 days.

Complications

Pertussis infections in the training room can lead to rapidly spreading illness among other athletes and staff. Pertussis can also cause reactive airway disease and bronchitis. Pertussis can be complicated by pneumonia, dehydration, weight loss, and sleep disturbance—all of which can affect the athlete's return-to-play status as well as overall performance.

Return to Sports

Athletes with confirmed or probable pertussis should be isolated for 5 days from the start of treatment to prevent spreading of the disease. The athlete should also be evaluated to ensure resolution of respiratory symptoms.

Influenza

Influenza is an acute respiratory illness caused by influenza A or B viruses. Influenza is a common seasonal cause of acute bronchitis.

Clinical Presentation

The diagnosis of influenza should be considered if the athlete presents during the winter months with the abrupt onset of fever, headache, myalgias, malaise, nausea, and vomiting. These symptoms are generally accompanied by cough and sore throat.

In uncomplicated influenza, there are few physical exam findings. The health care provider in the training room should document the vital signs. The patient may appear flushed. The findings may also include mild cervical lymphadenopathy and hyperemic oropharynx. The eyes may be watery or reddened. Otherwise, the exam will likely be unremarkable.

Diagnosis

Outpatient laboratory diagnosis of influenza can be accomplished by the detection of the virus or viral antigen in nasal washes or throat swabs.

Treatment

There are two classes of antiviral drugs available for the treatment of influenza: With appropriate treatment, the duration of the symptoms may be reduced by 2 to 3 days.

Symptomatic treatment is also important in influenza. Acetaminophen or ibuprofen may be beneficial for fever, headache, or myalgias. Cough suppressants may be helpful in the appropriate clinical scenario. Athletes should be instructed to maintain proper hydration and rest during the acute illness.

Complications

Close follow-up of athletes with severe influenza illness is imperative to ensure that no complications are arising. Dehydration and acute bronchitis are common complications of influenza.

Prevention

There are measures available to help prevent the illness caused by influenza. Annual vaccination is available.

Return to Sports

To prevent the spread of influenza, the athlete should be kept away from the training room, practices, and competitions until 5 days after the onset of symptoms. Return to full activity should be delayed until the illness has fully resolved. Athletes should be evaluated for any signs of fever, dehydration, or impaired respiratory status prior to full clearance.

Myocarditis

Myocarditis is an inflammatory disease of the cardiac muscle that can have a wide spectrum of clinical presentation and outcomes. Myocarditis is one of the most challenging diagnoses in cardiology. Acute myocarditis can progress to dilated cardiomyopathy, heart failure, arrhythmias, and death. If unrecognized in the training room, myocarditis can produce lethal results.

Causes

Myocarditis has a wide variety of etiologies, both infectious and noninfectious. The most common infectious causes are viruses. The most frequently associated are coxsackie B virus, adenovirus, hepatitis C, cytomegalovirus, echovirus, influenza, and Epstein-Barr virus. The most common etiologies of myocarditis found in the training room are viral illnesses—especially coxsackie B virus, adenovirus, and echovirus. Myocarditis can also result from drug hypersensitivity, radiation, and chemical or physical agents.

Clinical Presentation

The diagnosis of myocarditis requires a high index of suspicion in the appropriate clinical setting. A wide range of symptoms can be present in an athlete suffering from myocarditis. The patient may be asymptomatic or may simply give a history of a preceding upper respiratory infection or flu-like syndrome. The patient may also present with chest pain or symptoms of heart failure. The athlete may present with fever, malaise, and arthralgias. The diagnosis of infective myocarditis should be considered when an athlete presents with cardiac complaints or arrhythmia issues in the course of a recognized systemic infection.

It is imperative to document vital signs in the training room. The physical exam may be normal. If the myocarditis is severe, the cardiac exam may reveal tachycardia, a muffled first heart sound along with a third heart sound, and a murmur of mitral regurgitation. The exam may also reveal findings of heart failure such as edema and pulmonary crackles from fluid overload, depending on the severity of the illness. If there is associated pericarditis, a pericardial friction rub may be heard. The exam may also reveal findings consistent with an upper respiratory infection.

Diagnosis

Routine blood and urine laboratory tests are generally normal in myocarditis. Cardiac enzymes may be elevated, specifically the MB (muscle and brain) fraction of creatine kinase (CK-MB) and troponin I. The electrocardiogram (EKG) may be normal or abnormal. The most common EKG findings are transient, nonspecific ST-T wave abnormalities. Chest radiograph findings range from normal to cardiomegaly. Echocardiogram may reveal decreased ventricular function.

Cardiac magnetic resonance imaging (MRI) is becoming a more widely available tool to detect myocardial abnormalities. The definitive diagnosis of myocarditis is made by endomyocardial biopsy with histologic evaluation.

Treatment

Viral myocarditis is usually a self-limited disease. Treatment is generally supportive. However, myocarditis may progress to dilated cardiomyopathy and heart failure. Most therapy regimens are directed toward treatment of heart failure and potential arrhythmias in serious cases.

Complications

Most patients with viral myocarditis recover completely. However, athletes with viral myocarditis are at risk for heart failure, cardiomyopathy, and associated pericarditis. These athletes are also at risk for arrhythmias and sudden cardiac death.

Return to Sports

Exercise and training can be deleterious in athletes with myocarditis. According to the current Bethesda Conference recommendations, athletes with probable or definitive evidence of myocarditis should be withdrawn from all competitive sports and should undergo a convalescent period of about 6 months following onset of clinical manifestations. After 6 months, athletes may return to training if the following conditions are met:

- Left ventricle function, wall motion, and cardiac dimensions return to normal.
- Clinically relevant arrhythmias are absent on ambulatory Holter monitoring and graded exercise testing.
- Serum markers of inflammation and heart failure have normalized.
- The EKG has normalized.

Pericarditis

Pericarditis (inflammation of the pericardium) may be caused by a wide variety of infectious and noninfectious processes. Pericarditis can have a wide range of clinical presentations from asymptomatic to severe hemodynamic compromise. A careful history and knowledge of the clinical presentation of pericarditis are important in establishing the diagnosis. If the diagnosis is missed, pericarditis can become life threatening for the athlete.

Causes

Pericardial disease has multiple etiologies, including infectious, neoplastic, inflammatory, degenerative, vascular, and idiopathic. Infectious and idiopathic causes will likely be the most common etiologies in the training room. These causes are found in 90% of cases of acute pericarditis.

Clinical Presentation

The presentation of acute pericarditis varies depending on the etiology. In infectious or idiopathic acute pericarditis, the major clinical symptom is chest pain. The patient may describe the pain as retrosternal, exacerbated by coughing or deep inspiratory effort. The pain may also radiate to the back. The chest pain in acute pericarditis is often positional—worsened in the supine position and relieved by sitting upright and leaning forward. The athlete may also complain of fever. Patients may also present with an associated flulike illness with cough, fatigue, myalgias, or arthralgias.

It is imperative to document vital signs for athletes with cardiac or respiratory complaints. The vital signs may indicate severity of cardiac compromise. The pericardial friction rub is the cardinal physical sign of acute pericarditis. The physician should also look for signs of cardiac tamponade on exam: hypotension, tachycardia, jugular venous distention, and pulsus paradoxus (defined as an inspiratory systolic decrease in arterial pressure of 10 millimeters of mercury pressure [mmHg] during normal breathing).

Diagnosis

Laboratory tests to consider include complete blood count (CBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and cardiac enzymes. The EKG is abnormal in 90% of patients with acute pericarditis. In acute pericarditis, the chest radiograph is generally normal. An echocardiogram should also be obtained in patients with suspected acute pericarditis. The echocardiogram is often normal unless there is an associated pericardial effusion.

Treatment

The initial treatment decision the physician must make is inpatient or outpatient treatment. If the athlete has simple uncomplicated acute pericarditis and is clinically stable, outpatient treatment with close follow-up may be appropriate. If high-risk features are present or if the patient is clinically unstable, inpatient treatment is recommended. High-risk features are illustrated in Table 2.

Table 2 High-Risk Features in Acute Pericarditis

Subacute onset
Fever (temperature >100.4 °F)
Leukocytosis
Acute trauma
Evidence of cardiac tamponade
Immunosuppressed state
Large pericardial effusion without significant response to NSAID treatment
History of oral anticoagulant therapy
Failure to respond to NSAID therapy within 7 days

Primary therapy goals for idiopathic or viral pericarditis are pain relief, resolution of inflammation, and resolution of effusion if present. Current recommendations include the use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs). Close monitoring and follow-up are imperative for all athletes diagnosed with acute pericarditis.

Complications

While pericarditis usually resolves within a few days to weeks, life-threatening complications can occur. If an associated pericardial effusion is present, this may proceed to a cardiac tamponade—which is a cardiac emergency. If the pericardial inflammation does not resolve, it may lead to chronic pericarditis. Chronic pericarditis may subsequently lead to constrictive pericarditis.

Return to Sports

The current Bethesda Conference Guidelines recommend exclusion of the athlete with acute pericarditis from competitive sports. These athletes can only return to full activity when there is no evidence of active disease.

Acute Rheumatic Fever

Acute rheumatic fever (ARF) is an inflammatory disease that may develop after an infection with streptococcus bacteria and can involve the heart, joints, skin, and brain. The cardiac manifestations associated with acute rheumatic fever, valvulitis, or carditis can be a potentially serious infection found in the training room.

Cause

ARF results from infection with a "rheumatogenic" strain of Group A streptococcus. Studies have shown that an estimated 3% of individuals with untreated Group A streptococcal pharyngitis will develop rheumatic fever.

Clinical Presentation

The clinical presentation is variable. The Jones Criteria shown in Table 3 are established guidelines to aid in the diagnosis. The onset of rheumatic fever follows a latent period of 7 to 35 days after a preceding Group A streptococcal infection.

On exam, the carditis is usually associated with a murmur of valvulitis. The exam may reveal sinus tachycardia, an S3 gallop, a pericardial friction rub, and/or cardiomegaly. The valvulitis may be characterized by a pansystolic murmur of mitral regurgitation (MR), best heard at the apex, with radiation to the left axilla.

Diagnosis

The diagnosis of ARF is a clinical one but requires supporting evidence from clinical presentation as well as microbiological and immunological labs. To fulfill the Jones Criteria, either two major criteria or one major and two minor criteria *plus*

Table 3 Jones Criteria for Rheumatic Fever

Major	*Minor*
Carditis	Fever
Polyarthritis	Arthralgia
Chorea	Previous rheumatic fever or rheumatic heart disease
Erythema marginatum	
Subcutaneous nodules	

evidence of an antecedent streptococcal infection are required. An EKG and echocardiogram are important diagnostic tools to assess for cardiac involvement.

Treatment

Hospital admission is recommended for all cases to ensure complete and proper investigation. The main treatment goals are to confirm the diagnosis, treat cardiac failure, reduce the duration of symptoms, and ensure ongoing secondary prophylaxis and clinical follow-up. The mainstay of treatment for ARF is NSAIDs, most commonly aspirin. Antibiotic treatment with penicillin should also be given for 10 days. The athlete will also need long-term antibiotic prophylaxis after the acute episode has resolved.

Complications

ARF can cause permanent cardiac damage. The mitral valve is more commonly involved than the aortic valve. Mitral stenosis (MS) is the classic finding in rheumatic heart disease and may require surgical correction. Other potential complications of ARF include heart failure, myocarditis, pericarditis, arrhythmias, and endocarditis. The athlete must have close monitoring and follow-up prior to any return to exercise.

Return to Sports

If the athlete has no cardiac involvement with ARF, once antibiotic treatment is complete and the athlete is afebrile, gradual return to play may be initiated with close physician observation. This is normally about 3 to 4 weeks into treatment. The athlete should also have resolution of polyarthralgias and chorea if present prior to return to play. Prolonged bed rest is no longer recommended after ARF. All athletes with cardiac involvement should be followed by a primary care physician, cardiologist, and dentist.

Endocarditis

Infective endocarditis (IE) is a serious febrile infection that rapidly damages cardiac structures, spreads to extracardiac sites, and, if untreated, can progress to death within weeks. To avoid overlooking the diagnosis of IE, a high index of suspicion must be maintained.

Causes

A variety of microbial agents can cause IE. Staphylococci, streptococci, and enterococci represent the majority of cases. The most common risk factor in athletes is structural heart disease.

Clinical Presentation

Fever is the most common symptom. Other common symptoms include chills, night sweats, anorexia, dyspnea, cough, chest pain, and myalgias. The most common findings on physical exam are fever and a heart murmur. In an athlete with a preexisting murmur, a new or changing murmur may be noted. Other findings on exam may include splenomegaly or cardinal peripheral manifestations such as petechiae, splinter hemorrhages, osler nodes, janeway lesions, or roth spots.

Diagnosis

The diagnosis of IE should be investigated when athletes with fever also present with one or more of the cardinal manifestations of IE. The incorporation of clinical, laboratory, and echocardiographic data is central to the diagnosis.

Treatment

Treatment is usually started in the hospital with parental antibiotics but may be completed in the outpatient ward once the patient is afebrile and follow-up blood cultures are negative. Antibiotic therapy should be selected as appropriate based on blood culture and sensitivities results. Depending on the pathogen involved, antibiotic treatment should last between 2 and 6 weeks.

Complications

If left untreated, IE can progress to valvular damage, severe heart failure, and potentially fatal arrhythmias.

Return to Sports

From an infectious standpoint, prior to return to competition, the athlete should have completed at least 2 to 6 weeks of appropriate antibiotic treatment and should remain afebrile with negative follow-up blood cultures. The athlete will require close monitoring with frequent follow-ups. Once the antimicrobial treatment is complete, a repeat echocardiogram should be done to establish a new baseline. Repeat physical examinations are important to look for any signs of heart failure. Prior to any initiation of antibiotic therapy for any febrile illnesses, the athlete should have three sets of blood cultures obtained from separate sites. The athlete will also require thorough dental evaluations to ensure oral hygiene.

Punch Drunk Syndrome

Punch drunk syndrome (PDS) is a neurological disorder that occasionally affects professional boxers and other professional athletes, such as wrestlers and American football players, who suffer repeated head trauma. It represents the late or chronic effects of repeated head trauma and is also frequently referred to as dementia pugilistica (DP), chronic traumatic encephalopathy (CTE), chronic boxer's encephalopathy, traumatic boxer's encephalopathy, and boxer's dementia, depending on the source cited. PDS develops over a period of years, with the average time of onset being about 12 to 16 years after the start of a career in boxing. The condition is believed to affect around 15% of professional boxers, but it can also affect other types of athletes. Famous sufferers include Jack Dempsey, Joe Louis, and Sugar Ray Robinson, among others.

The Pathophysiological Basis of PDS

PDS was first described by Harrison S. Martland in 1928 as being characteristic of boxers who had suffered frequent, repetitive head trauma of concussive or subconcussive force. In his landmark article "Punch Drunk," Martland described the early symptoms of PDS as a slowing and confusion of thought processes, nonfluent speech, slowed muscle movement, and hand tremors. Occasionally, these progressed to a more chronic state that manifested with marked truncal ataxia, gross mental deterioration, and a syndrome similar to Parkinsonism.

Over the next half-century, multiple retrospective studies were conducted that supported Martland's observations. In *Brain Damage in Boxers* (1969), Roberts reported on 224 British boxers and found a similar "dose response" in the nature of symptoms. In his study, 17% of the cases demonstrated chronic neurological deficit attributable to boxing, and the prevalence of injury increased with increasing boxing exposure.

Pathological evidence of this was offered by Corsellis et al. in 1973 in the article "The Aftermath of Boxing." They conducted postmortem studies on the brains of 15 boxers. Corsellis's team documented four types of changes in the brain tissue. The most common was rupture of the septum pellucidum (leading to cavum septum pellucidum), which they correlated with the emotional lability and rage reactions of the boxers. The second was scarring of the undersurface of the cerebellum, which was thought to occur due to the cerebellum being repeatedly forced through the foramen magnum. This cerebellar injury was associated with slurred speech, slowing of motor movements, and a broad-based gait. In some, there was progression of pathological changes, which was characterized by a decrease of pigment in the substantia nigra. This is also seen in Parkinson syndrome, and four of the boxers who had tremors and rigidity of the limbs were actually hospitalized with Parkinson syndrome. The fourth change was neurofibrillary tangles that represent tau protein deposition in nerve cells. These neurotoxic tau protein deposits were especially prevalent in the medial temporal lobes. This was seen in more than 90% of the boxers. Corsellis et al.'s study also demonstrated that the most successful boxers had the most brain damage. They reasoned that this was because the boxers had the longest careers, fought the most fights, and had consequently received the most head trauma.

Table 1 summarizes the findings of Corsellis et al., and although four different areas are presented, only 8 of the 15 cases had all four pathological features present. Corsellis also reported PDS findings in jockeys, professional wrestlers, parachutists, and even a case of battered wife syndrome. The table outlines the major clinical signs and symptoms seen with respect to areas of the central nervous system that are damaged in patients who develop PDS.

A less severe form of PDS that has only the neurofibrillary tangles and is clinically manifested by recent memory failure, depression, and erratic emotional behavior has been reported in retired National Football League football players (Mike Webster, Andre Waters, Terry Long, and Justin Strzelczyk) and Chris Benoit, the wrestler.

Other pathological hypotheses have also been considered. In 2001, Geddes et al. examined slices of brain from patients who had had multiple mild traumatic brain injuries and found changes in the cells' cytoskeletons, which they suggested might be due to damage to cerebral blood vessels. Furthermore, as it has not been conclusively shown that repeat concussions necessarily lead to cumulative brain damage, some scientists argue that boxers who get chronic traumatic encephalopathy are

Table 1 The Four Main Components of Chronic Brain Damage in Punch Drunk Syndrome

Area Damaged	*Clinical Symptoms and Signs*
Septum pellucidum, adjacent periventricular gray matter, frontal and temporal lobes	Altered affect (euphoria, emotionally lability) and memory
Degeneration of substantia nigra	Parkinson syndrome (bradykinesia, rigidity, gait instability, and tremor)
Cerebellar scarring and nerve loss	Slurred speech, loss of balance, and coordination
Diffuse neuronal loss	Loss of intellect, Alzheimer syndrome

Source: Adapted from Cantu RC. Chronic traumatic encephalopathy in the National Football League. *Neurosurgery*. 2007;61(2):223–225.

genetically predisposed to it. For example, it has been suggested that boxers with the apolipoprotein Eε-4 gene may be at higher risk for CTE.

Clinical Features of PDS

Two common chronic brain injuries that occur are postconcussion syndrome (PCS) and PDS.

PCS is the second late effect of a concussion. It consists of headache (especially with exertion), dizziness, fatigue, irritability, impaired memory, and concentration. While its true incidence is unknown, its persistence indicates an alteration in neurotransmitters and correlates with the duration of posttraumatic amnesia. These athletes should be evaluated with a computed tomography (CT) scan and neuropsychiatric testing while symptoms persist. Return to competition must be deferred until all diagnostic and clinical findings are normal; otherwise, the athlete is at risk for the controversial second-impact syndrome (SIS). SIS is a rare condition in which the brain swells rapidly and usually catastrophically after a person suffers a second injury before the symptoms from the first injury have subsided. Even the mildest grade of concussion can lead to SIS, and the condition is often fatal (~50%) if not severely debilitating (~100%). It is thought that SIS occurs due to the loss of autoregulation of the cerebral vasculature, and treatment is generally nonsurgical and supportive in nature.

PDS represents the chronic effects of repeated head trauma of concussive and subconcussive force that lead to anatomical patterns of brain injury with correlating clinical features. The characteristic features include emotional lability with mood swings and a diminished ability to control one's temper (which can be violent). The prevalent mood is generally one of fatuous cheerfulness, but depression and paranoia may also occur. Often, cognitive function deteriorates, and dementia may ensue. Other signs and symptoms due to substantia nigra injury include Parkinsonism-like features (bradykinesia, rigidity, gait instability, and tremors), while cerebellar injury leads to slurred speech, loss of balance, and incoordination.

While the studies of Martland, Roberts, and Corsellis demonstrated the pathophysiological basis of PDS and correlated it to the clinical features, current technology such as the CT scanner and magnetic resonance imaging (MRI) can assist with the diagnostic aspects of PDS. In one report using the CT scan, it was demonstrated from the data that even boxers with a moderate number of bouts may suffer cerebral atrophy. Furthermore, the authors found that the degree of atrophy correlated to the number of bouts the athlete had participated in. Other articles have since confirmed or indicated similar findings.

Conclusion

The previously cited studies do document cerebral injuries and attempt to correlate them to the athlete's sport and mechanism of injury, but a cautious interpretation of the data is warranted as they were all retrospective and cross-sectional in design. Additionally, it is not absolutely certain that all pathological and clinical changes followed chronic head trauma, as there could be other confounding factors in the athlete's personal and social lifestyles. Furthermore, although these studies were limited by the absence of a control group, the athletes in question belong to a selective group in themselves, and therefore, drawing any conclusions while comparing them with the population at large would be inappropriate and inconclusive.

Nevertheless, as current and future technology is incorporated into the diagnosis and management of PDS and other similar conditions such as traumatic encephalopathy, relevant and important data should present themselves that would help make identifying and supporting the athletes at risk easier and perfunctory. Indeed, the time has arrived for prospective studies to be carried out to ascertain the true incidence of PDS and other related conditions, but this should only be considered in concert with the formation of independent, qualified committees so as to eliminate any bias that could occur.

Puncture Wounds

Millions of Americans across the country are involved in athletics and recreational activities on a daily basis. Inherent to many of these endeavors is the risk of trauma to the dermatologic system. The most frequent types of mechanical skin injuries are abrasions, lacerations, and puncture wounds. The majority of skin trauma (approximately 50%) involves the head and neck, with the second most common site of injury being the upper extremities (approximately 35%). This entry discusses puncture wounds and will review the common histological and anatomic structures relevant to the skin, the approach to evaluation of a puncture wound, the management of these wounds, and the complications of these injuries.

Puncture wounds are defined as a wound to the skin in which the opening is relatively small as compared with the depth. These wounds are most often caused by a narrow pointed object, such as a shard of wood, glass, or metal. There are myriad sporting activities that may cause puncture injuries to the skin. Some of the common puncture wound injuries in sports are caused by metal cleats, fishhooks, and accidental tooth penetration. There are also case reports of hockey sticks breaking and causing wooden or composite puncture wounds with retained foreign bodies. Other, more rare but potentially devastating puncture wounds seen in hockey are deeply penetrating wounds from skates involving the axillary or carotid arteries. Surfing and open-water swimming carry the risk of puncture wounds caused by stings from aquatic creatures such as needlefish or stingrays. Fencing injuries can also be quite dangerous and have included puncture wounds through the chest wall, causing a collapsed lung, and wounds to the neck, causing laryngeal injury. Many of these activities have protective equipment designed to minimize puncture injuries, but it is the participants who must ensure the proper use and maintenance of equipment to fully protect themselves from puncture wounds and their potential complications.

The first step to understanding and treating these wounds is to briefly review skin anatomy. Skin is composed of three histologically and functionally distinct layers. The outermost layer is the epidermis. This layer serves as the first line of defense against pathogenic organisms, maintains the separation between our fluid-filled bodies and the outside environment, and protects against destructive ultraviolet (UV) rays from the sun. This layer can vary in thickness from 0.075 millimeters (mm), for example, along the eyelid, to 0.6 mm, as in the soles of the feet. The next layer is the dermis, which contains a variety of structures, including sensory nerves, various oil and sweat glands, very small arteries and veins, and finally hair follicles. These structures are anchored in a dense connective tissue called collagen. Finally, there is the subcutaneous layer, which is composed mostly of fatty tissue, which serves to insulate and mechanically protect the underlying structures. When grossly viewing these layers, the epidermis is the thin fleshy outer layer, followed by the dermis, which is whitish and denser appearing. Last, the subcutaneous layer is yellow with globules of fat. These layers can usually be visualized when evaluating puncture wounds.

The majority of puncture wounds involve only the epidermal and dermal layers of the skin and heal well with simple wound care and hygiene. However, once an object has penetrated into the subcutaneous layer, the medical provider must increase his or her vigilance to look for more insidious injuries to the underlying structures, as well as unseen retained foreign bodies. Beneath these layers of skin, there are many vital structures and organs that can easily be damaged by puncture wounds. Due to the nature of the puncture wound, a serious underlying injury can easily go unnoticed if full clinical evaluation is not performed.

The location on the body, mechanism, environment, and material of the penetrating object are the key components to understanding how to manage puncture wounds. When considering the location of the puncture wound, injuries requiring immediate attention by a physician include injuries to the larger blood vessels, in which it can be difficult to stop bleeding; injuries causing neurologic compromise; and injuries into a tendon/tendon sheath or joint space. Other site-specific areas requiring prompt physician evaluation include the eye/eyelid, face, neck, chest, abdomen, and genitals. In these cases, vital organs may be damaged, and identification of injury may not be evident until many hours later. If injuries to these areas are clearly complicated, transport to the emergency department and appropriate specialist involvement are warranted.

When evaluating a puncture wound, it is first necessary to obtain a very good history, including the following:

- Type of penetrating object, including its breakability
- Force of the object when it entered the skin
- Location of the wound on the body
- Environment in which the puncture took place (i.e., water or land)
- Time elapsed since the injury
- Relevant medical history of the patient, including the last tetanus vaccination

The next steps are to inspect and treat the wound in the following order:

- If you are on the scene of the incident, *ensure that the area is safe* for yourself and the patient.
- *Use universal precautions* to protect yourself and your patient from unintended exposures to blood-borne diseases.
- *Inspect* the wound.
- If necessary, *stop the bleeding* with direct pressure on the wound.
- If you have the supplies, gently *irrigate* with sterile saline, and remove any visible foreign bodies. (*Note:* It is not recommended to probe for deeper foreign bodies as you may cause more damage to the underlying structures and increase the risk of infection.)
- Attempt to *visualize the depth* of the wound.
- *Clean the wound* by gently scrubbing or rinsing the wound with an agent such as chlorhexidine gluconate. (*Note:* It is no longer recommended to use hydrogen peroxide as it may destroy healthy tissue as well as pathogens.)
- *Do not suture* puncture wounds, to avoid sealing in a potential foreign body or infection.
- *Cover* with a sterile dressing and apply pressure with tape.
- Arrange for *tetanus vaccination* based on the current Centers for Disease Control and Prevention (CDC) guidelines (see Table 1).

The most common complications of puncture wounds are infection and retained foreign bodies. These are often interdependent issues as foreign bodies often harbor pathogenic organisms, which thereby seed infection into the surrounding tissue. If there is suspicion of the presence of foreign bodies, further evaluation with X-rays is indicated. This method will detect most radio-opaque objects. Other methods such as ultrasound, computed tomography, and, rarely, magnetic resonance imaging (MRI) are needed to further characterize foreign bodies or infections that are unseen by plain X-rays.

The choice of antibiotic coverage for infected wounds depends on the penetrating material and the environment. The majority of cases involve staphylococcus and streptococcus species located on the patient's own skin. If the penetrating object has soil, saliva (human or animal), or other fecal contaminants, a broad spectrum of antibiotics will be needed to cover the large variety of potential

Table I CDC Summary Guide to Tetanus Prophylaxis in Routine Wound Management

	Clean, Minor Wounds		*All Other Wounds*	
History of Tetanus Immunization (Doses)	*Td*[a]	*TIG*	*Td*[a]	*TIG*
Uncertain or <3 doses	Yes	No	Yes	Yes
3 or more doses	No[b]	No	No[c]	No

Source: Centers for Disease Control and Prevention (2010). http://wwwnc.cdc.gov/travel/yellowbook/2010/chapter-2/tetanus.aspx.

a. For children <7 years old, DTaP or DTP (DT, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For children ≥7 years of age, Td is preferred to tetanus toxoid alone. For adolescents and adults up to age 64, tetanus toxoid as Tdap is preferred if the patient has not previously been vaccinated with Tdap.

b. Yes, if >10 years since the last dose.

c. Yes, if >5 years since the last dose. More frequent boosters are not needed and can accentuate the side effects.

pathogens. Puncture wounds occurring in the water also necessitate broadening of antibiotic coverage.

Other complicating factors include patients who have medical comorbidities that limit the body's ability to fight infection or appropriately heal tissue damage. The most common and most concerning comorbidity is diabetes, especially if the wound involves the foot. These patients more often develop infection in the bone, and some studies estimate a fivefold increase in the need for multiple surgeries or amputation to clear an infection from a puncture wound. Other compromising factors include HIV (human immunodeficiency virus) infection, peripheral vascular disease, and cancer, as well as smoking.

Fortunately, the majority of puncture wounds are uncomplicated and rarely limit further participation in the activity in which they occurred. Knowledge of the underlying anatomic structures and suspicion of foreign bodies are essential for further management of puncture wounds. Furthermore, proper use of sporting equipment and understanding the environment in which you play can help avoid most puncture wounds altogether.

Q

Q Angle

The *Q angle,* or quadriceps angle, is often measured when a physician is examining and evaluating a patient for knee pain. This angle is an important indicator of the biomechanical forces that act on the knee.

Measurement

The Q angle is formed between two lines representing pulling forces on the knee. The first line is the longitudinal axis of the femur (thigh bone), which represents the line of pull of the quadriceps muscles on the knee. This line is created by measuring from the center of the patella (kneecap) to the anterior-superior iliac spine of the pelvis. The second line represents the pull of the patellar tendon on the kneecap. Measuring from the center of the patella to the tibial tubercle creates this line (see Figure 1). The normal Q angle values are 17° in females and 14° in males. Women naturally have a larger Q angle than men because women tend to have wider pelvises than men. Other causes for increased Q angle include knock-knees (genu valgum), femoral anteversion, and other slightly abnormal alignment of the legs.

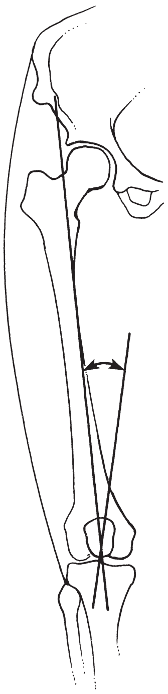

Figure 1 The Q Angle

Note: The Q angle is an important indicator of the biomechanical forces acting on the knee.

Problems Associated With a Large Q Angle

A larger-than-normal Q angle is associated with a disorder called abnormal quadriceps pull. In a patient with a large Q angle, the kneecap will be pulled sideways when the quadriceps muscle contracts. This increases the biomechanical stress on the knee during strenuous or repetitive activities and thus increases the likelihood of knee pain and injury. The abnormal pull of the quadriceps on the patella can also cause abnormal tracking of the patella in the femoral groove (the normal "track" in which the patella moves). The pain associated with this abnormal tracking is called patellofemoral pain syndrome. An increased Q angle also places a patient at increased risk for chondromalacia of the knee, patellar subluxation, and anterior cruciate ligament injuries.

Treatment

The goal of treatment is to decrease an abnormally large Q angle. One of the most effective ways to achieve this goal is to use custom-made, flexible orthotics. These shoe inserts are designed to help reduce stress on the knee.

Quadriceps Strain

The quadriceps femoris muscle is located in the front of the thigh and is made up of four muscles: (1) rectus femoris, (2) vastus medialis, (3) vastus lateralis, and (4) vastus intermedius. The rectus femoris is in the middle of the thigh and covers the other quadriceps muscles. The vastus muscles are all deep to the rectus femoris and lie next to each other. The vastus medialis is the most medial, the vastus lateralis is the most lateral, and the vastus intermedius is in between the lateralis and medialis.

The rectus femoris originates from the ilium and therefore crosses both the hip and knee joint, whereas the vastus muscles originate from the femur and cross only the knee joint. All four of these muscles attach to the patella via the quadriceps tendon.

The quadriceps muscles are used to extend the knee as well as decelerate knee flexion when the heel strikes the ground. Because the rectus femoris muscle crosses the hip joint as well as the knee joint, it also functions as a hip flexor. These muscles are active during running, jumping, and walking. These muscles are composed predominantly of Type II fibers, which make them well suited for forceful rapid activities; however, they tire more easily than muscles composed of mainly Type I fibers, which are better suited for sustained activities.

Quadriceps muscle strains are actually small tears in the muscle. Muscle strains usually occur when an eccentric contraction occurs. An eccentric contraction occurs when the force generated by the muscle cannot overcome the resistance placed on the muscle. This causes the muscle fibers to lengthen as they contract (Figure 1). This type of contraction is used as a method of decelerating a body part or an object.

The musculotendinous junction is the location within the muscle where the strain most often occurs. Muscles that cross two joints in the body, such as the rectus femoris, are more susceptible to strain.

Quadriceps strains most often occur in individuals who are older and skeletally mature—that is, their *physes,* or growth plates, have closed. Younger, skeletally immature patients tend not to have quadriceps strains; oftentimes if a muscular strain is sustained, it is a low-grade strain. Instead of muscle strains, younger athletes are more susceptible to avulsion fractures. An avulsion fracture of the anterior-superior iliac spine can be caused by a forceful contraction of the quadriceps muscle in a child or adolescent who still has an open apophysis.

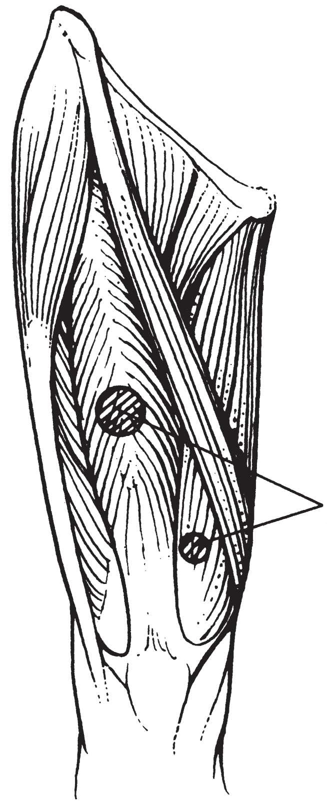

Figure 1 Quadriceps Muscles Strain

Notes: A quadriceps strain is among the most common injuries in sports. The quadriceps muscle most commonly injured is the rectus femoris, because, unlike the other three quadriceps muscles, it crosses two joints, the hip and the knee.

Histology

Muscle strains are tears that occur at a short distance from the musculotendinous junction. In the acute phase, there is disruption and hemorrhage in the substance of the muscle. By the second day, an inflammatory response may occur, and there may be edema within the muscle. One week after injury, fibrous tissue may be present, and this scar tissue remains within the muscle permanently.

Presentation

History

Athletes who participate in activities that involve a lot of sprinting are most susceptible to quadriceps strain. This includes, but is not limited to, hurdles, long jump, football, soccer, and basketball. Athletes who have a quadriceps muscle strain will sometimes state that they felt a popping or snapping in their thigh, immediately followed by a sharp pain. The pain has an abrupt onset.

Physical Exam

Often the athletes cannot walk properly and feel tightness in the affected thigh. It may be difficult for them to straighten their knee against resistance because it causes pain. Bruising may very well be noted over the area of injury. There is localized tenderness at the myotendinous junction. Varying degrees of swelling can occur depending on the severity of the strain.

Classification System

Quadriceps strains vary in severity. The severity of a muscle strain is classified according to its grade, with Grade 1 injury being the least severe and Grade 3 injuries being the most severe. First-degree injuries occur when the muscle is stretched, but there is no macroscopic damage. These are the least severe type of strain. Athletes usually recover rapidly from these injuries, with no functional loss. A second-degree injury occurs when the tendon or muscle is partially torn. This usually causes more bruising and inflammation than a first-degree injury and takes longer to recover. A third-degree strain is the worst type of strain, and this happens when there is a complete tear of the muscle or tendon. These athletes cannot perform at all secondary to their injury for quite some time, and depending on the location of their injury, they may need surgical repair. A practical grading for quadriceps strains is to class Grade I strain with those in which painless knee flexion is greater than 90°; second-degree strains have a flexion of 90°, and third degree strains have flexion less than 90°.

Treatment

The treatment of quadriceps muscle strains varies depending on the severity of the injury. Once an athlete has suffered this injury, it is more likely to recur if the quadriceps has not healed completely. Therefore, the best treatment of quadriceps strain is to prevent it from occurring. This can be done with well-ordered and strictly controlled stretching and warm-up programs before each practice and competition.

After a muscle strain has occurred, the initial treatment is rest, ice, compression with elastic wraps, and nonsteroidal anti-inflammatory drugs (NSAIDs). All these treatments aim to reduce the acute inflammatory response that occurs when a muscle is strained.

After a short rest, usually lasting a few days, physical therapy is initiated. Physical therapy consists initially of passive stretching, and exercises are started to restore full range of motion. The earlier that motion can be restored in a painfree manner, the better. In the early stages after a muscle strain, the athlete should not be pushed to the point of fatigue in physical therapy, because this may reinjure the area. Only when the athlete has no noticeable strength deficit, has full range of motion of the hip or knee, and is painfree should he or she return to sports. Allowing athletes to return to their respective sport before they have regained full strength and are painfree can be detrimental to them as it sets them up for repeated injuries.

If an athlete continues to have severe pain for longer than a few days after injury and is unresponsive to the aforementioned treatment options, one must consider obtaining X-rays, which would show bony injury. If no bony injury has occurred and a complete tear is suspected, magnetic resonance imaging (MRI) is the test of choice to show soft tissue injuries, such as tears of muscles, tendons, or ligaments.

Prognosis

The patient outcome for muscle strain is usually very good, especially when only a minor injury has occurred. However, major strains can take a longer time to heal and can result in limited range of motion and weakness for some time. There are relatively few complications from muscle strain, with the most common being reinjury, weakness, and fibrosis. The aforementioned complications most frequently occur with the more severe injuries and rarely occur in less severe, or Grade 1, strain. Reinjury can be prevented by ensuring an appropriate rehabilitation period before the athlete is allowed to return to sport. If a symptomatic area of fibrosis occurs, most often associated with the most severe strains, aggressive stretching should be started and modalities such as ultrasound can be employed.

Summary

Quadriceps strains occur at the myotendinous junction. These injuries are sustained when a forceful contraction of the quadriceps occurs, most often during running or jumping activities. This injury is suspected when there is an abrupt onset of localized pain in the region of the quadriceps. Initial treatment is aimed at decreasing the inflammatory response by the use of NSAIDs, rest, ice, compression, and elevation. Compression and elevation also help by limiting swelling and hematoma formation. Athletes should be transitioned into passive stretching and range-of-motion activities within the first few days after injury. Athletes should be allowed to return to full activity only when there is resolution of pain and swelling, and full muscle strength has been regained.

Quadriceps Tendinitis

Quadriceps tendinitis is an overuse injury of the lower extremity characterized by pain over the quadriceps tendon or the superior pole of the patella. The condition is often grouped with other overuse injuries such as patellar tendinitis and

Sinding-Larsen-Johansson syndrome. Both patellar and quadriceps tendinitis are often referred to as "jumper's knee," with studies showing a career prevalence of more than 20% in elite athletes and 40% to 50% in high-level volleyball players. Most cases of jumper's knee are secondary to patellar tendinitis, whereas quadriceps tendinitis is much less common.

Anatomy

The knee is a complex joint that consists of both the femorotibial and patellofemoral joints. It connects the femur to the tibia and fibula and includes the patella (kneecap), which is the moveable bone in front of the knee. The patella tracks along the femoral groove of the knee joint during motion and is encompassed by tendons, acting as one unit to ensure fluid motion. These tendons include the quadriceps and patellar tendons. The quadriceps tendon is an extension of the quadriceps muscles and inserts on the superior pole of the patella. The tendon is composed of three layers: (1) the superficial, (2) the intermediate, and (3) the deep laminae. As the quadriceps muscles contract, a force is exerted along the quadriceps tendon that acts on the superior aspect of the patella. The force is carried through the patellar tendon, which extends from the inferior aspect of the patella to the tibial tuberosity, leading to lower leg extension.

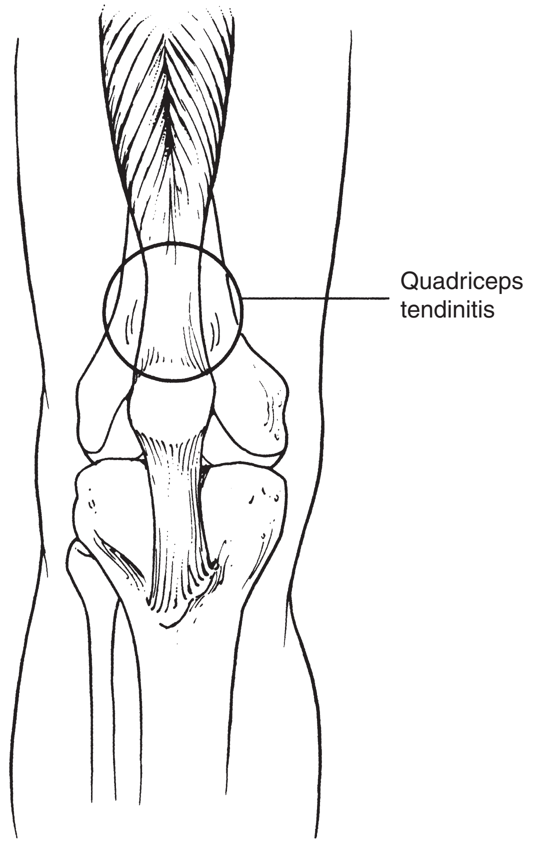

Figure 1 Quadriceps Tendinitis

Notes: Quadriceps tendinitis is an inflammation of the tendon that attaches the quadriceps muscle to the patella. Although less common than patellar tendinitis, it is of substantial concern to the athlete because it affects the all-important extensor mechanism.

Causes

Overuse injuries are common in athletes, with tendon injuries occurring frequently as the tendon takes much of the force and stress of the muscle-tendon unit during exercise. Quadriceps tendinitis is actually a tendinosis consisting of partial tears or degenerative changes to the quadriceps tendon secondary to repetitive forces that surpass the body's ability to repair the damage (Figure 1). This degenerative condition most often occurs in jumping and leaping sports such as volleyball, basketball, soccer, and track-and-field events, all of which place a high amount of repetitive trauma on the tendon. Other studies have shown that risk is increased with higher training volumes, increased training intensity, harder training surfaces, and lower flexibility of the quadriceps and hamstring muscles. Male athletes are also about twice as likely as females to develop unilateral jumper's knee, and the greater force generated by males when jumping has been considered the culprit.

Clinical Evaluation

History

Patients will complain of pain over the anterior aspect of their knee and focused at the superior pole of the patella. The pain may be gradual or abrupt at onset, but frequently these injuries have an insidious onset. The pain becomes worse with athletic activity and is amplified with resisted knee extension or passive hyperflexion of the knee. A classification for severity of jumper's knee consists of four stages. In Stage 1 pain occurs after practice or a game, while in Stage 2 pain is also present at the beginning of activity and remits after warm-up. Stage 3 is increasingly more severe as pain remains during activity, limiting the athlete's ability to participate in sports. Finally, Stage 4 represents complete tendon rupture.

Physical Exam

On examination, assessment is focused over the lower extremities, starting with a careful inspection of the joints to assess for swelling, bruising, or warmth. The contour and shape of the leg muscles, especially the quadriceps, should be carefully assessed to evaluate for decreased muscle bulk or wasting. Range-of-motion testing may provide diagnostic clues if discomfort with full passive flexion is noted. Next, palpation of the knee joint and surrounding landmarks is done. With quadriceps tendinitis, point tenderness over the quadriceps tendon and/or the superior pole of the patella is elicited. Pain is further reproduced with resisted knee extension. Additionally, the knee joint is assessed for stability, and lower extremity strength and neurovascular testings are completed.

Diagnostic Tests

History and physical exam are often sufficient to make the diagnosis. X-ray imaging is usually negative and serves more to rule out other etiologies. For example, in adolescent athletes, multipartite patellae, which can have a similar presentation, can be ruled out via X-ray imaging. In chronic cases, degenerative changes at the patellofemoral joint may be indicated on X-ray. More advanced and costly imaging, such as magnetic resonance imaging (MRI), should be reserved for unclear etiologies, failure of conservative management, and/or worsening pain or new symptomatology.

Treatment

Conservative management is the mainstay of treatment, focusing on stopping the offending activity until symptoms subside, pain management, and a stretching and strengthening program. This approach is often successful with complete recovery of the athlete. However, the more severe the case, the less likely conservative management will be successful. Conservative management is most often successful for Stage 1 and Stage 2 cases, while Stage 3 cases usually require an extended rest period and reduction in training and playing time for good results to be achieved. Studies have indicated that up to half of the patients with Stage 3 cases will fail conservative management, which may necessitate surgical intervention, depending on the athlete's desire to participate in his or her sport at a high level and on the athlete's future goals. If quadriceps tendinitis goes untreated and more strain is put on the tendon, it could potentially lead to tendon rupture. Surgical intervention is indicated for this scenario.

Nonsurgical Treatment

Initial treatment for quadriceps tendinitis consists of cessation of the offending activities, pain management, icing, stretching, and progression through a strengthening program focusing on exercises for the quadriceps and hamstrings. Local corticosteroid injections should be avoided as they could lead to tendon degeneration and increased risk of tendon rupture. Conversely, the effectiveness of extracorporeal shockwave therapy (ESWT) has recently been considered given its use in treating other tendinopathies. ESWT is thought to create an environment more suitable for tissue healing. More research needs to be done in this area, and the Food and Drug Administration (FDA) has not yet approved the use of ESWT for quadriceps tendinitis.

Surgical Treatment

Surgery is used for cases refractory to nonsurgical therapy, usually after completion of a 4- to 6-month trial period of conservative management, and for complete tendon rupture. The purpose of surgical intervention is to induce healing at the bone-tendon junction, debride degenerative tissues, and remove abnormal bone. Postoperative management is a gradual process, focusing on regaining range of motion followed by recovery of muscle strength. If these goals have been achieved, the athlete may gradually resume full sports participation at 6 months postoperatively, although the previous level of play is generally not achieved until after 12 months. There are a variety of surgical techniques used, and studies report varying surgical outcomes.

Prevention of Injury

Injury prevention is essential as quadriceps tendinitis can require a long recovery period and a decrease in level of play. Prevention should be the focus of athletes and coaches, especially those participating in high-risk sports. Prevention involves maintaining quadriceps strength and flexibility. Off-season conditioning programs should focus on strength training, and individual athletes should be eased into the sport/training program. The athlete and/or coaching staff should keep potential extrinsic and intrinsic risk factors in mind, such as the training surface. At the onset of pain, therapy should not be delayed because an optimal outcome is more likely to occur with early intervention.

Return to Sports

Certain guidelines should be followed before allowing an athlete with quadriceps tendinitis to participate again in his or her sport. The guidelines consist of a graduated process to full participation. First, the athlete should have full range of motion of his or her affected lower extremity. Second, appropriate quadriceps strength must be exhibited. Quadriceps on the affected side must be at 80% to 85% of the expected strength, which can be evaluated by comparing it with the unaffected side. If both legs were involved, then computerized isokinetic testing could be used to confirm strength. When the individual is able to complete functional testing at 70%, he or she can begin participating in sport-specific drills. Once the athlete can perform functional testing at 85% to 90% capacity, he or she can participate in full practice and return to games. This should occur through a stepwise process, starting for only a quarter of the time, then half the time, and so forth. At any point, if the athlete starts to have pain, he or she should refrain from participation.

Racquetball and Squash, Injuries in

Racquetball and squash are popular sports played around the world by recreational and elite athletes alike. While neither is an Olympic sport, both have world championship competitions and are played at international events such as the Pan-Am Games. Racquetball and squash games take place on a court surrounded by four walls and involve using a racquet to hit a rubber ball off the front wall of the court. A racquetball court measures 40 feet (ft) long by 20 ft wide by 20 ft high. In comparison, a squash court measures 32 ft long by 21 ft wide.

Athletes who play racquetball or squash are prone to certain types of injuries due to the specific demands of their sport. Because of the fast-paced nature of both games and the occasional, unpredictable ricochet of the ball during play, eye and facial injuries are the two most common injuries suffered in these sports. Also seen are upper extremity injuries such as elbow and wrist sprains, shoulder sprains, lateral epicondylitis, and de Quervain tenosynovitis. Common lower extremity injuries include ankle sprains, Achilles rupture, knee ligament injuries, and meniscal tears.

Eye Injuries

Eye injuries are caused by either the racquet or the ball striking the eye during play. Shots that frequently lead to injury include hitting the ball off of the back wall. This shot is hit with force so that it has enough energy to hit off of the front wall; however, if a player misplays the ball or steps into its trajectory, the ball can accidentally hit the player in the eye. Another frequent cause is when a player turns to see the hit of the opponent playing behind him or her and the forward-traveling ball hits the front player in the eye. In squash, eye injuries are generally more severe because the ball is smaller and can easily fit into the eye socket. Almost all eye injuries occur when the player is not wearing eye protection; therefore, wearing eye protection is highly recommended.

A wide range of eye injuries can occur from participation in racquetball or squash, but the two most common eye injuries seen are hyphemas and corneal abrasions. A *hyphema* is a collection of blood in the anterior chamber of the eye, often caused by trauma. Hyphemas will cause blurry vision, pain, and increased flow of tears. When the ball (or racquet) hits the eye, the eye momentarily undergoes an increase in internal pressure due to the distortion of the shape of the eyeball on impact. This can cause a tear in the small blood vessels and leads to bleeding, with the blood collecting in the anterior chamber of the eye. A severe bleed can fill most of the anterior chamber of the eye. This is sometimes called an "eight-ball hemorrhage" because the eye appears black. While the blood itself is not harmful to the eye, it can obstruct the movement of fluid within the eye and cause glaucoma. It is also important to consider that the eye has sustained a force strong enough to cause injury and could also have other internal injuries that are not immediately obvious.

Therefore, prompt evaluation by an ophthalmologist is recommended.

Treatment for minor hyphemas includes keeping the head elevated (do not lie flat) so that the blood pools to the bottom of the eye, avoiding straining, and using eye drops prescribed by a physician to reduce intraocular pressure. Severe hyphemas will require frequent monitoring by an ophthalmologist. Eventually, the blood from the hemorrhage will resorb. It usually takes a few weeks to see complete resolution.

A *corneal abrasion* is a common eye injury that occurs when a part of the cornea is scraped (or scratched) away. In racquetball and squash, this usually occurs when the ball or racquet makes contact with the eye or when one player accidentally pokes the other in the eye. A corneal abrasion is painful and will cause tearing. Photophobia (increased sensitivity to light) and feeling as though there is something in the eye are also common symptoms. The abrasion usually heals without a problem. Treatment includes eye rest and not using contact lenses until the abrasion is healed. Most minor abrasions heal in 24 to 48 hours. Larger abrasions can take up to 1 week to heal. Larger abrasions may be treated with antibiotic drops to help prevent infection.

In squash, the ball is smaller and firmer and therefore can cause more severe eye injuries such as globe rupture or retinal detachment. *Globe rupture* occurs when the outer membrane of the eye is disrupted due to trauma. This is a full-thickness tear in the membranes of the eye and is a very severe injury. The eye will most likely be disfigured as a result of the injury, and it will be obvious to others that medical attention is needed. Symptoms include a significant decrease in the ability to see and double vision. Globe rupture is an emergency and requires immediate medical attention.

Retinal detachment is also an emergency that requires prompt medical treatment. Trauma to the eye can cause the retina to peel away from the underlying supportive tissues. Symptoms include a sensation of flashing lights, floaters, vision loss, and distortion of vision. It is crucial to seek help right away because quick medical attention can be vision sparing. The best prevention for all eye injuries is to wear proper eye protection endorsed by the Canadian Standards Association (CSA) or American Society for Testing and Materials (ASTM). Wearing eye protection can help prevent almost all eye injuries incurred in racquetball and squash. Unfortunately, protection is not worn by all players, especially novice players.

If the ball or racquet misses the eye but strikes the face, it can cause facial lacerations or contusions (bruises). Frequently, this occurs to the player who gets in the way of his or her own racquet. While most lacerations are not serious enough to require medical treatment, larger lacerations require sutures to ensure proper healing.

Upper Extremity Injuries

Common upper extremity injuries suffered by racquetball and squash players include elbow and wrist sprains, shoulder separation, lateral epicondylitis, and de Quervain tenosynovitis. Shoulder separation, or *acromioclavicular (AC) separation*, can occur when a player's shoulder takes the brunt of the impact when diving or hitting a wall while going after the ball. An excessive force placed on the shoulder can cause a disruption in the ligaments that connect the acromion to the clavicle (collarbone). Severe separations can cause a deformity where the collarbone sticks out more prominently under the skin. Most separations heal with rest, but a severe separation requires surgical correction.

As with other racquet sports such as tennis, frequent squash and racquetball play can lead to overuse syndromes such as *lateral epicondylitis* (tennis elbow). This is the most common upper extremity injury seen in both racquetball and squash players. Frequent backhand shots can cause an inflammation of the muscles that extend the wrist. These muscles attach to the outer part of the elbow and cause pain in that location. Another upper extremity overuse injury is *de Quervain tenosynovitis*, an inflammation of the tendons that causes pain in the wrist right below the thumb. Pain is increased when gripping or turning the wrist. Injection of steroids into the area of inflammation is the appropriate treatment if rest does not relieve the pain.

Lower Extremity Injuries

Both games require quick changes in direction and sharp cuts. As with any activity of this nature, ankle sprains, knee ligament injuries, meniscal tears, Achilles tendon rupture, gastrocnemius (calf muscle) tear, and lower back strains can occur. It is impossible to tell with what frequency these injuries occur because most are minor and the injured player does not seek care from an emergency department or a physician. These injuries, if severe, could sideline a player for several months.

Referred Pain

Referred pain is a rather broad term used to describe a phenomenon where pain is perceived at a site adjacent to or even distant from the site of pathology. There is no universally accepted definition, and hence different authors in the medical literature have used the phrase to describe different clinical entities that may present to the sports medicine clinician.

One of the most well-known examples of referred pain is the pain of *angina,* which can be perceived not only in the chest but can *radiate* to the jaw, to the back, or down the arm. This type of visceral pain, where an internal organ is injured, is a relatively common cause of referred pain in general medicine. *Radicular pain*, in which a spinal nerve root is inflamed, is another commonly seen example of referred pain.

Referred pain can also be seen in chronic musculoskeletal dysfunction (specifically in myofascial pain syndromes), as a manifestation of joint pain, and also in association with peripheral compressive neuropathies. This is not an exhaustive list. This entry describes the various clinical scenarios that might present to the sports medicine clinician.

It is always incumbent on the sports medicine clinician to keep the entities of referred pain in mind when developing a differential diagnosis in the treatment of an individual athlete. What at times may appear to be a straightforward biomechanical issue can, at its root, be a more complex phenomenon involving referred pain from a distant site of pathology. Due diligence in eliciting an exhaustive history and conducting a thorough physical exam is of paramount importance. Finally, it is always important to revise one's diagnosis if the patient is not achieving the treatment goals within the anticipated time frames. Referred pain entities are a not infrequent cause of treatment failures.

An Example

Elbow overuse injuries in an athlete can provide an example of the type of differential diagnostic thinking the clinician should practice.

Tennis elbow is, indeed, frequently related to local soft tissue inflammation and degeneration (e.g., lateral epicondylitis). However, pain of the lateral aspect of the elbow and forearm can relate to intraarticular dysfunction (e.g., osteochondritis dissecans of the capitellum). Moreover, it can also be seen in some clinical entities of referred pain. For instance, cervical discogenic neck pain can present with lateral arm pain. Radial tunnel syndrome can mimic lateral epicondylitis very closely, but in the former, the pain generator is not a tendinosis but rather a compression neuropathy of the radial nerve. Trigger points, seen in mysofascial pain syndromes and described in more detail below, can often be found in the wrist extensors or the triceps and give rise to radial-sided elbow pain that can resemble classic tennis elbow.

Types of Referred Pain

Visceral Pain

Pain in the viscera can be perceived as originating from a site distant from the affected organ. The location of the pain is typically the cutaneous dermatome sharing the same spinal cord level as the visceral input. As an example, the pain of cholecystitis (inflammation of the gallbladder) can occasionally be perceived in the scapula, since nociceptive inputs from the gallbladder enter the spinal cord between T5 and T10, which is the dermatome overlying the scapula.

Visceral pathology resulting in referred pain can account for pain in almost any area of the presenting athlete's body. However, some of the more notable examples encountered by the sports medicine clinician include the following:

- *Anginal pain*, previously mentioned, is an exceedingly important type of referred pain to keep in the differential diagnosis, especially when treating middle-aged or older athletes. The pain is typically described as constant, heavy, and radiating across the left chest wall, into the jaw, and down the left arm. Anginal pain has all too frequently been attributed to musculoskeletal chest pain or even reflux disease. Maintaining a high degree of suspicion in the patient with risk factors is of paramount importance given the high degree of morbidity and mortality seen in angina.
- *Kehr sign* is considered a classic example of referred pain. It is the onset of acute pain in the shoulder related to the presence of blood or other irritants in the peritoneal cavity. It is classically related to a ruptured spleen, in which case the pain is most commonly experienced in the left shoulder, but the sign has been used to describe pain in either shoulder with diaphragmatic or intraperitoneal pathology other than a ruptured spleen—for example, an ectopic pregnancy.
- A *pneumothorax* or *pneumomediastinum* can present as back or anterior chest pain. The pain is typically diffuse and less easily localizable than that associated with a focal musculoskeletal injury. There is typically an element of associated respiratory distress seen in the patient under evaluation.
- *Pelvic* or *testicular masses* sometimes present as chronic groin pain with radiation into the hip or upper thigh.

Peripheral Compression Neuropathies

Several peripheral neuropathies, discussed in detail in other entries in this encyclopedia, can present with pain distal to the area of pathology as the chief complaint. The typical mechanism is compression of a nerve or nerves, giving rise to distal sensory and motor pathology. Below are some examples:

- *Thoracic outlet syndrome* can present with pain in the shoulder, arm, or hand (typically ulnar-sided pain) as a result of compression of the nerves passing from the neck and thorax through the "thoracic outlet," a space defined by the rib cage and the clavicle. Various structures can be implicated in the impingement; the presentation of pain distal to the impingement is a classic example of referred pain.
- *Meralgia paresthetica* is a painful condition of the proximal, anterior thigh seen with a mononeuropathy of the lateral femoral cutaneous nerve. There is typically focal entrapment of the nerve at the site of the inguinal ligament, and distally, pain will develop over the anterolateral thigh.
- *Carpal tunnel syndrome* is a well-known compression neuropathy of the median nerve as it passes through the carpal tunnel of the wrist. The presenting complaint is often pain in the first three digits and the radial aspect of the fourth in the affected hand (see Vol. 1, pp. 238–241).
- *Guyon tunnel syndrome* can affect the bicyclist. Pressure from bicycle handlebars can cause a compressive neuropathy of the ulnar nerve in the Guyon canal of the wrist, resulting in motor and sensory findings in the fifth and fourth digits of the hand.
- *Tarsal tunnel syndrome* is a painful condition of the foot in which the posterior tibial nerve is impinged and compressed as it travels through the medial ankle in what is known as the tarsal tunnel. It resembles in many ways the compressive neuropathies of the medial and ulnar nerves of the hand and wrist. Symptoms include burning pain and numbness in the heel and plantar surface of the foot.
- *Piriformis syndrome* can be considered in this same classification. In classic piriformis syndrome, the piriformis muscle of the patient's hemipelvis will become constricted, and impingement of the ipsilateral sciatic nerve will develop. Classic sciatica can develop and may

be difficult to distinguish from radicular pathology of the lumbosacral spine (see Vol. 3, pp. 1098–1100).

Joint Pain

Focal articular dysfunction can sometimes present, somewhat paradoxically, with pain perceived less in the affected joint than in an adjacent joint. This situation is most often encountered in the pediatric population.

The pain of hip pathologies such as Legg-Calvé-Perthes disease and slipped capital femoral epiphysis not infrequently originally manifests as knee pain.

The wise clinician should remember the classic dictum to examine the joints both proximal and distal to the presenting complaint when doing a thorough examination. In the setting of a new patient, particularly a pediatric one, complaining of knee pain, a brief but focused examination of the hip is important.

Cervical, Thoracic, and Lumbosacral Dysfunction

Radiculopathies, or inflammations of spinal nerve roots, are rather common causes of referred pain. Radiculopathies are characterized by pain that appears to radiate out from the spine down an arm or leg or across the torso. Causes of radiculopathies include deformities of the intervertebral disks or the vertebrae themselves, where bone or disk material can impinge on the spinal nerve root, evoking pain in a characteristic pattern depending on the level of impingement.

A thorough understanding of associated dermatomes, myotomes, reflex patterns, and muscle innervations is crucial for the clinician evaluating a patient with a possible spinal radiculopathy. For instance, pain that radiates down the leg into the lateral foot (especially when provoked by a cough or trunk flexion) can be characteristic of disk pathology at the L5-S1 level.

Myofascial Pain Syndrome

This is perhaps the most complicated and, to most clinicians, least familiar type of referred pain discussed in this entry.

Myofascial pain syndrome is a common painful muscle disorder caused by myofascial trigger points. It is sometimes confused with fibromyalgia but is a distinctly different disorder. It has been written about most extensively in the osteopathic and physiatry medical literature.

Patients typically present with localized, persistent pain that often results in decreased range of motion of the muscle in question. The athlete may have a history of an acute injury in this area or a history of a more chronic, repetitive stress injury. Postsurgical myofascial pain is seen as well and is often attributed to surgical scars and tissue under tension after surgery.

The patient will present with so-called trigger points (TrPs), which can produce referred pain as well as motor and even autonomic dysfunction in characteristic patterns. TrPs are circumscribed nodules, approximating 1 centimeter in diameter, found in muscle; they are palpable, taut bands, and when they are pressed, the patient will recognize the tenderness as the familiar pain for which he or she is presenting for evaluation.

On examination, the pain elicited on palpation is referred in a pattern characteristic of the TrPs for that muscle. Palpation often also will elicit a local twitch response. There can be painful limitation of range of motion when attempting to stretch the muscle, and there is often some weakness of the muscle. Neurologic deficits are typically absent on physical examination.

Myofascial trigger responses are consistent from patient to patient. The points have been most extensively and systematically evaluated by the physicians Janet Travell and David Simons, who essentially mapped the patterns of TrP location and radiation. Their textbook is a classic in the field and gives the location of TrPs for nearly every skeletal muscle in the body, along with associated patterns of referred pain (see the Further Readings).

There is still some considerable controversy over the methodology for consistently diagnosing TrPs and over the theory of how TrPs arise and why they produce specific referred pain patterns. Several mechanisms have been proposed, but scientific evidence is lacking.

Once the TrPs have been identified and other pathologies in the differential diagnosis excluded, treatment of the myofascial pain can be pursued. The long-term clinical efficacy of the therapies has not been established. Multiple modalities can be used, including pharmacology, acupuncture, physical therapy, osteopathic manual medicine techniques, and massage. The "spray-and-stretch" technique and injections of TrPs are two of the more common techniques.

The spray-and-stretch technique uses a topical cold spray (e.g., ethyl chloride) and involves passively stretching the affected muscle while simultaneously spraying the area with the spray. It is thought that the temporary, mild anesthesia effected by the spray allows the muscle to be passively stretched to its normal length, thus inactivating the TrPs and resolving the referred pain.

For TrP injections, small-gauge needles are used, and a local anesthetic (e.g., lidocaine) or sterile saline is injected into the palpated TrPs of the affected muscle in an attempt to inactivate them. As with all injections, attention to procedural detail will minimize complications such as infection or, worse, pneumothorax.

Renal Injury

The kidney is the most commonly injured intra-abdominal organ in some sports, such as rugby union. Varieties of renal injury include renal trauma and exercise-induced hematuria, which may or may not be traumatic in origin. Renal traumatic injuries may be relatively asymptomatic, even with repeated blows, such as in boxing, or they may result in renal contusions, causing microscopic or gross hematuria.

Occult Hematuria

Hematuria is a common condition in the general population. Occult hematuria without radiographic evidence of injury is extremely common in several sports and is often specifically attributed to *exercise-induced hematuria.* Occult hematuria is defined as greater than three red blood cells (erythrocytes) visualized per high-powered field on microscopy. Estimates vary between 13% and 38% as to the prevalence of occult hematuria in an otherwise healthy adult population. Athletic populations are generally considered to have a much higher prevalence. One study reported swimmers, track-and-field athletes, and lacrosse players to have an incidence of around 80% and football players and rowers, about 55%. Among boxers, 73% were noted to have occult hematuria after a fight.

Pathophysiology

There are many proposed mechanisms for non-traumatic hematuria. Etiologies can be best conceptualized by considering the source of the blood from the urethra proximally to the bladder, the ureters, and the kidneys themselves. During exercise, renal plasma flow may decrease from the normal 700 to 200 milliliters (ml)/minute, with the decrease being proportional to the intensity of the exercise. Blood is shunted to skeletal muscle by vasoconstriction of the renal blood vessels. Subsequently, the functional unit of the kidney, the nephron, can suffer hypoxic damage, which can result in increased glomerular permeability and hence an increased frequency of erythrocytes being excreted into the urinary tract. The relatively greater vasoconstriction in the efferent glomerular arterioles may also increase filtration pressure and achieve stasis of blood flow in the glomerular capillaries. These phenomena can also increase the rate of erythrocytes being excreted.

Exercise can also induce trauma to the bladder; for example, bladder contusions are seen on performing cystoscopy after a distance-running event. In this circumstance, the posterior bladder wall is believed to ram the thicker, rigid bladder base. Cumulative impacts likely result in contusion, particularly when the bladder is empty.

Cyclists can traumatize their urethra or prostate due to the bicycle seat's position, especially if this is placed preferentially high to enhance performance.

It should be noted that occult or exercise-induced hematuria should resolve after the athlete recovers from strenuous exercise. If this resolution does not occur, a broader differential diagnosis should be entertained.

Renal Traumatic Injury

Kidney trauma from a direct blow is particularly common in football and rugby, ice hockey, soccer, horseback riding, gymnastics, boxing, sledding, and skiing. Blunt trauma from a direct blow is the most common mechanism, though penetrating injury can occur in sports involving high velocity or force. Younger patients require special attention, as renal injury is more common than splenic or hepatic injury. Up to 30% of renal trauma in children is related to sports. This may be caused by a proportionally larger kidney size or the lack of musculoskeletal protection. The kidney is well protected by the ribs, abdominal muscles, back muscles, and supporting fascia. However it is mobile, making it susceptible to injury by sudden deceleration forces or puncture by a fractured rib.

Clinical Evaluation

A thorough history and physical examination are warranted in the evaluation of hematuria. If not witnessed, an explanation of the mechanism of injury is essential when blunt abdominal trauma is suspected. If the hematuria is gross, specific questioning about the onset with regard to initiating micturition can help determine if the source is the urethra (immediate), the bladder neck/prostate (terminal), or the ureter or kidney (throughout). Clots indicate nonglomerular bleeding, large thick clots suggest a bladder source, while thin stringy clots are more common with ureter sources.

Physical exam technique should follow the traditional medical model of inspection, palpation, percussion, and auscultation. Inspection can reveal contusion or abrasion of the flanks in particular, but it should include visualization of the abdomen, the back, and the genitalia to exclude other signs of injury. Palpation of either flank may reveal tenderness: The kidneys are "ballotable," meaning bimanual palpation with either hand on opposite sides of the torso reveals an awareness of a floating kidney moving between the two. Lumbar spine transverse process or rib fractures may be suspected with tenderness noted on palpation of these structures. Percussion can help determine the presence of peritonitis, and auscultation can elicit bowel sounds unless an ileus has developed and the intestines have ceased to function. Hemodynamic instability may be present and can be ascertained from vital signs such as elevated heart rate and diminished blood pressure.

Urinalysis and Laboratory Evaluation

The laboratory work-up begins with a urinalysis. Urine dipstick urinalysis for red blood cells has been noted to have a sensitivity of 91% to 100% and a specificity of 65% to 99%. Microscopic evaluation of the urine for erythrocytes is the next step, with abnormally shaped erythrocytes suggesting a glomerular source and intact erythrocytes suggesting a nonglomerular source.

A repeat urinalysis 24 to 72 hours after the initial episode of hematuria is required. If the hematuria clears after 24 to 72 hours and the patient is less than 40 years of age, then a diagnosis of exercise-induced hematuria can be made. Further evaluation is required in the presence of a concerning history or physical exam if the patient is older than 40 years, has recurrent episodes of hematuria, or has not engaged in vigorous exercise. An algorithm outlining the evaluation of the athlete with hematuria helps guide the diagnostic process (Figure 1). It should be noted that 2% to 4% of traumatic renal injuries do not demonstrate hematuria.

Imaging

Computed tomography (CT) scan has replaced intravenous urography as the imaging study of choice in the hemodynamically stable patient with blunt renal trauma. An injury to the kidney is shown by CT in the image on page 1207. CT can provide precise delineation of a laceration, determine the presence of a hematoma or retroperitoneal bleeding, and indicate the presence of urinary extravasation or devascularized renal parenchyma. CT is indicated in adult patients with (a) penetrating injury, (b) gross hematuria, (c) microscopic hematuria with shock, or (d) suspected major associated intra-abdominal injury. The current practice recommendation is to image all children with

blunt trauma and hematuria regardless of blood pressure or degree of hematuria.

Management

Management of the athlete with renal trauma, of course, depends on the severity of injury. The goal is to preserve functioning of the renal parenchyma and minimize morbidity. Injury severity is graded based on the American Association for the Surgery of Trauma organ injury severity scale for the kidney, which has been validated to determine the need for surgical repair or nephrectomy. One reported series indicated that of 59 sports-related kidney injuries, 5 required surgical intervention and 2 resulted in nephrectomy.

Gross hematuria should always be evaluated in a hospital setting. The majority of sports-related renal trauma cases involve contusion and can be managed conservatively with observation, bed rest, and supportive therapy. Nonoperative management is appropriate as long as the athlete is not in hypotensive shock, there is no expanding hematoma, and there is no free extravasation of urine by intravenous contrast CT. Nonoperatively managed athletes with renal contusion should be observed until the hematuria clears, and they should be excluded from contact sports for 6 weeks.

Return to Sports and Prevention

Once exercise-induced hematuria has resolved, there is no contraindication to a return to sports. There is no evidence that repeated episodes of exercise-induced hematuria lead to urorenal complications. Athletes should be encouraged to stay hydrated and not to completely empty their bladder before vigorous activity.

Complete healing of traumatic renal injury is essential before return to sports. Most renal injuries heal within 6 to 8 weeks. Microscopic hematuria may persist for 3 to 4 weeks after injury. Return to contact or collision sports may be delayed 6 to 12 months in athletes with more extensive renal injuries. Some athletes may choose not to return to sports.

Resistance Training

Resistance training is one of the pillars of exercise that is essential for overall health and fitness as well as for athletic performance. Typically, resistance training is referred to as weight training or "lifting." Resistance training is much more than just biceps curls and shoulder presses with dumbbells. This entry briefly discusses the body's adaptations to resistance training, as well as the sources of resistance that the body may use.

Resistance Training Adaptations

Resistance training adaptations are both *acute* and *chronic*. Acute responses to resistance training occur primarily in the neurological, muscular, and endocrine systems. Chronic responses to resistance training are seen in the muscular, skeletal, endocrine, cardiovascular, and neurological systems. Anthropometric (body composition) adaptations are also seen as chronic adaptations to resistance training.

Acute and Chronic Neurological Adaptations

When a force is applied to a muscle, a signal is transmitted that activates the muscle cells. When performing resistance training, the number and intensity of signals that are transmitted are increased until the muscle fatigues. The two neurological factors that govern muscle force are motor unit recruitment and rate coding. Motor unit recruitment is simply the size of the muscle force created by the muscle contraction for a given task. For example, fewer motor units in the biceps brachii muscle are recruited when performing a biceps curl with a 10-pound (lb; 1 lb = 0.45 kilogram [kg]) dumbbell than with a 50-pound dumbbell. According to the kinesiologist R. N. Enoka, motor unit recruitment is based on the size principle, which states that the motor units that recruit slow-twitch fibers recruit fewer fibers than the motor units that recruit fast-twitch fibers. Rate coding governs motor unit firing. During resistance training, the muscles fatigue with each repetition of a given movement pattern, and as a result, the rate coding becomes impaired and the firing sequence becomes less and less precise.

Chronic adaptations would result in a more efficient sequence of recruitment of motor units, making the muscle less apt to fatigue from neuromuscular factors. Other chronic adaptations to the neurological system include increased motor unit firing and decreased co-contraction of the antagonist muscles. Co-contraction takes place when both agonist and antagonist muscles fire at the same time. The decrease in the co-contraction of antagonist movement when the agonist muscles are being called on for work allows for greater movement efficiency.

Acute and Chronic Muscular Adaptations

One of the acute effects of muscle during resistance training is the depletion of metabolic substrates, such as creatine phosphate and glycogen. Due to the depletion of these two fuel sources during resistance training, muscle power production decreases. Another significant acute muscle adaptation during resistance training is the intramuscular elevation of hydrogen. This results in a "burning" sensation in the muscles on multiple repetitions. The elevation of hydrogen ions in the muscle results in decreased intramuscular pH. Chronic adaptations from resistance training include increased cross-sectional size of the muscle fibers, also known as muscle hypertrophy. Hypertrophy of muscle occurs in Type I and Type II muscle fibers; however, Type II muscle fibers have a greater response. Manipulation of volume and intensity of resistance training will cause more or less hypertrophy to these respective muscle fiber types. The chronic adaptation of increased cross-sectional size of the muscle fibers results in an increase of muscle strength and power. Another chronic adaptation to the muscles, which has been proven in animals but not yet in humans, is a phenomenon called *hyperplasia*. This is when the number of muscle fibers increases. The resulting hypertrophy and possible hyperplasia of muscle fibers cause a relative increase in protein synthesis. This is essential for the repair of muscle fibers in acute response to resistance training.

Acute and Chronic Endocrine Adaptations

There are two major types of hormones produced by the pituitary glands that respond to resistance training: *protein* and *steroid hormones*. Growth hormones and insulin are major protein hormones, while testosterone and estrogen are major steroid hormones. Resistance training acutely increases the concentration and release of both anabolic and catabolic proteins and steroid hormones. Growth hormones, testosterone, and insulin are anabolic hormones that facilitate the growth and recovery of muscle tissue on completion of a resistance training session. However, equally muscle-degrading hormones, or catabolic hormones, are released during and after resistance training. The increase of cortisol, epinephrine, and norepinephrine secretion during resistance training can have positive short-term effects, but the long-term effects are negative. Higher volume and intensity of resistance training routine will elicit a greater release of epinephrine. Therefore, it is prudent to eat proteins and carbohydrates pre- and postresistance training to prevent a catabolic effect from cortisol, epinephrine, and norepinephrine. Chronic adaptations to the endocrine system include an increased resting level of testosterone and increased sensitivity of tissue response to the release of protein and steroid proteins.

Acute and Chronic Skeletal and Body Composition Adaptations

Adaptations of the skeletal system do not occur acutely but rather over the long term. Recent research has indicated that bone mineral density (BMD) increases or is maintained in postmenopausal women who regularly participate in resistance training. Generally, postmenopausal women are at greatest risk of osteoporosis, referred to as the demineralization of bone. It would take 6 to 8 weeks of regular resistance training to see a positive improvement in BMD.

Body composition changes are seen as a chronic adaptation to resistance training. Body composition is broken down into *fat mass* (subcutaneous fat) and *fat-free* mass (bones, muscle, etc.). Fat-free mass is primarily increased due to muscle hypertrophy from regular resistance training. As a result, the energy expended by the body to maintain the muscle mass is greater (increased caloric expenditure), causing a decrease in fat mass. The connective tissue in the dermis also increases its elasticity, making the skin tighter and resulting in an overall younger-looking body. The length of time for these chronic adaptations to be seen will vary depending on a person's gender, chronological age, training age, and genetic makeup.

Modalities of Resistance Training

When a person says that he or she does resistance training, people assume that the person uses "weights." However, the means used to produce acute and chronic adaptations of resistance training may vary significantly. The means that will be discussed within this entry are not the only types, but they are the ones most frequently used. The major modalities are

- gravity,
- inertia,
- fluid resistance, and
- elastic resistance.

Gravity

Every object has mass; therefore, the earth's gravity will affect each object's density and mass. When people say that they use weights for training, they are actually referring to the gravitational forces affecting an object that is shaped ergonomically for ease of use and repetitive use. According to the principles of biomechanics, resistance training with "weights" varies significantly from training with "machines." The key principle is that all forces acting on an object used for resistance training act in a downward direction.

Inertia

The basic physics learned in grade school can be applied to resistance training. Newton's first law states that unless an unbalanced force is applied, a body in motion tends to remain in motion and a body at rest tends to remain at rest. Newton's second law states that force equals mass times acceleration; therefore, if an object has a small mass, a greater acceleration will have to occur on the object than if the same force were applied to an object with a greater mass. When performing resistance training, the force applied by agonist muscles to a given mass (weights or a body under gravitational forces) at a constant rate is equal to the downward force of gravity on the said mass. Inertial resistance along with gravitational pull act on the mass that is being moved by any type of acceleration. The inertial resistance is equal to the accelerative force applied to the object from the opposite direction. An example of this would be when lifting a barbell off the ground. If the mass of the object is 60 kg, then the initial force applied upward would have to be greater than 60 kg because the initial force must have acceleration to overcome the inertial force as well as the gravitational force. Once the initial force is applied to the object, the amount of force applied does not have to be as great to perform multiple repetitions.

Fluid Resistance

The classic example of fluid resistance training is swimming. The fluid resistance in this case is water. Fluid resistance is also a factor in activities such as cycling, baseball, and golf. These activities are examples of air resistance. The resistance from water and air come in two forms, surface drag and form drag. The friction of the water and the air along with the inertial and gravitational forces create a different dynamic of collective forces to move an object.

Elastic Resistance

Heavy-duty rubber bands, tubing, and springs are forms of elastic resistance. The premise of using elastic resistance is that the greater the stretch of the band or spring, the greater the force needed to overcome the resistance. If the density is too great, the muscle will not be able to complete the full range of movement of a particular exercise. Elastic resistance may be integrated with gravitational resistance as well as fluid resistance to create yet again another variable for the muscle to adapt to.

Respiratory Conditions

Exercise can be highly beneficial for patients with pulmonary diseases. Proper control can be achieved through control of the environment and the use of medications to allow safe participation.

Asthma

Asthma is a pulmonary condition that involves chronic inflammation of the airways, which leads to bronchial hyperreactivity or spasm. Symptoms may include wheezing, cough, chest tightness, and shortness of breath. In the United States, asthma is present in about 6% to 7% of the child population, and an estimated 17 million adults have chronic asthma.

The inflammation and spasm of the airways create an obstruction to airflow and thus generate the symptoms of wheezing, cough, and shortness of breath. The degree of airflow obstruction can be measured with a peak flow meter, or spirometry. These instruments can measure the volume and speed of airflow, which can be compared with the standards for age and height to assess any deficits. Patient complaints of symptoms of tightness, wheezing, or cough are important in making the diagnosis of asthma even if these symptoms are not present at the time of examination. The diagnosis of asthma is confirmed when the airflow obstruction can be reversed by bronchodilator medication and repeat spirometry or if peak flow measurements normalize. The severity of asthma is classified on a scale from mild to severe according to the frequency of symptoms, lung function, and the medications needed to maintain control.

Chronic asthma results from changes in the cells lining the bronchial tubes. These cell changes cause edema, inflammation, mucus production, and spasm of the bronchial tubes. Allergens are a common trigger of asthma flare-ups, especially in patients with a personal or family history of allergic skin disease. Other asthma triggers may include hot or cold exposure, smoke, pollutants, food allergies, molds, stress, or exercise.

Exercise-Induced Asthma

Exercise-induced asthma involves a temporary airflow obstruction triggered by physical exertion. The symptoms are similar to those experienced in asthma but are induced only by exercise and improve at rest. Exercise-induced asthma affects approximately 12% to 15% of the general population and up to 40% of allergy sufferers. Symptoms of wheezing and chest tightness develop within 5 to 10 minutes of strenuous exercise and resolve after 30 to 60 minutes of rest. Less common symptoms of cough, fatigue, difficulty keeping up with peers during training, or even stomachache may indicate exercise-induced asthma. At rest, the athlete may have a normal pulmonary exam but may show signs of allergies such as "allergic shiners" or nasal polyps. If wheezing is present at rest, the diagnosis of chronic asthma must be considered. A trial of treatment with avoidance of triggers such as cold exposure or nonsedating antihistamines may give additional supportive evidence to diagnose exercise-induced asthma. Some patients benefit from inducing a refractory period of 1 to 3 hours by performing submaximal exercise for 15 to 30 minutes before sports participation. Forming a diagnosis of exercise-induced asthma based on a clinical exam only will likely generate either over- or underdiagnosis of the problem. The diagnosis is made most accurately with spirometry performed after an exercise or environmental challenge, combined with the clinical assessment.

Complete pulmonary function tests typically conducted in a lab provide helpful data regarding an athlete's pulmonary function. Part of the complete pulmonary function test is the *spirometry,* which measures the airflow and volumes of the lungs and can be performed in an office visit or even with a portable device. The diagnosis of exercise-induced asthma is most accurately made following an appropriate exercise challenge. Whenever possible, the athlete should be tested by a sport-specific challenge in the appropriate environment (i.e., the ice rink for skaters, the pool for swimmers, etc.) and should reach an intensity of 80% to 90% of the maximal heart rate for 5 to 8 minutes. The FEV_1 (forced expiratory volume in 1 second) is the volume of air an athlete can expel in the first second of a forced expiration and is the most important parameter examined in determining airway obstruction. The spirometry measurements are typically taken before exercise, followed immediately by a postexercise challenge, and then every 5 to 10 minutes for up to 20 to 30 minutes postexercise. If the FEV_1 decreases on any reading by more than 15% from the pre-exercise values, then the diagnosis of exercise-induced asthma is confirmed. An athlete may have equivocal findings on spirometry but may show clear symptoms with exercise.

Many of the medications used to treat asthma are restricted by the World Anti-Doping Agency due to their potential effect of performance enhancement. Additional pulmonary testing may be necessary to provide appropriate documentation to allow use of these medications in the athlete. It is important to clarify the regulations that govern the athlete's participation in competition.

The goal of treatment for the athlete is proper control of symptoms and pulmonary function with exercise. As previously described, conservative treatment with avoidance of triggers, use of antihistamines, and induction of a refractory period can be considered. The first line of drug treatment involves the short-acting beta-2 agonists, such as albuterol. These medications stimulate the beta-2–type receptors in bronchial tissue, resulting in relaxation of the smooth muscle and therefore decreasing bronchoconstriction. Athletes do well with one or two puffs of the inhaler 15 to 30 minutes prior to exercise, which typically gives 2 to 4 hours of benefit. For longer events, additional doses may be required, or a long-acting beta agonist (e.g., salmeterol) may be needed for extended coverage. Since inflammation is frequently a part of asthma, inhaled anti-inflammatory medications such as cromolyn may be useful as a second-line agent for maintenance and prevention. Inhaled steroids also offer benefits to some athletes but require about 2 to 4 weeks of consistent dosing to achieve the desired effects. Inflammation may also be controlled with regular dosing of oral leukotriene inhibitors such as montelukast. In choosing a medication regimen, the substances banned by specific organizations must be considered.

Other Respiratory Disorders

Trauma

Pulmonary contusions result from a blunt injury to the chest wall that causes injury to the lung tissue with bleeding and swelling. Patients should be monitored for hypoxia, and adequate pain control is important to avoid complications of pneumonia resulting from poor inspiratory and expiratory efforts due to pain. Diagnosis is made based on the computed tomography (CT) scan, and treatment involves rest and support. Pneumothorax is the collapse of the air-filled lung tissue, resulting either from blunt trauma or spontaneously at rest or with exertion. Symptoms may include pain, cough, or shortness of breath, depending on the amount of lung tissue collapsed. Diagnosis of pneumothorax is based on the physical exam and chest X-ray. Treatment with rest, oxygen, and close monitoring is usually adequate until symptoms resolve. Athletes typically can return to activity gradually after 3 to 6 weeks depending on the symptoms and exercise tolerance. SCUBA diving is discouraged after a pneumothorax.

Hyperventilation Syndrome

Hyperventilation involves rapid and shallow breathing, often under circumstances of injury or severe stress and anxiety. Patients have trouble breathing, feel faint and confused, have numbness of the extremities, and may have muscle spasms. The athlete should be assessed for significant cardiac and pulmonary symptoms and problems but will usually improve with reassurance and slowing of the breathing rate. Rebreathing into a paper bag can be helpful in correcting the carbon dioxide level in the lungs, which is altered by the hyperventilation.

Exercise-Induced Anaphylaxis

Exercise-induced anaphylaxis is a potentially life-threatening reaction involving symptoms of a severe allergic reaction with itching, hives (urticaria), throat swelling, and spasm of the vocal cords, causing airway obstruction and a severe drop in blood pressure. It is an uncommon problem without a clear cause. Some associations that have been observed include a history of allergies; consuming shellfish, celery, or aspirin; hot/humid weather conditions; and vigorous exercise. Treatment is similar to that for other severe allergic reactions—rescue epinephrine injections and antihistamines.

Chronic Lung Disease

Chronic obstructive pulmonary disease (COPD) most often results from tobacco use or other environmental exposures, causing deteriorating pulmonary function due to obstruction of airflow. Although exercise cannot reverse the disorder, moderate levels of daily exercise have been shown to improve the symptoms of shortness of breath and the patient's ability to complete daily activities. Physician clearance is recommended prior to a patient with COPD beginning any exercise program.

Respiratory Infections

Respiratory tract infections, specifically upper respiratory infections (URIs), are one of the most common medical illnesses encountered in the care of athletes. Exercise can influence the immune system. Moderate exercise can be protective, while excessive exercise can decrease immunity. URIs are best managed through prevention. Avoiding overtraining and getting adequate rest and proper nutrition should be central to an athlete's training program. In winter sports, use of the influenza vaccine should be considered. URI symptoms run their course in 7 to 10 days, and the goal of treatment is alleviation of symptoms. Decongestants and antihistamines may be helpful but can cause sedation or affect temperature regulation. Reminders about basic hygiene, with hand washing and preventing the spread of respiratory droplets, are important in team sports. Athletes may continue to participate on a limited basis if there is no fever, proper hydration is maintained, and no symptoms of vomiting or diarrhea develop. Secondary bacterial infections such as bronchitis or pneumonia may develop and will require additional treatment.

Retrocalcaneal Bursitis

Bursae are fluid-filled sacs located at points of contact between bony landmarks and overriding tendons. There are at least 150 bursae distributed symmetrically throughout the human body. Additional bursae can develop in areas of increased friction. Each bursa acts as a cushion that minimizes friction and allows smooth, gliding interactions between bones and tendons. The bursa is lined by a membrane that secretes synovial fluid. Synovial fluid serves to lubricate the area and facilitate motion in confined joint spaces. Without the bursae, limb movement would be painful.

Retrocalcaneal bursitis is inflammation of one or both of the bursae located just above the insertion site of the Achilles tendon to the heel bone (calcaneus). The Achilles tendon connects the calf muscles to the heel. There are potentially two bursae at this site: (1) the subcutaneous bursa is located superficial to the tendon (closer to the skin, on top of the tendon) and (2) the subtendinous bursa is located deep in the Achilles tendon (below the tendon or between the tendon and the heel bone). Normally, only the subtendinous bursa is present in the heel. However, with abnormal or repetitive pressure to the heel, a protective bursa (subcutaneous) can form between the tendon and the skin (Figure 1). People at risk of developing this bursa include runners and women who frequently wear high-heeled shoes.

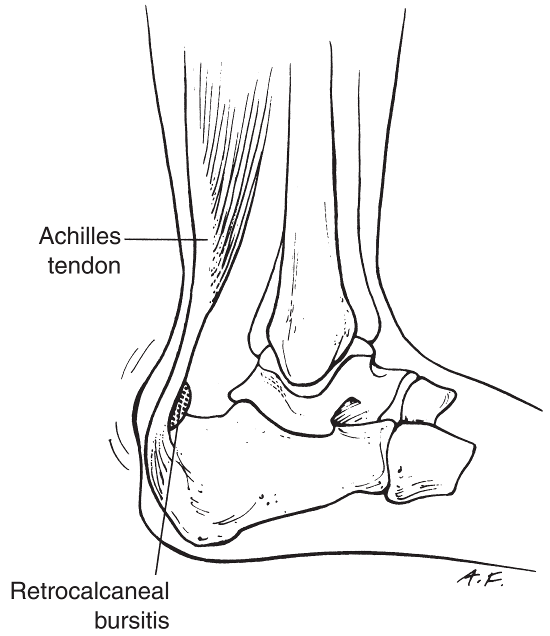

Figure 1 Retrocalcaneal Bursitis

Notes: Retrocalcaneal bursitis usually develops because of irritation of the retrocalcaneal bursa from the back of the shoe. Wearing high heels can cause this condition; hence, it is referred to as "pump bump."

Irritation of a bursa can be *acute* or *chronic*. The various etiologies underlying bursitis include trauma (inflammatory or hemorrhagic bursitis), infection, and arthritic conditions such as osteoarthritis, rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), gout, and pseudogout. Overuse or repetitive microtrauma is the most common cause of retrocalcaneal bursitis.

Retrocalcaneal bursitis is diagnosed in patients of all ages and levels of activity. It is common in athletes, particularly runners. Individuals who participate in repetitive or vigorous activity or who suddenly increase the intensity of activity without proper conditioning are at increased risk for bursitis. Causes include hill-running or stair-climbing, rapidly increasing speed (such as suddenly contracting the calf muscles when sprinting), poor biomechanics, and overuse associated with tight hamstring or calf muscles. Research suggests that poor-fitting shoes with a rigid heel counter generate excessive friction and can cause bursitis. An excessively cushioned shoe may also be a culprit, due to greater stress on the Achilles tendon as the heel sinks deep into the shoe and the consequent irritation of the retrocalcaneal area.

Clinical Presentation

Patients with retrocalcaneal bursitis typically present with posterior heel pain localized directly over the bursa, increased pain with ankle motion (specifically, up-and-down movement of the foot, such as standing on tiptoes), and warmth and redness at the posterior heel. Sometimes there is a noticeable swelling, casually termed a "pump bump" due to its association with wearing high-heeled shoes (or other tight-fitting footwear). Generalized swelling can extend up to the knee. Retrocalcaneal bursitis can present with limping, and symptoms may be worst when first beginning an activity after resting. The pain decreases as the activity continues.

Types of Bursitis

Retrocalcaneal bursitis mostly occurs in the form of *inflammatory bursitis*, typically due to repetitive microtrauma. Recurring injury to the bursa triggers dilation of nearby blood vessels and increased vascular permeability, meaning that the vessels leak. That fluid, along with proteins, infiltrates the bursa. Inflammation causes synovial cells (lining the joint capsule) to multiply and thereby increases fluid production. In the acute setting, early inflammation causes the bursa to become distended. The additional bulk is perceived as foreign by the immune system, and this stimulates further inflammation.

In cases of chronic microtrauma, the wall of the bursa becomes thickened, and the contents of the bursal sac are altered. Rather than synovial fluid, the bursa is filled with granular, brown, inspissated blood and calcifications. Its gritty contents create more friction when bone and tendon move against the bursa.

Hemorrhagic bursitis is characterized by bleeding directly into the bursa. It is typically caused by violent trauma inflicted on the overlying tissues and rarely occurs at the retrocalcaneal bursae. Rapid accumulation of blood causes an acute enlargement of the bursa and accompanying pain. The increased bursal mass hinders mobility of the nearby joint.

Infectious bursitis is another possible, yet uncommon, type of retrocalcaneal bursitis. Predisposing factors include diabetes, alcoholism, steroid therapy, uremia, trauma, skin disease, and a history of noninfectious bursitis. Patients will present with extreme tenderness, warmth, and erythema at the site, and there is often evidence of injury to the overlying skin. Infection often occurs from direct introduction of bacteria through traumatic injury or by the spread of cellulitis. Acute swelling and erythema warrant aspiration of the bursa and analysis of the fluid.

Bursitis due to crystal deposition is associated with various arthritic conditions, including RA, gout, and pseudogout. On aspiration, various types of crystals may be seen based on the underlying illness. Crystal deposition and the arthritides are less common causes of bursitis.

Differential Diagnosis

Following are the conditions that need to be ruled out before arriving at a diagnosis of retrocalcaneal bursitis:

- Achilles tendinitis
- Haglund disease: impingement of the bursa between the Achilles tendon and a bony prominence on the back of the upper calcaneus (Haglund deformity); aggravated by bending the ankle upward
- Achilles tendon rupture
- Plantar fasciitis
- Stress fracture of the calcaneus
- Avulsion fracture at the calcaneus
- RA
- Gout
- SLE
- Seronegative spondyloarthropathies

Evaluation

Bursitis is typically diagnosed by physical examination. Patients often present with abrupt onset of swelling and localized tenderness over the bursa, pain with range of motion of the adjacent muscles and tendons, and warmth and redness of the overlying skin. The swelling may be discrete, as in the pump bump. It can be unilateral or bilateral. The pain may worsen with dorsiflexion (bending the ankle upward as if to walk on your heels), because this tightens the Achilles tendon and therefore puts pressure on the inflamed bursa. However, pain can also be exacerbated by plantarflexion (pointing the toes), because this stresses the Achilles tendon attachment site to the heel. Chronic bursitis may also present with disuse atrophy and weakness.

When considering retrocalcaneal bursitis, it is important to obtain a thorough medical history, including duration of symptoms, history of repetitive movement (i.e., excessive running, walking, jumping), type of footwear used and any recent changes, recent occurrence of fever, history of rheumatic conditions (e.g., RA, SLE, gout), surgical history, and recreational activities.

If the physical exam is not highly suggestive of bursitis, diagnostic testing may be done, including laboratory studies, aspiration of the bursa with fluid analysis, and radiological studies. Laboratory studies can help evaluate other possible etiologies, including gout (uric acid level), RF (rheumatoid factor), and seronegative spondyloarthropathies (human leukocyte antigen B-27 level, erythrocyte sedimentation rate, C-reactive protein). X-rays can be used to look for stress or avulsion fractures of the calcaneus as well as a Haglund deformity. Bone scans and computed tomography (CT) assist clinicians in ruling out a stress fracture. Magnetic resonance imaging (MRI) is usually reserved for cases requiring surgery. It is helpful for differentiating inflammation of the subcutaneous versus the subtendinous bursa; however, this can often be determined by physical examination.

Treatment

Treatment of bursitis should include pain control as well as rehabilitation and prevention of future injury. A seven-step plan, represented by the acronym PRICEMM (*p*rotection, relative *r*est, *i*ce, *c*ompression, *e*levation, *m*edication, and *m*odalities), has gained wide acceptance among health care providers. PRICEMM has been used as a framework for customizing a patient's rehabilitation plan.

The first step of treatment is to eliminate pressure from the affected area and to protect the joint. Movement and pressure of the inflamed area can exacerbate symptoms and impede healing. Soft-foam padding and orthopedic felt can be used to protect the affected area from increased friction or pressure. Slitting the heel counter of the shoe (cutting a "V" groove into the back of the shoe) or inserting a thick heel pad to raise the heel may help decrease friction at the retrocalcaneal bursae. For runners, it has been recommended that they change their footwear, especially if the symptom onset corresponds to wearing a new pair of shoes.

Relative rest should be prescribed to encourage patients to continue participation in exercise but to choose activities that will not further irritate the bursa. Initially, activity should be modified to avoid movements that exacerbate the pain. The overall goal should be for the patient to refrain from the triggering activity but to maintain fitness level by participating in alternative activities such as swimming. Continued physical activity accelerates the rehabilitative process. Bed rest or immobilization of the associated joint after the inflammation subsides is not advisable and should be discouraged in cases of bursitis.

Application of an ice pack will help decrease inflammation and swelling, allowing the bursa to return to its normal shape and consistency. Ice is also an effective analgesic. Direct application of ice to the skin should be done at least twice a day for 10 minutes at a time.

Compression of the affected bursa can be accomplished with an elastic bandage. While the bursa is wrapped, the extremity should be elevated above the level of the heart to decrease the amount of swelling. Elevation of the extremity for 20 to 30 minutes several times daily will facilitate removal of fluid from the affected area.

Various modalities have aided the healing of irritated and inflamed bursae. Electrical stimulation, ultrasound, and phonophoresis have been used to decrease inflammation and reduce pain. These procedures are typically done by a physical therapist. Physical therapy is often prescribed for patients experiencing weakness in an extremity or a decline in range of motion.

Medications of choice for bursitis are nonsteroidal anti-inflammatories (NSAIDs) or aspirin. The goal of using these medications is to alleviate pain and allow the patient to resume activity and participate in a rehabilitation program. NSAIDs are typically used for 4 to 6 weeks if symptoms have been present for fewer than 3 weeks at the time of diagnosis. While NSAIDs and aspirin are the preferred initial treatment, some patients will require additional medication if conservative management is not effective. Corticosteroid injections are not recommended due to the risk of injecting the Achilles tendon and the association with Achilles tendon rupture. Adverse effects on the tendon have been documented with injections of the bursae, the tendon, as well as the surrounding structures. Therefore, they are only used for the most severe, intractable cases.

Surgery is another option for treatment of bursitis; however, it is very rarely done. The main surgical candidates are patients with chronic bursitis or infectious bursitis. In chronic cases that have not improved with traditional therapy, surgery may be done to correct an anatomical abnormality, such as a bone spur. Both endoscopic as well as open surgery can be done. In cases of infection, the bursa may be opened and drained ("incision and drainage" procedure) or removed entirely.

Rhinitis, Exercise-Induced

The athlete, like everyone else, can have multiple problems related to the nose. Because of its prominent position on the face, the nose is frequently involved in trauma, leading to nasal discomfort and potential problems with congestion and leaking of fluid. Athletes also can have other nasal conditions found in the general population, such as allergic rhinitis and nasal infections, which may alter their performance.

Nose Anatomy and Function

The nose has two passageways, which contain the superior, middle, and inferior turbinates, bones that are lined by the same mucosa that covers the rest of the respiratory system. The mucosal lining contains many blood vessels that help warm and moisten the air that is inspired through the nose. The sympathetic and parasympathetic nerves reach the blood vessels and mucosa of the nose, and according to the message they carry, the blood vessels dilate (parasympathetic) or constrict (sympathetic) and the glands in the lining of the nose secrete fluid (parasympathetic). Other important cells in the mucosa of the nose include mast cells and basophils, which can release the chemicals that cause the symptoms of nasal allergies. Antibodies can also participate in the same release of chemicals from the mast cells and basophils by binding to different allergens in the environment. Several sinuses (ethmoid, sphenoid, and maxillary) and the nasolacrimal duct drain into the nose, and any swelling or distortion of these openings can lead to obstruction of this drainage system so that fluid builds up in the involved sinus. The nose also acts as a filter for polluted air by removing many different-sized particles from the air inhaled.

Physiologic Response to Exercise

During exercise, the release of epinephrine and norepinephrine increases the sympathetic tone, causing constriction of the nasal vessels. This helps to make more room in the nose and decreases airway resistance. Exercise also decreases blood flow to the nose because more blood is redistributed to the working muscles. In addition, the alar dilator muscles (nose muscles) work with each inspiration to increase the opening of the nostrils to allow more inflow of air. Higher-intensity exercise speeds up these physiologic changes. Exercise can decrease airway resistance in the nose by as much as 50%.

Rhinitis in the Athlete

Athletes can complain of fluid draining from their nose for many different reasons. Three categories of rhinitis are allergic, nonallergic, and mimics of rhinitis. Allergic rhinitis is usually seasonal, perennial, or occupational. It involves the athlete being presensitized to a particular allergen. The nasal mucosa with specific antibodies comes into contact with the allergen, resulting in the release of chemicals from the mast cells and basophils. Many different chemicals including histamine are released, causing nasal secretions and postnasal drip, itching, and sneezing. Nonallergic rhinitis includes trauma, environmental triggers that act at the level of the blood vessels to increase permeability and thus cause rhinitis, and infections. There is no specific antibody to allergen needed to trigger the mast cells to release their chemicals. Environmental triggers that can cause rhinitis include temperature or weather changes, cold exposure, particulates in the air, ozone, glues, paints, and cleaners. The common cold is the usual culprit for the new development of rhinitis, which lasts for several days. Conditions that can mimic the symptoms of rhinitis include a deviated nasal septum, nasal tumors, enlarged turbinates, and even less common mimics such as sarcoidosis and Wegener granulomatosis.

Clinical Evaluation

The nose needs to be examined through the nostril with a light source. The exam includes looking for any polyps, signs of prominent blood vessels (bluish blush), a deviated septum, and tenderness of the sinuses. Often with allergic rhinitis, the athlete will have "shiners" under the eyes related to blood congestion in the sinuses. Allergy skin testing and allergy blood tests can be done to identify which allergens the athlete should avoid and can guide the decision to desensitize the athlete to the allergen.

Treatment

Treatment depends on the severity of the symptoms and their effect on performance. Some of the medications used to treat nasal congestion can decrease athletic performance and may not be approved for use in athletes at higher levels of competition. For athletes with allergic rhinitis, antihistamines can decrease the symptoms. Unfortunately, antihistamines can also cause drowsiness; dryness of the nose, eyes, and throat; and potentially impaired sweating, making the athlete more sensitive to heat produced during exercise. Nasal steroids work for both allergic and nonallergic rhinitis because of their anti-inflammatory effects and because they decrease permeability of the nasal mucosa. Nasal cromolyn is also helpful to decrease congestion related to inhaled allergens. Intranasal anticholingerics can be effective to decrease symptoms of rhinitis. For severe symptoms, systemic corticosteroids can be used for 3 to 5 days. It is important to identify and avoid medications that are associated with rhinitis. Common drugs associated with rhinitis include oral contraceptives, aspirin, nonsteroidal anti-inflammatories, and decongestants that are used for a long period.

Complications of Rhinitis

Because mucosal swelling causes rhinitis, it can cause obstruction of the openings of the sinuses. If the obstruction occurs long enough, about 10 to 14 days, it may cause sinusitis, a bacterial infection of the sinuses. If the athlete also has concurrent asthma, the rhinitis and associated postnasal drip often increase the reactivity of the airways, making the asthma more difficult to control. Rhinitis is also associated with blockage of the eustachian tube, which drains fluid from the ear to the throat. As a result, pressure builds up in the ear and causes ear discomfort. Because the blood vessels are engorged in the nose with rhinitis, they are more prone to injury, and nosebleeds occur more frequently.

Rhomboid Muscle Strain and Spasm

The *rhomboid* is a muscle located in the mid to upper back, connecting the thoracic spine (backbone) to the medial border of the scapula (shoulder blade). The rhomboid serves as a scapula stabilizer when one moves the arm overhead and also reaches for objects. The term *strain* describes a stretching or partial tearing of the muscle, resulting in inflammation and pain. A *spasm* is an involuntary contraction of a muscle. Depending on the mechanism of injury, the rhomboid muscle can be strained, in spasm, or, in some cases, both.

Injury Occurrence

A typical rhomboid injury may occur with either compression or overstretching of the muscle. Athletes who participate in overhead sports remain at risk for rhomboid injuries. Mechanisms such as serving a tennis ball, rowing in a crew, or throwing a baseball pitch can strain the rhomboid and result in subsequent spasm. Non–sports-related activities that may cause rhomboid strain include carrying a heavy backpack over one shoulder and poor posture when sitting at a desk.

Symptoms

After the injury occurs, patients can develop pain or muscular knots between the scapula and the thoracic spine. This pain can be constant, especially in a patient with poor posture. Otherwise, the patient may only feel symptoms if the compromising activity is repeated (e.g., serving a ball). The patient will typically not experience any radiating signs or symptoms except for those along the rhomboid muscle fibers. Frequently, patients also exhibit symptoms over the trapezius muscle (located superior and superficially to the rhomboid).

Diagnosis

The sports medicine physician typically diagnoses rhomboid spasm or strain with direct palpation of the muscle fibers as well as range-of-motion reproduction of symptoms. A patient could also perform an "air push-up" to compare scapula movement.

Treatment

Different options exist for the treatment of rhomboid spasm or strain. First, a patient can perform a home exercise program. A home exercise program includes performing a series of exercises with at least 20 repetitions twice daily to allow for both muscle strengthening and improvement in range of motion.

The first basic stretch involves a scapular range-of-motion stretch, which essentially looks like a shoulder shrug. Moving the shoulder counterclockwise or clockwise will help improve range of motion of the shoulder. Shrugging the shoulder and holding the shoulders back together for 5 to 10 seconds can also stretch the muscle.

The second stretch involves a pectoralis muscle wall stretch. The patient should go to a corner of the room, placing the hands at about 90° abduction (shoulder height), and perform a wall "push-up." This stretch allows the patient to strengthen and lengthen the muscle. The patient can hold down for 5 to 10 seconds again to maximize lengthening of the muscle. A similar stretch may be performed using elastic resistance bands and tubing. Placing the hands at the same angle, the patient can retract with the band offering resistance. A fourth stretch includes placing the hand on the affected side against a door frame and tilting the body back. This stretch again improves shoulder stabilization and proprioception.

Finally, patients can clasp their hands together and reach directly in front of them. This technique is similar to progressive resistance training, which helps stabilize the shoulder. The patient should apply ice for approximately 20 minutes after performing the home exercise program to help decrease any reflex inflammation.

In addition to the home exercise program, the patient may take nonsteroidal anti-inflammatories (NSAIDs), such as ibuprofen or naproxen, for 10 days to increase the anti-inflammatory effect. After this time, the medicine simply serves as a pain reliever.

Massage treatment can be helpful to decrease spasm. Athletes may place a tennis ball on the floor under their rhomboid muscle and roll over the ball in an up-and-down fashion to release the rhomboid spasm.

If the spasm is unresponsive to the home exercise program and ice application, trigger point injections can be given. Trigger point injections consist of a 25-gauge (or lower), 1.5-inch (3.81-centimeter) needle with an anesthetic (lidocaine 1%). Evidence-based medicine shows that a slight triggering (needling) of the muscle spasm with the syringe can decrease the involuntary spasm directly. Lidocaine serves as a pain reliever for the needling. Following the trigger point injection, osteopathic manipulative treatment may be performed. A technique called myofascial release involves adding pressure with the thumb over the muscle spasm to decrease the contraction. The trigger point injection decreases the muscle spasm.

If these techniques are not effective, then the patient may attend formal physical therapy twice weekly for 6 weeks. Treatments may be augmented from the home exercise program to focus on the specific area of the rhomboid that was unresponsive to prior treatments.

Return to Sports

The athlete should have no residual range-of-motion deficiency or weakness prior to return to sports. Early return to play without appropriate treatment may disrupt the athlete's typical playing form or style. A tennis player or volleyball player may need an altered serve to maintain strength. A crew member may not exhibit his or her typical form on a rowing stroke. This adaptation could lead to further back pain as a result of muscular compensation.

Prevention

Similar to the lumbar core stabilization program, scapula stabilization is essential for performing activities of daily living as well as sports-related activities. Any patient with a history of rhomboid strain and spasm should consider a daily home exercise program to maintain scapula stabilization.

Rib Fracture and Contusions

Rib injuries are a common cause of chest wall pain in the athlete. It is vital to differentiate pain from an injured rib from other causes of discomfort such as referred pain from the spine, a systemic process like arthritis, or more life-threatening symptoms like a pneumothorax.

Typically, rib injuries occur in the athlete due to overuse or trauma. These injuries may be classified as either contusions or fractures. *Contusions* are bruises to the soft tissues and associated bony structures. Stress fractures tend to occur when there is repetitive stress placed on the rib by mechanisms such as muscle contraction(s). Fractures can occur with direct or indirect injury. Indirect injuries occur with a spontaneous and powerful contraction of a muscle that leads to breakage of the bone. Avulsion fractures occur in the lower ribs due to contraction of the external oblique muscles. This injury has been described in a javelin thrower. Direct injuries occur when the ribs sustain a blunt force. Athletes most at risk for rib stress injuries are those who use their shoulder and thoracic girdle muscles repetitively, such as baseball pitchers, rowers, and gymnasts, while those at risk for direct trauma typically play or are involved in contact sports.

Understanding the anatomy of the chest wall will help the practitioner and athlete prevent and diagnose rib injuries. The chest wall houses the heart, lungs, and major vessels. There are 12 ribs in the chest wall. The first 7 are considered "true" ribs as they attach to the sternum via costochondral cartilage. The 8th through 10th ribs are referred to as "false" ribs since they attach not to the sternum but to adjacent ribs via costochondral cartilage. The term *floating ribs* refers to the 11th and 12th ribs, which have no attachment anteriorly. The ribs attach posteriorly to the spine. Muscles involved in throwing, rowing, and weight lifting attach to the ribs at various points. The practitioner must always be on the alert for associated injury given the potential for injury to the underlying lung, cardiac, and vasculature structures. For example, fractures of the lower ribs can lead to injury to structures within the lung and the abdomen.

Athletes with rib fractures will present with various symptoms depending on their fracture location and type. Athletes may present with localized pain directly over the involved rib. There may be associated muscle spasm, bruising, and hesitancy to take a deep breath in.

The ribs most susceptible to blunt trauma are the fourth through the ninth ribs. Athletes can sustain more than one rib fracture. These athletes typically receive significant blunt trauma to the chest wall. They may have difficulty taking a deep breath due to pain, splinting of their chest wall, and are at risk for a *pneumothorax* (air around the lungs) or *hemothorax* (blood around the lungs). These athletes should be evaluated in an emergency department. Not all acute rib fractures can be diagnosed on x-ray, especially if they are located on the front or side of the chest and involve the first five ribs. Plain films are useful for diagnosing other injury such as pneumothorax. It has been recommended that individuals require X-ray who have suspected fractures of either Ribs 1 or 2, or 9 through 12; multiple rib fractures; are elderly; or have the potential for pathologic fractures.

Treatment of fourth through ninth rib fracture depends on the patient's level of comfort and ruling out other associated underlying life-threatening injuries. This can be done with oral pain medication. Athletes are encouraged to take deep breaths during the recovery process to avoid collapse of the small airways. Binders are no longer recommended because they result in decreased ventilation.

The first and second ribs require a lot more force to fracture than the rest of the ribs. Acute traumatic fractures can be indicators of more significant injury involving the great vessels or other organs within the chest wall. Fractures to the first rib have been documented in overhead athletes, that is, baseball, basketball, weight lifting, and tennis. The muscles involved in throwing, such as the scalene muscles, cause fatigue to the bone with repetitive use. Stress injuries can occur with rapid changes in training like increased time or intensity. Acute fractures can also occur with motions such as swinging a bat without any direct contact. Athletes will complain of pain in the back of the shoulder. This can be either subacute in cases of stress injury or acute with an associated "pop" with indirect or direct trauma. The clinician may perform a chest X-ray to evaluate the fracture. However, triple-phase bone scan is the imaging modality of choice. Other options do include computed tomography (CT) scan or magnetic resonance imaging (MRI).

Treatment of first and second rib fractures involves adequate analgesia and a sling to the involved shoulder girdle to prevent provocative maneuvers. Healing can take up to 8 weeks. It is not uncommon for these to have a delayed or fibrous union. Surgery is recommended for a persistently painful nonunion.

Stress fractures to ribs beyond the first and second occur when there is an increased load to the bone. The bone fatigues and develops microfractures that then lead to stress fracture. This occurs via repetitive muscle contraction with an increase in training (time, volume, intensity) or a change in technique. Rowers and golfers are at increased risk due to their use of muscles such as the serratus anterior. Rowers may need to have equipment changes such as changing the shape of the oar to prevent further occurrences. Athletes will complain of pain over their back. Given the elastic nature of the chest wall, taking a deep breath can aggravate the symptoms. Treatment of these stress injuries is similar to stress injuries to the first and second ribs: modified activity, analgesia, and prevention.

The examiner should perform a thorough physical exam including a heart, lung, and abdominal exam in any athlete at risk for a potential rib injury. There may be point tenderness on palpation (although palpation may be difficult if the fracture occurs under the scapula). Chest X-ray may be diagnostic; however, triple-phase bone scan is again the modality that will confirm the diagnosis. Treatment involves allowing time for the bone to heal. This usually takes 4 to 6 weeks of relative rest with a gradual progression toward competition by 8 weeks. It is important for athletes to have someone evaluate their technique, strength, training schedule, and flexibility to avoid further injury.

Rib Stress Fracture

Stress fractures occur when a bone fails to withstand repetitive stress. Activities such as running or jumping generate forces of multiple times a person's body weight and place weight-bearing bones under a lot of pressure. Thus, stress fractures usually occur in bones that are weight bearing. However, stress fractures can also occur in bones that are not weight bearing, such as the ribs. Rib stress fractures are caused by multiple mechanisms and can occur in athletes who participate in golf, rowing, canoeing, swimming, running, baseball (especially pitchers), javelin throwing, weight lifting, tennis, basketball, surfing, and squash. Rib stress fractures can also be caused by strenuous coughing, backpacking, or pregnancy. Rib stress fractures are seen most often in rowers. There has been an increase in the incidence of rib stress fractures among rowers since the arrival of new, more technologically advanced equipment. Rib stress fractures in rowers account for much time lost from training and competition. Women are more likely than men to suffer a rib stress fracture. No one knows definitively why women are more susceptible than men; however, in general, women's bones have less bone mineral density than men's and thus may be more susceptible to stress fractures.

Anatomy

The ribs are 12 paired bones in the chest that make up the rib cage. The first 10 ribs attach to the sternum (breastbone) and the spine. The ribs are connected to the sternum by the costal cartilage. Ribs 11 and 12 are floating ribs and do not connect to the sternum at all. The rib cage protects the heart, lungs, and other vital organs. The ribs, together with the diaphragm, enable inspiration and expiration (breathing). Most often, rib fractures occur centrally on the first rib, laterally on Ribs 4 through 9, and posteriorly on the upper ribs. There are several muscles that attach to the rib cage. One of these, the serratus anterior, is the muscle most often implicated as a cause of stress fractures. The serratus anterior attaches on the lateral part of the first eight ribs and wraps around the side of the body to attach posteriorly to the scapula.

Causes

Stress fractures occur when a bone fails to withstand the stress placed on it. When the stress or injury occurs at a rate faster than can be repaired by the bone, a fracture develops. The repetitive nature of many sports, such as rowing, produces a pattern of repetitive strain that is produced on a frequent basis. Repetitive muscle forces acting on the ribs are a possible cause of the imbalance that can lead to a stress fracture.

There is no consensus as to the exact mechanism that leads to stress fractures in rowers. Various causes include stress from the serratus anterior, pull from the abdominal muscles, or muscle fatigue, which weakens the protection the muscles provide to the ribs, thus making them more susceptible to injury. New equipment and increased use of indoor rowing ergometers seem to be contributing factors to the problem. Modern oar technology allows for more loading of the oar than the traditional wooden oars and is suspected to contribute to the increasing incidence of rib stress fractures among rowers.

A golfer can develop a stress fracture if he or she repeatedly strikes the ground by accident while swinging. This commonly occurs with novice golfers. The collision of the club with the ground causes traction of the serratus anterior muscle, which over time causes damage to the rib and leads to a stress fracture. Stress fractures also occur in golfers who dramatically increase the number of swings they take per week. Injury from the increased load is most likely due to repetitive muscle use.

The first rib is susceptible to stress fracture in people who do a lot of work overhead, such as throwers, weight lifters, or even wallpaper hangers. It is believed that the first rib is susceptible to injury because it has two grooves on the upper surface, on which the subclavian vein and artery rest. The bone is thin in these areas. In addition, the first rib must endure stress from the downward force of the intercostal and serratus anterior muscles as well as the vertical forces of the scalene (neck) muscles. The combination of muscle traction and the thin area of the bone makes those who spend a lot of time throwing or working with their arms over their head susceptible to first rib fractures.

Symptoms

Rib stress fractures can present in a variety of ways. The symptoms will vary depending on the rib that is injured and the location of the injury. Pain will be felt at the point of injury but can also be felt along the distribution of the nerve that accompanies the rib (intercostal nerve). An irritation of the pleura (lining of the lung) can also occur. The pain initially starts with activity only but eventually becomes present with almost all motions (including breathing) as the injury progresses. The pain experienced will intensify when breathing deeply, coughing, laughing, or sneezing.

Most rowing stress fractures occur in Ribs 4 through 8. Sweep rowers (those with a single oar) most often have fractures anterior and lateral on the rib as opposed to posterior. There is no connection between the rower's side of the boat (port or starboard) and the side of the body where the stress fracture is located. Scullers (rowers with two oars) get anterior stress fractures just as often as posterior fractures.

Golfers with stress fractures will have pain in the upper back. Usually, the pain is located on the side of the nondominant hand. Many do not seek treatment immediately because they think they have a muscle strain. First rib stress fractures can produce a dull, aching pain in the shoulder or collarbone. The pain will follow a similar pattern as mentioned above but will especially occur with overhead activities.

Diagnosis

A history and physical exam are the first steps when diagnosing a stress fracture. Tenderness to palpation will be present over the area of the stress fracture. To confirm the diagnosis, radiographs are needed. Plain radiographs will sometimes miss the diagnosis; however, if healing is already taking place, a callus will be visible. Because plain films often do not reveal the fracture, the best test to detect the stress fracture is skeletal scintigraphy (bone scan). On these films, the stress fracture will light up as a "hot spot" over the rib where the injury has occurred. Computed tomography (CT) scans are not ideal for making the initial diagnosis but are helpful to monitor healing and may be ordered 4 to 6 weeks after the diagnosis to aid in deciding when an athlete can be cleared to return to athletic activity.

Treatment

Stress fractures are treated nonoperatively. The initial treatment for rib stress fractures involves rest for 4 to 6 weeks from activities. The athlete must take particular care to avoid movements that provoke pain. Return to physical activity must begin gradually and should start with basic activities before slowly reintroducing sport-specific activities. The technique and the biomechanical form of the athlete should be evaluated to identify the problem areas that might have led to the injury. Errors in biomechanical form should be corrected before allowing the athlete to return to play. Pain can be controlled with pain medication. After 4 to 6 weeks, higher-level athletes might undergo a CT scan to confirm bony healing. If there is no evidence of bony healing on CT images, the athlete would perhaps benefit from a longer period of rest. In some cases, healing will never occur, resulting in a nonunion. However, athletes have been able to eventually return to play free of pain despite not achieving bony healing.

Rib Tip Syndrome

Rib tip syndrome is a condition that is often misdiagnosed or undiagnosed and can subsequently lead to months or years of unresolved abdominal and/or thoracic pain.

This syndrome was first described in 1919 but was not officially named until 1922. The syndrome, variously called slipping rib syndrome, clicking rib, displaced ribs, interchondral subluxation, nerve nipping, painful rib syndrome, rib tip syndrome, slipping rib cartilage syndrome, traumatic intercostals neuritis, and 12th rib syndrome, is associated with hypermobility of the anterior end of a costal cartilage.

Anatomy

The human rib cage is part of the human skeleton within the thoracic area. A typical human rib cage consists of 24 ribs, 12 on each side of the thoracic cavity; the sternum; and the 12 thoracic vertebrae.

In the front, the upper seven ribs are attached to the sternum by means of the costal cartilages. Due to their elasticity, they allow movement when inhaling and exhaling. The 8th, 9th, and 10th ribs join with the costal cartilages of the ribs above. The 11th and 12th ribs are known as floating ribs as they do not have any anterior connection.

Causes

The cause of the painful rib syndrome is not known. Although it is often related to minor trauma, constrained posture, or previous abdominal surgery, the etiology of rib tip syndrome remains unclear because many patients do not recall any such event.

According to the original mechanical description, Ribs 8 through 10 (false ribs), which are not connected to the sternum but are connected to each other via a cartilaginous cap or fibrous band, tend to be the most mobile and susceptible to trauma.

The weakness of the rib-sternum (sternocostal), rib-cartilage (costochondral), and/or rib-vertebral (costovertebral/costotransverse) ligaments leads to rib hypermobility. This allows a rib to slip behind the rib above it, and the slippage or movement can lead to irritation of the intercostal nerve, strain of the intercostal muscles, sprain of the lower costal cartilage, or general inflammation in the affected area.

Symptoms

This disorder may account for 1% to 5% of all patient visits in a general medical practice. Cases have been reported in children as young as 7 years as well as individuals in their mid-80s, with the syndrome affecting females slightly more than males. Among athletes, wrestlers seem to be the most commonly affected, but it can be a problem in just about any sport.

The painful rib syndrome consists of three features: (1) pain in the lower chest or upper abdomen, (2) a tender spot on the costal margin, and (3) reproduction of the pain on pressing the tender spot.

The main symptom is upper abdominal pain, equally common on either side and occasionally bilateral. The pain is precipitated by movement and certain postures (e.g., bending, coughing, deep breathing, lifting, reaching, rising from a chair, stretching, and turning in bed) and is invariably reproduced by pressure at one or more points on the costal margin.

The rib end may also subluxate across the medial attachment site or another rib border. This will lead to a popping, clicking, snapping, grating, or "giving way"' sensation, associated with a sudden, often severe, exacerbation of pain. The pain may then fade away over the course of minutes to 1 to 2 hours or may persist as a lesser, dull pain punctuated by severe periodic exacerbations induced by subluxations.

Diagnosis

Rib tip syndrome has a large variety of differential diagnoses, such as cholecystitis, esophagitis, gastric ulcer, hepatosplenic abnormalities, stress fracture, inflammation of the chondral cartilage, and pleuritic chest pain. The definitive diagnosis is usually made based on the history and physical examination.

As part of the diagnosis, the clinician needs to look for an association between certain movements or postures and pain intensity. Determine if the patient has experienced recent trauma (although it may not always be present), and reproduce the symptoms (e.g., pain, clicking) with the hooking maneuver. A positive hooking maneuver is a reproduction of the pain event induced by the examiner curving his or her fingers under the costal margin and gently pulling superiorly and anteriorly, inducing subluxation of the offending cartilage.

Often, one may also be able to identify the affected rib by pressing on the ribs in the midaxillary line. Movement of the disrupted rib end can reproduce the symptomatic pain of the slipping rib. The intercostal nerve block or rib block is recommended to confirm the diagnosis, as demonstrated by the abatement of symptoms.

Radiologic imaging (X-ray, sonography, bone scan, computed tomography [CT], or magnetic resonance imaging [MRI]) is generally not useful in the diagnosis of slipping rib syndrome but may be of value in ruling out other conditions in the differential diagnosis.

Treatment

There are three modes of treatment for slipping rib syndrome: (1) simple reassurance, (2) intercostal nerve block or rib block, and (3) surgical repair or resection. For an athlete wishing to compete within a few days of treatment, the intercostal nerve block may be very useful.

Treatment should initially be conservative, but if the symptoms persist or recur, surgical excision is indicated. Surgery may be necessary more often than not to provide definitive treatment.

Nonsurgical Treatment

Once the diagnosis of slipping rib syndrome has been made, the patient should be educated concerning the condition. Simple reassurance and avoidance of movements or postures that exacerbate symptoms may be sufficient to elicit a successful outcome. Certain strength training maneuvers that involve the trunk/core might need to be avoided by the athlete for a period of time.

Patients can also consider other conservative measures such as icing, stretching, ultrasound treatments, hot packs, nonsteroidal anti-inflammatory medications, physical therapy (e.g., soft tissue mobilization, myofascial release, anterior-posterior mobilization from T9 through L2), stretching, and strengthening activities. Osteopathic manipulation can also be used to restore maximal painfree movement of the rib cage through the appropriate use of myofascial release and functional techniques.

Before recommending surgical excision of the rib tip, temporary relief of pain can be obtained from local injection of steroid (e.g., methylprednisolone acetate) and local anesthetic (e.g., 1% lidocaine) into the painful sites.

Surgery

Surgical treatment is typically reserved for those in whom conservative/nonsurgical management has failed. The procedure can usually be done in an outpatient setting, but in some cases, the patients may need to be kept in the hospital overnight for observation.

The point of maximal tenderness is localized preoperatively, and the resection is centered at that point. A subperiosteal/subperichondrial resection of the involved rib and cartilage is then performed. Care should be taken to avoid entering the pleural space. If this were to occur, simple aspiration and closure of the pleura is performed, avoiding placement of a tube thoracostomy.

Surgical excision of the subluxating cartilaginous rib tip is the definitive therapy. Patients with a long history of pain can obtain relief by cartilage excision. This involves little morbidity and can frequently be performed under local anesthesia.

After Surgery

The patient is restricted from activity for 6 weeks following surgery. After this time, light rehabilitation exercises can begin, and the patient is then progressed through the rehabilitation program as tolerated. Return to contact sports is recommended once full-intensity noncontact activities are tolerated. In some cases, a "flak jacket"–type rib protector may be helpful for return to play in the first few weeks to months.

Risk Factors for Sports Injuries

Millions of people participate in sports each year. In the United States alone, there are an estimated 30 million children who participate in organized sports and approximately 150 million adults who participate in non–work-related physical activity. With this level of participation, a significant number of sports-related injuries are bound to occur. These injuries are a significant problem and cost to society. Identifying the common risk factors and mechanisms of injury is a necessary condition for strategizing and creating preventive programs.

Types of Risk Factors

Risk factors are typically classified as *intrinsic* or *extrinsic*. An *intrinsic* risk factor is an *internal* factor that can predispose one to injury. Intrinsic risk factors include age, anatomy, fitness level, gender, previous injury, and psychological factors. For example, according to injury data, boys between the ages of 10 and 14 are at higher risk for a sports-related injury.

An *extrinsic* risk factor is an *external* factor that can influence a person's susceptibility to injury. Extrinsic risk factors include clothing, coaching, equipment, hours of exposure, playing surface, technique, training, and the weather. For example, frostbite is the freezing of the skin that results from exposure to very cold temperature. Air temperature, wind speed, and moisture all affect the rate at which the body loses heat. Playing on a muddy or uneven surface would increase the likelihood of ankle or knee injury.

Risk factors can also be categorized as *modifiable* and *nonmodifiable*. *Modifiable* risk factors refer to those that can be altered by preventive strategies to reduce injury. *Nonmodifiable* risk factors, such as age and gender, cannot be altered. While nonmodifiable risk factors are important to consider, more emphasis is often placed on modifiable risk factors, since they can be altered to reduce injury rates.

Sports injuries result from a complex interaction of the above intrinsic and extrinsic risk factors, coupled with an inciting or triggering event. For example, an intrinsic risk factor can predispose an athlete to injury, but injury will not occur by itself. The athlete will have to be exposed to an extrinsic risk factor, followed by an inciting event that leads to injury. To clarify further, an example would be a female adolescent with weak hamstrings and hip instability (intrinsic risk) who is playing soccer on an uneven surface (extrinsic risk) and gets pushed (inciting event), leading to rupture of her anterior cruciate ligament.

The importance of gaining a better understanding of the risk factors for sports injuries is that if we can identify these risk factors and modify or develop preventive strategies, then we can influence the health of athletes in a positive manner. Research continues to look at the complex interaction between risk factors that leads to injury and is focused on the development of risk reduction techniques. The determination of the cause of sports injuries needs to account for the varied nature of these injuries by including as many risk factors as possible. Risk factor studies need to be carefully designed. Ideally, this design would include a group of athletes with similar demographics and risks who can be followed over time. The group size would also need to be large enough to give it the power for statistical significance.

The other important condition to help clinicians, and ultimately the population at large, to better understand risk factors for sports injuries is for the individuals conducting the research to convey the data and statistics in meaningful terms. For example, the mean playing time before an injury occurs is x, or the chances of injury in a season are y. The uncertainty in the estimate of a risk factor statistic provided by a study also needs to be clearly conveyed.

Studies published to date on the risk factors for sports injuries often have methodological limitations and inadequate sample sizes, and because of this, as well as the issues outlined above, it is still difficult to definitively establish the cause-and-effect relationship of many perceived risk factors and the subsequent sports injuries. However, published research data have suggested specific risk factors; the following are some examples.

Baseball

Ongoing efforts to reduce baseball injuries have led to the introduction of protective equipment, softer baseballs, and better coaching and pitching programs to reduce overuse injuries. Safety balls have reduced the risk of ball-related injuries, with reduced-impact balls being the most effective. However, no safety ball can remove all risk of injury. Better coaching techniques, appropriate field conditions, and proper equipment may further reduce injury potential. For example, teaching young batters to turn away from the oncoming ball, along with not using the on-deck circle, may help prevent injury. Correct sliding technique and breakaway bases also decrease injury. Also, monitoring of pitch counts has been shown to reduce the incidence of overuse injuries related to the elbow and shoulder.

Football

Helmet modifications have been successful in reducing facial and dental trauma. There is ongoing research looking at helmet modifications and the risk of concussion. Improper use or fit of helmets increases injury risk. A recently designed shoulder pad that incorporates a cooling system has been shown to decrease core body temperature, thus potentially decreasing the risk of heat-related illness. Improvements in coaching technique and rule changes have reduced the risk of cervical spinal injuries in football. Coaches have taught players not to use the top of their helmets to tackle, block, or strike opponents and that contact should always be made with the head up and never with the top of the head or helmet. The "spearing rule," which penalizes players for lowering their head and making contact with the top or crown of the helmet, was implemented at the college and high school levels in 1976. This rule change caused a dramatic reduction in the number of quadriplegic injuries.

Soccer

Shin guards decrease the average force transmitted to the leg during trauma and decrease the risk for tibia fracture. Like other types of protective gear, shin guards must be used properly and worn during the game or practice to reduce the risk of injuries. A change in the anchoring of soccer goalposts has decreased the risk of head trauma: Padding systems on stationary goalposts in soccer have a similar effect to breakaway bases in softball and baseball—a reduction in injuries without altering the enjoyment or flow of the game, with the benefit of a potential reduction in associated health care costs.

Ice Hockey

In hockey, catastrophic head, neck, and eye traumas have decreased with the use of helmets, full face masks, and mouth guards, and the incidence of traumatic blindness has significantly lessened. Studies have concluded that full face masks offer the best protection against facial, eye, and head injuries without an increased risk of neck, concussion, or spinal cord injuries. Mouth guards decrease the risk of dental and oral-facial trauma. Body checking accounts for many injuries in young athletes, and many organizations have imposed restrictions on this for youths below certain ages.

Overuse Injuries

The type, frequency, intensity, and duration of training play a major role in the etiology of overuse injuries. The etiology of overuse running injuries, for example, includes extrinsic factors (training errors, use of old shoes, running surface irregularities) and intrinsic factors (poor flexibility, malalignment). The risk of injury is higher in an individual with poor alignment and flexibility who is wearing old shoes and running more than 40 miles (mi)/week on rough, hard terrain than in an individual with good flexibility, normal alignment, and new shoes who is running fewer than 30 mi/week on flat, soft terrain.

Playing Technique

Research has focused on the playing technique. One area of particular interest is the high rate of noncontact anterior cruciate ligament (ACL) injuries in young female athletes engaged in contact or cutting sports such as soccer and basketball. Prospective studies have shown a significant decrease in ACL injuries in female athletes engaged in soccer and basketball who are taught a structured technique of cutting and turning before engaging in their sports. Their rate of injury was significantly less compared with controls.

Prevention of Sports Injuries

Risk factor determination for sports injuries is paramount to designing prevention programs. Before preventive measures can be implemented effectively, it is critical to determine what types of injuries occur, who sustains them, and why they occur. This continues to be challenging to definitively determine. Injury surveillance programs currently in place and those being developed will help facilitate this. However, it is critical to refine the methods of data collection and to attempt to minimize the fragmentation of reporting. Through effective programs, sports injury reduction will be achievable.

Rotator Cuff Tears, Partial

The *rotator cuff* is made up of four muscles whose tendons merge to be inserted on the humerus. The subscapularis is anterior, and the suprapinatus superior and the infraspinatus with teres minor are posterior. The function of the rotator cuff is to keep the humeral head centered on the glenoid of the scapula, thus optimizing the effect of the other muscles around the shoulder. The rotator cuff can also initiate movement by itself.

This group of tendons can frequently tear. A tear that does not involve the full thickness of one or more tendons is called a *partial tear*.

Types

There are three types of partial tears: (1) bursal-side tear (BT), confined to the bursal (outer) surface of the tendon; (2) intratendinous tear (IT), found within the tendon; and (3) joint-side tear (JT), present on the side of the tendon adjacent to the joint (inner side).

Incidence

The true incidence of partial tears is not known. Most data have been obtained from cadaver and imaging studies. Yamanaka and Fukuda reported an incidence of supraspinatus partial-thickness and full-thickness tears of 13% and 7%, respectively, in a group of 249 cadaveric specimens in 1987. Partial-thickness tears were further grouped as bursal sided (2.4%), intratendinous (7.2%), and articular sided (3.6%). However, several authors have noted that, clinically, articular-sided tears are two to three times more common than bursal-sided tears. In fact, in a population of young athletes, articular-sided tears constituted 91% of all partial-thickness tears.

Partial tears of the suprapinatus are the most common, but tears can also occur in the infraspinatus and subscapularis.

Pathology

Causative factors can be broadly categorized as either intrinsic or extrinsic to the rotator cuff tendons.

Intrinsic causes may be subclassified into metabolic and vascular changes that lead to degenerative tearing or intratendinous lesions developing from shear stress. A zone of relative poor blood supply is seen on the articular surface of the rotator cuff 1 to 2 centimeters from its insertion on the humerus. This area is particularly at risk for tear.

Extrinsic causes include subacromial impingement (trapping of the tendon by the acromial spur), shoulder instability (typically anterior), internal impingement (trapping of the tendon by the humeral head), a single acute traumatic injury, or repetitive microtrauma.

Often, more than one of these factors (either intrinsic or extrinsic) is responsible for the development of a partial-thickness tear. The articular surface of the rotator cuff has an ultimate stress to failure that is approximately half that of the bursal surface, with thinner and less uniformly arranged collagen bundles. It is believed that articular tears are due to intrinsic pathologic changes of the rotator cuff, whereas bursal-side tears are associated with subacromial impingement on an underlying, milder pathologic change of the rotator cuff.

Diagnosis

Pain, especially at night, is the most irritating symptom. Partial tears can be more painful than full-thickness tears.

The results of impingement tests, such as the Neer and Hawkins tests, with or without subacromial local anesthetic injection, are often positive in the presence of partial-thickness rotator cuff tears, although occasionally these test results are negative, especially in the high-level, well-conditioned athlete.

> *Neer test:* The Neer impingement sign is elicited when the patient's rotator cuff tendons are pinched under the coracoacromial arch. The test is performed by placing the arm in forced flexion with the arm fully pronated (thumb pointing to the floor). The scapula should be stabilized during the maneuver to prevent scapulothoracic motion. Pain with this maneuver is a sign of subacromial impingement.
>
> *Hawkins test:* The Hawkins test is another commonly performed assessment of impingement. It is performed by elevating the patient's arm forward to 90° (with the elbow bent) while internally rotating the shoulder forcibly. Pain with this maneuver suggests subacromial impingement or rotator cuff tendinitis.

Loss of supraspinatus muscle strength with complete or near-complete resolution of pain after a subacromial injection of local anesthetic suggests the presence of a full-thickness rotator cuff tear, whereas maintenance of strength with or without pain on supraspinatus testing suggests either rotator cuff inflammation or a partial-thickness tear.

Evaluating Rotator Cuff Strength

The following tests are used to evaluate the strength of the rotator cuff muscles:

> *Supraspinatus test (empty-can test):* Abduct the shoulders to 90° in forward flexion with the thumbs pointing downward. The patient then attempts to elevate the arms against the examiner's resistance.
>
> *Infraspinatus test:* With the arms at the sides, the patient flexes both elbows to 90° while the examiner provides resistance against external rotation.
>
> *Subscapularis test (lift-off test):* The patient rests the dorsum of the hand on the back, in the lumbar area. Inability to move the hand off the back by further internal rotation of the arm suggests injury to the subscapularis muscle.

The examination is completed by assessing the shoulder for associated pathology such as instability, biceps lesions, and capsular contractures (loss of internal rotation), which can cause internal impingement.

On plain X-ray, a subchondral cyst in the greater tuberosity may also be seen in the presence of rotator cuff pathologic abnormalities.

Ultrasound is a valuable and cost-effective procedure, although it is very operator dependent. It can detect partial tears with an accuracy of over 90%.

Magnetic resonance imaging (MRI), with injection of a contrast medium into the shoulder (arthrography), is the most accurate method of imaging. A significant advantage of MRI, and more specifically magnetic resonance arthrography, is the ability to diagnose concomitant abnormalities, which is critical to providing optimal treatment. Placement of the arm in a position of *ab*duction and *e*xternal *r*otation (ABER view) has also been a useful adjunct to routine imaging to identify not only articular-surface tears but also biceps lesions.

Diagnostic arthroscopy allows both diagnosis and treatment of partial tears.

Treatment

The treatment depends on the associated conditions. If an isolated problem is diagnosed clinically and radiologically, then initially nonoperative treatment can be attempted. Alternatively, patients may undergo operative treatment.

Nonoperative Treatment

Patients with partial-thickness tears due to suspected external acromial impingement are treated similarly to those with rotator cuff tendinopathy and subacromial bursitis. Activity modification with avoidance of overhead or pain-provoking activities is recommended, along with a short course of a nonsteroidal anti-inflammatory medication to reduce the associated pain and inflammation of the condition. A dedicated physical therapy program is recommended, with specific attention directed toward reestablishing and/or maintaining normal shoulder kinematics with stretching of the contracted capsular structures.

Anterior capsular tightness is addressed by stretching in external rotation with the arm at the side to avoid placing the shoulder in a zone of impingement (60°–120° of abduction). Posterior capsular contractures are eliminated by stretching with the arm in adduction and internal rotation and horizontal, cross-body adduction. Thermal modalities (e.g., moist heat, ultrasound) can be used to facilitate the reduction of pain and improve motion, although data to support their use are limited. Subacromial or intraarticular corticosteroid injections can also be used judiciously, depending on the location of the tear, for those patients with persistent symptoms unresponsive to other means of pain reduction. No more than two or three injections are recommended because of their potentially deleterious effect on the rotator cuff tissue, especially in younger athletes. As pain decreases and shoulder motion improves, attention is focused on strengthening the rotator cuff and periscapular musculature. Strengthening of the shoulder girdle musculature is recommended to restore normal scapulothoracic mechanics to stabilize the platform on which the glenohumeral joint functions. Left unaddressed, scapulothoracic dyskinesia increases the likelihood of extrinsic acromial impingement on the rotator cuff.

Throwing athletes with coexistent anterior shoulder instability, internal impingement, or both are treated similarly, with pain reduction through the use of anti-inflammatory medications and strengthening of the muscles of the rotator cuff and shoulder girdle complex. Particular emphasis should be placed on stretching the contracted posterior capsular tissues, which have been shown to result in the loss of internal rotation.

Eccentric and plyometric strengthening of the rotator cuff should be included in the rehabilitation program to mimic the deceleration and follow-through phase of the throwing motion. Trunk and lower extremity strengthening should also be emphasized during this time, as significant throwing strength is generated from these areas. Attention to core strengthening reduces the degree of effort that the shoulder and arm must exert to produce power during throwing. Restoration of correct throwing mechanics is followed by a progressive throwing program specific to the demands of the patient's sport.

Operative Treatment

Operative treatment is still controversial, and clear guidelines are not available. The options include

- debridement,
- rotator cuff repair, and
- debridement/repair with or without subacromial decompression (removal of the acromial spur).

Bursal tears generally do poorly with debridement alone, and repair is preferred, especially given its better blood supply.

Indications for repair of articular-sided tears are controversial, but generally, repair is indicated if the tear involves greater than 50% of the tendon.

Intratendonous tears are treated by debridement of the nonviable tissue and repair of the defect with sutures.

Outcomes of Treatment

With conservative treatment, 80% of tears will improve. The best form of treatment for the overhead athlete is a matter of debate, with good results reported with both debridement and repair. Treatment for the baseball pitcher is problematic, with poor results reported for debridement alone and a significant risk of failure to return to the previous level with repair.

Rotator Cuff Tendinopathy

Rotator cuff tendinopathy is a common cause of shoulder pain and results in a substantial number of doctor visits annually. Shoulder pain can have many sources, but rotator cuff disorders are highly prevalent in the athletic population. In particular, sports that require overhead activity put athletes at higher risk. These sports include swimming, tennis, baseball, golf, volleyball, and gymnastics.

Traditionally, the term *tendinitis* has been used to describe a painful tendon injury. However, as clinicians and researchers have begun to learn more about what causes dysfunction and pain in tendons, the term *tendinitis* is less widely used to describe tendon injuries. Instead, beyond the initial acute injury, the terms *tendinopathy* and *tendinosis* are increasingly used to describe chronic tendon disorders.

Anatomy

The shoulder joint is one of the most complex joints in the human body. In discussing rotator cuff tendinopathy, we will be referring to the *glenohumeral joint*. This joint is composed of the glenoid fossa (socket) of the scapula (wing bone) and the head of the humerus bone (upper arm bone). Because of the structure of this joint, a human is able to reach up overhead and across the body or even scratch his or her own back, a remarkable range of possible motions for one joint. However, because of this extreme range of motion, the body needs many large and small muscles to hold the glenohumeral joint in place. The rotator cuff, composed of four muscles, acts as the primary source of this stability. The four muscles are the supraspinatus, infraspinatus, teres minor, and subscapularis. They form a roof over the head of the humerus, securing it in the glenoid fossa.

Among the four rotator cuff muscles, the supraspinatus muscle and tendon are the most commonly injured. This is thought to be partly due to their anatomical location in the shoulder. The supraspinatus muscle courses from an attachment on the scapula outward to its tendinous attachment on the humerus. As they pass over the head of the humerus, the muscle and tendon travel underneath a forward projection of the scapula called the acromion process (Figure 1). As the glenohumeral joint moves, the supraspinatus structures can be pinched in between the acromion and the head of the humerus, causing injury.

Causes

Two separate forces cause rotator cuff tendinopathy. These are commonly referred to as the *intrinsic* and *extrinsic* mechanisms. Intrinsic forces refer to changes in a tendon, and extrinsic forces refer to factors involving the structures surrounding a tendon.

The intrinsic mechanism refers to overload and degeneration of the tendon with sports activity. A tensile force placed across the tendon of a rotator cuff muscle during a contraction of the muscle can cause overload and eventual breakdown of the inherent tendon structure. Repetitive tensile overload especially puts the tendon at risk for injury. A baseball pitcher provides a good example for this. As a pitcher decelerates his or her arm after releasing the ball, the rotator cuff muscles around the shoulder contract in order to help stabilize the joint, placing a large amount of force across the tendon. Repetition of this motion hundreds of times can predispose the tendon to breakdown and continued degeneration.

The extrinsic mechanism refers to the compressive forces applied to the tendon from the surrounding

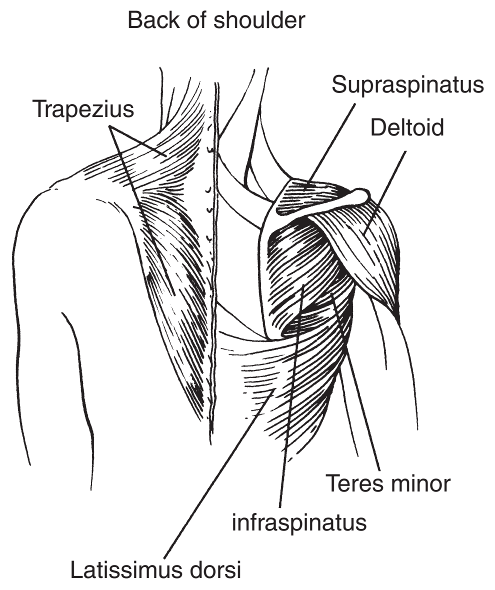

Figure 1 Muscles of the Shoulder

Note: Back view, showing the muscles of the rotator cuff.

structures. Various structures in the shoulder can be the source of compression, the most common being the undersurface of the acromion process. As the arm is brought overhead, the rotator cuff muscle or tendon can become entrapped between the humeral head and the acromion. This may cause microdamage, including contusion or tear to the tendon and muscle. This microdamage causes inflammation and dysfunction within the muscle, causing more instability and secondary compression and breakdown, thus creating a degenerative cycle of injury.

Symptoms

Athletes with rotator cuff tendinopathy will complain of pain with any overhead activity. Initially, the pain will only occur during the causative sport-specific activity, but it may progress to include normal daily activities, such as putting on a shirt or brushing their hair, as the severity of the tendinopathy increases. The shoulder pain will often be present at night, especially when lying on the affected shoulder. Apart from pain, athletes will also experience a measurable decline in performance, such as decreased speed or accuracy in a pitcher or decreased endurance in a swimmer.

Diagnosis

To determine if an athlete's shoulder pain is due to rotator cuff tendinopathy, a complete shoulder exam is required. The physical exam will begin with a thorough neck exam to make sure that a nerve problem in the neck is not the cause of the shoulder pain. During exam of the shoulder, the athlete will be asked to move the shoulder through all planes of motion, to look for deficits. If rotator cuff tendinopathy is present, the athlete will have pain with movement and in particular when bringing the arm over the head, a motion commonly referred to as the "painful arc." Other findings on the physical exam consistent with rotator cuff tendinopathy include weakness with rotator cuff strength testing as well as a positive Neer test or Hawkins-Kennedy test. The Neer and Hawkins-Kennedy tests attempt to cause external compression of the rotator cuff and consequently re-create the patient's pain.

X-rays may be used during the initial evaluation of shoulder pain. The size and shape of the acromion can be assessed to determine the likelihood of compression of the rotator cuff against this structure. Otherwise, in the athletic population, not much is learned from plain X-rays.

Apart from X-rays, two other imaging modalities may be used to explore for evidence of rotator cuff tendinopathy. One imaging technique commonly used is magnetic resonance imaging (MRI). An MRI scan is used to determine the extent of injury and may show inflammation or injury within the rotator cuff tendon, atrophy (shrinking) of the rotator cuff musculature, or extra fluid surrounding the affected tendon-muscle structure (a response to injury). Ultrasound can also be used to determine the extent of injury if rotator cuff tendinopathy is suspected. In addition to what is noted on the MRI scan, an ultrasound evaluation can be used to assess the health of the affected tendon and to note any microdamage of that tendon or even of the humeral head.

Diagnosis can be made based on the symptoms and physical exam alone. However, further imaging with X-ray, MRI, or ultrasound can be used to help confirm the diagnosis and to aid in creating the athlete's treatment plan.

Treatment

The basic treatment of rotator cuff tendinopathy can be divided into *acute* and *subacute* therapy. In the absence of a severe rotator cuff tear, the treatment of rotator cuff tendinopathy is nonsurgical.

Acute Therapy

Acute therapy is required after the initial evaluation of the athlete, particularly if there is significant shoulder pain or dysfunction. This therapy consists of rest, cryotherapy (ice), and nonsteroidal anti-inflammatory medications (NSAIDs; e.g., ibuprofen). To have proper rest, the athlete must avoid any aggravating activity, including all overhead motion. Cryotherapy can be used in the first few days following diagnosis to aid in pain relief and help reduce inflammation. NSAIDs are believed to also aid in pain relief and the reduction of inflammation. These medications are typically used for 10 to 14 days during the acute period and only as needed thereafter.

If there is significant pain and dysfunction, a referral to a certified physical therapist (PT) or doctor of physical therapy (DPT) may be pursued for additional acute adjunct therapies. These may include electrical stimulation (E-stim), phonophoresis or iontophoresis, and therapeutic ultrasound. These additional therapies may also be performed by a certified athletic trainer (ATC) if the athlete has access to one. Phonophoresis and iontophoresis use sound waves and electrical current, respectively, to push anti-inflammatory medication through the skin to the site of injury. An additional adjunct therapy that may be used for the treatment of rotator cuff tendinopathy is acupuncture.

Subacute Therapy

Physical Therapy

The use of physical therapy for the treatment of rotator cuff tendinopathy has a variety of goals. Acute therapeutic goals, as discussed above, include pain relief and the reduction of inflammation. Thereafter, the next goal should be to achieve the return of full, nonpainful range of motion in the shoulder joint. For the most part, physical therapy cannot be progressed until full range of motion has been achieved. After this motion is regained, the therapy will then be used to restore the strength and function of the rotator cuff muscles. In addition to strengthening the four rotator cuff muscles, the rehabilitation program will aim to restore the function of all the muscles surrounding the shoulder, including those that control the movement of the scapula.

At the end of a routine rehabilitation treatment program, the patient will be able to return to normal activities of daily living. However, in the treatment of athletes, the goal lies far beyond these basic activities. Sports place much greater demands on the shoulder joint than normal activities of daily living. Therefore, after full range of motion and strength have been restored, the athlete will be guided through a sport-specific prehabilitation program. The additional prehabilitation aids in the return to sport-specific activity by simulating the demands of the athlete's sport. For example, tennis players may perform a service-type motion using a 5-pound dumbbell as they progress back to sport.

Other Treatments

Most athletes will find improvement and/or resolution of symptoms with the above treatments. However, if no improvement is seen in 2 to 3 months, other methods of treatment should be considered:

Steroid injection: Often in sports medicine, a physician will use an injection of a steroid solution into a joint if chronic inflammation is thought to be the cause of the joint pain and dysfunction. Shoulder pain is no exception, and steroid injections are often used for the treatment of rotator cuff tendinopathy. A glucocorticoid solution is the medicine used for injection, in combination with a local anesthetic such as lidocaine or marcaine. Typically for rotator cuff tendinopathy, the goal of injection is instillation of medicine into the subacromial space, the area between the acromion and the head of the humerus.

Surgery: In the absence of a rotator cuff tear, surgery is rarely indicated for rotator cuff tendinopathy. However, if there is no improvement in the athlete's shoulder pain after completing 3 months of the above therapies, surgical exploration may be considered. Minimally invasive arthroscopic surgery is performed to confirm the diagnosis and, if present, to repair the damaged rotator cuff tissue.

Rowing, Injuries in

Rowing is a sport that has existed for centuries and was one of the first sports included in the modern Olympics. It consists of two main categories: *sweep rowing* and *sculling*. In sweep rowing, sometimes referred to as crew, each rower holds one oar and places it in the water on the rower's right (starboard) or left (port). Sweep events include the pair, four, and eight. While the eight always has a coxswain (the person who steers the boat and commands the rowers), there are separate event categories for the pair and four with coxswain (coxed pair and coxed four) and without coxswain (straight pair and straight four). In sculling, each rower has two oars and places them in the water simultaneously on each side of the boat. Sculling events include the single, double, and quad (one, two, and four rowers, respectively).

The rowing stroke is composed of four different parts: the catch, drive, finish, and recovery. At the catch, the body is fully compressed, and the oar handle is rotated and lifted to place the blade into the water. The drive consists of extending the legs and then swinging the back past 90°. At the finish, the arms carry the momentum generated by the legs and back by pulling the handle to the body and then pressing the oar down and rotating it out of the water. The final phase of the stroke is the recovery, the reverse of the prior two phases. Here, the arms extend away from the body, the body pivots forward at the hips, followed by the legs compressing back into the catch. The rower moves on a seat with wheels in the boat while repeating the phases of the stroke.

In addition, there are two weight categories: open weight (no weight restriction) and lightweight (in general, 126-pound (lb) boat average with 130-lb individual maximum for women and 155-lb boat average with 160-lb maximum for men). There are slight variations to these rules depending on the event and regatta. The weight control methods of lightweights should be monitored, as excessive caloric restriction and other weight loss techniques can increase the risk of injury and illness. Lightweights are at risk for eating disorders, and female lightweights are at risk for the female athlete triad, both of which are addressed in other entries of this encyclopedia.

Rowing on the water or performing the rowing motion on an ergometer (on-land rowing machine) has great cardiovascular benefits as well as skeletal benefits for the spine. However, because rowing involves repetitive movements, this sport can lead to overuse injuries. This risk is increased as rowers aggressively increase training loads on the ergometer, on the water, and in the weight room. Tissues adjust to increased training loads at different rates. Muscles adapt most quickly, followed by bones, ligaments, tendons, and then cartilage. Thus, in addition to muscular injuries, as loads are increased when muscles adapt sufficiently, excessive strain is placed on the other tissues, leading to fractures, inflammation, and/or tears.

During the drive, up to 4.6 times the body weight is loaded on the lumbar region. Along with back extension and flexion, sweep rowing involves a twisting motion of the spine in the direction of the oar. The back is therefore the most commonly injured site in rowing. Injuries include vertebral disk problems (bulges, herniations, etc.), spinal fractures (spondylolysis and spondylolisthesis), and muscle strains. Even the sacroiliac (SI) joint may sometimes become painful because of rotational stress at the site, leading to partial shifts in a joint that is typically nonmoving.

The repetitive strain on the upper body may also lead to rib stress fractures and/or muscle and cartilage injuries near the ribs. The rowing stroke involves simultaneous activation of the intersecting serratus anterior and external oblique muscles, which both attach to the ribs and have partially opposing actions. This can cause strain at the ribs, sometimes leading to a stress fracture. The intercostal muscles are located between the ribs and help move the chest wall with inspiration and expiration. These too can become injured with repetitive deep breathing and resistance throughout the stroke. Costochondritis (inflammation where the ribs attach to cartilage at the sternum) may also be a result of this overuse.

While the power needed to propel the boat through the water largely comes from the back and legs, the placement of the oar(s) in the water and the turning of the oar handle when removing the oar from the water (feathering) require upper extremity dexterity. Without a relaxed, proper grip on the handle, athletes may develop wrist and forearm complaints such as carpal tunnel syndrome and intersection syndrome (crossover tendinitis: inflammation of the tendons that cross over one another in the forearm).

Significant leg injuries are less common in rowers than injuries in other areas of the body, but the hyperflexion and extension of the knee at the catch and finish of the stroke, respectively, can lead to knee pain as the knee cap (patella) shifts (patellofemoral syndrome) and the iliotibial (IT) band on the outside of the leg becomes tight (IT band syndrome). There have also been cases of hip labral (lining) injury, believed to have occurred from the extreme flexion and extension rowers use in the sport. In the upper and lower limbs, numbness can sometimes occur when nerves become entrapped as muscles swell and are not properly, regularly stretched.

Finally, because of the contact of the hands with the oar, the buttocks with the seat, and the calves with the tracks on which the seat slides, these areas are all at risk for skin abrasions, calluses, and infections.

Most rowing injuries may be prevented with good technique, appropriate stretching, strengthening of the opposing muscles, and decreasing the volume of activity or cross-training when pain begins. However, when the pains do not resolve with conservative measures, the athlete's technique should be scrutinized, and he or she should be evaluated by a health professional. Physical therapy and modification of technique may improve muscle strains and tendinitis. Rest and bracing may be needed for more serious injuries. Surgery for vertebral disk injuries, carpal tunnel syndrome, patellofemoral pain, and labral tears is recommended only for recalcitrant cases.

Rugby Union, Injuries in

Rugby union is a highly physical game played by more than 3 million men, women, boys, and girls ranging in age from 6 to 60 in more than 100 countries across five continents. It is a collision team sport with a significant risk of injury. Injuries can be sustained by every part of the body, but the injury profile of the game is relatively consistent with respect to which injuries occur most commonly and which cause the greatest numbers of days lost from playing and training. Those providing medical care to rugby union players need to offer best-practice treatment protocols for these injuries and develop specific injury prevention strategies for the injuries that cause the greatest numbers of days of absence.

The Modern Game

The game is played by two teams of 15 players each on a field measuring a maximum of 100 meters (m) by 70 m plus 2 m in goal areas. Teams attempt, by carrying, passing, kicking, and grounding the ball, to score as many points as possible. The laws of the game, governed by the International Rugby Board (IRB), aim to minimize the risk of injury and ensure that the game is played in a sporting spirit by people of all shapes and sizes while emphasizing that the contest for possession is paramount. There are specific law variations for those under 19 years of age and for seven-a-side rugby union. Senior rugby is a collision sport consisting of two 40-minute halves, comprising passages of open play interspersed with up to 500 contact/collision events per game, approximately 50% of which are tackles (where one or more tacklers attempt to stop or impede the ball carrier with the use of their arms) and 25% are rucks (where players from both sides attempt to drive over the grounded, tackled player and ball). A maul develops when a tackled player is not forced to the ground and players attempt to wrestle the ball free. A unique element of the game, the scrummage, is used to restart play after a range of infringements. Eight forwards from each side link arms in a 3-4-1 formation, and the players in the front rows of each pack of eight lock heads with their opposite numbers. A lineout is used to restart play if the ball passes out of play over the sideline. Here, the team that did not send the ball out of play throws the ball down the middle of two lines comprising at least two players from each team, who compete for the ball in the air.

Rugby Union Injuries

Incidence

Injuries occurring during matches constitute the largest proportion of the rugby-related injuries reported, typically accounting for 80% to 90% of all injuries. The great majority of match injuries are the result of direct contact with an opposing player. The risk of sustaining an injury in a rugby union match appears to be higher than in many other sports irrespective of the definition of injury. However, the incidence is much lower in senior amateur (15–74 injuries per 1,000 player-hours), schoolboy (7.0–28), and women (3.6–7.1) players than in professional players (68–218). The severity of rugby union injuries is typically reported in terms of days lost from playing and training. The average elite senior game typically results in two players from each side being injured for an average of 18 days each.

Injury Profile

The lower limb is the most common location of injury, with the proportion of injuries sustained ranging from 41% to 55%. More specifically, the knee, the thigh, and the ankle are the sites most commonly injured. Also, injuries to the lower limb, in particular knee joint injuries, appear to be disproportionately severe. Medial collateral ligament (MCL), chondral/meniscal, and patellofemoral/extensor mechanism injuries are the most common knee injuries; however, anterior cruciate ligament (ACL) and MCL injuries cause the greatest number of days of absence. Thigh hematomas

Rugby union scrum. Due to the frequent physical contact in the game, the incidence of collisions is relatively high, as is the risk of sustaining an injury.

Source: Can Stock Photo.

("dead legs") and hamstring muscle strains are the most common thigh injuries; the impact of hamstring muscle injuries, in particular, on the overall injury burden may be reduced by appropriate eccentric hamstring training and complete rehabilitation of these injuries. Lateral ankle ligament injuries are the most common ankle injury and, together with Achilles tendon injuries, make up the greatest proportion of ankle injuries that lead to absence from play and training.

Head and noncatastrophic neck injuries frequently represent the next highest proportion, ranging from 12% to 33% of all injuries, although variations in the definition of injury employed can alter these proportions significantly. Lacerations to the head and face and concussions are the most common head-and-neck injuries, followed by facial fractures.

The upper limb represents a smaller proportion of the injuries (15%–24%); of these, shoulder injuries are the majority. Shoulder injuries also appear to be disproportionately severe. Acromioclavicular joint and rotator cuff injuries are the most common shoulder injuries, although shoulder dislocations and clinical episodes of shoulder instability lead to the greatest number of days lost from play and training. The injury profile in schoolboy players is similar to the profile seen in senior players but is characterized by a higher proportion of upper limb injuries.

Injury Events

Tackles are the match event responsible for the highest number of match injuries and the greatest time lost from play and practice because they are by far the most common contact event. The relative propensities (assessed by comparing how often an event is associated with injury against the frequency [%] with which the event occurs in the game) of contact events to cause injury are scrum and collision, high; maul and tackle, average; ruck, low; and lineout, very low.

Specific Injuries

Catastrophic Spinal Injury

Nonfatal catastrophic (spinal) injuries have received considerable focus in the medical literature due to their devastating consequences. These are defined as a brain or spinal cord injury that results in permanent (>12 months), severe (>50% loss) functional disability and is usually the consequence of a fracture dislocation of the cervical spine (at C4-C5 or C5-C6). Nevertheless, these injuries are extremely rare, with a historical aggregated worldwide incidence of between 1 and 5 cases per 100,000 players per season. The vast majority (approximately 80%) of cases are split equally between the scrum and the tackle. There have been a number of changes to the laws of the game in an attempt to reduce the risk of these injuries. In January 2007, the process by which the two front rows come together (engage) at the scrummage was modified in an attempt to reduce the force of impact and further control the engagement process. Early reports on the consequences of this law change are positive. The importance of optimal on-the-pitch management, appropriate cervical immobilization, and urgent transfer to a specialist unit in optimizing the long-term outcome of these injuries cannot be overstressed.

Concussion

The incidence of concussion in the elite game is reported to be 4.1 per 1,000 player-hours. Concussion in rugby union is evaluated and managed by standard clinical procedure. Subsequent return to play is guided by IRB Regulation 10, which states that the concussed player should undergo a mandatory 21-day stand-down from playing and training unless he or she is symptom-free and is cleared to return to play by an appropriately qualified neurological specialist. Approximately half the asymptomatic elite players with access to specialist medical advice return to play in 7 days or less. At the under-19 level and below, the 21-day stand-down is mandatory.

Blood Injuries

The laws of the game allow for the temporary replacement of a bleeding player for up to 15 minutes so that the bleeding may be controlled. In all other circumstances, the replacement of an injured player is permanent and cannot be reversed during a game.

Injury Prevention Strategies

General

Rugby injury causation is multifactorial in nature, and injury prevention strategies need to minimize the effect of the interplay between

- intrinsic player risk factors (typically by increasing the resilience of the player to injury through conditioning and prehabilitation initiatives) and
- exposure to extrinsic risk factors (typically by protecting the athlete by optimizing the player's technique in all elements of the game and ensuring that the laws of the game are consistently applied).

Comprehensive injury prevention programs (such as New Zealand's RugbySmart program) are increasingly showing that a reduction in injury risk is achievable without altering the essential nature of the game.

Padded Equipment and Headgear

One potential method of reducing injury risk is by the wearing of padded equipment and mouthguards; although there is no stipulation that this equipment must be worn in the laws of the game. The thickness and density of the shoulder pads, headgear, and chest pads that may be worn during matches is restricted by the IRB. Research to date indicates that padded headgear does not reduce the incidence of concussion in rugby union and shoulder pads do not reduce the incidence of shoulder injuries, although a reduction in the incidence of superficial scalp and facial injuries in selected positions when headgear was worn has been demonstrated. Mouthguard use, principally to reduce dental injury, is strongly encouraged but not mandated in rugby union.

Running a Sports Medicine Practice

During the past half-century, numerous major advancements in medical science and technology, performance enhancement, and injury prevention and rehabilitation have had an impact on sports medicine. While these improvements have not dramatically changed the nature of sports medicine, they have changed its practice. In a period of rapid change, the demands of modern sports medicine, combined with changes throughout the health care system, have required new ways of organizing and managing the business of a sports medicine practice.

Sports medicine is the medical subspecialty that is generally concerned with one overarching mission: the prevention, diagnosis, and treatment of illness and injury related to participation in any athletic exercise or contest. To accomplish a mission as comprehensive as this, much depends on having a multidisciplinary, complementary approach to health care delivery that uses both operative procedures and nonsurgical techniques. This has been the basic element of sports medicine practice since the days before Galen's remedy for wounded tendons led to his appointment as physician to the gladiators in Greece during the second century CE. But more recently, several significant social transformations have made new demands on the practitioners of sports medicine.

More than at any other time in history, the 20th century brought to sports at least two interrelated changes that had a direct bearing on sports medicine:

(1) the increasing specialization of the medical profession, in large part due to the rise of people who used their knowledge and learning as a basis for developing skills that allowed them to perform highly specialized, productive work in fields such as athletic training, physical therapy, nutrition, psychology, sport science, and coaching; and (2) increased access to, news about, and participation in recreational-, amateur-, and professional-level athletic activity. The latter of these changes alone required that medical practitioners be knowledgeable about a wide array of physical, physiological, psychological, and environmental factors across a diverse population. What emerged as a result was a context of sports medicine that gave a new status and function to its practitioners.

This new reality encouraged the establishment and proliferation of sports medicine clinics. The sports medicine clinic intends to provide a single location in which all manner of evaluation, testing, and treatment can be offered to the patient-athlete. The comprehensive activities of analysis and prescription that occur within it are performed by a cooperative variety of specially educated, trained, and experienced practitioners. Sport medicine clinics are wide-ranging in size and function and often go beyond the domain of physicians and surgeons to include athletic trainers and physical therapists, coaches and sport scientists, nutritionists, psychologists, podiatrists, chiropractors, masseuses, and other such professionals.

Today's sports medicine clinics are an outgrowth of partnerships such as that of Robert Kerlan and Frank Jobe, who began acting as physicians and orthopedic consultants to a number of professional sports teams in the United States during the mid-1950s and 1960s. Although a good many physicians and surgeons throughout the world—and especially in Europe—had for centuries contributed to the development and breadth of sports medicine, the practice and clinical research led by Kerlan and Jobe produced numerous innovative surgical procedures that were in turn used to treat any patients who required orthopedic care.

While such enterprises have since become increasingly commonplace, sports medicine continues to be practiced and administered in clinical settings of all sizes, extents, and locales. For instance, family medicine physicians and physiatrists, like orthopedic surgeons, have built on the training of their residency programs by undergoing subspecialty training in sports medicine. As subspecialists, they can command higher rates of insurance reimbursement for clinical work and have to deal much less with traditional family medicine responsibilities such as overnight calls and patients who are hospitalized for longer periods of time. But regardless of the pathway one takes, the leadership of a sports medicine practice requires the competence, skill, and responsibility of a physician, as in any medical practice.

Tasks, Demands, and Implications

The term *sports medicine* denotes a specific practice area. But it is not adequate to reduce its function and work to a single description. Sports medicine physicians, often with the assistance of various medical staff and administrative personnel, may practice in clinics, private offices, and in athletic teams' facilities. Though these practices are among the few health care businesses that remain consistently lucrative, sports medicine is not immune to all the forces that have an influence on medicine and health care today. And they are also affected by many of the same forces that have an impact on any of today's small- and medium-sized businesses.

As for any organization, the first and most important question in managing a sports medicine practice is to determine its specific purpose and mission. What the practice sets out to do, how it will perform, what impact it will have, and what services it will discharge for the benefit of patients and the community are of utmost importance. The basic definition of the practice governs the types of patients it will provide care for and how it will go about doing so.

Because patients have individually different reasons for accessing the sports medicine practice, the physician, as leader of the practice, must define the mission accordingly. This is achieved not by looking at what the physician thinks the practice should be but by looking at the needs, interests, expectations, and values of existing and potential patients. Constant changes in population structure and behaviors can make this a difficult task. Yet the physician has to pay attention to which aspects of the practice will satisfy the patient. The physician must therefore decide on what parts of the practice should be maintained or abandoned and how those decisions fit the purpose and mission. Such consideration helps the patient better understand the services offered by the practice; it also helps employees of the practice better understand how and where they contribute to the endeavor.

Of further consideration for the physician and other managers of the practice is how the practice will attract patients and employees and to what type of facility. There is a consequent need to consider objectives, such as for human resources and capital, financial planning and investment, marketing, information, and technology. There is also a need to think through what results will be expected, how they will be qualified and quantified, and how the aforementioned resources will be used to influence those results. And results are further achieved by recognizing the relative strengths of the practice and the people within it. By defining the mission and converting it into results that are oriented toward action, the performance of the practice can then be planned.

Any of the tasks and demands of a modern sports medicine practice must be measured against the reality that medicine and health care have undergone rapid and enormous changes in the past 40 years or so. Although sports medicine physicians are at times positioned above the fray, they too have come to realize that the professional lives of physicians are increasingly defined by group practice relationships, health maintenance organizations, and corporate and government versions of "managed care." During this span of time, physicians have reported perceptions of decreased control over medical decisions and referral processes and ethical concerns related to the compliance requirements of legislation such as the Health Insurance Portability and Accountability Act (HIPAA). Within these concerns is the potential for some treatment options and explanations to go unexplored due to time, financial, and accessibility constraints. Another subtext that has gained attention of late is the relationship between medical professionals and the pharmaceutical and medical device industries. But there is a range of other professional ethical issues specific to sports medicine that must be regarded to varying degrees depending on the type of practice.

One of the primary responsibilities of any physicians is to keep the patient well-informed about care and treatment options. When it comes to caring for the athlete, the physician must balance the health needs and the athletic goals of the patient—and the two are not always in accord with each other. Sports medicine has historically sought to provide a means of enhancing athletic performance while preventing athletic injury. But as fame and fortune through athletic feats have increased over time, the focus on performance enhancement has superseded the interest in injury prevention, and some of the traditional boundaries of clinical practice have been diminished in the practice of sports medicine. Today's sports medicine physician must be prepared to readjust thinking about how to behave with regard to patient confidentiality and third-party knowledge, informed consent, treatment methods and decisions about return to competition, use of performance-enhancing and recreational drugs, the application of new technology such as genetic engineering, and advertising of services. These factors are especially serious for the team physician, who must also consider any conflicts of interest because of arrangements and affiliations with different sports teams.

As more people participate in more sports and continue to develop even new ones, it is difficult to adequately estimate the extent of sports medicine in today's world. But it is easy to recognize that the precepts that held true in the sports medicine of antiquity are the basic elements around which today's sports medicine practices can organize and manage their business.

Running a Strength Training and Conditioning Facility

The day-to-day operation of a strength and conditioning facility requires a dynamic and knowledgeable staff. Of utmost importance to the staff is the safety and progress of the athletes in training. To provide superior support and guidance, the staff must have superior knowledge, the ability to respond effectively in case of an emergency, and equipment that has been proven safe and effective. The following text will provide guidelines and suggestions to effectively run strength and conditioning facilities for athletes.

Personnel

Recruiting and Staffing

Staffing a strength and conditioning facility is a high priority to ensure effective assistance for athletes in attaining their strength and conditioning objectives for their particular sport. The management, owner, or recruiter who is hiring training staff for the facility should consider the following criteria:

- Applicants should have a degree from an accredited university or college in exercise science or related coursework that highlights exercise physiology, human anatomy, biomechanics, nutrition, exercise prescription, sport psychology, and kinesiology. The National Strength and Conditioning Association has adopted an Educational Recognition Program that provides a list of institutes that meet or exceed these requirements. A bachelor of science (BS) degree is an excellent start for any person who is seeking a career as a strength and conditioning coach; a master of science (MS) degree is preferred by recruiters.

- Personnel with degrees in exercise science or related disciplines should have a minimum of 4 years of coursework and practical application through internships and practicum requirements. Many of these courses, as well as hands-on experience, prepare them for secondary certifications. All strength and conditioning coaches must be certified to administer cardiopulmonary resuscitation (CPR) and to use an automatic external defibrillator (AED). Professional certification organizations requiring continuing education as well as adherence to codes of ethics will increase the credibility of a strength coach's candidacy. The most widely recognized certifying bodies are accredited through the National Commission for Certifying Agencies (NCCA). The American College of Sports Medicine (ACSM), National Strength and Conditioning Association (NSCA), American Council on Exercise (ACE), and National Academy of Sports Medicine (NASM) are among the recognized certifying agencies that strength coach candidates should seek out for credibility. Each organization has different scopes and specialties, so the strength coach seeking additional credibility should research the agencies from which he or she is seeking certification.

- Strength coaches have greater credibility when they have aligned themselves with other health professionals to create what the NSCA calls a "performance team." This is when a candidate or staff has been teamed with other fitness professionals whose specialties complement the specialties of others on the team. For example, a performance team may include a strength coach, nutritionist, athletic trainer, massage therapist, and team physician. This team will help the athlete achieve greater results, especially if the common goal is increased athletic performance and decreased propensity to injury. A dynamic staff with complementary skill sets not only helps the facility to run smoothly but also, by its comprehensive expertise, can prevent the occurrence of incidents that could result in personal injuries and consequent lawsuits.

Staffing Hierarchy and Responsibilities

The staff hierarchy in strength and conditioning facilities is usually different from that of public fitness centers. Apart from the performance team, the staff in the strength and conditioning facility includes a head strength coach, one or more assistant strength coaches, and student coaches or interns. The head strength coach is responsible for all exercises that are implemented to improve the strength and conditioning of the athletes and all other facets of the facility. Some of those facets include, but are not limited to, scheduling the athletes' training times, developing staff skills, delegating staff to athletes and teams, setting up staff hours and responsibilities, keeping open the channels of communication with the performance team and team coaches, and keeping the equipment up-to-date and safe.

Facility

Several very important components factor into the space used for the facility: the square footage that makes up the strength and conditioning facility, the layout of the equipment (i.e., the floor plan), and the location relative to the location of the athletes who will be traveling to the facility.

Location and Program Needs

Determining the location of the facility depends on several variables. First, what is the demographic? Is it composed of youth, high school, or collegiate athletes in the towns or amateur and professional athletes in a state or region, who will be migrating to the facility for their conditioning needs? Second, how many athletes will use the facility? Third, what are the strength and conditioning needs of the athletes who are going to be using the facility? Then, how will the conditioning work into the athletes' schedules? Last, what is the training age of the athletes using the facility?

If the demographic is youth and high school athletes, it is necessary to have the facility allow for the drop-off and pickup of the young athletes. The facility should also have plentiful parking near the facility to accommodate team buses or vans. If the demographic is made up of amateur- or elite-level athletes from the surrounding towns or counties, the facility should be located near major routes so that the commute to the center is simple and accessible.

It is necessary to know how many athletes will be using the facility at peak time. For example, with high school athletes, the strength coach needs to know the maximum capacity of the facility for the safety of the athletes who will be conditioning at one time.

When considering the athlete's conditioning requirements, the head strength coach will need to know the particular requirements of the sport that the athlete plays and the training age of the athlete using the equipment. For example, the ratio of Olympic lifting equipment to resistance training machines may be higher for amateur athletes than for middle school or high school populations, which are relatively new to resistance training. Another consideration is the type of athlete using the facility. If the athletic population is primarily football players, then the need for free weights, plyometric boxes, and Olympic lifting stations is higher than the need for resistance training machines, which would be more applicable to athletes recovering from injury.

It is very important to fit strength and conditioning into the athlete's schedule. The performance team must work together with athletic directors, sports medicine teams, and the governing body that dictates the regulation of the athletes' contact time with coaching staff. For example, the NCAA directs the coaches of collegiate sports teams (with the exception of the strength and conditioning coach) as to the number of formal practices they can have with their athletes during the off-season semester.

Space Considerations

Once a location is found that meets the needs of an effective facility, the design of the strength and conditioning area must also fulfill several requirements:

- Accessibility
- Observation location
- Ceiling height
- Flooring needs
- Environmental factors

Accessibility

Accessibility of the strength and conditioning facility has several implications. Accessibility of the center refers to which floor it is on, the size of the doorways and walkways, and whether these doorways and walkways are unobstructed. The ground floor is ideal for a strength and conditioning facility due to the heavy weights and machinery that will be loaded onto the floor. If the facility is not on the ground floor, then the flooring needs to be stable enough to avoid any structural damage from dropping weights or other heavy equipment. The minimum requirement for load-bearing capacity is 100 pounds/square foot (ft^2), or 488 kilograms/square meter (m^2). To complement the floor's load capability, it should also have sound-absorbing features to avoid disturbance to the dwellings, offices, and classrooms nearby.

Doorways and walkways need to be accessible for the handicapped and large enough to move equipment in and out of the facility. All doors in and out of the strength and conditioning floor must be double doors with a removable middle post. All doorways must remain free of obstructions, especially the emergency exits. These exits must also be well marked with standard lit signs above the doorways.

Observation Area

It is imperative for the strength coaches to have a full view of the strength and conditioning floor, therefore the viewing room or office must have large windows that allow the staff to see all areas when they are not on the floor.

It is recommended that ceiling height have 12 to 14 ft (3.66–4.27 m) of clearance with low-hanging items such as fans; lights; heat, ventilation, and air-conditioning (HVAC) systems; or sprinkler systems. For all structural elements, local building codes must be observed.

Flooring

Flooring needs are very simple in strength and conditioning facilities. The flooring is either carpeting or heavy-duty rubberized material. Carpeting can provide a softer look to the facility and can be any color. It should be located in areas of the strength and conditioning facility where cardiovascular conditioning and stretching are performed. Carpeting should be antibacterial and durable. Rubberized flooring can also be of different colors, thicknesses, and textures. The best thickness for flooring is ⅛ to ¼ inch (in.; 1 in. = 2.5 centimeters). Rubberized flooring is designed as interlocking squares or mats that can be rolled out for large areas. If there is a large enough budget for the facility, then having rubber flooring poured in is the best option due to its durability. More important, there are no seams that the athletes could trip on, or that could become unsanitary over time. It is important to note that if the facility is to have a combination of carpeting and rubberized flooring, it is important to have a smooth transition between the two areas, either with beveled edges from the carpeting to the rubber flooring or having the two areas flush with each other.

Environmental Factors

The training conditions of the facility should be controllable. Lighting, humidity, temperature, circulation, and sound are factors that need to be kept consistent to optimize the environment for strength and conditioning of athletes. The facility needs to be well lit with overhead fluorescent lighting and with windows to allow natural light in as well. Well-balanced lighting throughout the facility allows for better maintenance of equipment and the overall cleanliness of the facility, and the strength coach will be able to better watch the athletes executing the exercises. When setting up the layout for equipment for the facility, it is important to be cognizant of glare from mirrors or from sunlight through the windows, so that when the athletes are performing an exercise, their attention is not distracted by blinding light.

HVAC systems are key to successful training in a strength and conditioning facility. When athletes are exercising in very cold or very hot temperatures, body systems can be taxed to physically dangerous levels. The ACME recommends that the temperature range be between 68 °F and 72 °F (20 °C–22 °C), whereas Armitage-Johnson suggests having the temperature of the facility between 72 °F and 78 °F (22 °C–26 °C) with a relative humidity of 60%. It is preferable to have HVAC systems that can be controlled in different areas or zones of the facility so that warm-up and cooldown areas are slightly warmer than the high-intensity strength and conditioning areas. Indoor temperature should remain consistent because drastic changes in temperature in the facility can cause the relative humidity to increase and therefore cause damage to equipment due to corrosion. Some authorities recommend that an acceptable air circulation in a facility is 8 to 12 air exchanges per hour, while 12 to 15 exchanges per hour is an optimal level. Locker room air exchanges should be slightly higher, at an approximate level of 16 exchanges per hour. Depending on the ceiling height of the facility, ceiling fans can assist in maintaining the level of the air exchanges.

Miscellaneous Facility Layout Needs

Other things to be taken into account when considering the optimal operation of a training facility are electrical supply, telecommunications, storage, mirrors, signage, locker rooms, and water supply. Electrical outlets need to be relatively dense in areas where cardiovascular equipment is located and should be grounded at 110 volts (V). For larger pieces of equipment, such as treadmills, 220 V is necessary. Mirrors should be placed in areas where the form of particular exercises needs to be seen for visual feedback for the athlete and the coaches. Telecommunications include the location of the phone, cable jacks, and wireless routers within the facility. Telephone receivers should be wireless or cordless so that the coach has access to them while training athletes all over the facility. Having wireless Internet capabilities and laptop computers is preferred for immediate record keeping during strength training sessions and uploading data from testing batteries. Water fountains should be installed in strategic locations so that athletes can get to them quickly for hydration without extending the down time between exercises. Locker rooms should be equipped with shower facilities; there should be large lockers for athletic equipment, lavatories, and individual changing rooms. Some of these components may depend on the age and gender of the athletes.

Facility Layout

When deciding the optimal layout of the strength and conditioning facility, multiple factors come into play:

- Grouping like equipment
- Grouping like conditioning areas
- Flow of traffic
- Spacing of equipment

Grouping all strength equipment with similar functionality is convenient for the strength coach and the athletes for two main reasons. The first reason is that it is easier for the strength coach to observe and coach each athlete in a session when they are all together. When observing form and technique for high-level resistance training, the coach's attention should not have to be spread across the entire facility. The second reason for having like equipment in the same area of the facility is to allow athletes who are doing the same exercises to "spot" each other. Thus, athletes and programs can be scheduled so that there is proper spotting and no waiting for the different exercises.

When designing the transition between different conditioning areas in the facility, careful thought needs to be given to determining the locations of the stretching/warm-up, cardiovascular, power, and strength training areas. It is preferable to have the cardiovascular equipment in the carpeted area of the facility (if there is such an area) and near both a wall and a window. This will give the athletes more space for stretching and warming up. The stretching area should be in an area of the facility that does not obstruct the flow of traffic and allows athletes to have plenty of space, approximately 36 to 49 ft^2, depending on the size and number of athletes. Taller pieces of equipment should be placed against the wall, whereas shorter and smaller pieces can be placed in the center of the facility to allow better visibility for the coaches observing their athletes. The spacing of equipment depends on the type of equipment. Resistance training and cardiovascular training equipment can be much closer to each other than free weights. The general recommendation for a safe space between cardiovascular and resistance training machines is approximately 24 in., while the safe distance between free weight stations is 36 in., that is, 36 in. between the distal portions of the moving equipment. An example of this type of spacing would be the distance between two barbell bench press stations. Each station should allow for a minimum of three or four people to fit into the designated area, one athlete to perform the exercise and three other athletes to safely spot. This would be the case for power lifting exercises such as barbell squats. As for Olympic lifting stations, there should be 4 ft between the stations and room for three or four people in and around each station to rotate through.

Facility Maintenance and Daily Needs

It is crucial that the facility's cleanliness be maintained for the safety and health of the athletes. A cleaning and equipment maintenance checklist must be kept on a daily and weekly basis. If the resistance training and cardiovascular equipment is not maintained, the cost of repairs and replacement will strain the capital expenses budget. Chains, rods, and moving joints of equipment must be kept clean and well lubricated, allowing for smooth movement when athletes are exercising on the equipment. Assigning staff or interns to specific areas or equipment will result in a clean and well-maintained facility. If the facility's cleanliness is not kept up, the risk of a viral and/or staph infection increases; a single outbreak can affect an entire team and result in major performance setbacks at pivotal points in training or competition.

Scheduling Training and Conditioning of Athletes

Factors that dictate the scheduling of strength and conditioning sessions include the following: (a) whether the athletes are in-season, (b) the sport the athletes play, (c) the number of athletes on the sports team, (d) the skill level of the athletes, and (e) even the position that the athletes play in their sport.

Peak time in the facility depends on the athletes' outside obligations (school, work, or skills training or team practice). Early-morning training sessions are ideal for training athletes who are in-season when they have team practice in the afternoon, and vice versa. Athletes who are in-season have priority over peak times of the facility due to strict team practice schedules and to optimize training adaptations. Even though in-season athletes have priority, they do not usually spend a great deal of time on their conditioning (usually about 1 hour for 2–3 days/week), because they are in the maintenance phase of their training. During the off-season, athletes will come for training at a time adjacent to the peak times of the facility. Off-season athletes' off-field conditioning sessions are longer in duration (1.5–2 hours for 4 days/week) than in-season athletes' sessions since they do not always require to attend team practices on that same day. Athletes who are recovering from injury will come into the facility at nonpeak times so that they can work more closely with the strength coach during their rehabilitation process.

The strength coaches need to determine the maximum number of athletes who can use the facility at the same time, for two main reasons: (1) the risk of injury to the athletes if there is overcrowding and (2) the time potentially wasted if athletes have to stand idly waiting for space or equipment. For example, during the American football preseason, the increased volume of athletes challenges strength and conditioning facilities at universities and high schools because the facilities often are not large enough to handle the extra players. To have the appropriate number of Olympic and power lifting stations for a full football team would require more than 15 stations. The ratio of athletes to coaches must not exceed 10:1 in junior high facilities and 15:1 in high school and collegiate facilities, according to Armitage-Johnson. Therefore, at large schools and in professional team facilities, it is standard to have four or more strength coaches working with the athletes at once. If the athlete-to-coach ratio cannot stay within those requirements, it is important to stagger the athlete's training times at the facility. When the training sessions are staggered, the strength coaches are able to give each athlete the same amount of time to focus on the exercises that require the most attention to detail. Using the example of an American football team again, the strength coaches can work on each athlete's Olympic lifting technique equally if groups of four athletes are scheduled every 15 minutes. This enables the coaches to provide the necessary directions for a highly technical exercise.

Conclusion

Operating and staffing a strength and conditioning facility offers many challenges for strength coaches, athletic directors, and facility owners. If the coaches, owners, performance teams, and athletes all focus on the ultimate goal of improving athletic performance, the challenges will be minimized. Having quality equipment and knowledgeable strength coaches on the staff ensures that the athletes and team coaches will value conditioning as an essential step to achieving the ultimate performance goals.

Running Injuries

Despite the growing popularity of rival fitness forms such as aerobic dance, mountain biking, in-line skating, stair-climbing, and cross-country skiing simulators, running remains a perennial favorite. Surveys show that more than 26 million adult Americans run regularly.

The appeal of running is obvious: Almost everyone can do it, it can be done almost anywhere and at any time, and it is inexpensive. Running not only continues to hold the interest of millions of Americans, but every year, it attracts legions of new participants drawn to its health benefits and unique advantages.

More than almost any other health fitness activity, however, running has a downside: injuries. Most runners at one time or another suffer from a running-related ailment that puts them out of action, sometimes permanently. It is estimated that 80% of runners sustain injuries.

Most debilitating running injuries could be prevented by addressing the initial symptoms before they develop into full-blown overuse injuries—namely, at the sport ache stage. A runner's sport ache is almost always related to one of these five components: exercise intensity, anatomical factors, conditioning, technique, and equipment. The runner who determines which of the above components has caused the running sport ache can manage the problem by addressing that component.

Exercise Intensity

Injuries can occur when runners substantially increase the frequency, duration, or difficulty of their training regimen. Frequency refers to how often they run, duration to how long they run, and difficulty to how hard they train. Frequency and duration are self-evident. Difficulty is more complex.

Not only does difficulty encompass factors such as how far or fast a person runs, but it also involves the type of surface the runner uses. Runners increase the difficulty of their training regimen when they switch from running on grass or clay to running on roads or from running on flat surfaces to running over hills. Softer does not always mean better. For instance, running on sand stresses the Achilles tendon and can cause tendinitis in that area in the back of the lower leg.

Because the body's tissues need time to adjust to the demands of increased repetitive motions, such as the impact of feet pounding against the running surface or the repetitive extension and contraction of the Achilles tendon, increases in the frequency, duration, or difficulty of a runner's training regimen must be gradual.

It is generally considered safe to increase the frequency, duration, or difficulty of a running regimen by 10% without making adjustments. But when substantially increasing the intensity of one of the three components of a running regimen, it is necessary to make temporary adjustments to one or both of the other elements:

Increase in exercise frequency ⇒
Reduce duration and/or difficulty

Increase in exercise duration ⇒
Reduce frequency and/or difficulty

Increase in exercise difficulty ⇒
Reduce frequency and/or duration.

By how much, though, should the runner cut back? When runners intensify one element of their training regimen, they should cut back on the other two elements of their training regimen by 20% and then increase them by 5% each week until they have reached their previous level. For instance, if it takes a runner 1 hour to run 5 miles, and he or she does this every other day on grass, if that runner switches from grass to concrete, he or she should reduce the running speed and time.

Any pain or joint stiffness is a warning that the runner is increasing the other elements too quickly, and further cutbacks should be made.

Anatomical Factors

One of the most common reasons why some athletes sustain overuse injuries while others do not is that they have anatomical abnormalities that place additional stress on the surrounding structures. In daily activities, these anatomical abnormalities do not cause problems, but when they are subjected to the repetitive stress of running, overuse injuries may occur. The most common anatomical abnormalities of the lower body are flat feet, high arches, knock-knees, bowlegs, unequal leg length, and turned-in hips (*femoral anteversion*).

Anatomical abnormalities may be difficult to overcome. For example, runners who lack rotation in the hips, particularly internal rotation, may never be able to run without a repetitive pattern of injuries. These participants may have to take up a fitness activity other than running.

A runner who has an anatomical abnormality or suspects that there might be one should consult a sports orthopedist as soon as he or she develops a sport ache.

To realign the lower body and prevent the anatomical abnormality from creating problems, the orthopedist's most frequent course of action is to prescribe either shoe inserts (orthotics) or an exercise program.

Although orthotics are often prescribed to correct high arches, they are frequently ineffective. Sometimes "static stretching" of the arch is of some assistance in alleviating the problem. The runner should stand on a board inclined at an angle of 35° for 20 to 30 seconds at a time, with the toes first facing downward, then upward (when doing these static stretches, the toes should be pointed inward slightly). If the pain continues, the runner may not have any choice other than to take up a different sport.

Runners with bowlegs are susceptible to iliotibial band friction syndrome—inflammation of the tissue on the outer side of the knee. Bowlegs cause the iliotibial band to stretch over a longer distance, making it tighter over the outer side of the knee joint, where symptoms develop. To prevent this condition, runners with bowed legs should take care to stretch the iliotibial band during their prerunning stretch.

Conditioning (Including Muscle Imbalances)

A person whose sole form of exercise is running is often poorly conditioned with respect to the relative strength and flexibility of his or her muscles. That is because when running is done exclusively, it can cause imbalances in muscle strength and flexibility.

The consequence of these imbalances is threefold. First, they can cause stresses to the underlying tissues; second, they can pull certain parts of the anatomy out of alignment; and third, they may interfere with proper running form. All three can lead to overuse injuries.

Stresses Caused by Muscle Imbalances

Tight muscles may be responsible for any number of overuse running injuries. Excessive tightness in the musculature on the outside of the thigh (iliotibial band) can cause pressure on the underlying structures, leading to overuse injuries around the outer side of the knee *(iliotibial band friction syndrome*) and the outer side of the hip (*trochanteric bursitis*). Tight muscles and tendons in the back of the lower leg (gastro-soleus/Achilles tendon unit) can cause *Achilles tendinitis*, inflammation of the thick cord of tissue that connects the calf muscles to the back of the heel, and *plantar fasciitis*, inflammation of the connective tissue underneath the foot that connects the toes to the heel (plantar fascia).

Malalignments Caused by Muscle Imbalances

The most frequent sites of malalignments caused by muscle imbalances are the back and the knee.

Low back pain is common in runners. Often, it is caused by tightness in the muscles in front of the hip (psoas) and behind the thigh (hamstrings) relative to the stomach muscles (abdominals) and the muscles in the front of the thigh (quadriceps). Such an imbalance can cause a postural abnormality called "swayback" or *lordosis*, in which there is an excessive front-to-back curve in the lower spine.

Kneecap pain is another frequent complaint in runners. The most common kneecap problem is patellofemoral pain syndrome, which is usually caused by the kneecap (patella) tracking improperly in its groove at the front of the bottom of the thighbone. Often, this problem is caused by the tightness and strength of the muscles in the back of the thigh (hamstrings) relative to the muscles in the front of the thigh (quadriceps). In such circumstances, the quadriceps cannot maintain the proper straight-ahead alignment of the lower and upper leg when the person runs; as a result, the lower leg "spins out" during the running cycle, which in turn causes excessive stress to the outer side of the kneecap.

The strength ratio between the quadriceps and hamstrings can be measured using the type of strength training machines found in the gyms of most health clubs. The "leg extension" machine measures the strength of the quadriceps; the "leg curl" machine measures the strength of the hamstrings. The strength differential ratio between the quadriceps and hamstrings should be no less than 3:2 in favor of the quadriceps, or problems may occur. In other words, a runner who can lift 80 pounds (lb) with his or her hamstrings using the leg curl machine should be able to lift at least 120 lb with his or her quadriceps using the leg extension machine.

Yet another muscle imbalance–related cause of kneecap pain concerns an imbalance between the muscles in the inner and outer sides of the quadriceps muscles in the front of the thigh, the vastus medialis and vastus lateralis, respectively. Frequently, the outer thigh muscles are tighter and stronger than the ones on the inner thigh. Because these muscles attach to either side of the kneecap, the tighter and stronger outer thigh muscles can cause the kneecap to be pulled to the outside with each step when running, a tracking problem that may in turn result in chronic kneecap pain.

Foot-Strike Problems Caused by Muscle Imbalances

The third problem associated with muscle imbalances is their effect on running form. Running causes tightness in certain areas, notably the psoas muscles in the front of the hip, the hamstring muscles in the back of the thigh, and the gastro-soleus/Achilles tendon unit in the back of the lower leg.

Runners with this pattern of tightness tend to have a much briefer than normal foot strike because their muscles are so tight that they cannot perform the optimal, relaxed heel-to-toe foot strike. Their feet spend much less time on the ground with each step, meaning that they have to absorb much more stress every time they hit the ground. Although the time differential may seem very minor, when one considers that the runner may take 10,000 steps every hour, the consequences may be dramatic.

If the runner is diagnosed with an imbalance in strength and\or flexibility, he or she should participate in a conditioning program to redress that imbalance. Conditioning also encompasses sport ache prevention exercises that need to be done before and after running sessions.

One of the most common reasons why athletes get injured is because they do not prepare their bodies for the demands of exercise with a structured workout that includes warm-up and cooldown periods. Every running session should include five stages: (1) limbering up (5 minutes), (2) stretching (5–10 minutes), (3) warm-up (5 minutes), (4) the run, and (5) cooling-down and cooldown stretching (10 minutes).

Technique

Running would seem to be an elementary activity learned in childhood, but many people run with a poor technique. This may not cause problems when running short distances in daily activities but may result in overuse injuries when those people participate in distance running.

For instance, runners who land excessively hard on their heels may develop a sport ache in their foot. Conversely, those who run on their tiptoes can develop tightness in the calf muscles and Achilles tendons, with the resulting problems.

The following are some general guidelines on running technique:

- Run in an upright position, avoiding excessive forward lean. Keep the back as straight as is comfortable, and keep the head up. Do not look downward at your feet.
- Carry your arms slightly away from your body, with the elbows bent so that the forearms are roughly parallel to the ground. Occasionally, shake and relax the arms to prevent tightness in the shoulders.

- Land on the heel of the foot, and rock forward to drive off the ball of the foot. If this is difficult, try a more flat-footed style. Running on the balls of the foot will cause the runner to tire quickly and make the legs sore.
- Keep your strides short. Do not force the pace by reaching for extra distance.
- Breathe deeply with your mouth open.

Improper running technique may be associated with the tightness caused by running itself, due to muscle imbalances (see the section Conditioning [Including Muscle Imbalances]). Specifically, runners with characteristic tightness in the psoas muscles in the front of the hip, the hamstring muscles in the back of the thigh, and the gastrosoleus/Achilles tendon unit in the back of the lower leg tend to have a much briefer than normal foot strike because the muscles are so tight that they cannot perform the optimal, relaxed heel-to-toe foot strike. Their feet spend much less time on the ground with each step than they should spend, meaning that they have to absorb much more stress every time they hit the ground. To restore proper running form, athletes with tightness in the previously mentioned muscle groups should engage in a flexibility program.

Equipment

Runners exert with each step a combined force of three to four times their body weight. That force is absorbed by the running surface, the shoe, and the foot and leg. The less force the limb absorbs, the less risk there is of overuse injury. That explains why it is better to train on slightly softer surfaces, such as clay or grass, than on cement or asphalt, which has less "give." It also explains why shoes are the most important item in the wardrobe of most athletes.

Shoes are especially important for runners. The right footwear makes for an enjoyable, injury-free running experience, while the wrong footwear can cause discomfort and ailments ranging from ankle sprains to heel spurs to knee cartilage tears. Thankfully, improvements in the past decade have contributed to a decline in many footwear-related overuse injuries. Still, knowing how to select the right footwear is knowledge all runners need to have.

It is especially important for the runner with an atypical foot type to select an appropriate running shoe. For instance, if the runner overly pronates (the foot rolls inward) when running, he or she is susceptible to kneecap pain, iliotibial band syndrome, and tendinitis. That runner therefore needs a shoe that will help minimize that pronation. If the runner's foot excessively supinates (rolls outward) while running, he or she needs an entirely different type of shoe to avoid the characteristic foot, shin, and kneecap pain seen in runners with that foot type.

When Is Self-Care Not Appropriate for a Complaint?

If ever in doubt about the symptoms or proper care of an injury or if self-care measures fail to improve the condition within a reasonable amount of time (2–4 weeks), the athlete should consult a doctor. It may also be necessary to see a doctor if an overuse injury has been allowed to become severe or when symptoms include the following:

- Pain before, during, and after running
- Performance affected by pain
- Normal movement affected by pain
- Pain when pressure is applied to an area
- Swelling
- Discoloration

Common Overuse Injuries in Running

If a sport ache is not addressed, it will usually develop into a full-blown overuse injury. The following are the most common overuse injuries seen in runners.

Foot Overuse Injuries

- *Stress fractures in the foot/heel bones:* A series of microfractures that develop in one or more of the bones in the foot, usually the long bones of the midfoot
- *Morton neuroma:* A nerve inflammation in the foot caused by the nerve being pinched between the third and fourth toes or, less often, the second and third toes
- *Plantar fasciitis/heel spurs:* Inflammation of the plantar fascia where it attaches to the heel bone, which if allowed to worsen may form a bone spur

- *Bunions:* A deformity of the big toe that causes it to angle outward by more than 10° to 15°, so that the tip of the toe points toward the smaller toes (a bunionette is the same condition, but it affects the little toe)
- *Hammertoe:* A buckling-under of the end of the second toe, which may eventually become permanent

Ankle Overuse Injuries

- *Osteochondritis dissecans of the ankle:* Damage to the joint surface, which if allowed to worsen may lead to chips of bone and cartilage falling into the joint
- *Peroneal tendinitis:* Inflammation of the tendon that runs behind the outer ankle bone

Lower Leg Overuse Injuries

- *Achilles tendinitis:* Inflammation of the thick tendon that connects the calf muscles to the heel
- *Medial tibial pain syndrome:* Inflammation of the membrane (periosteum) that covers the shinbone (tibia)
- *Stress fractures of one or both of the shinbones:* A series of microfractures in the lower leg caused by repetitive, low-intensity stress
- *Compartment syndrome:* An overswelling of the muscles in their membranous encasements—an effect that compresses the muscles and nerves within these compartments, causing tightness, numbness, and muscle weakness

Knee Overuse Injuries

- *Iliotibial band syndrome:* Inflammation of the iliotibial band where it rubs against the outer part of the knee joint
- *Osteochondritis dissecans of the knee:* A small divot in the surface of the knee joint, which may eventually break off and fall into the joint
- *Kneecap pain syndrome:* A variety of disorders centering on the kneecap

Hip, Pelvis, and Groin Overuse Injuries

- *Osteitis pubis:* Inflammation of the disk of cartilage (symphysis) that connects the right and left parts of the pubic bone
- *Stress fractures at the top of the thighbone*: A series of tiny cracks in the thighbone just below the ball of the hip joint
- *Trochanteric bursitis:* Inflammation of the bursa sac that lies over the hip joint

Back Overuse Injuries

- *Mechanical low back pain:* Vague pain and stiffness in the lower back, sometimes accompanied by muscle spasm
- *Slipped disk/herniated disk/ruptured disk:* Degeneration in the lower back disks that causes pressure on the nerves

Structure the Workout Properly

Without proper preparation for the physical demands of running, runners are at a greatly increased risk of developing an overuse injury.

Every running session should include 5 minutes of limbering up, 5 to 10 minutes of stretching, 5 minutes of warm-up, and, after the run, 10 minutes of cooldown and cooldown stretching.

Limbering Up (5 minutes)

Muscles must be warmed up before they can be safely and effectively stretched for a run. Raising the body temperature makes the muscles more lubricated and elastic. As body temperature rises, joints increase their secretions, and so there is less friction. Ideal limbering-up exercises include a light jog, riding a stationary bike, a brisk walk, rope skipping, use of a rowing machine, and use of stair-climbing machines.

It isn't necessary to get tired during the limbering-up phase. The limbering-up stage is complete when the runner breaks into a sweat.

Stretching (5–10 minutes)

Five to 10 minutes of stretching exercises should be done after the limbering-up period. Particular attention should be paid to the lower extremities. Remember not to overstretch and to hold each stretch for between 30 and 60 seconds. Do each stretch between one and three times, depending on preexisting levels of flexibility, area-specific tightness and previous injuries, and the chosen sport or fitness activity.

Warm-Up (5 minutes)

The warm-up should ideally last 10 minutes. An effective warm-up for a runner is to perform a walk-jog, then slowly increase it to a run. When warming up for running, the heart rate should be 50% of the maximum heart rate.

Cooling Down (5 minutes) and Cooldown Stretches (5 minutes)

Ending a long run suddenly can cause light-headedness or even fainting. A 5-minute cooling down period helps avoid sudden changes that can cause such problems.

The purpose of the cooldown is to let the heart rate return to normal. Toward the end of the run, runners should gradually slow down to where they are walking. If engaged in competition, continue to walk briskly after reaching the finishing line.

Stretching is also a part of the cooldown period. Stretching for 5 minutes after a run prevents muscles from tightening too quickly. It lessens muscle discomfort and can help maintain general flexibility.

Although most runners recognize the need for a properly structured workout session, many neglect this crucial aspect of preventive sports care. As a result, many get injured. In this fast-paced world, it is difficult enough to find time to exercise, let alone the time for pre- and postexercise workout regimens. But it is absolutely crucial for a person who is going to participate in vigorous exercise to structure his or her workout properly. From an injury standpoint, no exercise session at all is better than a poorly organized one.

S

Sacroiliac Pain

As the link between the spine and the lower extremities, the sacroiliac (SI) joint plays a prominent role in both acute and chronic low back pain. Low back pain is a common problem in both the general population and in athletes. Due to its complex anatomy and biomechanics, the SI joint can be a difficult clinical entity to accurately diagnose and treat. A thorough understanding of its anatomy and functional biomechanics is required to appropriately manage the patient with low back pain due to SI joint dysfunction.

The approach to the athlete with low back pain starts with an accurate and thorough history and physical examination, with special attention to the mechanism of injury and careful palpatory and functional clinical examination techniques. A comprehensive treatment program is required, including functional core and abdominal strengthening, improving lower extremity flexibility, manual medicine, and possibly medications. Other complementary techniques, such as prolotherapy, SI joint injections, and acupuncture may provide benefits but are less well researched.

Anatomy

The region surrounding the SI joint consists of three bony structures: the sacrum, the pelvis, and the lumbar vertebrae. Connecting these structures and providing its movement and function are several muscles, tendons, and ligaments. For example, the sacrotuberous ligament is a fibrous tissue that connects and stabilizes the sacrum and the ischial tuberosity of the pelvis. Its site of attachment on the ischial tuberosity is shared with the long head of the biceps femoris, one of the three components of the hamstring muscle group. The importance of this anatomical relationship is that tight hamstring muscles will often lead to low back pain due to a strain on the sacrotuberous ligament and into the SI joint. Overlying this ligamentous sling is the thoracolumbar fascia, which is a sheet of connective tissue that provides attachment points for multiple major muscle groups of the spine, abdomen, and upper and lower extremities (Figure 1). The breakdown and degeneration of these soft tissue structures often leads to instability in the region, which in turn promotes chronic pain syndromes.

The adult SI joint is a synovial joint, meaning that it is encased in a joint capsule that helps maintain its balance and integrity. The bony structure is described as an L-shaped articulation with a long (upper) vertical pole and a short (lower) horizontal pole. It has also been described as an S- or a C-shaped articulation. There is much variability in SI joint size, shape, and contour, even within the same person. As the population ages, the SI joint develops different elevations and depressions within the cavity in response to repetitive stresses. Due to its role in the transfer of forces between the torso and the lower extremities, the SI joint endures demanding biomechanical loads during sports activities. As a result of these repetitive forces, the joint capsule thickens, and the underlying bone can be eroded, ultimately resulting in arthritic changes.

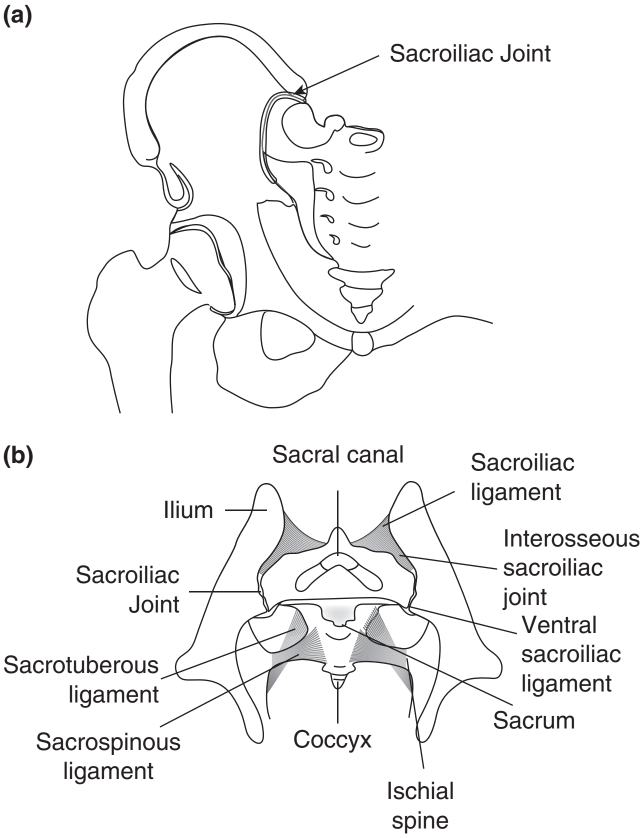

Figure 1 (a) Sacroiliac Joint and (b) Coronal Section of Sacroiliac Joint and Surroundings, Showing Ligamentous Attachments

Although it was previously thought that there is very little motion in the SI joint, most clinicians now accept that there is motion in it throughout life. The hormones released during pregnancy and the increased weight of the baby result in a significant increase in the motion at the SI joint during pregnancy. This is a common reason for low back pain during pregnancy. Further studies and observations have demonstrated that asymmetrical patterns of motion at the SI joints also lead to movement at the pubic symphysis, which is the point where the two pelvic bones meet in the front. Pubic symphysis asymmetry can lead to groin and pelvic pain.

Motion at the SI joint during the normal gait cycle occurs as combined activities in opposite directions at the right and left pelvic bones. At heel strike when stepping forward with the right foot, the right pelvic bone rotates backward and the left pelvic bone rotates frontward. While this is happening, the front surface of the sacrum turns toward the left, the top surface of the sacrum levels off, and the spine straightens upward, slightly turning to the left. Moving toward the right foot midstance, the right pelvic bone rotates frontward, and the sacrum rotates right, while the lumbar spine rotates to the left. The process is repeated in the opposite direction as the left foot approaches heel strike.

Diagnosis

The approach to diagnosis is based on several components, including the subjective complaint of pain, as well as a functional biomechanical examination and the clinician's palpatory findings. There are several SI joint screening tests commonly used. When these tests are used in combination with a thorough history, careful examination, and appropriate diagnostic imaging, an accurate diagnosis and treatment regimen can be established.

The differential diagnosis is broad and can include a number of orthopedic, soft tissue, and visceral conditions that may refer pain to the low back and sacral regions. Some important diagnoses to consider are infections and inflammatory conditions such as arthritis, tumors, fractures, pregnancy, vascular conditions, and hip problems.

When the history and physical examination do not completely uncover the cause of the low back pain, one should consider performing standard radiographs of the lumbosacral spine and pelvis. It is important to obtain oblique views to fully assess the SI joint. If the diagnosis remains elusive or the athlete is not responding to treatment as expected, a further diagnostic workup may include a bone scan, computed tomography (CT) scan, or magnetic resonance imaging (MRI) scan. Laboratory studies may be necessary to rule out infectious or metabolic conditions.

Treatment

Once the diagnosis has been made, treatment generally includes analgesic and/or anti-inflammatory medications. Physical therapy targeting core strengthening and a functional therapeutic exercise program for the lower extremities and pelvis should be initiated. It is important that the demands of the athlete's sport be carefully considered in the design of the rehabilitative program. Using sport-specific concepts in the functional treatment program allows one to reintroduce the loads and motions of a sport in a controlled clinical fashion. Hands-on treatments, including massages, Rolfing, and various manipulative approaches, have been used with varying degrees of success. Finally, injection therapy with local anesthetics, cortisone, and/or prolotherapy can be of benefit, especially in refractory cases. It is important to match the diagnosis with the most appropriate treatment protocol.

Sailing and Yacht Racing, Injuries in

Sailing and yacht racing is a long-standing competitive sport. The America's Cup, first won in 1851, is the oldest active international sports trophy. The few studies that document medical concerns of sailing involve highly experienced sailors. Injuries and illnesses occur with similar frequency to other noncontact sports. These concerns are mostly minor, yet some are life threatening. The tendency for injury increases as the wind velocity rises. Medical concerns differ in dinghy and large-boat sailing. Further differences are seen based on boat class, kind of race, level of experience, and crew position. Disabled sailors have injury patterns similar to those of able-bodied sailors. Yacht racing is generally considered a safe sport; however, sailors, governing bodies, boat designers, and sports medicine personnel need to be aware of the associated risks.

Dinghy

Dinghies range in length from 2 to 6 meters (m) and are typically sailed by one to three people. Racing may include multiple short, back-to-back races or one long course. To keep a boat from turning over and to enhance forward momentum, it is important to keep the hull of the boat relatively flat against the water. This is accomplished by *hiking*, the action of leaning much of one's body weight over the edge of the boat. Hiking is usually from a seated position, with bent or straight knees. Dinghies are often equipped with hiking straps, under which sailors slip their feet and lean out to balance the boat. Hiking causes the most injuries in dinghy sailing. Hiking relies heavily on lower extremity and trunk muscle groups. The forces are translated to the lower back and knee.

Collegiate and Olympic dinghy racers are extremely competitive, and they often round marks close together. Injuries tend to be open wounds, sprains, strains, contusions, or fractures. The most common sites of injury are the lumbar spine, knee, and shoulder. The spine is susceptible to ligamentous, muscle, and disk injuries. Repetitive movements, improper lumbar positions, and weak abdominal muscles contribute to excessive loading.

Poor posture and weak core strength can lead to back and knee pain, body aches, fatigue, reduced strength, and muscle imbalance. Sailors should try to achieve a neutral spine/neck and proper scapula setting, "think tall," and avoid a slumped position. Common knee injuries are ligamentous or meniscal injuries, patellar tendinitis, and patellofemoral pain syndrome. Young women may be at greater risk for knee injuries from hiking due to often internally rotated knees. A proper hiking technique with correct strap placement and foot position limits the torque and imbalanced forces on the knee. Land-based hiking benches are quite useful to work on body positioning and muscle strengthening. The shoulder is at risk for rotator cuff and biceps tendinitis because the sailor is steering, trimming a sail(s), or doing both. In high winds, the loads are larger and necessitate persistent contractions of the shoulder muscles.

Another medical concern of dinghy racing is stress to the cardiovascular system. This system should be assessed when doing a preparticipation evaluation since a sailor's cardiorespiratory demands increase with increasing wind velocities and cardiac output and blood pressure rise significantly during strenuous hiking. Another concern for both genders is that of eating disorders, as some classes have weight limits.

Youth racing is very popular. There are 132,000 registered Optimist boats with sailors between the ages of 8 and 15 years. Most youths are required to wear life jackets when racing, though very few programs mandate children to wear a sports helmet. There is not much written on sailing injuries in this age-group. However, growth spurts are often associated with reduced coordination, which may lead to injuries. This typically occurs for girls between 11 and 13 years and boys between 13 and 15 years.

Large Boat

Large-boat competitions may be held on a single day or multiple days, with one or more races per day, local or offshore, or even around-the-world endurance contests. Radio consult provisions permit racers to discuss medical concerns with other racers or gain medical advice via satellite communication. Seldom is medical evacuation required. Sports medicine concerns in large-boat racing include injury, illness, and, rarely, fatalities.

Many large-boat ocean races have an almost century-long tradition. Two had been relatively free of fatalities until one extreme storm occurred during each of them, resulting in 21 deaths. Man overboard (MOB) and head injuries are the most common causes of death while sailing.

There is a high fatality risk from hypothermia or drowning with MOBs during a storm. Sails need to be expediently doused/changed. Even with a global positioning system (GPS), a boat can get 1 mile (mi; 1 mi = 1.61 kilometers) away in 5 minutes and take 20 minutes to return to the MOB site. The overboard sailor may be at risk for hypothermia, drowning, or near drowning. Even if the sailor is found, it may be technically difficult to retrieve the possibly unconscious sailor.

Head injuries while sailing have caused more than 20 deaths in the past 60 years. A direct blow from a moving boom, spinnaker, or jockey pole is typically responsible and often knocks the athlete overboard. Violent weather puts extra stresses on boat parts, often causing unexpected breakages. Life jackets and harnesses greatly increase survival.

Different crew positions have differing responsibilities and tend to have different patterns of injury. A number of actions in yacht racing are sudden, sporadic, and powerful, such as hoisting a large sail. Others may be repetitive and prolonged, such as long-distance steering. Bowmen, grinders, and helmsmen are particularly at risk for injury.

Many above-deck injuries occur from overuse or direct impacts with boat hardware. Falls on deck or down stairs or hatches or while getting on or off a boat often result in injuries. Below-deck injuries typically result from violent and sudden movements of the boat during rough conditions or from cuts and burns incurred while working in the galley.

A 2006 study of America's Cup sailors by V. J. Neville and colleagues, published in the British *Journal of Sports Medicine,* noted an incidence of 5.7 injuries per 1,000 hours of sailing and off-boat training. Training injuries occurred almost four times more frequently than sailing injuries. Twice as many acute injuries as overuse injuries were seen.

The most common injuries encountered while racing are to the upper extremity (finger, hand, shoulder), head and face, and spine and neck. The types of injury most often seen are abrasions, contusions, burns (thermal, rope, sun), closed fractures, lacerations, ligament sprains, tendinopathies, and head injuries without loss of consciousness. Training injuries include sprains, tendinopathies, and muscle strains.

Illness among racing/training sailors tends to be infrequent and minor. The 2006 study by Neville and colleagues showed a 3.1 incidence of illness per 1,000 sailing and training hours.

Upper respiratory tract infections, seasickness, and gastrointestinal issues are the most common illnesses. Contributing factors are a stressful training routine, close living quarters, rough seas, and contaminated water. Sitting on wet, salty surfaces with infrequent bathing causes dermatologic issues. Insomnia, hypertension, sunburn, headache, and infections are also seen.

Medical Preparation

All yachts should be equipped with a medical kit and a communication system that at least two sailors are trained to use. For long offshore racing, a very high-frequency (VHF), single sideband and a satellite system for voice/e-mail are necessary, in addition to an arrangement with a local hospital or telemedicine company for emergencies. Each yacht should designate a medical officer who has attended a marine medical course. Drills for emergencies such as MOBs should be practiced.

Conclusion

While the incidence of injury and illness remains low in competitive sailing, there is room for prevention. Sports medicine personnel can aid the athlete by advising strength and endurance training, cardiovascular fitness, proper nutrition and hydration, prompt medical attention, and mental and safety preparedness. Further research documenting medical concerns, particularly among young sailors, is needed.

Salt in the Athlete's Diet

Human blood contains sodium chloride (NaCl)—common salt—in solution and, in addition, contains smaller quantities of other ions. Electrolytes such as sodium chloride cannot be stored, nor can they be manufactured in the body. These electrolytes must be obtained from our diet. Sodium and potassium salts are needed in greater quantity than any other electrolyte. Maintaining an equilibrium between the salt loss and dietary intake is vital.

A fluid and electrolyte balance is critical to optimal exercise performance. Many athletes, especially endurance athletes, often do not meet their fluid requirements during exercise. However, successful athletes come close to meeting fluid needs, at the same time accounting for their salt loss. Increasing ambient temperature and humidity can increase the rate of sweating on average to 1 liter (L)/hour. Depending on the individual, exercise type, and exercise intensity, sweat rates can range from extremely low values to more than 3 L/hour. Overhydrating with a low or negligible sodium intake can result in reduced performance and hyponatremia. Adding salt to the sports drink actually promotes better absorption in the gut. Sodium also becomes important in the recovery period.

The minimum amount of urinary sodium lost in a day is between 4 and 6 grams (g). This does not include the amount of salt lost in sweat. A dietary intake of 5 to 10 g of salt/day or 2 to 3 kilograms (kg)/year is necessary to maintain homeostasis.

Athletes have varying degrees of salt concentration in their sweat. Those with high salt concentrations may need more salt than the average sweating athlete.

Salt consists of sodium and chloride ions, which are important for normal physiologic functioning. High sweat rates in athletes result in the loss of both fluids and sodium. Fluid replacement with hypotonic solutions such as water will lead to incomplete rehydration and possible complications such as hyponatremia, decreased performance, and heat-related illnesses. There is significant individual variation in the sodium lost during activity. In some, the losses can be replaced by the normal dietary intake, whereas in others, the losses can be so dramatic that extra salt needs to be added to the diet. There are various methods to raise the sodium intake, such as increased use of table salt on foods, eating salty snacks, adding salt to sports drinks, and the use of salt tablets. The emphasis on fluid replacement is also important, but care must be taken to avoid overhydration. Simple measures such as recording the daily pre- and postexercise body weight aid in making fluid and sodium ingestion decisions.

Sweat has an average sodium concentration of 10 to 100 millimoles (mmol)/L. The sweat rate, the amount of fluid lost in 1 hour, can be as high as 3 L/hour. Insufficient substitution can lead to cramps and, as noted earlier, hyponatremia. This is particularly true in hot, humid weather. Athletes can lose up to 5 g of sodium/hour. This can cause a negative balance in the total exchangeable sodium of 30%.

Researchers at the Cleveland Clinic have developed a formula to estimate an athlete's salt loss:

$$\text{Salt loss} = 0.0263 \times \text{Sweat [Na]} \times \text{Weight loss.}$$

As mentioned earlier, the sweat sodium concentration can range between 10 and 100 mmol/L. For simplification purposes in this example, the sweat concentration is set at 50 mmol/L. For individualized calculations, the specific salt concentration of the athlete's sweat should be used.

Example: If a player loses 10 pounds (lb; 1 lb = 0.45 kg) during practice with a sweat sodium concentration of 50 mmol/L, he or she will have lost $0.0263 \times 50 \times 10 = 13.15$ g of salt.

The use of sports drinks has increased dramatically in recent years. How much do these sport drinks actually help in stabilizing the sodium balance?

Modifying the preceding formula, the sodium salt content of a beverage can be assessed as follows:

$$\text{NaCl (g)} = 0.00252 \times \text{[Na] (milligrams [mg]/vol)} \times \text{vol.}$$

A popular beverage targeting athletes has 110 mg of sodium in 8 ounces (oz; 1 oz = 29.57 milliliters [ml]). If an athlete drinks one 20-oz bottle of it, he or she will have consumed

$$0.00252 \times 110/8 \times 20 = 0.693 \text{ g of salt.}$$

In the example above, the athlete lost 13.15 g of salt. To replace that by just drinking the sports drink (second example), he would have to drink nineteen 20-oz bottles!

An average diet contains between 8 and 10 g of salt. Thus, much of the sodium lost in an event will be replenished by regular dietary intake. If, though, an athlete has a weight loss of 5 lb or more during an athletic event, a salt substitution should be considered. A basic rule would be to supply 1 g of salt and 500 ml (=16 oz of fluid) for each pound of weight loss over 5 lb.

Scaphoid Fracture

The *scaphoid* is one of the small bones of the wrist. It is the most frequently fractured carpal bone, accounting for 71% of all carpal bone fractures. The incidence of fracture is greater in young and middle-aged men, typically those between 15 and 60 years.

Many cases of painful wrists due to a fractured scaphoid are seen in the emergency department. Early diagnosis is important as 90% of all acute scaphoid fractures heal if treated early. On the other hand, a delay in diagnosis can lead to a variety of adverse outcomes.

Anatomy

The wrist is made up of eight carpal bones, which are arranged in two rows (Figure 1). The scaphoid is the most lateral bone of the proximal row. It articulates with the radius superiorly.

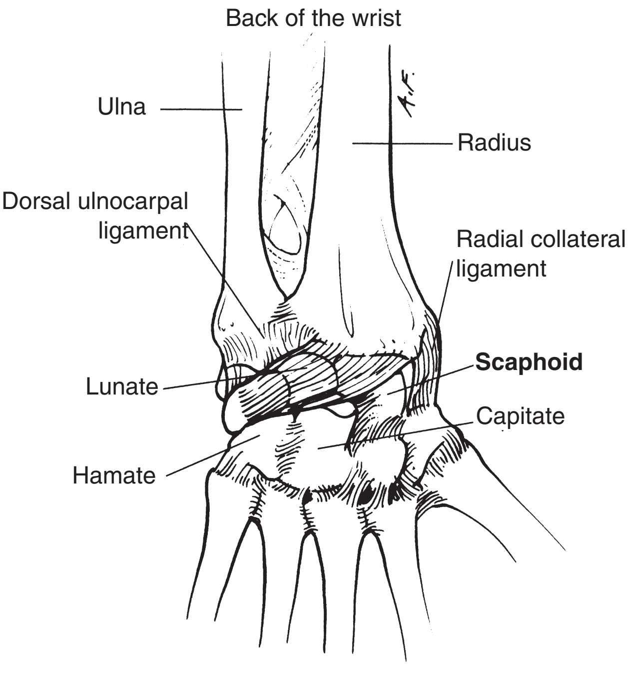

Figure 1 Anatomy of the Wrist

On surface anatomy, it is located below the anatomic snuffbox—a triangular depression lying below the thumb, best visible when the thumb is extended. This boat-shaped bone is key to wrist motion and stability. It can be divided into four distinct parts: the proximal pole, the wrist, the distal body, and the tuberosity. Most scaphoid fractures occur at the waist and the proximal pole.

The scaphoid is supplied by the radial artery near the tubercle and waist. The blood supply to this bone is paradoxical, going from distal to proximal. Thus, fractures in this part heal slowly, and the bone fragments may even fail to fuse.

Causes

Most patients who have broken their scaphoid have done it while participating in sports such as football or basketball; two-wheeled sports such as motocross, bicycle motocross (BMX), and cycling; or in an automobile accident. It usually happens from a fall on an outstretched hand (FOOSH) with the wrist pronated (palm facing backward).

Symptoms

A fracture of the scaphoid almost never shows any obvious deformity of the wrist. Symptoms of a fracture include pain at the base of the thumb and a swelling around the wrist. Loss of the concavity of the anatomic snuffbox is usually seen.

Pain may subside and then return as a deep, dull ache that may worsen when the thumb is moved or the hand grips an object. In some cases, the pain is not severe and may be mistaken for a sprain.

Clinical Evaluation

Physical Examination

The age and sex of the patient are considered together with the mechanism of injury. It is important to compare the injured wrist with the uninjured wrist.

The following observations on performing specific maneuvers suggest a fracture of the scaphoid:

- There is tenderness on palpation at the anatomical snuffbox.
- The scaphoid tubercle is tender. Extend the patient's wrist with one hand, and apply

pressure on the tuberosity at the proximal wrist crease with the other.

- Absence of tenderness on performing the first two examinations makes a scaphoid fracture highly unlikely.
- There is pain on performing the "scaphoid compression test." This test involves longitudinally compressing the patient's thumb along the line of the first metacarpal.
- Pain is felt on pronation followed by ulnar deviation.
- There is reduced range of motion of the hand.

Imaging

There are various imaging options to figure out the fracture in a patient with a suspected scaphoid injury:

- *Radiography:* Anteroposterior, lateral, and oblique radiographic views of the wrist are required. A special radiograph called a scaphoid view is also recorded occasionally. Nondisplaced fractures (fractures in which the bone fragments have not been displaced) are usually not seen on initial radiographs.
- *Bone scintigraphy:* It is a cost-effective and accurate method for assessing occult scaphoid fractures.
- *Magnetic resonance imaging:* It is a highly sensitive, noninvasive modality that can not only detect occult scaphoid fractures but can also access bone healing and evaluate for bone contusions and ligamentous injuries.
- *Ultrasonography:* Ultrasound examination is not appropriate in the initial evaluation of a suspected scaphoid fracture. Nevertheless, it is reliable and accurate in identifying occult scaphoid fractures.

Treatment

Nonsurgical Treatment

Scaphoid fractures are usually not visible on X-rays immediately after an injury. A wrist injury suspected of a scaphoid fracture by examination should be casted, with follow-up examination done in 7 to 14 days. However, it is possible that the fracture line is still not visible; in such cases, an MRI or CT scan may be necessary to confirm the diagnosis.

In a fracture where bone is not displaced (bone fragments are in the right place) and/or fractures that do not extend across the bone's length, simple treatment with cast immobilization may heal the fracture within 9 to 12 weeks; inclusion of the thumb in the cast is usually recommended. Recovery is monitored by examining plain radiographs. If the fracture does not heal, surgery is recommended.

Surgical Treatment

Surgery is indicated in the following situations:

- When the bone is displaced (fragments are not in their anatomical position) and is hence at a higher risk of nonunion (failure of bone to heal)
- When the athlete is anxious to return to play as soon as possible (Surgery allows the patient to get early mobilization and complete functionality in a shorter duration. This reduced time spent in a cast also helps reduce muscle atrophy.)
- When the scaphoid fracture is undiagnosed initially, with nonhealing (nonunion)
- In a nondisplaced fracture when healing does not occur in a timely manner with cast immobilization
- When the fracture is in the middle or proximal part (nearer the forearm), since it may not heal with only the cast because of the reduced blood supply in this part of the bone

Two surgical options are available: (1) open reduction and internal fixation and (2) closed reduction and percutaneous fixation. The former is for displaced fractures, whereas the latter is for fractures that have minimal displacement. In the surgical method, cannulated screws or wires are used to stabilize the fragments. The length of the incision and the area where it is placed depend on the degree of displacement of the fragments and the part of the scaphoid that is fractured. It can be on the front or back of the wrist. The incision is larger when fragments have to be realigned into their anatomical position before they are stabilized with screws. Postoperatively, the hand is placed in a cast and regularly monitored with radiographs to check the progress of the healing process. The bone heals within 8 to 12 weeks.

Even with surgery, this fracture takes time to heal or may not heal properly. If the bone does not heal, a bone graft is added in addition to internal fixation. (The grafts are usually taken from the patient's pelvis.) During this process, the hand is placed in a cast. Bone grafts speed up the healing process, and the cast is usually removed in 3 weeks, allowing rehabilitation exercises of the hand and wrist. Also, in fractures where the blood supply has been severed, special grafts, called vascularized grafts, are used that have their own blood supply.

Complications

The proper treatment of scaphoid fractures is extremely important. If the bone fails to heal, it is called a *nonunion*. One cause of nonunions, as noted earlier, is the poor blood supply to the fractured part, which results in bone death. This is referred to as *avascular necrosis*. Nonunion and avascular necrosis subsequently lead to arthritis of the wrist, resulting in pain and a reduced range of motion; the person experiences difficulties in performing even normal activities such as lifting and gripping.

Rehabilitation

Cast immobilization and functional disuse can lead to swelling (edema) of the injured wrist. Elevation and active motion of the uninjured joints of the hand can help avoid this fluid accumulation. During the healing period, the patient must avoid any strenuous activity with the injured arm, including lifting, pushing, pulling, and throwing. Participation in contact sports must be avoided, and care must be taken to avoid activities that increase the risk of falling onto the hand.

After the cast is removed, active range-of-motion (ROM) exercises for wrist flexion and extension and radial and ulnar deviation are performed to overcome the stiffness. About 2 weeks later, passive range-of-motion (PROM) exercises are started, together with gentle muscle-strengthening exercises. Progressive strengthening over several weeks by means of weight bearing and other activities will help restore complete functionality to the wrist.

Scheuermann Kyphosis

When viewed from the side, the human spine has a series of normal curves. The lower back or lumbar spine is curved anteriorly (*lordosis*). The upper back curves outward and is referred to as a *thoracic kyphosis*. This is a C-shaped opening anteriorly. The cervical spine maintains a mild lordosis. When any of these curves are excessive, they can cause pain and cosmetic deformity. The normal thoracic kyphosis is between 20° and 40°. There are several causes of excessive kyphosis. A congenital fusion or abnormality may cause a fixed kyphosis noted early in life. Later in life, osteoporosis may cause an excessive kyphosis, or dowager's hump, due to compression fractures. In the adolescent, there are two causes of noted kyphosis. One is postural, due to slouching and poor spinal extension strength, and is usually correctible with postural strengthening. The second is *Scheuermann kyphosis*.

Scheuermann kyphosis is a developmental fixed deformity of adolescence. By definition, there are at least three consecutive vertebrae involved, with anterior wedging of 5° or more. The prevalence has been estimated to be between 4% and 8% of the population. It is usually recognized during the adolescent growth spurt. When detected with spinal growth remaining, it can be minimized with exercises and bracing. Thus, early recognition is important.

Etiology

There have been a number of theories as to the causes of Scheuermann kyphosis. Genetic factors have been strongly implicated, but there has been no specific genetic marker identified. Some have attributed this to an osteochondrosis, which refers to a loss of blood supply to the growth cartilage rings that are located on the superior and inferior parts of each spinal vertebral body. Repetitive compression of the anterior portion of this ring will inhibit the growth and cause anterior wedging. In keeping with this theory, muscular imbalances with stronger anterior trunk muscles would put excessive pressure on the anterior ring apophysis. Furthermore, it has been noted in industrial workers in excessive forward flexion. There has also been a noted association with elite levels of water skiing in the preadolescent and adolescent age-groups. Other possible etiologies include transient osteoporosis and growth hormone imbalance.

With regard to gender, some studies have indicated that there is a male predominance, while others have shown a more equal, 1:1, ratio.

Clinical Presentation

The most common presentation is a cosmetic deformity noted by parents during the adolescent growth period. It is a very gradual development that is usually painless. Parents often consider this to be postural. About 25% of these adolescents have an associated scoliosis of less than 25° to 30°. Scoliosis is a lateral curvature of the spine. Kyphosis is best detected on forward flexion, viewed from the side (see photo, right column). Scoliosis is also seen on this forward flexion test but viewed from behind. Scoliosis will manifest with an asymmetry of the rib humps in flexion. When a kyphosis is detected, one should determine if it is fixed or postural. When the patient extends backward or is prone while suspended on the elbows, the postural kyphosis is corrected, while the Scheuermann kyphosis remains.

One of the significant problems of excessive kyphosis is loss of self-esteem. The kyphosis may cause a cosmetic deformity and make the individual appear heavier. Although the adolescent may complain of pain at the apex of the deformity, it is more common for an adult to complain of pain. It is likely that in the adult, the local degenerative processes of the disk and posterior spinal elements are causing focal irritation. The increased thoracic kyphosis alters the biomechanics of the lumbar spine, with increased lordosis to compensate. This excessive lordosis may cause stress in the posterior elements of the lumbar spine with a spondylolysis (stress fracture). Although quite uncommon, neurologic compression may also occur with peripheral manifestations. These may include pain radiation to the chest wall, to the abdominal wall, or into the legs.

Imaging

The standard evaluation of a suspected kyphosis includes a standing series of the thoracolumbar spine, which involves posteroanterior (PA) and lateral views. The PA view will detect any scoliosis. The lateral view is useful for determining the amount of kyphosis using the Cobb method (Figure see radiograph, next page). This measures the angle from the superiormost vertebrae to the inferiormost vertebrae. To meet the criteria of Scheuermann kyphosis, there must be an overall kyphosis of more than 45°, and at least 5°, with three consecutive wedged vertebrae. A lateral radiograph in extension may be considered if there is a question whether the kyphosis is more postural.

If there is a kyphosis, one must determine bone growth as improvement can only occur in the setting of remaining spinal growth. Therefore, the pelvic portion of the plain PA radiograph will help determine the remaining growth potential by calculating the Risser score of the iliac crest growth cartilage (Figure 1). The iliac apophysis ossification appears laterally to medially. Each 25% is divided into the first four scores. Risser I is the

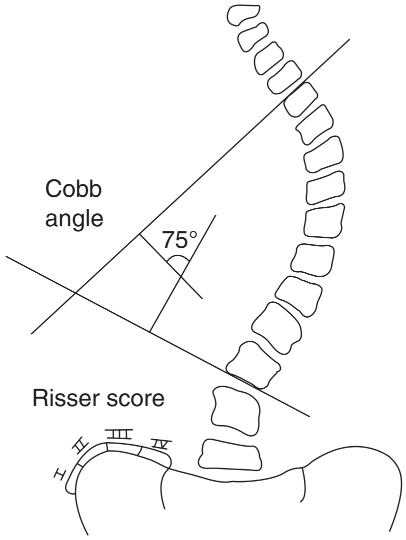

Figure 1 Risser Score

Source: Pierre A. d'Hemecourt.

appearance of the first 25%. Risser II is the first 50%. Spinal growth is most noted up to Risser II. A left hand/wrist radiograph may also be obtained for bone aging.

Further imaging with an MRI scan is useful if there is significant pain. This will demonstrate any significant disk disease as well as spinal cord abnormalities such as a syrinx (cystlike structure).

Treatment

The ideal treatment candidate is the adolescent with significant growth potential and a curve in excess of 45°. Treatment consists of an upper back extension–based strengthening program combined with a core stabilization program. This is an important part of the treatment and is very useful for the postural component. Bracing is also optimal here. Usually, the apex is at T7 or above it and requires a Milwaukee brace. This brace comprises a pelvic girdle, a pad at the curve apex, and a shoulder with a cervical ring fixation. Ideal treatment is at least 18 hours/day for the first year and nighttime wear until skeletal maturity. Radiographs are repeated every 4 to 6 months. This brace is not well tolerated and at times is just used for nighttime wear. When the kyphosis has an apex below T7, a more tolerable thoracolumbarsacral orthosis (TLSO) is used. The TLSO is also continued until skeletal maturity.

Surgical intervention is reserved for those curves in excess of 75°. The Milwaukee brace is ineffective at this degree of curvature. The surgical stabilization usually involves an anterior and posterior approach with fusion with fixation. A posterior-only approach may be followed if there is some flexibility to the curve, but this provides less curve correction than does the combined approach. Complications can include spinal cord injury, nonunion of the fusion, and infection. The results can be very satisfying.

Return-to-Sports Considerations

There is no real restriction to play in most of these athletes unless there has been a surgical fusion with instrumentation. In the latter case, contact sports are a contraindication. In the nonoperatively treated group, sports participation of all kinds is encouraged as long as the principles of sports biomechanics are addressed. In sports that require forward thoracolumbar flexion such as crew and wrestling, the athlete is instructed in upper back extension postures with a good upper back–strengthening program. When bracing is used, the athlete is usually allowed out of the brace for all practice and competition events. This allows better compliance and enhances spinal stabilization.

Sciatica

Low back pain affects a significant portion of the population, with epidemiologic studies reporting a lifetime prevalence of 49% to 70%. *Sciatica*, also referred to as *lumbosacral radicular syndrome*, is a type of low back pain that is characterized by pronounced posterior radiating leg pain. The pain follows a distribution served by a lumbar or sacral spinal nerve root and is often accompanied by sensory, motor, or tendon reflex abnormalities. The prevalence of sciatica has been estimated to be around 2% to 10%. This prevalence is likely higher in athletes, especially high-level or elite athletes, due to the increased physical demands placed on the spine during many athletic activities. Clinicians that care for athletes must have a good understanding of the causes, diagnosis, and treatment of sciatica to expedite a safe return to athletic activity.

Anatomy

In the lower back, the lumbar spine is composed of five vertebral bodies. The sacrum, a large triangular bone consisting of five fused vertebrae, connects the lumbar spine and the tailbone or coccyx. The spinal cord traverses through the spinal canal of the vertebrae, and nerves coming off the spinal cord travel through the spinal canal and exit through small openings on the sides of the vertebrae called *foramina* (singular foramen). The sciatic nerve is the largest and longest nerve in the body and originates from a group of nerves in the lower back. It then runs through the buttock and down the lower leg, supplying motor and sensory functions to the thigh, knee, calf, ankle, foot, and toes. Between each of the vertebrae is a vertebral or spinal disk that serves as a shock absorber. Each disk is composed of two parts: (1) an outer tough exterior (annulus fibrosis) that surrounds and contains (2) an inner jelly-like material (nucleus pulposus).

Causes

The leading etiology of sciatica (approximately 90% of cases) is a herniated disk causing nerve root compression. Other etiologies include lumbar stenosis (narrowing of the lumbar spinal canal), facet joint osteoarthritis, spinal cord tumors, and infection. Disk prolapse is more commonly identified as a cause of nerve root compression among younger athletes (20- to 50-year-olds), while osteophytes and degenerative disease are often the culprits in older athletes. The red flags for life-threatening etiologies have been widely recognized, and more aggressive and urgent workup is needed if these are identified (Table 1). Several factors have been shown to increase one's risk for sciatica: age (peak between 45 and 64 years of age), increasing height, mental stress, cigarette smoking, strenuous physical activity, and exposure to vibrations from vehicles.

Clinical Evaluation

History

The first step in managing an athlete with sciatica is to recognize the condition. The physician's

Table 1 Red Flags for Low Back Pain

History or Physical Exam Clue	*Possible Diagnostic Etiology*
Saddle anesthesia	Cauda equina syndrome
Urinary retention	Cauda equina syndrome
Bowel or bladder incontinence	Cauda equina syndrome
Loss of rectal tone	Cauda equina syndrome
Major motor or sensory loss	Cauda equina syndrome, significant herniated disk
History of cancer	Metastatic disease
Age over 50 years	Neoplasm
Unexplained weight loss	Neoplasm
Nighttime pain	Neoplasm or infection
Fevers	Spinal infection
Recent infection (pyelonephritis, cellulitis, etc.)	Spinal infection
Vertebral tenderness	Spinal infection or fracture
Unrelenting pain	Spinal infection, neoplasm, or fracture
Immunosuppression	Spinal infection
Intravenous drug use	Spinal infection
Fall in osteoporotic patient	Vertebral compression fracture
Trauma (motor vehicle accident, fall from a height, etc.) in young patient	Vertebral fracture

Source: Susan Bettcher and James Borchers.

main diagnostic tool is obtaining a thorough history and performing a comprehensive yet focused physical examination. Patients frequently report a shooting, radiating, or burning leg pain that extends to the ankle and foot, often with athletic activity. Pain commonly travels along the lateral and posterior aspects of the thigh and leg. These symptoms are often accompanied by a component of numbness or a tingling sensation. Sciatica pain attributed to disk herniation can increase with maneuvers such as coughing and with running activities.

Physical Exam

The physical exam should include inspection, palpation, and range-of-motion testing of the lower back and legs, along with documentation of vascular integrity. Emphasis should be placed on neurological testing. A key diagnostic tool to help assess for radiculopathy is the *Lasegue sign,* more commonly referred to as the straight leg raise test. For this maneuver, the clinician elevates the supine patient's extended leg without his or her assistance. The test is positive if sciatica is reproduced between 10° and 60° of elevation. A second maneuver is the crossed straight leg raise test. This test focuses on raising the unaffected leg; a positive result occurs if pain is reproduced in the affected leg. A variation of the above tests, the seated straight leg test, is performed with the patient seated. The leg is extended until there is 90° of flexion at the hip. The test is positive if pain is elicited as the leg is raised. If one or more of these maneuvers are positive and the pain description is consistent with sciatica, a diagnosis of sciatica can be made.

Diagnostic Tests

Performing laboratory or imaging studies is often not necessary when diagnosing sciatica as these tests do not affect the typical treatment course, which is conservative management. However, if any red flags are present, further workup should be initiated at the time of diagnosis. In addition, imaging studies are often indicated if the diagnosis is uncertain or if there is a lack of response to conservative management after 6 to 8 weeks. Imaging can be used to help identify the pain source, such as a herniated disk. This information can be used to determine if surgical intervention is indicated. Disk herniations are frequently seen on computed tomography (CT) scans and more commonly on magnetic resonance imaging (MRI) scans. The findings must be correlated to the distribution of symptoms, and a decision must be made as to whether the pattern makes sense. Imaging studies depend on various factors (availability of testing, patient health, cost, etc.) and the physician's preference.

Treatment

The overall prognosis for sciatica is good as a majority of patients and athletes recover from related disabilities within a couple of weeks to months. However, the symptoms can become chronic, and a minority of athletes can continue to have pain for periods greater than 1 year. The mainstay of the treatment is conservative management, which focuses on pain control. However, if there is a lack of clinical improvement after 6 to 8 weeks, surgical intervention can be considered. The effectiveness of certain conservative measures and the optimal timing of surgery still need to be established.

Nonsurgical Treatment

Conservative management involves one or more of the following: patient education, bed rest, remaining active, use of analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs), epidural steroid injections, physical therapy, spinal manipulation, acupuncture, traction therapy, and behavioral treatment. While there is no solid evidence for the effectiveness of any of these measures, bed rest is no longer recommended because no significant difference in pain and functional status measures has been seen when compared with staying active. As such, physicians recommend that their athletes with sciatica remain active but avoid activities that aggravate their pain. Formal physical therapy is also recommended by certain providers and may be helpful in individuals with more severe pain and/or disability. For athletes with access to training facilities, a certified athletic trainer can guide the rehabilitation and monitor a graduated return to play. Physicians often prescribe NSAIDs for the initial pain associated with sciatica. Other non-NSAID analgesic pain medications, muscle relaxants, and antidepressants may be used instead of or in addition to NSAIDs. A conservative treatment plan should be made in conjunction with the athlete, keeping in mind the current knowledge of treatment modalities, our understanding of the expected course of sciatica, and the athlete's performance goals.

Surgical Treatment

An immediate neurosurgical referral needs to be made for the cauda equina syndrome, which is characterized by saddle anesthesia, decreased rectal tone, and changes in the urination and bowel functions. Urgent referrals should be made if progressive paresis and/or acute severe paresis are present. Other nonurgent referral indications to neurosurgery, neurology, or orthopedic surgery include severe pain in spite of adequate medication, uncertain diagnosis, and lack of clinical improvement after 6 to 8 weeks. Surgical intervention can be undertaken in cases of refractory sciatica in which there is an identifiable source of pain, such as lumbar disk prolapse. Surgery aims at removing the disk herniation through surgical diskectomy or microdiskectomy. There may be an initial improvement in leg pain and faster recovery in individuals treated with early surgery, but the long-term outcomes of surgery have not been shown to be better than those managed conservatively. As such, providers need to discuss the available evidence and knowledge of treatment modalities and outcomes with their affected athletes so that they can make well-informed decisions.

Scoliosis

Scoliosis is an abnormal curvature of the spine when viewed from the back. In this position, the spine normally appears as a straight line from the occiput to the pelvis. With scoliosis, this may appear as a single C-shaped curve or a double S-shaped curve. There is often an associated rotational component that presents with a rib hump or lumbar prominence, depending on the location of the curve. The overall prevalence of scoliosis is 2% to 3%. However, severe curves occur in less than 0.1% of the population. The prevalence of minor curves is equal between men and women, but more significant curves demonstrating progression are at least five times more common in women.

Scoliosis curves may be described by the location of the apical vertebra. This is the vertebra that is most deviated from the midline. There are 7 cervical vertebrae, 12 thoracic vertebrae, and 5 lumbar vertebrae. The position of the apical vertebra defines the curve level: cervical from C2 to C6, cervicothoracic from C7 to T1, thoracic from T2 to T11, thoracolumbar from T12 to L1, lumbar from L2 to L4, and lumbosacral from L5 to the sacrum. Single or multiple curves may be seen. The curve is further defined by the direction of the convexity (outer portion of the curve). A curve that is convex to the right is called dextroscoliosis; convexity to the left is levoscoliosis. Curves may be single or multiple.

The objective of scoliosis identification is to prevent the progression, which may be associated with functional deformity, cosmetic deformity, and potentially pain in the adult. The young woman athlete is often seen with this on preparticipation examination.

Classification

Scoliosis may be classified according to the etiology. Curves may be secondary to congenital, neuromuscular, and idiopathic causes. Congenital causes usually reflect bony abnormalities, as a result of which one is born with the spinal vertebrae incompletely separated from an adjacent level or incompletely formed. These curves often present early in life.

Neuromuscular scoliosis refers to curves that are secondary to neurologic and muscular disorders. Spinal cord abnormalities such as a syringomyelia (a cystic-like structure in the cord) and a tethered cord may cause an abnormal curvature. Some inherited muscular and neurologic diseases such as muscular dystrophy may present with a gradually progressive curve. Connective tissue abnormalities such as Marfan syndrome and Ehlers-Danlos syndrome also fall in this category. Certain tumors such as neurofibromatosis and osteoid osteomas also represent neuromuscular causes.

At least 80% of scoliosis cases are classified as *idiopathic*, which means that there is no known cause. Idiopathic scoliosis is further subclassified by the age of onset:

- *Infantile, under the age of 3:* Unlike the older idiopathic forms, this is more prevalent in the male population and has a more positive ability to be corrected on its own.

- *Juvenile, between 3 years and 10 years of age:* This has a much higher risk of progression and must be monitored closely. It also has a significant risk of comorbid spinal cord abnormalities that must be considered.
- *Adolescent idiopathic scoliosis, over the age of 10 years:* This is the most common entity and is most often seen in the young woman athlete.

Numerous hypotheses have been postulated regarding the cause of scoliosis. However, it remains unclear. Chromosome mapping has made specific identifications, but there appears to be an incomplete genetic expression. Other factors that have been considered include abnormalities of growth hormone secretion, melatonin secretion, and skeletal muscle contractile protein.

Evaluation

Often, the young athlete presents with a curve that was noted on a routine examination. The history and physical examination should focus on excluding significant causes and determine the risk of progression. This will assist in determining the need for more advanced imaging and testing. It is important to determine at which age it was first noticed for classification. The presence of pain or neurologic complaints is important. The family history of scoliosis should be determined. The highest risk of curve progression occurs during the adolescent growth spurt. This growth spurt precedes the onset of puberty in women, manifested with the onset of menses. Thus, the premenarchal (prior to the first menstrual cycle) woman is at a higher risk of progression. In the male athlete, the onset of puberty, with testicular enlargement and pubic hair development, precedes the growth spurt. Growth in the female athlete continues for up to 2 years after menarche.

The physical examination includes the height. This is important in following the adolescent to determine the cessation of growth. This occurs when there is less than 1 cm of growth in a 6-month time period. The physical examination is performed in the usually disrobed adolescent to look for skin abnormalities, such as café au lait spots, hairy patches, and dimpling, which may indicate underlying cord abnormalities such as neurofibromatosis and spina bifida. One should also examine for connective tissue disorders. The stigmata of Marfan syndrome should be assessed in the tall woman more than 5 feet (ft) 10 inches (1.75 meters [m]) and men more than 6 ft (1.8 m) in height. Tall athletes with two or more of the following major criteria of Marfan syndrome should be referred for genetic testing and echocardiography:

- *Ocular:* lens dislocation, myopia (nearsighted)
- *Cardiovascular:* mitral valve prolapse, aortic rupture
- *Musculoskeletal:* scoliosis, anterior chest wall deformities (pectus excavatum and carinatum), long thin fingers (arachnodactyly), arm span longer than the height, and a high-arched palate.
- Family history of *Marfan syndrome*

A neurologic examination should be complete, looking for abnormal reflexes such as Babinski reflexes (up-going toes with plantar foot stroking) and hyperreflexia. These may indicate a spinal cord abnormality.

The degree of scoliosis is initially evaluated with the evaluator standing behind the patient with the forward-bending test. With this maneuver, the curve becomes more obvious due to the rotational component, which makes the ribs more prominent on the convex side. This is more accurately assessed using the scoliometer. This is placed on the spine in the forward-flexed posture and quantitates the degree of rotation. When the scoliometer reads 7 or more, the patient should have an X-ray to determine the severity of the curve. If one uses a lower number such as 5, the specificity diminishes, and excessive numbers of radiographs are ordered. However, it is important to realize that not all scoliosis cases involve a rotational deformity. Thus, when the spine appears curved even without rotation, a radiograph should be considered.

When indicated, the initial imaging should be a full-length posteroanterior (PA) and lateral spine X-ray including the pelvis. Each curve is identified and quantified using the Cobb method (Figure 1). The top of the curve is determined at the level at which the vertebrae deviate the most from the central axis. The bottom of the curve is determined similarly. A line is drawn across the top of the uppermost vertebra, and one is drawn across the lowermost vertebra. Perpendicular lines to these are made to intersect. The intersection angle determines

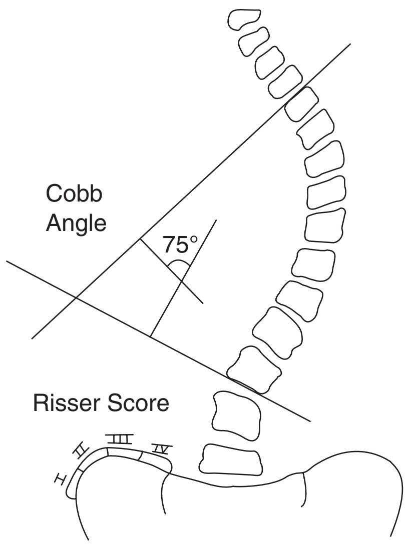

Figure 1 Cobb Angle and Risser Score

Source: Pierre A. d'Hemecourt.

the extent of the curve. The curve must be greater than 10° to be classified as scoliosis. Lesser curves are referred to as spinal asymmetry.

The pelvic portion of the plain PA radiograph helps determine the remaining spinal growth potential by calculating the Risser score of the iliac crest growth cartilage (iliac apophysis). The iliac apophysis ossification appears from lateral to medial. Each 25% is divided into the first four scores. Risser I is the appearance of the first 25%. Risser II is the first 50% (Figure 1). Curves are more likely to progress in the early Risser scores of I or II.

The degree of the curve and the Risser score help determine the risk of progression. Curves less than 20° have a lower risk of progression unless the Risser score is less than I (22% risk of progression). A curve from 20% to 29% has a much higher risk of progression.

Further imaging with an MRI scan is considered when there are findings in the history and physical examination that indicate a neurologic concern as well as head, neck, or spinal pain. This should also be done on patients with juvenile onset and, according to some authorities, on patients with left-sided thoracic curves. The MRI scan should be a spinal screen that looks at the entire spine, including the junction with the occiput, to evaluate for a Chiari malformation (herniation of the cerebellar tonsils into the spinal canal).

Treatment

Observation

In mild curves, measuring less than 20°, observation is appropriate. The timing of this will depend somewhat on the age. Athletes less than 12 years of age or with a Risser score of I or less should be followed every 4 months. Older athletes can be followed every 6 to 8 months with a PA spine X-ray. Curves between 20° and 29° should be monitored more frequently, every 3 to 6 months. A progression of 5° may indicate a need for bracing.

Bracing

Curves that progress more than 5° should be considered for bracing. Curves more than 30° are also braced. Once initiated, the patient should have an initial PA radiograph of the spine in the brace to determine the degree of correction, as a value greater than 20% is a good prognostication for bracing efficacy. Bracing is continued until skeletal maturity, which is usually 1 to 2 years postmenarche.

Bracing may take several forms. The Boston overlapping brace is a commonly used thoracolumbarsacral orthosis (TLSO). It is worn ideally for 23 hours/day but has been used for 16 hours/day.

Rarely, a larger brace, the Milwaukee brace, is used to involve the cervical spine (cervicothoracolumbosacral orthosis [CTLSO]). This is used for high thoracic and double thoracic curves. Compliance is more difficult. There are two nighttime braces, the Charleston and Providence braces. Some studies indicate that they limit the progression of the curves. The data on the efficacy of all bracing are controversial and are being verified by ongoing clinical trials.

Surgical Intervention

Skeletally immature athletes who have a curve in excess of 50° are candidates for surgical stabilization, with consideration of the same for those with curves between 40° and 50°. Those adolescents who progress more than 5° while being managed in the brace are also considered for surgery. The surgical procedure usually involves segmental instrumentation and fusion. Curves that are very rigid may require an anterior thoracoscopic release.

Sports Participation

Sports participation is encouraged at all levels of scoliosis. Although physical therapy has not been shown to be helpful in managing the curve, the athlete should maintain cross-training and core stabilization for normal athletic conditioning. Full sports participation is encouraged. For some sports that emphasize repetitive asymmetrical spinal loading, such as rhythmic gymnastics, athletes are encouraged to cross-train to lessen these forces.

Many sports can be played while wearing a brace. In some sports such as gymnastics and swimming, the brace is removed during athletic competitions. However, if spinal instrumentation is performed, collision sports are contraindicated.

SCUBA Diving, Injuries in

Exploring the underwater world is a wonderful experience enjoyed by a wide variety of people. However, diving involves risks to health not encountered in other sporting activities and should not be attempted without certified instruction and assessment by a knowledgeable physician. This entry gives a brief overview of some common problems associated with diving and how to avoid them.

Diving can be done by swimming on the surface while breathing through a snorkel, holding your breath, or breathing compressed air from a tank or a hose (hookah). Problems can arise when the diver descends underwater because the pressure exerted by the water above the diver's body increases with depth. If this increased pressure unequally compresses the air and fluid spaces in the diver's body, an injury may result. In addition, breathing compressed gas at depths may cause another set of problems as gas is absorbed into the tissues, fluids, and spaces of the body. When the diver ascends to the surface, if the subsequent release and expansion of those gases occur in a rapid and uncontrolled manner, an injury known as decompression sickness may result.

Problems Caused by Water Pressure

Perhaps the most common problem in diving is the "ear squeeze," which results from the compression of the air behind the eardrum. Most of us experience this when diving to the bottom of a swimming pool. Special swallowing maneuvers can equalize the pressure in this middle part of the ear by opening the eustachian tube, which connects the throat with the middle ear. In a person with nasal congestion, the eustachian tube may be blocked, and equalization maneuvers may not work. Increasing the depth and pressure without equalization will eventually result in eardrum rupture and bleeding in the middle ear. While this may relieve the pressure difference and the pain, it can cause permanent damage or, worse, a sudden disequilibrium that could complicate a safe return to the surface. It is important not to dive when nasal congestion is present and middle ear equalization is not possible. Unless decongestants or allergy medications completely resolve nasal congestion and do not cause any side effects such as drowsiness, diving should be postponed. A similar, milder squeezing of the middle ear occurs when an airplane passenger descends to the higher air pressure at ground level.

The sinuses can similarly be "squeezed" and injured by increasing pressure as a diver descends, especially if nasal congestion blocks the sinus openings, preventing equalization. "Mask squeeze" occurs when the air in the mask is compressed and the mask presses on the face. It can cause headaches and bruising but is easily avoided with techniques learned in a diving course.

Problems Caused by Breathing Compressed Air

All gases, including the nitrogen and oxygen in ordinary air, can cause problems when they are breathed at increased pressures underwater. Compressed nitrogen can cause a mildly euphoric state with impaired judgment, which could be fatal for the diver or his buddy. This nitrogen narcosis is sometimes called the "rapture of the deep." Oxygen, which is lifesaving in many situations, can cause lung damage or even convulsions if breathed at high pressures. "Technical divers," who perform prolonged or very deep dives, often fill their tanks with special mixtures of oxygen, helium, nitrogen, or hydrogen to avoid these problems. But all gases have the potential to cause toxicity in certain situations.

Problems Caused by Ascent (Decompression Illnesses)

Self-contained underwater breathing apparatus (SCUBA) regulators, which were invented by Jacques Cousteau and Emile Gagnan, make SCUBA diving possible. As the diver descends to a higher-pressure environment, the regulator makes increasingly pressurized air available to fill the lungs. Surprisingly, it is the return to the lower pressure at the surface that is more dangerous than the descent. To understand this, let us review two laws of physics that you learned in high school and possibly forgot shortly thereafter.

Boyle's law states that at a constant temperature, the product of the pressure and volume of a gas is a constant. Thus, if the pressure increases, the volume decreases, and vice versa. The real-world application is that as a diver returns to the lower pressure at the surface, the volume of the gas in his or her lungs expands. For this reason, it is critically important that the return to the surface be slow, controlled, and with attention to exhaling this increased volume of gas. Otherwise, the alveoli, the tiny sacs in the lungs where blood and air meet, may burst, resulting in a pneumothorax. This is a leak that causes air to collect outside the lungs and compress it. In a similar fashion, air in the middle ear or sinuses may cause injury as the volume increases—a reverse squeeze.

Henry's law states that at a constant temperature, the amount of a gas dissolved in a liquid is directly proportional to the pressure of that gas above or around that liquid. As the pressure changes, the amount of gas dissolved in the liquid also changes. In diving, we are mostly concerned with the pressure of a gas in the alveoli and the amount of that gas dissolved in the blood capillaries surrounding each alveolus. Henry's law reminds us that as the pressure of nitrogen (the main gas in compressed air) increases in the lungs, the amount of nitrogen in the blood also increases. Conversely, when the diver ascends, and the pressure of nitrogen in the lungs decreases, the amount of nitrogen that can be kept dissolved in the blood and tissues also decreases. Some of this nitrogen, following Henry's law, must come out of solution, usually in the form of bubbles. While our bodies have other ways of quickly exchanging oxygen and carbon dioxide, the exchange of nitrogen is limited to simple diffusion.

Therefore, there are two mechanisms that change the gases in the body on ascent from a depth. Henry's law describes the increase in the amount of gas coming out of solution in body tissues such as fat, muscle, organs, and blood, and Boyle's law describes how the volume of that or any other gas increases. This may produce two main categories of decompression illnesses—decompression sickness and gas embolism.

The first, *decompression sickness,* results from the collection of gas where it does not usually exist—in and around joints, muscles, and nerves. It has been called "the bends" because of a doubled-over posture that may occur in the victims. A less serious condition occurs when gas collects in the skin.

The second, *gas embolism,* arises from bubbles in the blood causing the blockage of small arteries. Most people are familiar with embolic blockages of the blood vessels caused by blood clots in the heart or brain, which cause heart attacks or strokes. In a similar fashion, gas bubbles may cause embolic blockages in small arteries, with the same effects. While the heart and brain are the most common places for serious damage from gas emboli, other organs such as the kidneys and lungs can also be affected.

In addition to blocking the small arteries, the increasing size of the bubbles or gas collections may burst things. Even the small decrease in pressure that occurs when ascending in a pressurized aircraft might add to decompression from diving, and, therefore, air travel should not occur for several hours after diving.

Decompression sickness and gas embolism can usually be prevented through careful attention to diving techniques, especially ascending in an orderly, planned, and controlled fashion. If they do occur, initial treatment is breathing pure oxygen, which decreases the amount of nitrogen in the lungs, favoring the diffusion of nitrogen out of the tissues because of the resulting gradient.

A decompression illness that is not improving or results in serious symptoms should be treated in a hyperbaric (high-pressure) chamber, where the patient can be returned to high pressures in the hope of returning the gas to solution and then decompressing slowly, thereby allowing the gas to come out of solution gradually without causing damage. (One such hyperbaric center is The Duke Center for Hyperbaric Medicine and Environmental Physiology: 919–684–6726, Hospital 24 Hour 919–684–8111.)

Specific Injuries and Medical Concerns

Asthma may cause narrowing of the small airways, which could make equalization of pressures difficult and increase the chance of pneumothorax and gas emboli if alveoli burst in an area that cannot be equalized. Traditionally, persons with asthma were prohibited from diving. However, current recommendations are that well-controlled asthma is usually compatible with diving if the candidate is symptom-free with medication. What is critical is that the asthma be well controlled. All persons with asthma, but especially divers, must see a physician and take prescribed medications regularly to ensure optimal control. Conversely, on a related topic, anyone who has had a spontaneous pneumothorax should not dive. Chest X-rays are often done as part of a diving examination to look for this, but previous pneumothoraces are usually not detectable, and so a medical history is important in these cases.

Seizures, dizziness, migraine headaches with vision or balance changes, and panic attacks are other conditions that may not be too concerning in ordinary activities; however, if they occur under water, a safe return to the surface may be compromised, and their occurrence may be fatal. Similarly, symptoms of heart disease, which might be treated easily on the surface, may lead to drowning if they occur under water. Persons with these conditions are usually advised not to dive. In addition, a minimum level of physical fitness is required to dive safely because the diver may be confronted with unexpected challenges from weather, currents, temperature, and other physical conditions related to the diving environment. Also important is the possession and practice of good judgment to avoid situations that increase the risk of accidents.

Additional information can be requested from the Divers Alert Network, a nonprofit organization that maintains a comprehensive website and an emergency hotline for diving accidents (www.diversalertnetwork.org; 919–684–4DAN [4326]).

Seasonal Rhythms and Exercise

Changes in seasons across the calendar year lead to variations in the weather and environmental conditions in most locations across the globe. Such variations exhibit a period of about 1 year ± 2 months and, thus, can be defined as "seasonal" rhythms. Seasonal rhythms are influential in determining patterns of behavior in a wide range of living organisms. These rhythms also have the potential to affect human behavior as we: (a) possess an internal body clock that is responsible for subtle rhythmic changes in a range of physiological functions across various time periods, and (b) are susceptible to the demands of external factors. The spatial distribution of humans across a wide range of climatic zones means that variability in environmental conditions across the calendar year is a common experience for most people. This makes understanding the potential impact of these seasonal changes on important social behaviors such as exercise, in both the recreational and the elite athlete, useful to the sport and exercise scientist. This knowledge may help inform the development of effective interventions to enhance health-related fitness, as well as highlight the best strategies for competitive athletes in optimizing performance.

The Basis for Seasonal Rhythms

Seasonal rhythms are linked to fluctuations in the prevailing climatic conditions observed at any given time of the year. These climatic conditions are, in their simplest terms, a direct consequence of the daily axis of rotation of the earth being inclined at 23.5° from the vertical and the elliptical orbit of the earth around the sun. This tilted orientation produces a seasonal variation in the duration of daylight from the equator to the poles. The angle at which the rays of the sun strike the surface of the earth also varies according to the season. This leads in turn to marked differences in the ambient temperature and other climatic and weather conditions that partly depend on the latitude and the prevailing topography. Such environmental changes, along with alterations in the amount of daylight, have the potential to be very influential on human social behavior. This is especially pertinent to activities, such as exercise, in which such environmental factors will affect important characteristics of the exercise stress (e.g., type, frequency, duration, and intensity). Changes in these variables will subsequently have consequences for both the acute physiological responses to exercise and the adaptations that follow chronic exposure to activity in both a health setting and a performance setting.

The potential theoretical importance of seasonal rhythms is not currently reflected in the amount of available research in the field. Methodological issues have undoubtedly had an effect as appropriate experimental designs and methodologies are very difficult to use in this field. More important though is our increasing ability to control both our climatic conditions and our exposure to light in our immediate surroundings. As a result, our habitual activities and behaviors are in theory no longer tightly bound to seasonal fluctuations in day length and climate and are more likely to depend on cultural, religious, and economic influences. These influences will clearly reduce the amount of the seasonal variability to be observed in human populations in Western industrialized societies and, thereby, potentially limit the ability of such rhythms to influence behavior. Nevertheless, seasonal variation can still affect many aspects of the work of the sport and exercise scientist, especially when the external environment strongly facilitates or acts as a barrier to exercise participation.

Seasonal Variation in the Physiological Responses to Exercise

The seasonal variation in ambient temperature and environmental conditions provides one basis for the existence of seasonal rhythms. Aspects such as metabolic rate and the physiological response to a given exercise stress are highly susceptible to such changes. This may either result in alterations in the social behavior of individuals or act to change the underlying physiology, a process known as acclimation. Characteristics of the human thermoregulatory system exhibit seasonal variation primarily as a consequence of acclimation. Sweating, a vital component of the body's heat loss response during exercise, is altered both with respect to its initiation and amount during summer because of the repeated exposure to elevated temperatures. Other thermoregulatory changes include variations in the core temperature response to an exercise stress and altered individual subjective thermal sensations to a given heat challenge. The time of the year can also affect other aspects of the exercise response, including causing changes in the hematocrit and alterations in the respiratory exchange ratio, with relatively more fatty acids being used as a fuel in the winter. Such changes may be partly mediated by the changes in body temperature associated with exercise because the core temperature is an important determinant of the metabolic response to exercise, elevating carbohydrate usage when levels are high.

Annual cycles in day length are also relevant to the existence of circannual rhythms as they have the potential to alter both the intrinsic elements of the body clock and exogenous behavioral factors. The relationship between seasonal changes in both day length (photoperiod) and night length (scotoperiod) and the behavioral, metabolic, and biochemical responses to exercise in humans remains uncertain. Seasonal changes of the natural photo- and scotoperiods at high latitudes have an effect on melatonin secretion in humans as discussed previously, though there is no consensus on whether humans generally display a seasonal rhythmicity in melatonin secretion. This limits the direct evidence that is available to support the theory that changes in the extent of melatonin control the effect of photoperiod, as occurs in animal models. Evidence that other circadian rhythms also display seasonal variation is also relatively weak in healthy humans. This may suggest that humans in industrialized countries live in environments in which the photoperiod may have lost its status of primary *zeitgeber* (a cue that synchronizes a person's "internal clock" to the earth's light/dark cycle).

Seasonal Variation in Physical Activity Patterns

Substantial evidence exists for significant seasonal variation in the physical activity of free-living adults in most industrialized countries. These changes display a sinusoidal pattern, with peak values occurring in summer for the majority of measures of physical activity. The most common habitual physical activities associated with leisure, such as walking for pleasure, gardening, lawn mowing, bicycling, hiking, and running, all display significant seasonal variation in industrialized populations. A variation in occupational activities seems to be able to explain less of the variability in activity patterns unless the local population is nonindustrialized and is, therefore, subject to specific periods of high levels of activity (e.g., during harvesting of crops). These reductions are also observed in humans who live at high latitudes during periods when one would assume that physical activity would be desirable to help protect against the climatic conditions. Changes in daylight hours seem to be important in these variations, though the more favorable environmental conditions in summer to carry out an active lifestyle will no doubt also play a role.

Seasonal Variation in Physical Fitness and Health

The maintenance of physical activity over the whole year is important for the health of individuals. Such changes in activity are also likely to have consequences for alterations in physical fitness. The best aerobic performances are frequently recorded in subjects at summertime—that is, unless individuals maintain high levels of physical activity in winter in specific recreational activities (e.g., winter sports such as skiing). These circumstances may limit the reductions observed in fitness and lead to more stable performance levels across relevant time periods. The impact of seasonality on health-related issues is, however, much more complicated as these relationships can be extremely variable and complex. It has been suggested that the month of birth may be related to the susceptibility to certain illnesses, though these associations should in no way be interpreted as being indicative of a direct relationship between different times of the year and disease risk. Changes in activity across the annual cycle may also compound problems with glycemic control in Type 2 diabetics. Epidemiological data do, however, highlight the idea that the incidence and mortality of cardiovascular disease, such as coronary heart disease, is increased in winter compared with the spring. This trend may be related to the seasonal variations in a number of risk factors (e.g., body weight, oxidant/antioxidant processes, calorie intake) as a result of changes in temperature, lifestyle, and human physiology (e.g., blood pressure). These relationships would indicate that such variations in cardiovascular-related morbidity may be reduced by the careful modification of external environmental factors, such as better housing, improved heating, and changes to seasonally driven lifestyles.

Viral infections and influenzas are also more likely in the colder months, with the most commonly cited explanation being the increased "crowding" indoors of susceptible persons in the winter. Exercise-induced bronchospasm also shows seasonal variation, with a twofold increase in incidence in dry seasons compared with other times of the year. This would suggest that such conditions may be complicated by environmental factors such as dry air, the ambient temperature, and the presence of environmental allergens, such as pollen, in individuals. Mental health may also be more susceptible to challenges at certain times of the year. The long hours of darkness in winter, especially in the northern latitudes, can lead to a depression known as *seasonal affective disorder*. The seasonal effect on the diurnal rhythm in melatonin may partly explain these occurrences and open the possibility of the use of a combination of bright light and exercise as a therapeutic tool.

Seasonal Variation in Competitive Sports Performance

The types of sports in which athletes participate, as well as the training behavior of elite athletes, are clearly influenced by the seasonal changes in the weather. Skiing, ice skating, hurling, and ski jumping are naturally all "winter sports," while other sports, such as cricket and tennis, are primarily played in the warmer summer temperatures. The distinctness of the temporal location of such activities within the calendar year has recently become blurred, with the development of indoor facilities that allow a variety of climatic conditions to be simulated. The accessibility of long-distance travel across hemispheres to reverse seasons has also enabled competitions to be scheduled at nontraditional times. As climatic conditions vary as a function of the time of year and geographical location, it is likely that athletic performances could be associated with additional physiological demands in some circumstances. For example, changes in environmental conditions, especially the ambient temperature, will alter the metabolic and physiological responses to a range of exercise stresses. The increased presence of seasonal allergens such as pollen may also compound any physiological changes. Travel across time zones will also not be without its own consequences if events are scheduled close to arrival times as the athlete groups involved may face additional difficulties in preparing for competition.

An understanding of the seasonal variation in sports performance is also complicated by exogenous factors that mask any inherent endogenous circannual rhythms. Elite athletes "periodize" or "cycle" their training throughout the year. Periodization involves the adoption of cyclic variations in the intensity and type of training stimuli and the amount of rest. The calendar year is traditionally divided into three distinct phases: the preparatory period, the competitive period, and the recovery phase, each of which has its own specific objectives and associated training load. It is therefore of little surprise that variations in performance in a range of physiological parameters (e.g., maximal oxygen consumption, anaerobic power, isometric and isokinetic strength, body composition) are associated with the different training phases that are adopted. This evidence would suggest that seasonal changes in performance are a consequence of external factors rather than any inherent internal seasonal rhythm.

More conclusive evidence for circannual rhythms in competitive sports performance may come from the observation of subtle differences within specific phases of the periodized year. Using this approach, a significant component of the exogenous changes in activity associated with the periodized year should be removed as the training stimulus should be much less variable. Team sports such as soccer show such subtle variations in the work rate completed by players during games at different stages of the competitive season. Such variations are not associated with alterations in the physical capabilities of players or their physiological characteristics as these do not tend to vary greatly within the competitive season. Large inter-individual differences in these data, as well as a failure to control other known determining factors of a player's work rate (e.g., opposition), do, however, preclude firm conclusions regarding the origin of these variations to be made on the basis of the data currently available.

Future elite performers may also be dictated partly by an observed seasonal birth bias. Age categories in youth sports are often managed by having a birth cutoff point to determine eligibility. Comprehensive evidence from a number of athletic groups (e.g., soccer, hockey, baseball) indicates that participants in underage teams tend to be born at the start of the competitive year. This provides these individuals with a chronological advantage over those born later in the year, which tends to be replicated in a maturational superiority. This early selection bias can carry through to those selected for elite adult competitions in later years. This phenomenon cannot be attributed to any endogenous circannual rhythm as the bias can be altered if the initial date for eligibility is changed. As such, coaches and selectors are advised to acknowledge the influence of such factors and compensate for them accordingly.

Another area directly relevant to competitive sports performance that displays a high degree of seasonal variation is the incidence of injury. There is clear seasonality in the frequency of injuries incurred by athletes participating in a wide range of sports, though this variation differs between sports. The highest injury rates seem to occur during the competitive season rather than the preparation periods. The multifactorial nature of the causes of sports injuries makes it very difficult to clearly attribute these differences in injury to any one specific factor. It is clear that a variety of exogenous factors, such as environmental conditions (both high and low temperatures can increase the risk of injury) and changes in the amount and intensity of activity, can predispose an individual to injury. Endogenous factors may also play a role. For example, vitamin D levels in the body can be increased in response to environmental light. This fat-soluble vitamin promotes growth and mineralization of bones and increases the absorption of dietary calcium. This may mean that bone mineral density varies seasonally, with the lowest values observed in the winter months. This, when combined with the low levels of activity at this time of year, may lead to a weaker skeleton and increase injury disposition. Such changes may, however, be minimal in an athletic population that maintains high levels of activity across the calendar year.

Seizure Disorder in Sports

A seizure is a common, serious neurological event affecting approximately 10% of individuals during their lifetimes. Each year, an estimated 300,000 individuals in the United States, including 120,000 children and adolescents, will experience their first seizure. Team doctors and coaches should be familiar with caring for an athlete who has a seizure during an event. While athletic participation is generally encouraged for individuals who have had a single seizure or diagnosis of epilepsy, many factors are considered. This entry discusses recent guides for participation, safety and first-aid measures, and special considerations for athletes with a seizure disorder.

Definitions and Risk of Recurrence

The brain normally functions through a network of neurons that send and receive bioelectrical signals maintaining our homeostasis at rest and performing purposeful activities. In simple terms, a *seizure* is a neurological event during which normal brain messaging is interrupted by chaotic neuronal hyperactivity, resulting in loss of targeted function. *Epilepsy* is a condition in which an individual is susceptible to recurrent seizures.

Seizures originating in a discrete, localized region involving one side of the brain are called *focal* or *partial seizures.* Focal seizures are categorized into simple seizures, in which specific functions (e.g., unilateral muscle twitching) are affected, and complex seizures, in which the mental alertness and state of consciousness are affected. Typical clinical features include unresponsiveness, staring, or confusion, as well as gaze deviation, lip smacking, drooling, or semipurposeful hand movements. This abnormal bioelectrical activity can continue to spread to the opposite cerebral hemisphere, resulting in a secondarily generalized tonic-clonic seizure, historically described as a *grand mal* seizure or *convulsion.* Focal seizures may be caused by a variety of recognized pathology, including trauma, stroke, tumor, developmental structural abnormality, or infection irritating certain regions of the brain. Often, no clear cause or etiology can be determined.

A generalized seizure involves both cerebral hemispheres. The various subtypes of generalized seizures include absence, myoclonic, atonic (drop events), and generalized tonic-clonic. Absence seizures are brief, abrupt staring episodes or lapses in attention, most commonly seen in children. Myoclonic seizures are shocklike muscle twitches, most commonly presenting in adolescents. Primary generalized seizures often recur, typically have genetic etiologies, and commonly result in a diagnosis of epilepsy. Some conditions such as juvenile absence epilepsy and juvenile myoclonic epilepsy require lifelong therapy.

For the witness to a seizure, it is helpful to record the duration, recurrence, and clinical features of the seizure, such as the side of the body involved and the injuries sustained. A medical evaluation is required for anyone experiencing a first seizure. Through this evaluation, an electroencephalogram (EEG), neuroimaging, and consultation with a neurologist will determine the likelihood of recurrence and any necessary preventive therapy. A safety plan will also be devised in the case of a future seizure.

The overall risk of additional seizure in an individual having a single focal seizure is approximately 30% to 50%, while primary generalized seizures are very likely to recur without treatment. Some clinical factors may provoke a seizure, but it is important to make these determinations and any activity restrictions on an individual basis. Typical exacerbating factors include fever/infection, sleep deprivation, alcohol, some specific medications, and noncompliance with prescribed preventative anticonvulsant therapy. Many patients report stress and "overactivity" as factors, though these are hard to systematically evaluate and define. Rare cases of reflex epilepsy have been associated with aerobic exercise, reading, or other specific stimuli. Hyperventilation may provoke some generalized seizures though athletic participation and exertion typically do not. While traumatic brain injury can provoke a seizure, participation in contact sports, such as football or hockey, has not been shown to trigger seizures. Although precautions and an individualized plan are essential, aerobic exercise and athletic participation are recommended for individuals with a single seizure and for those with epilepsy.

Participation Guides

While athletic participation is encouraged and has clear health benefits, risks should be addressed in a thoughtful, practical manner in each individual setting. This risk-benefit analysis will consider the seizure type, likelihood of recurrence, present control, potential injury should a seizure occur, and reasonable safety precautions deployable. In 1997, the International League Against Epilepsy trimmed the list of restricted activities to self-contained underwater breathing apparatus (SCUBA) diving and sky diving. Obviously, some activities involve higher degrees of scrutiny and absolute seizure control, such as motor sports and precision shooting/archery and activities involving heights, such as rock climbing. Gymnastics, horseback riding, sailing, and swimming/diving are other sports requiring discretion, close supervision, and control of seizures prior to participation, due to risks of personal injury. Cycling, skating, and skiing also require seizure control and routine personal protection such as helmets. Contact sports such as football, hockey, and soccer do not have restrictions beyond close supervision and routine safety procedures. Aerobic activities and weight training should be undertaken with typical safety precautions. The speed, intensity, and setting of the activity will dictate the necessity of seizure control prior to participation as many individuals with active, uncontrolled epilepsy benefit from jogging, golf, and court sports such as tennis and basketball.

Safety and First Aid

In the event that an individual experiences a seizure, simple first-aid measures can be promptly implemented. Although a seizure can be initially alarming, a calm, reassuring manner is helpful. First, prevent any additional injury, protecting the patient from falls, collisions, or drowning. Time the duration of the event, and note clinical features if possible. Do not restrain the individual. Loosen tight clothing if possible. If safe, turn the individual on his or her side as some individuals have excess secretions and may vomit, although rarely. Also, do not place an object in the individual's mouth that could create the potential for choking or dental damage. The person having a seizure will not swallow his or her tongue, as is commonly misconceived. Stay with the individual and seek emergency medical care (911) if the seizure lasts longer than 3 minutes. Some individuals with epilepsy may have rescue medications available that are typically used after a 3-minute seizure duration. If the seizure is recurrent or provoked by head trauma or the individual fails to demonstrate recovery over a 10-minute duration following the event, the individual should also be evaluated on an emergent basis. If it is the person's first seizure, a prompt evaluation is important. While emergency care is important for many, if the individual has recognized epilepsy and a self-resolving seizure lasting less than 3 minutes, emergency care may not be necessary. Many individuals feel tired, confused, and complain of headaches following a seizure; however, they should be able to be aroused and follow simple commands. It is important to stay with the individual until he or she has recovered. An individual who experiences a seizure should not return to immediate athletic participation. The Epilepsy Foundation of America has produced informative educational materials (www.epilepsyfoundation.org).

Prevention and Therapy Considerations

Therapeutic plans for individuals with epilepsy or for those who have experienced a single seizure often include a rescue medication in the event of a prolonged seizure lasting more than 3 minutes. These medications are typically a benzodiazepine such as diazepam or lorazepam, given by a rectal or buccal preparation. Nasal midazolam is beginning to be accepted as an alternative.

Preventative anticonvulsant medications, if necessary, should maximize the efficacy and tolerability. Clear cognitive function and alertness are critical to athletes. Lamotrigine and levetiracetam are medication options with infrequent sedation. Topiramate and zonisamide are effective medications for many types of epilepsy; however, for the athlete, special attention must be paid to hydration status and temperature control as these medications lead to a high incidence of kidney stones and reduced sweating, increasing the risk of hyperthermia and heat stroke.

Senior Athletes

Although some have suggested that the increased level of injuries diagnosed within the aging population is due to simply "outliving our warranties," a look into the subculture of senior—or masters—athletes reveals a number of individuals who are outperforming society's age-defined expectations. Athletes in the media spotlight, such as football player Brett Favre, cyclist Lance Armstrong, and swimmer Dara Torres, are redefining how we think about aging. However, these feats of enduring performance are not limited to elite-level athletes: Recreational athletes, including those who are abandoning the couch in pursuit of a more active lifestyle, have demonstrated some remarkable accomplishments of their own. Despite the fact that waiting rooms at doctors' offices across the country are filled with these "weekend warriors," sports medicine has largely ignored this group, preferring to focus on the child, collegiate, or professional athlete. The purpose of this entry is to illuminate the factors affecting performance and injury prevention in the aging athlete and to summarize the benefits of active aging, thereby dispelling the common notion that age is the sole factor contributing to an individual's activity level.

To maintain an active lifestyle as we age, it is important to understand the biology behind the aging process. At the cellular level, rapid cell division provides the human body with a remarkable regeneration capacity. It enables us to recover from injury rapidly throughout the childhood and early adult years. As we continue to age, our bodies become less efficient at these regeneration activities, resulting in stiffer tissues and a decline in overall performance. These changes occur not only at the macrolevel of muscles and joints but also at the microlevel of deoxyribonucleic acid (DNA). The way our genes are expressed also changes with age and activity level. The consensus among the general population is that this lapse in athletic prowess is an inevitable and irreversible part of the aging process. This consensus, however, is less grounded in science than in anecdote. Many studies are revealing the true capacity of our musculoskeletal system with aging and show that aging is not necessarily an irreversible decline from vitality to frailty.

We know from recent research efforts that "old" cells can be reprogrammed at the cellular level to behave like "young" cells by simply using exercise as medicine. In general, much more investigation into this decline and how much can be attributed to physical inactivity is needed. The high level of physical activity maintained by masters athletes throughout their lifespans make them model subjects for investigating healthy aging. By studying this population, we are able to eliminate the variable of physical inactivity or other health conditions when investigating the aging process.

The Longevity of the Masters Athlete

Masters athletes everywhere continue to debunk the common myth that turning 40 means slowing down. In a survey conducted by the Arthritis Foundation, 64% of masters athletes reported feeling an average of 11 years younger than their actual age, while 40% reported living a more healthy and physically fit lifestyle than in their 20s. Moreover, 33% of them boasted that they could beat their children in at least one sport. It is important to note that these people are not the exception but the standard. All individuals have the chance to maintain this high quality of life and functional capacity throughout their lifespans if they choose to avoid a sedentary lifestyle. Studies of performance decline in masters athletes indicate that the slowing phenomenon of the aging process does not have a significant impact until the seventh decade of life.

In a study of track athletes between the ages of 50 and 85 who participated in the 2001 National Summer Senior Games, running times across all distances declined with age. While this trend was expected, the surprising finding was the small degree of performance decline that occurred with age. Until the age of 75, the observed decline was slow and linear, with decreases of less than 2% per year. This decline was not found to be statistically significant. At age 75, however, the rate of decline jumped to approximately 8%. This trend of performance decline with age is shown in Senior Olympians competing at all distances, from the 100-meter (m) dash to the 10,000-m run. These results suggest that if disuse and disease are eliminated, individuals should be able to maintain high levels of functional independence until the age of 75. Therefore, the loss of independence before the age of 75 must be attributed to lifestyle habits, disease, or genetic predisposition.

Similar rates of maintained performance are also observed when investigating the scores of masters athletes on tests of aerobic capacity, such as the $\dot{V}O_2max$ and the lactate threshold test. An analysis of the $\dot{V}O_2max$ (peak oxygen uptake) scores of masters athletes over the age of 35 proposes that a 0.5% decline per year may be an intrinsic biomarker of the aging process. Women have displayed a slightly faster rate of decline than men in this area. These rates are much less than would be expected considering that a low $\dot{V}O_2max$ is believed to be one of the fundamental reasons behind decreases in functional capacity in the aging population. Research investigating declines in endurance performance with aging attributed poor performance to a reduced $\dot{V}O_2max$ and lactate threshold. In a study comparing healthy young adults, older sedentary individuals, and older endurance athletes, approximately 50% of the age-related differences witnessed in the $\dot{V}O_2max$ score were found to be the result of a smaller stroke volume. The remaining differences were attributed to a lower maximal heart rate and reduced oxygen extraction. However, as shown within the masters athlete group, these trends can be greatly diminished through high levels of habitual exercise. This suggests that any exaggerated rates of decline are the results of lower energy levels, decreased training intensity, and less time spent training. Only modest portions of these declines in performance are age related.

These moderate rates of performance decline also depend on factors such as gender and type of physical activity. Investigation of track-and-field records to examine the rate of performance decline show that strength deteriorates before stamina does. This is best seen in sprinters, as their declines in running speed are paralleled with a decrease in stride length. This is believed to be the result of a decrease in muscle strength, which requires athletes to take a greater number of strides to cover the same distance. However, when examining the times of Senior Olympian record holders, it was found that the rates of decline were most prominent among the endurance athletes. In swimmers, the sex differences were largest in the sprint events and smallest in the distance events. The data examining the rates of performance decline among types of swimming events also yield conflicting results, as some studies report a larger decline in sprint races while others find a larger decline in endurance races. Parallel to the runner's decrease in stride length, swimmers demonstrate a decreased stroke length, which results in an increase in stroke frequency. It is believed that the mechanisms of decline are different for each sport, depending on the demands of the activity; yet altogether, they remain gradual.

Injuries in Masters Athletes

The magnitude of evidence in favor of active aging raises an important question: If masters athletes are so healthy, why are they getting hurt? According to the U.S. Consumer Products Safety Commission, a 33% increase in injuries was witnessed within the masters athlete population from 1991 to 1998. Injuries are the number one reason for the stoppage of physical activity in this group and occur highest in sports such as cycling, basketball, baseball, and running. Investigation of the mechanism of these injuries reveals that 69% of masters athletes attempt to work through their pain to remain active. This is most likely why 60% of the injuries reported are the result of overuse and only 23% are the result of falls. Research has suggested a number of reasons for the increased incidence of injury witnessed within this group, the most notable of which is inappropriate training methods. Unpublished data from a study conducted by Wright and colleagues reveal that in a sample of masters athletes surveyed, 50% of the athletes devoted 5% or less of their total training time to stretching exercises. Of that group, 31.5% devoted only 0% to 2% of their time to stretching activities. This is without question an insubstantial amount of time. To avoid injury, masters athletes must train smarter than they did in their younger years. This includes proper nutrition, not overextending oneself when training, and adequate amounts of daily stretching, especially before intense bouts of exercise.

Muscle

Acute muscle strains account for a predominant portion of the injuries witnessed within the aging population. This is attributed to loss of flexibility as well as weak or fatigued muscles. The predisposition of masters athletes to these injuries is thought to be the result of their frequent participation in endurance sports. Investigation of the mechanism of these injuries reveals that the athletes often report changes in their training activities when recounting the onset of the injury. This supports the belief that older athletes do not transition from sport to sport as quickly as they did in their younger years and require a more extensive warm-up before commencing rigorous physical activity. Furthermore, all individuals have a responsibility to exercise, no matter at what age, to maintain stronger, resilient muscles that are more resistant to injury.

Tendon

Tendinosis in masters athletes commonly occurs as the result of overtraining. This subjects the tendon to repetitive microtrauma, which in turn causes it to stiffen. Other factors that can contribute to this age-related stiffening of connective tissues are decreases in water content, increases in elastin fibril thickness, and hormonal abnormalities, such as diabetes mellitus or an excess of corticosteroids. Three of the most prevalent types of tendinosis in masters athletes are rotator cuff tendinopathy, Achilles tendinitis, and tennis elbow. All this suggests that the gradual stiffening of tendons must be paralleled by changes in the masters athlete's training regimen if he or she is to avoid these injuries. Daily stretching exercises are paramount in avoiding tendon stiffening and the subsequent tendinosis.

Knee

In recent years, the consensus that exercise provides protective benefits to joints by reducing the incidence of degenerative diseases, such as osteoarthritis, has been a controversial issue. Traditionally, the prescribed therapy for knee pain has been modification of training activities, a technique not well received by many masters athletes. This makes the management of knee osteoarthritis one of the most challenging issues in sports medicine today since those affected by this disorder typically wish to maintain a high level of physical activity. Investigations of this disorder reveal that athletes symptomatic for knee osteoarthritis all demonstrated quadriceps weakness, reduced proprioception, and increased postural sway. Altered proprioception due to muscle fatigue may weaken the neuromuscular response and decrease the efficiency of protective muscular reflexes. This contradicts the paradigm that the aging athlete should not participate in activities that subject the knees to high levels of impact, such as running, as knee injuries can be avoided by maintaining quadriceps, core, and hip strength, as well as refraining from high-intensity workouts when fatigued.

Shoulder

Shoulder injuries, such as subacromial impingement and rotator cuff tears, are commonly associated with repetitive shoulder motion. Initially, the goal of shoulder surgery was to alleviate pain symptoms. Currently, the goal is to achieve a return to physical activities, which is becoming increasingly more common. Patients over 65 years demonstrate great success in recovering from subacromial decompression and rotator cuff repair, with a 94% satisfaction rate. The majority of these patients report a reduction in pain symptoms, independent living, and return to sports. Research investigating return to sports suggested that 80% of patients return to sports at their previous level of competition following surgery to their dominant shoulder. However, this becomes increasingly more difficult as patients pursue higher-intensity, higher-impact sports. Despite the success rates of these surgical procedures, these injuries are best treated through preventive efforts. Many athletes focus on building the "cosmetic" muscles, such as the biceps, triceps, and deltoids, while ignoring the exercises that work the smaller muscles, which are paramount for joint stability and avoiding injury.

Hip

Studies of women with lower extremity osteoarthritis revealed that fatigue was strongly associated with physical activity, while pain was more weakly associated with physical activity and was in the direction opposite to what was expected. This stresses the importance of fatigue management in helping masters athletes with osteoarthritis maintain high levels of physical activity. Hip arthroscopy is a method commonly used to treat labral tears and the early stages of osteoarthritis. It has yielded reproducible results in the diagnosis and treatment of intraarticular hip disorders in elite athletes. Hip arthroscopy could be a promising treatment for the aging population as many elite masters athletes refuse to modify their activities and do not have the degenerative changes to warrant joint replacement. Regardless of activity levels, the senior population will exhibit a redistribution of joint torques from plantarflexion to hip joint extension over time. However, the active elderly display a more pronounced increase of hip extension torque, which enables them to perpetuate the support torque at the level of young subjects. This age-related redistribution of joint torques is of pivotal importance since the active elderly use it as a means of compensating for diminishing muscle function. By maintaining flexibility, core, and gluteal strength, masters athletes may avoid hip injuries and continue to enjoy high levels of functional capacity.

Changes That Occur as We Age

Natural Aging: The Cardiovascular System

In the aging process, upkeep of cardiovascular function is imperative: Forty percent of deaths in people between the ages of 65 and 74 are the result of heart disease; for individuals over the age of 80, this proportion jumps to 60%. This is because many age-related physiological changes are witnessed in the cardiovascular system. For example, a 70-year-old heart has 30% fewer cells than the heart of a 20-year-old. The cardiac output of a 20-year-old is 3.5 to 4 times his or her resting capacity, while an 80-year-old can output only twice his or her resting capacity. During exertion, the maximum heart rate for a 20-year-old is between 180 and 200 beats per minute (bpm), while it is only 145 bpm for an 80-year-old. To some extent, these changes are part of the natural maturation of the heart. As part of the aging process, the maximum heart rate, the stoke volume, and the contractility of the heart will decrease. In the arteries, a decreased elasticity occurs, which results in a narrower space for blood to flow from the heart. This produces a rise in blood pressure and forces the heart to pump harder, which eventually leads to a thicker left ventricle. All these changes disrupt the heart's delivery of oxygen to the tissues, which affects performance, metabolism, and energy levels. Although these physiological changes may appear alarming, chronic high-level exercise and a healthy diet have long been associated with healthy cardiovascular function and a slowing of these changes.

Masters Athletes: The Cardiovascular System

Through endurance conditioning, one is capable of modifying maximum oxygen consumption, diastolic filling and relaxation, and arterial stiffness. In a prospective study of masters athletes across 20 years, less than 14% evidenced risk factors for coronary heart disease at the 20-year evaluation point. In addition, a study of the effects of vigorous endurance training reflected a low prevalence of hypertension in masters athletes when compared with controls, with the masters athlete group being 27.8% less likely to have used medication for hypertension at any time. While a lower body mass and decreased body weight may explicate this effect, researchers believe that other mechanisms exist whereby exercise may induce a decreased rate of hypertension.

Natural Aging: The Muscular System

Sarcopenia, or the loss of lean muscle mass, is one of the major contributors to the loss of independence in the aging population. This is because large decrements in muscle mass will lead to an increased risk of injury. As with the heart, skeletal muscles will lose cells as they age, as well as exhibiting increased stiffness and a reduced size of the muscle fibers, beginning around the age of 50. These changes result in a decrease in muscle mass, which in turn produces an equal or greater decline in muscle strength and power. In the sedentary population, this loss of lean muscle mass is approximately 15% per decade between the ages of 50 and 70. After 70, this loss reaches approximately 30% per decade. The clinical impression is that these changes are the result of compositional changes of the muscle as research has shown an increased fat infiltration in the muscle of the aging sedentary population. However, recent studies of masters athletes have discovered that this is not the case.

Masters Athletes: The Muscular System

A study of masters weight lifters revealed a muscle deterioration rate of 1.0% to 1.5% per year. Additional studies determined that an 85-year-old weight lifter is as powerful as an inactive 65-year-old. This indicates that competitive performance throughout the later life stages is still feasible and that maintaining an increased level of physical activity in late life is imperative for healthy aging. Furthermore, analysis of anaerobic muscle performance indicated that age-related rates of decline in women exceed those of men but only in events requiring explosive power. It is in these events that we witness the largest rates of decline for both sexes. To contest the paradigm that muscle undergoes many age-related composition changes, Wright and colleagues are currently conducting a study that investigates the role of chronic high-level exercise in preventing the loss of lean muscle mass and strength. Preliminary findings support the observation that fat infiltration did not increase with age and that total muscle area and quadriceps strength did not decline with age. This offers further support that by maintaining muscle mass and strength, masters athletes are able to stave off falls, functional decline, osteoporosis, or other factors that lead to the loss of functional independence.

Natural Aging: The Skeletal System

The loss of bone mineral density (BMD) associated with aging is another major contributor to the loss of independence in the senior population. Decreases in BMD can lead to osteoporosis, subjecting the individual to an increased risk of fracture. Risk factors for osteoporosis include decreased calcium intake, low levels of active exercise, smoking, and low levels of testosterone in men. The loss of bone mass is a major problem for both men and women over the age of 40. Women lose bone mass twice as fast as men, at a rate of 1.5% to 2% per year. This rate reaches 3% per year postmenopause.

Masters Athletes: The Skeletal System

When comparing whole-body BMD values of masters athletes and sedentary adults, the athlete group exhibited significantly larger values of BMD. In a study of masters athletes participating in the 2005 National Senior Games, it was found that the majority of the women had more normal bone density than weak bone density, even those who were more than 80 years old. The incidence of osteoporosis among this group of woman masters athletes was less than in the general population at any age. In other studies, a 0.8% increase in hip BMD was associated with each hour-per-week difference of high-level exercise in women. These increases were most prominent among premenopausal women. A study of femoral neck, spine, and whole-body BMD in men over 65 years of age determined that bioavailable testosterone, physical activity level, and body mass index (BMI) all contributed to the variance of BMD values at the femoral neck. Independent analysis of these three variables revealed that bioavailable testosterone accounted for 20.7% of this variance, physical activity for 9.0%, and BMI for 6.5%. Bouts of high-intensity resistance training resulted in sharp increases in testosterone levels in middle-aged and older men, which may further alleviate decreases in BMD. All this demonstrates that BMD may be maintained in the aging population through high levels of chronic exercise.

Natural Aging: Cartilage and Tendon

Both cartilage and tendon can deteriorate through atrophy or overuse. Maintaining these tissues is of primary concern for the aging population. Tendinitis is a painful inflammation of the tendon that is quite common in athletes over 40. This condition develops as the tendon experiences repetitive microtears through excessive movements or inadequate stretching prior to physical activity. The lack of stretching causes the fibers of the tendon to gradually become shorter. Tendinitis is most commonly seen in the elbow, wrist, biceps, shoulder, leg, knee, and Achilles. Ultimately, it occurs in the areas of the body that the individual uses most. Healthy cartilage can deteriorate by softening or fissuring. High-impact activities have been shown to exacerbate this wear of deteriorated cartilage. Fortunately, this is not always the case.

Masters Athletes: Cartilage and Tendon

These conditions can be easily avoided with smart training methods, such as a proper warm-up and stretching prior to strenuous physical activity. The best way to protect cartilage and tendon is to adequately address issues such as pain and fatigue as they arise. Ignoring symptoms such as pain or weakness will only subject cartilage and tendon to further abuse. Rest and moderation of training activities are imperative to protect the health of the body's cartilage. If masters athletes adopt the right training methods, they will obtain the most favorable results. For example, a study of healthy middle-aged women athletes revealed that participation in exercise that produced an increased pulse rate for a minimum of 20 minutes was positively associated with the volume of medial tibial cartilage. None of the women in this study exhibited knee cartilage deficits as a result of this activity.

Additional Benefits of Active Aging

While chronic exercise is a known preventer and antidote to many of the problems that plague the sedentary aging population, there exist additional benefits that exercise brings to the aging population that are not often discussed in the literature.

Cancer

Recent research suggests that exercise can not only prevent cancer but also significantly reduce the risk of cancer-specific mortality in individuals who increase their levels of exercise postdiagnosis, specifically in breast and colorectal cancer. Adjusting for age at diagnosis, stage of the disease, state of residence, interval between diagnosis and physical activity assessment, BMI, menopausal status, hormone therapy, energy intake, education, family history, and treatment modality, researchers discovered that women who regularly participated in high levels of physical activity had a significantly greater chance of surviving breast cancer. Reduced mortality rates were also witnessed in women with Stages I to III colorectal cancer who participated in at least 18 metabolic-equivalent task hours of physical activity per week. Further research is necessary to evaluate this trend as related to other cancers as well as the precise amount of exercise necessary to obtain these benefits.

Cognitive Function

While many studies have investigated the benefits of active exercise for one's physical health, the benefits specific to cognitive function have received little recognition in comparison. This is staggering since declines in cognitive function have become one of the major contributors to the loss of independence in the aging population. Recent studies indicate that regular exercise can reduce reaction time and increase serum levels of testosterone and growth hormone in elderly men. These hormones are believed to exhibit a protective effect on the risk of dementia and Alzheimer disease. Associations between these diseases and low levels of physical activity were more distinct among carriers of particular genotypes. However, chronic exercise at midlife and beyond suggests an ability to delay the onset of dementia and Alzheimer disease despite genetic susceptibility. At present, Wright and colleagues are investigating the effects of chronic high-intensity exercise on specific areas of thought processing ability: working memory, sustained and selective attention time, response variability, nonverbal problem solving, and reaction time.

Depression

Depression is a common condition in the later life stages. Studies have shown that depression is most likely to emerge when an individual transitions from an active to a sedentary lifestyle. It is associated with the largest decrease in duration of physical activity. When mobility status was assessed, individuals who were able to maintain high levels of mobility throughout the aging process exhibited fewer depressive symptoms despite their decline in overall physical activity.

Diabetes

In recent years, Type 2 diabetes has emerged as one of the most rapidly growing public health concerns worldwide. It is well known that obesity, diet, and levels of physical activity combine with genetic factors to increase the risk of developing Type 2 diabetes. While all these factors contribute independently, obesity has been shown to be the largest contributor to the onset of the disease. Those with diabetes or at highest risk of developing the disease engage in rates of physical activity that are significantly below the national average, as determined by a nationally representative survey of the U.S. population conducted by the Medical Expenditure Panel Survey. Although genetics is an important contributing factor, it is important to note that it is only part of the problem and must usually be coupled with unhealthy lifestyle choices for the disorder to develop.

Stroke

Studies on the preventive benefits of physical activity for stroke revealed that increased activity levels are associated with a reduction in stroke mortality. Test subjects were assessed by self-reports of occupational and leisure activities. In addition, moderate levels of exercise exhibited benefits among individuals already diagnosed with heart conditions such as left ventricular hypertrophy.

It is of paramount importance for the senior population to maintain increased levels of physical activity if they wish to remain functionally independent throughout midlife and beyond. While there exist many age-related changes that we cannot avoid, exercise is a known preventer and antidote to the ravages of age-related disease. People everywhere are starting to realize these benefits as the number of individuals above 50 participating in high-level sports continues to increase. Records of the New York City Marathon from 1983 to 1999 reveal that the number of runners over the age of 50 is increasing more rapidly than is the number of any other age-group. In addition, the race times of the masters athlete group are demonstrating significantly greater improvement compared with the younger runners.

While injuries do occur within this masters athletes group, this is primarily because the athletes do not change their training regimens to accommodate the physiologic changes their bodies are experiencing. To avoid these changes and still participate in chronic high-level exercise, these athletes must FACE their future. FACE is an acronym for the four components of fitness after 40 that are essential to maximizing performance and training effectively:

F—*F*lexibility

A—*A*erobic exercise

C—"*C*arry a load," or resistance training

E—*E*quilibrium and balance

Creating a balanced workout that touches on these cornerstones of physical fitness is a smart way to achieve one's fitness goals. FACE applies not only to competitive athletes but also to people of all ages and activity levels. Those who adopt an exercise regimen that embodies all these components will be able to reduce the slowing phenomenon that is so often thought to accompany life after 40.

Future efforts should focus on raising awareness about the benefits of active aging and preserving the longevity of masters athletes. This way, more individuals will be able to enjoy functional independence and the benefits of a healthy lifestyle into their later years. This is becoming increasingly more important each day as the baby boomer generation is now in their 60s and is starting to transition to the age of senior citizens. Therefore, time is running out for physicians to intervene and encourage the sedentary individuals within this group to start exercising before they reach the age of reduced functional capacity.

Sesamoiditis

The sesamoid bones of the foot were named because of their resemblance to sesame seeds. Unlike most bones, which are connected to each other through muscles and tendons, the two small sesamoid bones are found embedded in the muscle/tendon of the flexor hallucis longus muscle. Injury to these bones often occurs when great stresses are placed on the foot, such as in running and ballet dancing.

Anatomy

The flexor hallucis longus muscle is found on the undersurface (plantar surface) of the foot. It is responsible for flexing the great toe and is important in weight bearing and in transmitting forces through the foot, especially during push-off. The sesamoid bones act as a pulley for the muscle and, as such, allow much greater forces to be transmitted; a similar functional phenomenon elsewhere in the body is the kneecap (patella), which is also a sesamoid bone. The sesamoids also cushion and protect the joint where the big toe meets the foot (first metatarsalphalangeal joint).

Causes

Injury to the sesamoid bone/hallucis complex can occur as the result of a direct, acute injury or in a more chronic fashion, as in overuse or repetitive injuries. Either of the two sesamoid bones can be injured, but the medial sesamoid (closer to the inside of the foot or tibial side) is more commonly involved.

Fracture

Fracture of a sesamoid bone can occur as the result of a direct blow or forced hyperdorsiflexion (bending of the toe upward); alternatively, it can result from cumulative repetitive injury. A fracture results in immediate pain over the ball of the foot in the area underneath the great toe. There may or may not be swelling and bruising, and it may be difficult to bend or straighten the toe. Attempts at maintaining a normal gait will cause pain in this area of injury.

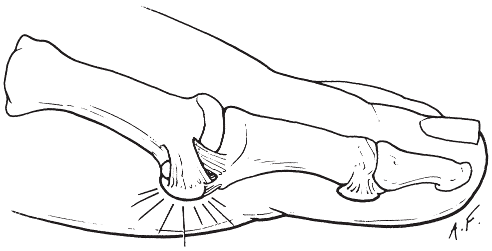

Figure 1 Sesamoiditis

Note: Sesamoiditis usually affects one or both of the sesamoid bones that lie within the tendon at the first metatarsalphalangeal joint.

Stress Fracture and Sesamoiditis

Not uncommonly, however, pain develops gradually in the same area and may be the result of a stress fracture or sesamoiditis. A stress fracture results from repetitive injury, often during a period of more intense or frequent training. In a stress fracture, the repetitive, frequent microtrauma to the bone overwhelms the bone's ability to heal itself. It occurs more frequently in ballet dancers and long-distance runners, for whom frequent, forceful toe-offs are necessary. Additionally, football players are at risk, especially when playing on artificial surfaces.

In a similar manner, irritation and inflammation of the bone and surrounding soft tissue structures—the muscle, tendon, and bursa, collectively called the sesamoid complex—can occur. This condition is called *sesamoiditis* (Figure 1).

Diagnosis

History and Exam

Evaluation of this type of injury can be performed by a health care provider comfortable with disorders in the foot and ankle. The patient's main complaint is pain under the first metatarsalphalangeal joint (the "ball of the foot"), which worsens with weight-bearing activity and is somewhat relieved with getting off the injured foot. A thorough history is often the key to diagnosis, especially in chronic injuries. In addition to the location and character of the pain, important clues on history include any changes in training (frequency, intensity, duration) and in the footwear and surface used by the athlete.

Examination of course focuses on the area of the sesamoid bone but should include a complete exam of the foot, ankle, and gait (if pain allows) to search for predisposing factors. Pain is often elicited in bending and straightening the toe, particularly bending the great toe upward. Tenderness is prominent in the area of the sesamoid bones.

Imaging

With acute and chronic injuries, X-rays can be helpful in making the diagnosis. Interestingly, the medial sesamoid is composed of two parts (bipartite) in about 11% of the population, and this sometimes makes the diagnosis of an acute fracture difficult. X-rays of the other foot are sometimes then done for comparison, or additional imaging may be necessary.

Management

Nonsurgical

Initial management of injuries generally includes activity and weight-bearing modification, in addition to relative rest, ice, and nonsteroidal anti-inflammatory medications such as ibuprofen. Treatment of an acute fracture may require immobilization and non–weight bearing for 3 to 4 weeks or longer, followed by the use of orthotics for the shoe and a slow, gradual return to activity.

A stress fracture may also require casting for a short period of time, but chronic injuries, including sesamoiditis and some stress fractures, are best treated by eliminating the repetitive stress that caused the injury. This may involve a period of rest from the aggravating activity and modification of the shoe with orthotics and inserts. These are designed to remove the stress from the sesamoid complex and may be a gel insert or J-shaped pads. A stiffer-soled shoe may also be helpful. Activities often need to be modified for at least 6 to 8 weeks. If painfree by 6 to 8 weeks, the athlete may then begin a gradual return to activity. It may take 3 to 6 months for symptoms to completely resolve in some cases of acute or chronic injury. Patients should continue to wear appropriate orthotics during this time and resume activity as tolerated.

In sesamoiditis, a diagnostic and therapeutic corticosteroid injection of the sesamoid complex may be beneficial, in addition to the previously mentioned management.

Surgical

If there is no improvement after 6 months, surgery may be considered to improve comfort and function. Surgery may be discussed as an earlier option for a highly competitive athlete who desires a chance to return to competition sooner.

If an acute fracture has not healed properly (nonunion), then curettage and grafting of the bone may be attempted. Pinning with screws may also be an option. If these are not viable options, or are unsuccessful, it may be necessary to remove the bone.

Excision of a sesamoid bone may also be indicated in refractory cases of sesamoiditis or a stress fracture. It is important for the surgeon to identify which sesamoid bone (medial or lateral) is the troublesome one as removal of both bones has often been found to result in a significant deformity of the joint connecting the great toe to the foot.

Postoperatively, the patient can expect to be in a non–weight bearing cast for at least several weeks. After this, weight bearing may begin gradually, with a total casting time of approximately 6 weeks. Once the cast is removed, additional orthotics for a longer period of time may be necessary as the patient progresses back to activity.

Sever Disease

Sever disease, also known as *calcaneal apophysitis,* was first described in the early 1900s. The calcaneal apophysis is a cartilaginous growth center located in the heel of the foot. Calcaneal apophysitis is a common cause of heel pain in growing, athletically active youth. Originally described as an inflammatory process, it has more recently been thought to result from overuse and weight-bearing injury to the growth center.

Anatomy

For descriptive purposes, the foot is divided into three areas: forefoot, midfoot, and hindfoot. The hindfoot contains two bones, the talus and the calcaneus. The calcaneus contains a vertically oriented C-shaped growth center located in the back of the heel. The growth center appears around age 5 to 9 and usually closes by age 13 to 16, when the calcaneus has achieved its mature adult shape. An additional cartilaginous growth center, the calcaneal ("traction") apophysis, is located where the Achilles tendon attaches to the bone.

Causes

Sever disease was originally described as an inflammatory process occurring within the calcaneal apophysis. Another proposed etiology was disruption of the blood supply to the growth center. Now, Sever disease is believed to be the result of repetitive mechanical stress applied to the apophysis by a tight heel cord (Achilles tendon) in an overactive young athlete.

This repetitive impact and shear stress on the growth center leads to microtrauma and injury at the junction of the bone and cartilage. This may occur during periods of rapid growth, such as a growth spurt, when the calf muscles and tendons cannot lengthen as quickly as long bones such as the tibia. An increased amount of athletic participation, including longer-duration, higher-intensity, and increased frequency of activities, contributes to the repetitive loading of the heel with weight-bearing activity. Sever disease does not occur after puberty, once the cartilage growth center fuses to become bone.

Symptoms

Sever disease is most common in active children 8 to 12 years old. It is slightly more predominant in boys. It presents with intermittent or daily heel pain and occurs on both feet in more than 50% of children. There is usually no history of an acute fall or direct injury to the heel. The child may describe the pain as located over the heel, and it may be severe enough to cause a limp, especially after participating in physical activity. While the pain may be present at rest or with daily activities such as walking, it is generally made worse with weight-bearing activities, such as running and jumping in sports activities. While all sports can make the symptoms of Sever disease worse, sports such as soccer, basketball, and running are common culprits. Heel pain may present at the beginning of a sports season or when the child is experiencing a growth spurt. The pain is usually absent in the morning, increases with activity during the day, and decreases with rest. Hard surfaces, such as a basketball court, or athletic shoes with little support and cushioning, such as soccer cleats, may worsen the symptoms.

Diagnosis

On physical examination, the most common finding is pain with compression of the inside and outside of the heel (the "squeeze test"). There should be no swelling, redness, or other skin or bone abnormalities. Usually, the gait is normal, but the child may walk with a limp. Many children also have a decreased flexibility or tightness of their calf muscles, resulting in limited dorsiflexion, the ability to pull or stretch a foot toward the head. The strength of the calf muscles is normal. Foot abnormalities such as pronation and flat feet may be present and worsen the condition. The child should otherwise be healthy, with no night pain or other signs or symptoms of systemic disease.

Plain radiographs are not routinely obtained because there are no findings that are diagnostic or specific for Sever disease. Findings such as irregularity of the growth center are often present on radiographs of asymptomatic feet. If the pain is unusual in character, other systemic symptoms are present, or the pain persists despite adequate rest and treatment, then plain radiographs may be considered to rule out other causes.

Treatment

The mainstay of treatment involves nonsurgical therapies. The most important treatment principle is to discontinue the repetitive activities that are causing the heel pain. This means completely avoiding or significantly limiting impact sports activities that involve running and jumping for some period of time.

The use of soft heel cups or heel lifts may help cushion and relieve the tension on the heel. Children should wear good-quality athletic shoes with an adequate shock-absorbent sole and avoid going barefoot at all times. Therapeutic exercises, such as stretching and strengthening of the calf muscles, may be prescribed under the supervision of a physical therapist.

As Sever disease is not an inflammatory process, anti-inflammatory medications are not indicated to decrease inflammation. Application of ice and the use of medications such as acetaminophen or ibuprofen may be helpful in reducing pain. Corticosteroid injections are not recommended. In rare cases, when the pain is severe and accompanied by a limp, crutches or immobilization may be used for a short period of time.

The majority of children are painfree and able to return to the desired physical activities within weeks to 2 months of proper treatment. A return to sports and physical activity is appropriate when the child can participate with minimal discomfort. Continued stretching, especially during growth spurts, may prevent initial or recurrent Sever disease. There are no known long-term sequelae of Sever disease.

Shift Work and Exercise

Approximately 3.6 million people in the United Kingdom work mostly on shifts, representing 14% of the British workforce. This proportion is similar in most other developed countries. Shift workers predominate in heavy industries and emergency services, but they are also increasingly found in finance and service industries. Data from epidemiological studies suggest that shift work, and especially night work, is associated with insomnia, gastrointestinal problems, obesity, heart disease, and cancer. Disruption of circadian rhythms during shift work is thought to be important in explaining these increased health problems. Nevertheless, the differences between shift workers and day workers in lifestyle factors, including participation in physical activities, have been generally underresearched.

On a behavioral level, shift work can restrict the opportunities to be physically active, although this can depend on individual choice of leisure pursuit (group or individual based). On a biological level, the disruptions to circadian rhythms and sleep that are associated with shift work can alter the normal physiological responses to a bout of physical activity as well as how well a particular exercise bout is tolerated. The latter issue might have implications for long-term adherence to physical activity regimens during shift work. Unfortunately, studies in which physical activity interventions are administered to shift workers are rare.

Physical Activity Behaviors During Shift Work

Workers and their families can alter their habits to cope with the disruption to domestic life that is associated with shift work, although women shift workers seem to have particular problems in balancing their work and domestic lives. Unlike the malleable domestic environment, organized leisure activities and training sessions for sports clubs are generally scheduled in the early evening and weekends to accommodate the day-working majority. This scheduling conflict makes it very difficult for the shift worker to participate in organized activities and has been found to contribute to the decision of some people to leave shift work altogether. Those shift workers who enjoy solitary or individual activities are probably not so disadvantaged. Individual shift workers who join fitness and health clubs can enjoy the benefits of "off-peak" membership costs and can use the facilities at less crowded times. Activities such as cycling, swimming, and jogging can also be carried out on an individual basis in the shift worker's own spare time. Nevertheless, organized competitions in these sports are still normally scheduled in the weekend, when it is more likely that a shift worker is at work. Moreover, the transient negative experiences of exercising while partially deprived of sleep and at times that are out of kilter with the "body clock" (e.g., in the early morning) might be perceived to be significant enough for the shift worker to stop these individual activities. Such attrition at an early stage in an exercise program would be unfortunate since there are, as discussed below, likely benefits of exercise to the shift worker.

Benefits of Physical Activity to the Shift Worker

Physical activity, when timed appropriately, may consolidate human circadian rhythms. Although purely correlational in nature, there is evidence that good tolerance to rapidly rotating shift work is associated with large amplitudes (mean-to-peak differences) of circadian rhythms, which tend to be observed more in physically active and fitter individuals than in sedentary people. Nevertheless, it may well be that those people who are naturally more tolerant of shift work are able to be more physically active, rather than vice versa. This "chicken or the egg" conundrum is common in many descriptive studies on shift work. There is no direct evidence to suggest that any unique circadian characteristics of physically fit shift workers mediate fewer short-term tolerance problems and better health compared with less fit workers.

It is known that habitual bouts of physical activity increase both the duration and the quality of nocturnal sleep in diurnally active people. The amount of slow-wave sleep (SWS), which is thought to be important for brain restoration and recovery during nocturnal sleep, is also increased by physical activity. It is possible that physical activity is beneficial via a reduction of anxiety, a sleep-inducing thermogenic effect, or long-term antidepressant effects or by mediating a circadian phase that is more amenable for sleep. Increases in sleep quality following exercise may be mediated by temperature elevation, which, in turn, increases SWS. Chronic physical activity promotes the sleep-onset process by inducing more proficient temperature downregulation. In a recent study on the effects of exercise on daytime sleep during partial sleep deprivation, it was found that sleep latency (the time it takes to enter sleep after retiring to bed) and wrist activity were reduced by exercise taken 4 hours prior to the sleep period, offering support that the favorable effects of physical activity on sleep quality translate to a shift work context. Nevertheless, shift workers who are motivated enough to exercise might attempt to exercise closer than 4 hours to a given sleep period or even at night. The exact consequences of these unusual timings of exercise bouts relative to the unusual timings of sleep periods are not known. Recently, it was found that there are no negative effects of exercise when taken close (within 2 hours) to the start of a sleep period, although this sleep period was taken at night by people living diurnally.

The temporal placement of physical activity may also affect the adjustment to shift or night work via advancing or delaying an individual's circadian rhythms. If circadian rhythms can be adjusted to times more amenable to the particular shift that is being worked, it is possible that feelings of fatigue, tiredness, sleepiness, and other short-term effects of working unusual hours can be attenuated. These improvements in shorter-term tolerance might, in turn, make exercise more tolerable to the shift worker and so aid the maintenance of participation in physical activity regimens. Nocturnal exercise can induce phase delays in the onset of melatonin secretion, but exercise-induced phase advances have not been confirmed in humans. At best, the phase-shifting effects of exercise on the body temperature rhythm are very small, and the substantial levels of activity (possibly 3 hours of exercise at 50% to 60% of maximal oxygen uptake) needed to obtain these small phase shifts are impracticable and may even be unattainable by the majority of shift workers.

Physical Activity Interventions During Shift Work

It has been speculated that improved workplace-based recreational facilities, to promote physical activity, might be useful for general tolerance to shift work. Nevertheless, there is little empirical support for such views. To date, there has been only one study in which a physical training intervention was administered specifically to shift workers. Mikko Härmä, and his colleagues in Finland, designed a training program for 119 women shift workers. Exercise sessions were administered between two and six times per week, between 60% and 70% of maximal heart rate, and for a 4-month period. It was found that this moderate physical training mostly benefited aspects of sleep. General fatigue decreased significantly in the training group during the whole cycle of rotating shift work, and scores on some tests of performance improved. The authors suggested that moderate exercise should be performed several hours before the main sleep period when on a morning or day shift schedule. Physical activity was advised before an evening nap, during a period of night work, although the researchers did not investigate the specific issues about the timing of the exercise.

Although there are predicted benefits of physical activity for the shift worker, there is evidence that the majority of shift workers do not follow the general guidelines to take more exercise. Whether this is due to the disruptive nature of shift work, feelings that an unhealthy lifestyle is acceptable providing that shift work continues to pay well, or the general reluctance to adopt a healthy lifestyle is, at present, unclear.

Shoulder Arthritis

Glenohumeral arthritis, or shoulder arthritis, is a rare but potentially debilitating condition in the young athlete. A number of treatment options are available, depending on the etiology of the condition, the extent of joint damage, and the functional deficit present.

Etiology

Degenerative arthritis can be classified as either primary, implying an unknown causative agent, or secondary, in which the underlying pathological mechanism has been established. Primary osteoarthritis is primarily an age-related disorder associated with repetitive stress on a normal joint. Athletes most at risk include those engaged in repetitive overhead activities, such as in cricket, baseball, weight lifting, and racquet sports. In contrast, secondary arthritis, which is more common in the younger athlete, usually has an underlying cause, such as a previous shoulder surgery, trauma, infection, ischemia, or inflammation. Capsulorraphy arthropathy can occur if the anterior shoulder capsule has been excessively tightened during stabilization surgery, thereby limiting movement, principally external rotation. Posterior translation during external rotation results in posterior glenoid erosion and capsular damage. Osteonecrosis (avascular necrosis) may be traumatic or atraumatic in origin. In traumatic cases, there is usually disruption of the vascular supply to the humeral head following a proximal humeral fracture. Atraumatic osteonecrosis may be idiopathic or secondary, resulting from smoking, steroid and alcohol use, or hematological disorders (sickle cell anemia and thalassemia). The patients are normally younger and may present with few diagnostic indicators besides pain. Inflammatory arthritides such as gout, systemic lupus erythematosus (SLE), psoriatic arthritis, and ankylosing spondylitis, though less common in athletes, form the second largest category of glenohumeral arthritis. In these conditions, multiple joints may be involved. Clinical findings of cervical spine pathology, the presence of a cuff tear, or bilateral glenohumeral involvement should prompt further hematological investigation. Glenohumeral septic arthritis is uncommon except in immunocompromised individuals. Localized erythema and warmth are highly suggestive of infection, and if confirmed by aspiration, urgent arthroscopic irrigation and debridement is required.

Assessment of the Arthritic Shoulder

A patient with glenohumeral arthritis usually presents with a history of progressive pain and stiffness. The pain commonly intensifies with use and interferes with sleep, especially when lying on one side. There may be crepitus on glenohumeral movement and an inability to perform tasks requiring shoulder rotation. Specific consideration must be given to symptoms and signs suggesting the possible underlying etiology. Initial examination of the shoulder should include inspection of the upper torso for signs of muscle atrophy and asymmetry. Careful assessment of the cervical spine is mandatory to identify sources of referred pain. The active and passive ranges of shoulder motion must be recorded. Examination usually reveals pain with a restricted range of movement, often accompanied by crepitus. Limited external rotation is a common finding in osteoarthritis and may require adjunctive therapy. The integrity and strength of the rotator cuff muscles should be assessed as this may influence the choice of treatment offered. This may, however, be difficult due to pain. Unlike in rheumatoid arthritis, most patients with osteoarthritis have preserved or only slightly diminished strength, indicating only mild, if any, rotator cuff dysfunction. It is also important during the assessment process to ascertain the nature of the sport played by the athlete, hand dominance, level of performance, and intention to return to competition.

Imaging the Arthritic Shoulder

The three preferred radiographic projections of the glenohumeral joint are a true anteroposterior view, a scapular outlet view, and an axillary view. The radiographic features of glenohumeral osteoarthritis typically include joint space narrowing, osteophyte formation, subchondral sclerosis, and cyst formation. Further imaging modalities are not always necessary, but computed tomography (CT) may be a useful aid in preoperative planning to assess the patient's bone stock and glenoid version. Magnetic resonance imaging (MRI) may be indicated when there is clinical suspicion of a rotator cuff tear, which may influence future management: For example, a major tear may rule out total shoulder replacement.

Conservative Treatment

There is wide variability in the presentation of degenerative glenohumeral disease. Significant destructive radiographic changes may be present, but an individual may continue to function well if his or her demands are low. On the other hand, individuals with limited radiographic findings may find themselves substantially incapacitated by pain. Given this inconsistency, the success of nonoperative therapy cannot be based on radiological findings but rather must be based on the patient's own views of his or her functional capabilities. Recognizing that the most common arthritides are progressive in nature, conservative management should be based on maintenance of function as well as improvement. The principles of conservative management in glenohumeral osteoarthritis include: (a) activity modification, (b) medication for pain relief, and (c) a self-conducted physiotherapy program. Activity modification requires a commonsense approach, whereby the patient limits its symptom-provoking activity. Activities such as racquet sports should be discouraged unless they are tolerable to the patient. This may seem a simple request; however, with such a large emphasis on continued participation in sports, many athletes are unwilling to forego playing despite the pain. The success of drug therapy in treating osteoarthritis is variable. Nonsteroidal anti-inflammatory drugs (NSAIDs) are often given to relieve symptomatic pain, but there is no evidence of its having any affect on disease progression. It is widely suggested that opiates should be avoided due to their potential for dependence. Omega 3 and glucosamine supplementation may be beneficial, although data regarding their efficacy are scarce despite widespread over-the-counter use. Intraarticular corticosteroid injections may provide temporary symptomatic relief in recalcitrant cases. Repeated injections are discouraged due to their catabolic effect on articular tissue and, therefore, should not be used as a mainstay of treatment. Intraarticular hyaluronan injections, although more costly, have been shown to have longer beneficial effects compared with corticosteroids, with fewer side effects. Physiotherapy typically involves gentle range-of-movement exercises to preserve and, if possible, improve joint motion, strengthen the rotator cuff muscles, and maintain glenohumeral stability.

Arthroscopic Treatment

Arthroscopic debridement may be employed to treat early glenohumeral osteoarthritis that has failed to respond to conservative management. Arthroscopy allows careful examination of the degree of cartilage damage and the integrity of the soft tissue envelope. Unstable chondral fragments and osteophytes can be removed and microfracture performed to stimulate cartilage regeneration. Associated pathology can be addressed by additional procedures such as the repair of labral/rotator cuff tears, subacromial decompression, or acromioclavicular joint resection. Arthroscopic debridement is principally a temporary treatment measure for shoulder arthritis, and its results depend greatly on the severity of the disease. It is however, a valid option for younger athletic patients, in whom more definitive procedures such as arthroplasty may be contraindicated due to the risk of component deterioration and subsequent failure.

Shoulder Arthroplasty

The principle indication for glenohumeral arthroplasty (joint replacement) is pain refractory to conservative and arthroscopic treatment. The procedure offers reliable pain relief and may result in secondary recovery of strength and function. Arthroplasty should be considered with caution in mild to moderate arthritis, in younger patients with high functional demands, and where there is a lack of glenoid bone stock or rotator cuff deficiency. It is important when counseling a patient with regard to prosthetic reconstruction that realistic expectations be set. The type of arthroplasty chosen must take into account patient factors such as age and activity levels, as well as the nature of the underlying pathological process, the pattern of joint destruction, and the integrity of the soft tissue envelope. Choices include humeral head resurfacing (total or partial), stemmed hemiarthroplasty, and total shoulder replacement (including reverse polarity). Where good bone quality remains, humeral head resurfacing using a pegged metal cap is a relatively simple technique providing a valid alternative to stemmed hemiarthroplasty, particularly in younger patients. This form of surgery is less invasive than traditional shoulder replacement and, therefore, recovery is typically much faster. Resurfacing can help prolong or avoid altogether the need for future joint replacement. It is therefore an attractive option for young athletes in whom undergoing arthroplasty at an early age carries a greater risk of future revision surgery. More normal anatomical relationships are maintained; potential errors in determining the humeral head height, glenoid version, and implant alignment are minimized; and stem-related complications are avoided.

Glenohumeral Arthrodesis

This is a fairly crude technique involving fusion of the humeral head to the glenoid and acromion, thereby relying solely on scapulothoracic rotation to move the upper limb. It is now rarely employed as cases unsuitable for modern replacement techniques are limited. Indications include severe septic arthritis and previous failed joint reconstruction with severe bone loss. Patients undergoing this type of procedure generally have significant functional limitation.

Conclusion

In the active individual, most cases of glenohumeral arthritis should be managed using the conservative methods detailed above. Once these are exhausted, surgical treatment must be selected on a case-by-case basis, considering the individuals functional demands, type and severity of arthritis, and residual bone stock. Patients with only minor arthritic changes may benefit from arthroscopic treatment initially, whereas those with extensive damage may require total arthroplasty. In these cases, where possible, less invasive techniques such as cementless resurfacing of the glenoid should be employed. Further long-term randomized studies are required to compare cementless humeral head arthroplasty with stemmed hemiarthroplasty and total shoulder arthroplasty if a conclusion about the optimal treatment of young arthritic athletes is to be reached.

Shoulder Bursitis

Bursae are flattish, fluid-filled sacs lined with synovial membrane that typically lie between bone and tendons or adjacent tendons; bursa sacs provide a smooth gliding surface for tendons to move along and may lessen the irritating friction that could otherwise occur between the tendon and other structures. At baseline, the fluid in the bursa is minimal. When the bursa becomes inflamed (as indicated by the suffix "itis"), it enlarges and the fluid contents increase. There are eight bursae in the shoulder. The primary or largest bursa, the subacromial bursa, is located just under the acromion, the rounded-off bony prominence located most laterally on the shoulder. While understanding the concept of *shoulder bursitis* is useful, it may not completely describe the root cause of the problem. The inflamed bursitis condition commonly occurs due to or in response to rotator cuff tendon inflammation from poor mechanics and/or overuse. The rotator cuff muscles are anatomically directly underneath the subacromial bursa; when one structure is inflamed, the adjacent structure becomes inflamed as well (Figure 1).

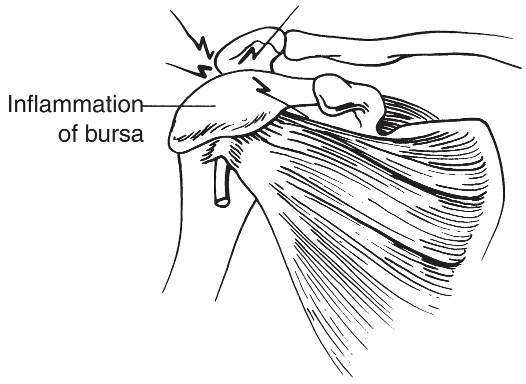

Figure 1 Inflammation of the Bursa Occurs Between the Rotator Cuff Tendons and the Shoulder Blade

Causes

When the bursa becomes inflamed, it swells up and occupies more space. In doing so, the swollen bursa can further limit the size of the space (the subacromial space) in which the rotator cuff tendon moves. In certain extremes of motion, this can cause a painful impingement phenomenon. This mechanism can lead to further irritation and pain. Rotator cuff tendinopathy may often be the underlying mechanism causing shoulder bursitis. The rotator cuff muscles, which become tendons when attached to bones, are the dynamic structures that allow for the tremendous range of motions in multidirections that the shoulder is capable of producing. There are four muscles that make up the rotator cuff: supraspinatus, infraspinatus, teres minor, and subscapularis. The shoulder is referred to as a ball-and-socket joint—the rounded ball of the humerus fits into the shallow, saucer-like socket of the glenoid. A golf ball resting on a tee is an appropriate analogy. This great mobility of the shoulder joint does come at a price, with the shoulder joint having increased susceptibility to injury and overuse.

Clinical Evaluation

Rotator cuff problems generally occur in older populations, ages 40 to 50, who may or may not be athletically inclined. It can present either insidiously, which may or may not involve an increase in certain shoulder movement activities, or in a more acute setting after a specific injury. Any change in the intensity, frequency, or duration of an activity, be it at work or at home, as well as any new activity could contribute to developing an overuse injury. Age-related changes to tendons result in their less pliable or elastic (rubber band–like) quality; this can lead to fraying, swelling in the tendon, calcified deposits, and frank tears. Thus, as we get older, we may be more prone to overuse injuries such as rotator cuff tendinopathy and shoulder bursitis, and unfortunately, we may recover less well from them.

In the athletic population, rotator cuff tendinopathy can develop in any overhead throwing or motion sport such as baseball and softball, racquet sports such as badminton and tennis, swimming, and water polo.

Examples of activities that patients describe are a weekend playing softball or playing fetch with a dog and carrying more than the usual bags of groceries or heavy suitcases on a trip. Occasionally, they may recall a specific incident, such as a fall on an outstretched hand or a sudden jerking or traction from catching a heavy falling object. Most of the time, however, a patient cannot say how the pain started.

Most commonly, the pain affects a fairly large area, directly over the shoulder, in the posterior neck/upper back, and, not uncommonly, down the arm over the deltoid region. Rarely does shoulder bursitis pain radiate past the elbow. The pain or soreness is not only exacerbated by heavy lifting or very strenuous activities, but it can also result from simple maneuvers performed in activities of daily living. This would include reaching up into a cabinet, lifting an arm up to the head to brush or shampoo one's hair, reaching behind to slip a hand into a jacket sleeve, pulling up a pair of pants, and turning a steering wheel, to name some of the most common exacerbating actions.

One common symptom of rotator cuff tendinopathy is nighttime pain that occurs with lying on the affected arm/shoulder. It can wake a person up if he or she should unintentionally roll over to that side. Usually, the "weakness" patients may have is the result of guarding against the pain, which would reflexively limit how much load they place on the shoulder. This is in contrast to any inherent or primary loss of muscle strength, intrinsic to the muscles or nerves itself.

Management

Rehabilitation

The mainstay of treatment for rotator cuff tendinopathy/shoulder bursitis is effective physical therapy/rehabilitation. Initial exercises would involve stretching, correcting muscle imbalance and improving coordination, and eventually strengthening of the rotator cuff muscles. For athletes, an evaluation of biomechanics and the entire kinetic chain function, as well as pinpointing of training errors, should be incorporated to prevent recurrence of problems.

Medication

For pain relief, nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen or naproxen are often prescribed. There is some evidence to suggest that NSAIDs may slow or harm the healing process in tendons; additionally, care must be taken to prevent gastritis/stomach ulcers. Liberal application of ice for 15 to 20 minutes three times a day is recommended for pain control without the risk of any significant adverse effects. An option for pain control, especially pain causing significant disruption in sleep or work, is a cortisone injection. An advantage of corticosteroid injection is that pain reduction may allow the patient to participate in physical therapy more effectively. Cortisone is a powerful anti-inflammatory and can be injected directly into the affected joint or area—for example, directly into the inflamed subacromial bursa.

Imaging

For diagnostic purposes, imaging can be obtained. Although plain films or X-rays will not show bursitis or rotator cuff tendons, they are helpful to look for bony abnormalities that are indirect signs of rotator cuff problems, such as calcifications in the tendon, down-sloping or hooked acromion, and other bony processes that can cause similar symptoms such as arthritis. If more advanced imaging is desired, either because a frank and complete tear is suspected and/or the patient is not improving or the diagnostic picture is more complicated, magnetic resonance imaging (MRI) can be considered. MRI is the imaging modality of choice to directly visualize and evaluate the rotator cuff tendons. The presence of a complete tear is not an automatic indication for surgery, as many patients do quite well with a course of aggressive rehabilitation and there are people with rotator cuff tears who have good range of motion, have good strength, and are functionally asymptomatic.

Operative

Operative treatments can be considered if there is no progress, unrelenting pain, or inadequate function. Most rotator cuff tendon surgeries can be done with arthroscopy, whereby small incisions and thin pencil-like instruments are used, and most often on an outpatient basis.

Calcific Bursitis

On occasion, calcium crystals may accrue in the bursa. This "calcific bursitis" can be very painful and subject to flare-up of severe pain. Surgery is sometimes required to remove the calcified bursa.

Shoulder Dislocation

The shoulder is the most frequently dislocated joint, and the injury is common in contact sports and activities with a potential for falling accidents, such as skiing or biking. It occurs commonly in young adults and can lead to significant disability for an athlete. Most dislocations result from trauma, and the majority (>90%) occur anteriorly.

Anatomy

The shoulder is a ball-and-socket joint. The humeral head (ball) sits in the glenoid (socket) and allows the large range of motion that humans have at the shoulder. This range of motion allows extremes of motion, such as those that an elite pitcher uses to throw the ball.

There are a number of structures that help stabilize the glenohumeral joint. First, to help the humeral head fit more snugly in the glenoid, the glenoid is surrounded by a ring of cartilage called the labrum. Second, the glenohumeral ligaments add further stability to the joint. These ligaments are thickened areas of the shoulder capsule, which encompasses the entire joint. Both the labrum and the glenohumeral ligaments can be injured when the humeral head dislocates out of the glenoid.

In addition, important arteries and nerves travel in this area and can be injured from a shoulder dislocation.

Causes

As mentioned, more than 90% of traumatic shoulder dislocations are anterior, with the head of the humerus dislocating out of the front of the glenoid. This usually occurs as the result of a fall with the arm in the abducted (held away from the body) and externally rotated position or when the arm is hit from the front when held in this same position, as can happen in a football tackle.

Less frequently (2–4%), the dislocation is posterior, with the humeral head dislocating out of the back of the joint. This usually occurs when the arm is forward elevated and internally rotated. These dislocations are less likely to occur from sports (although they can occur with the pass block in football) and are more likely the result of a motor vehicle accident, seizure, or electric shock (Figure 1).

Symptoms

The patient with an acutely dislocated shoulder is usually in a good deal of distress. He or she holds the arm slightly away from the body and in internal rotation. The patient avoids moving the joint due to the pain, and on examination, it will be found that there is little ability to rotate the shoulder.

If the patient has had previous shoulder dislocations, he or she may present without an acute dislocation but with complaints of the shoulder "popping in and out," especially when his or her arm is in the throwing position.

Diagnosis

In the acute setting, the history of the mechanism of the injury, as well as the physical exam, is usually enough to make the diagnosis. The examiner should always perform a good neurovascular exam (checking the pulses and nerve supply to the arm both in the central and peripheral distribution) as damage may have been done to important structures. The axillary nerve, which supplies the large deltoid muscle of the shoulder, is not uncommonly damaged from a shoulder dislocation. Axillary nerve integrity can be assessed by testing the sensation of the skin over the deltoid muscle on the outside of the arm.

It is also necessary to obtain X-rays to confirm the dislocation and the direction of the dislocation and to evaluate for other bony abnormalities such as fractures. Two specific fractures are commonly associated with a shoulder dislocation. A Hill-Sachs lesion is an impaction fracture of the back of the humeral head, and a bony Bankart lesion occurs when the labrum at the front of the glenoid is disrupted and pulls off a piece of bone. At least two views, and preferably three different views, of the shoulder should be obtained and are usually sufficient to make the diagnosis.

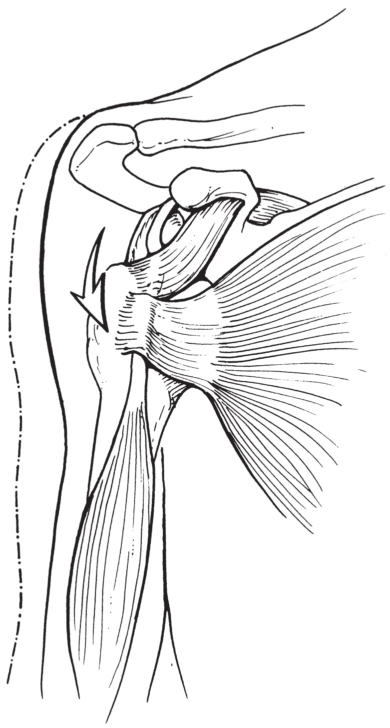

Figure 1 Shoulder Dislocation

Notes: Shoulder dislocations are relatively common because of the structure of the shoulder joint, which gives it great mobility. Unlike other joints in the body, the socket has almost no bony support, making it susceptible to injury in sports.

Management

Reduction

There are many different methods of reducing the dislocated shoulder (putting it back in place). The reduction is much easier to do if performed within a few minutes of the injury. After 15 to 30 minutes or so, muscle spasms and swelling make the reduction more difficult and painful and may necessitate patient sedation. Because of this, some providers may choose to forego X-rays (after ensuring a normal neurovascular exam) and attempt the reduction on the sidelines. This is especially true if the dislocation is a recurrence for the athlete.

Various reduction techniques can be done with the patient sitting or lying on his or her back and stomach. All methods use a countertraction force along the arm to help get the humeral head back over the glenoid rim. A simple method involves the patient lying on a table face down with the affected arm dangling off the side. A weight is tied to the arm to apply the force needed over time. Other methods involve the physician pulling gently downward on the arm while an assistant pulls upward on a sheet or towel wrapped around the patient's chest and under the armpit. As the shoulder relocates, a clunk may be felt.

Postreduction Care

After reduction, it is imperative to reassess the blood and nerve supply to the arm. X-rays should be taken to document that the reduction was successful and to assess for any bony abnormality in the setting of a first-time acute shoulder dislocation. A sling can be provided for the patient's comfort as well as to let the capsule and ligaments heal, especially if this is the first dislocation. For recurrent dislocations, the sling can be used as long as symptoms persist. The patient should be instructed in and begin early range-of-motion exercises, such as pendulum swings, to prevent shoulder stiffness and to allow a quicker return to function.

Rehabilitation after shoulder dislocation involves achieving range of motion and strengthening the muscles of the shoulder, in particular the rotator cuff and scapular stabilizers. These muscles help stabilize and support the shoulder joint.

Bracing may be used in athletes to protect them from the "at-risk" position of abduction and external rotation. There are a variety of braces on the market available to the athlete, all of which attempt to keep the arm from finding that at-risk position.

Surgery

Controversy exists regarding surgical correction of first-time dislocations. The statistics show that in young patients under the age 20, the rate of recurrence is 65% to 95%. In 20- to 40-year-olds, the rate is 60%, and above 40, only 10% will recur. This has led some to encourage young, active patients to consider surgical correction after the initial dislocation. The complications of recurrent dislocation include neurovascular injury, fracture, and degenerative arthritis of the shoulder joint.

Various surgical procedures for shoulder stabilization exist and can be performed open or arthroscopically. Open procedures use a large incision through which the surgery is performed, while arthroscopic surgery involves several small incisions made around the shoulder, with an arthroscope, or camera, used to visualize the shoulder joint.

Procedures to correct the unstable shoulder involve reattaching the torn ligaments and labrum and often eliminating any capsular redundancy. Unfortunately, sometimes a loss of external rotation of the shoulder results from the surgery. This can be detrimental to certain athletes, such as pitchers, who rely on excessive external rotation for their sport. The success rates for the two procedures are about equal now, with recurrence rates after surgery of 5% to 15%. The arthroscopic method affords less morbidity and the ability to see more of the joint itself.

Postoperative care involves a period of immobilization with a rapid introduction of range-of-motion exercises to prevent stiffness. As with nonoperative management, once painfree range of motion is achieved, gradual strengthening exercises are added.

Shoulder Impingement Syndrome

Shoulder impingement syndrome is a common source of shoulder pain in the general population as well as in the athletic community. Like other syndromes, shoulder impingement syndrome refers to a group of symptoms and diagnostic signs. As the name implies, this syndrome is caused by the compression of structures within the shoulder joint.

Athletic participation that requires overhead arm motion puts an athlete at risk for developing shoulder impingement syndrome. These sports include swimming, tennis, baseball, golf, volleyball, and gymnastics. In addition to overhead activity, a "loose" shoulder joint, the anatomy of the acromion, and disease within the acromioclavicular joint place an athlete at risk of developing this syndrome.

Anatomy

The shoulder joint is a very complex joint, with many structures. A good knowledge of the anatomy of this joint is essential for understanding shoulder impingement syndrome (Figure 1). There are two joints to be aware of, the *glenohumeral joint* and the *acromioclavicular joint.* The glenohumeral joint is composed of the glenoid fossa (socket) of the scapula (wing bone) and the head of the humerus bone (upper arm bone). The

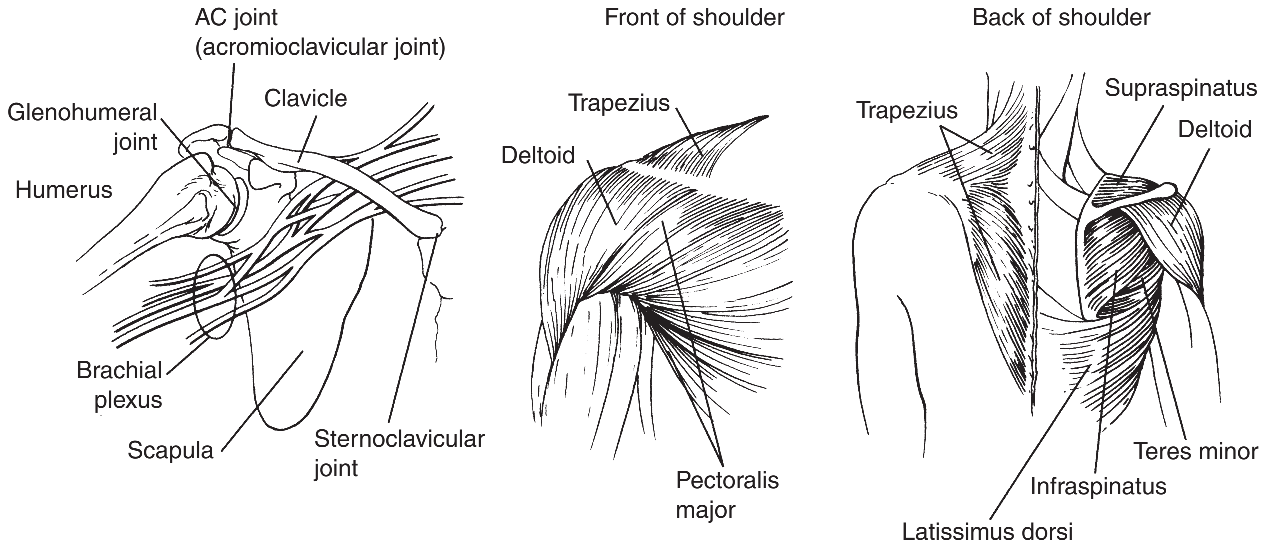

Figure 1 Anatomical Structures of the Shoulder

acromioclavicular joint is formed by the attachment of the outer part of the clavicle and the acromion process, a forward projection of the scapula.

Surrounding these bones are multiple tendons, ligaments, and muscles. More specifically, though, the following are anatomical structures important to a discussion of shoulder impingement syndrome: the rotator cuff complex (made up of four muscle-tendon units, the supraspinatus, infraspinatus, teres minor, and subscapularis), the subacromial bursa (a sac of fluid that lies underneath the acromion process), the labrum (a ring of cartilage in the glenohumeral joint), and the biceps tendon. All these structures may be internally compressed, causing shoulder impingement syndrome.

As mentioned, the anatomy of the acromion process has a role in causing shoulder impingement syndrome. This relationship was first noted by Dr. Charles Neer in 1972 in the *Journal of Bone and Joint Surgery*. He described three acromion types: Type I, flat; Type II, curved; and Type III, hooked (Figure 2).

Causes

Shoulder impingement syndrome is caused by the compression of structures surrounding the glenohumeral joint. Any source of weakness or dysfunction of the joint will result in instability and excessive motion of the humeral head. Surrounding the humeral head is the rotator cuff complex, together with the subacromial bursa. These structures are typically the ones impinged on. Compression commonly occurs between the humeral head and the acromion. A Type III, hooked acromion is mostly associated with shoulder impingement, but it may occur with any type of acromion morphology. Other structures in the shoulder may be the source of compression besides the acromion, however, and include the acromioclavicular joint as well as structures surrounding the coracoid process, another forward projection of the scapula.

Throwing athletes (baseball pitchers, javelin throwers, football quarterbacks) are at increased risk for shoulder impingement syndrome due to the extreme range of motion that is required of the shoulder to participate in their positions. The range of motion that places these athletes at risk is referred to as the “cocked position.” The cocked position is the point at which the athlete’s arm is maximally rotated overhead and extended behind the body. With the arm in this position, the stability of the shoulder is maximally stressed, causing excessive motion at the glenohumeral joint and subsequent compression of internal structures. Participation in these sports requires repetitive throwing motions, which may cause fatigue, weakness, and additional dysfunction of the glenohumeral joint, resulting in worsened compression and more severe impingement.

Source: AP.

Symptoms

Pain with overhead activity is the most common complaint. As the impingement worsens, pain is present outside activity and is typically located along the outside or back of the shoulder and occurs at night, especially when the patient lies on the affected shoulder. In addition to sports activities, the athlete may complain of pain when putting on a shirt or brushing his or her hair.

Initially, throwing athletes complain of increased stiffness in the shoulder and have difficulty with their warm-up activities. The pain is worse during the cocked position of throwing, as described above.

Diagnosis

As with all sports injuries, a diagnosis of shoulder impingement syndrome requires a thorough review of the history of the athlete's pain and an extensive physical exam. The physical exam starts with a thorough neck exam to make sure that a neck abnormality is not the cause of the shoulder pain. At the start of the shoulder exam, the athlete is asked to move the shoulder through all ranges of motion, looking for abnormalities or pain. If shoulder impingement syndrome is present, the athlete will have pain with movement and in particular when bringing his or her arm over the head, a motion commonly referred to as the "painful arc." Sometimes, with shoulder pain, strength can be diminished compared with the uninjured shoulder. However, in athletes, strength is typically preserved. Other special tests can be used to diagnose the presence of impingement on exam: These include a positive Neer test, Hawkins-Kennedy test, or Yocum test. The Neer, Hawkins-Kennedy, and Yocum tests attempt to cause external compression of internal shoulder structures, re-creating the athlete's pain. In a throwing athlete, pain can also be re-induced by moving the athlete's arm into an extended and rotated position, re-creating the cocked position of throwing. Reproduction of the troublesome pain is consistent with a diagnosis of a type of impingement called *posterior impingement*.

Plain radiographs (X-rays) may be obtained to look for bony abnormalities causing internal compression of shoulder structures. Radiographs will demonstrate the shape of the acromion as well as abnormalities in the acromioclavicular joint and coracoid process. All these, as mentioned above, can be a source of impingement, and their presence on X-rays makes a diagnosis of impingement for an athlete with shoulder pain more likely.

In addition to X-rays, additional imaging techniques may be used to diagnose shoulder impingement syndrome. Magnetic resonance imaging (MRI) is commonly used. In an athlete with shoulder impingement syndrome, MRI is used mostly to evaluate for the presence of specific causes or abnormalities in the shoulder that may be the source of pain, such as a rotator cuff tear or tear of cartilage in the glenohumeral joint. In the absence of specific abnormalities, the MRI scan of a shoulder with impingement syndrome will show some generalized inflammation or collections of fluid in the area of compression. Ultrasound, like MRI, can also be used to exclude other specific abnormalities as the source of pain.

Treatment

The treatment of most athletic injuries, including shoulder impingement syndrome, can be divided into *acute* and *subacute* therapy. In the absence of long-standing pain and dysfunction or the presence of other specific shoulder abnormalities (e.g., rotator cuff tear), the treatment of shoulder impingement syndrome does not include surgery. Some potential surgical interventions are discussed below.

Acute Therapy

At the time of initial evaluation, there may be significant pain and/or dysfunction. For this, acute therapy may consist of rest, cryotherapy (ice), and nonsteroidal anti-inflammatory medications (NSAIDs) such as ibuprofen. For appropriate rest, the athlete must avoid any aggravating activity, including all overhead motion or any sport-specific activity that re-creates his or her pain. Cryotherapy can be initially used to aid in pain relief and help reduce inflammation. In addition to cryotherapy, NSAIDs are also used to reduce pain and inflammation. These medications are typically used for 10 to 14 days and only as needed thereafter.

Additional acute therapies may be used for the reduction of pain and inflammation. These may be performed by a certified physical therapist (PT or DPT) or certified athletic trainer (ATC) and may include electrical stimulation (E-stim), phonophoresis, iontophoresis, or therapeutic ultrasound. Phonophoresis and iontophoresis use sound waves and an electrical current, respectively, to push anti-inflammatory medication through the skin to the site of injury.

Subacute Therapy

Physical Therapy

After the initial pain and inflammation are addressed, physical therapy should be focused on the achievement of full and nonpainful range of motion of the affected shoulder. Once this range of motion is achieved, physical therapy is then used to restore the strength and function of the shoulder musculature. The rehabilitation program is used to restore the function of all the muscles surrounding the shoulder, including those that control the movement of the scapula.

For a nonathlete patient, the rehabilitation program is complete once the patient returns to normal activities of daily living without pain. An athlete, however, must then be guided back to sport-specific activities after full range of motion and strength are regained. Certain sport activities place a much higher demand on the shoulder joint than normal daily activities. During a return-to-sports program, the athlete is taken through exercises that simulate the demands of the athlete's sport. For example, a football quarterback is asked to re-create his throwing motion, initially with light resistance and then using lightweight dumbbells.

Other Treatments

Completion of the above treatment programs will commonly result in full recovery for most athletes. However, if a full return to his or her sport activity is not accomplished in 2 to 3 months, the following treatment options may be considered.

Steroid Injection. Sports medicine physicians often use an injection of a steroid solution into the shoulder joint or subacromial space (an area between the acromion and the head of the humerus) if chronic inflammation is thought to be the cause of shoulder impingement syndrome. The goal of the injection is to reduce the inflammation and pain to help facilitate recovery and the ability to perform the rehabilitation program. Glucocorticoid solutions are used for injection in combination with a local anesthetic, lidocaine or marcaine.

Surgery. As stated before, in the absence of long-standing problems or specific abnormalities, surgery is rarely indicated for shoulder impingement syndrome. Long-standing shoulder impingement syndrome is defined as any dysfunction that has not improved with the above therapies or has lasted longer than 3 months. If there is no improvement in the athlete's shoulder pain after 3 months of the above treatments, surgical exploration with minimally invasive arthroscopic surgery may be considered. During this procedure, the surgeon will attempt to localize the source of the athlete's pain and repair damaged tissue. Also, if a Type III acromion is noted on plain radiographs, an acromioplasty procedure may be performed. During this procedure, the surgeon removes part of the undersurface of the acromion bone to help "decompress" the area of impingement—in other words, to make more room for internal structures to avoid future compression and impingement. Following surgery for shoulder impingement syndrome, in the absence of an extensive repair for a specific abnormality, the athlete can be expected to complete a course of physical therapy in 2 to 4 weeks and begin a return to sport-specific activities in 4 to 6 weeks.

Shoulder Injuries

Shoulder injuries occur as a result of both acute trauma and chronic overuse and affect both bony and soft tissue structures. Acute injuries as a result of falling or collision are seen mainly in collision, contact, and extreme sports, such as hockey, football, snowboarding, and skateboarding. Overuse injuries are becoming more frequent as a result of year-round competition and sport-specific training. Overuse injuries are seen commonly in sports such as swimming, baseball, volleyball, softball, and tennis. Shoulder pain occurs in 40% to 80% of swimmers and 50% to 95% of baseball players.

Overuse injuries result from microtrauma from repetitive movements of large rotational forces. They are often associated with joint looseness, mobility impairment, or muscle imbalances. Several risk factors contribute to such injuries. These risk factors include poor mobility, muscle weakness, muscle imbalance, and shoulder blade asymmetry. Additional risk factors in children and adolescent athletes include open physeal (growth) plates, joint laxity, and underdeveloped musculature.

Injury patterns to the athlete's shoulder are sport specific. In football, the shoulder is the second most commonly injured body part, next to the knee. Shoulder injuries are most often shoulder dislocations, shoulder separations, and collarbone fractures. Bicycling results in many shoulder injuries, usually collarbone fractures and shoulder separations from falling on the shoulder. Shoulder injuries are the most common injury to the upper extremity in wrestling, with shoulder separations being the most common. Repetitive microtrauma frequently results in multidirectional instability in swimmers and gymnasts.

Anatomy

There are four bony articulations in the shoulder: (1) the glenohumeral joint, (2) the acromioclavicular (AC) joint, (3) the sternoclavicular (SC) joint, and (4) the scapulothoracic articulation. The glenohumeral joint is a ball-and-socket joint. The glenoid cavity is relatively shallow and, therefore, inherently unstable. Additional stability is provided by the glenohumeral ligaments, glenoid labrum, and capsule, as well as the rotator cuff and scapular-stabilizing muscles.

The labrum is a ring of fibrous tissue that attaches directly to the glenoid fossa. It expands the size and depth of the glenoid cavity. The superior portion of the labrum inserts directly onto the biceps tendon, and the biceps tendon inserts on the supraglenoid tubercle. The shoulder capsule has three primary bands, called the superior, middle, and inferior glenohumeral ligaments. The anterior and posterior bands of the inferior glenohumeral ligament prevent anterior and posterior translation of the humeral head. The superior margin of the anterior band of the inferior glenohumeral ligament attaches to the glenoid fossa at the two o'clock position. When the shoulder is abducted and externally rotated, this broad ligament rotates anteriorly to prevent subluxation (partial dislocation) of the humeral head.

The rotator cuff muscles are the dynamic stabilizers of the shoulder and include the supraspinatus, infraspinatus, teres minor, and subscapularis. These muscles stabilize the position of the humeral head in the glenoid fossa, rotate the humerus, and help elevate the upper extremity. They also act to depress the humeral head as a counterforce to the deltoid, which acts to elevate the arm and force the humeral head superiorly. The rotator cuff muscles rely on optimal functioning of the deltoid and scapular-stabilizing muscles. The scapular-stabilizing muscles include the trapezius, serratus anterior, rhomboids, levator scapulae, and pectoralis minor.

Normal shoulder movement requires that the scapulothoracic joint, the AC joint, and the SC joint all move together smoothly. Smooth, integrated movement of these joints is necessary to achieve full upper limb elevation. Scapular movement removes the acromion from the path of the humeral head so that it does not become impinged.

There are unique differences in structure in the pediatric shoulder compared with adult shoulders. In the skeletally immature athlete, there is a growth plate at the proximal end of the humerus where new bone is formed. Approximately 80% of the growth of the upper extremity occurs at this physeal plate. The epiphyseal plates are relatively weaker than the surrounding ligaments, predisposing children and adolescents to growth plate fractures and avulsion fractures not seen in adults. Proximal humeral closure occurs by age 14 to 16 years in girls and age 16 to 21 years in boys.

Another difference in the immature shoulder is the higher proportion of Type III collagen. As growth and development progress, Type III collagen is steadily replaced by the more stable Type I collagen seen in adults. The presence of Type III collagen in younger athletes results in more shoulder laxity, which can contribute to shoulder instability, particularly in throwing and overhead athletes.

Evaluation of Injuries

Details of Injury

Details that can diagnose shoulder injuries include the date of onset of symptoms, whether there was a specific traumatic event, the mechanism of injury, the location of pain, the presence of mechanical symptoms or instability, and management of the injury to date. Previous shoulder injuries may predispose an athlete to future injuries, particularly if the injury was not fully healed. In overhead athletes, additional information, including what sport is played, the level of competition, the number of repetitions, and where in the overhead motion pain occurs, can help determine the exact injury.

Physical Findings

Injuries to the shoulder can result in muscle atrophy, asymmetry, discoloration, or deformity, as well as winging of the shoulder blade. There may be tenderness to palpation of the bony and soft tissue structures, including the SC joint, AC joint, clavicle, acromion, scapula, greater tuberosity of the humerus, deltoid, and proximal biceps tendon.

The range of motion of the injured shoulder may be decreased or painful in forward flexion (elevation), abduction, and external and internal rotation. The range of motion of the injured shoulder may be decreased in comparison with the uninjured side. The movement of the shoulder blade may also be abnormal with a shoulder injury (dyskinesia).

Muscle strength may be decreased with a shoulder injury. Specific muscles can be tested to determine any weakness or pain. The supraspinatus strength (thumb-down abduction at 30° horizontal flexion or "empty-can" test), infraspinatus strength (external rotation with the arm adducted), external rotation with the arm in a neutral position, subscapularis strength (lift-off test performed with the hand at the lower back and pushing away from the spine against resistance), and deltoid strength (abduction with the arm at the side) against resistance may all be affected by an injury.

Biceps tendinopathy can be assessed with the Speed test and the Yergason test. The Speed test is performed with the patient standing and the shoulder forward flexed against resistance with the elbow extended and the forearm supinated. Pain or tenderness in the bicipital groove indicates a positive test. The Yergason test is performed with the elbow flexed to 90° and the forearm pronated (hand turned upward). The patient actively tries to supinate (palm of the hand turned downward) the wrist against resistance. A positive test elicits pain in the bicipital groove.

Special tests for the shoulder include the anterior apprehension relocation test, the load and shift test, the O'Brien test, the anterior slide test, the sulcus test, and impingement tests. The anterior apprehension relocation test assesses anterior instability. With the patient supine and the arm hanging off the bed, the patient's shoulder is passively moved into external rotation until guarding is appreciated (positive test) or capsular-end feel is reached. After a positive apprehension test, a posteriorly directed force is applied to relocate the humeral head in the glenoid fossa (relocation test). Apprehension disappears, and there is an increase in passive external rotation.

The load and shift test assesses for anterior as well as posterior instability. With the patient sitting, the humeral head of the affected shoulder is grasped in the examiner's hand and anterior, and posterior force is applied to determine the amount of translation within the glenoid fossa. The following grading system is helpful: Grade 0 = *no translation,* Grade 1 = *translation up to the glenoid rim,* Grade 2 = *translation onto the rim (subluxation),* and Grade 3 = *translation over the rim or dislocation.* A comparison should be made with the uninjured shoulder.

The O'Brien test can be used to assess superior labral anterior-posterior (SLAP) injuries. With the patient standing, the injured arm is flexed forward to 90° with the thumb pointed down. The examiner applies a downward force to the arm while the patient resists. Pain in the shoulder joint is considered a positive test. The thumb is then turned upward, and the maneuver is repeated. This should not be painful. Unfortunately, pain can result from this maneuver in the presence of an AC injury, biceps tendinitis, or posterior instability, resulting in a false positive. SLAP lesions can also be evaluated by the anterior slide test. The athlete stands with hands on the hips. The examiner places one hand over the athlete's shoulder, and the other hand is placed behind the elbow. The examiner then applies a force anteriorly and superiorly while the athlete pushes back against the force. A positive test results in pain localized to the anterosuperior aspect of the shoulder, a pop or click in the same area, or reproduction of the athlete's symptoms.

The sulcus sign assesses for the presence of inferior instability. The patient should be seated and completely relaxed. With the shoulder in the neutral position, the examiner exerts a downward force on the humerus, looking for the presence of a depression or sulcus at the glenohumeral joint (positive test). A positive sulcus sign may indicate generalized ligamentous laxity or multidirectional instability. If generalized ligamentous laxity is suspected, patients should be assessed for hyperextension of the elbows and metacarpal-phalangeal joints and hyperflexion of the first carpometacarpal/wrist joint.

Sometimes pain in the shoulder can result from the humeral head butting up against the acromion (impingement). Impingement tests include the Neer and Hawkins signs. They evaluate the rotator cuff and subacromial bursae. The Neer test is performed with the athlete in the seated position. The examiner places one hand on the shoulder and passively flexes the shoulder forward until pain is experienced by the athlete. The Hawkins test is also performed with the athlete seated. The examiner stabilizes the shoulder with one hand while passively internally rotating the arm with the arm forward flexed and the elbow flexed to 90°. Pain in the shoulder indicates impingement of the humeral head by the acromion. An additional impingement sign is the crossover test, which confirms AC pathology. With the patient seated, the arm of the affected shoulder is adducted across the chest. A positive test elicits pain in the AC joint.

Investigations

Investigations that may be necessary to help determine the diagnosis in shoulder injuries include X-rays, a computed tomography (CT) scan, an ultrasound scan, a bone scan, and a magnetic resonance imaging (MRI) scan. In acute injuries, X-rays including anteroposterior views with internal and external rotation as well as axillary views should be performed to look for fractures. Calcific tendinopathy, arthritis, subluxation, or dislocation, as well as impingement, may be seen on X-rays. A CT scan can provide greater bony definition.

An ultrasound scan can be used to help confirm the suspicion of a muscle or tendon tear.

Examination can be performed as a static or dynamic investigation. The size of the tear and the thickness of the intact tissue can be measured. A dynamic examination may confirm impingement.

MRI scans have become increasingly helpful with the diagnosis of rotator cuff and labral tears, although arthroscopy remains the gold standard. MRI arthrography (injection of dye into the shoulder joint) is currently the recommended diagnostic study of choice for labral tears.

Types of Injury

Various types of shoulder injuries are listed in Table 1.

Prevention of Injury

Proper technique is important to avoid injury, particularly in overhead athletes. It should be taught early and reinforced throughout an athlete's career. Year-round conditioning should be encouraged,

Table 1 Shoulder Injuries

Common	*Uncommon*	*Must Not Be Missed*
Rotator cuff strain/tendinopathy	Rotator cuff tear	Tumor
Glenohumeral dislocation	Biceps tendinitis	Referred pain from thoracic/abdominal structures
Glenohumeral instability	Fracture (scapula, humeral neck, proximal humerus in children)	Thorax outlet syndrome
Labral tears (superior labral anterior-posterior [SLAP])	Arthritis	
Clavicle fracture	Neurapraxia (burner)	
Acromioclavicular (AC) joint separation/dislocation	Sternoclavicular (SC) separation/dislocation	
Little League shoulder	"Frozen shoulder"	
Shoulder subluxation	Bursitis	
Impingement syndrome		

Source: Author.

with emphasis on core strengthening and lower extremity strengthening.

In overhead sports such as football, baseball, softball, and tennis, proper technique should be reinforced to ensure that athletes are using their lower extremity strength to help impart force to the ball and limit the stress to the shoulder. Avoid "overthrowing."

To avoid overuse injuries, appropriate rest and recovery should be ensured. Athletes should take advantage of the off-season to allow muscle recovery. Athletes should not play the same sport all year round or participate on more than one team. In children and adolescents, restrictions in the number of repetitions, such as the number of pitches and types of pitches (no sliders or curve balls), can help reduce shoulder injuries.

Return to Sports

Before an athlete with a shoulder injury returns to sports, he or she should have attained full range of motion of the shoulder and full strength of the rotator cuff and scapulothoracic muscles, as well as core and lower extremity strength. Pain should be resolved. The athlete should have progressed through a functional exercise program consisting of sport-specific activities and drills that mimic the stresses that the athlete will encounter in practice and competition. The athlete must also demonstrate the appropriate mechanics for his or her particular sport to minimize the risk of reinjury and to achieve maximal performance.

Shoulder Injuries, Surgery for

The shoulder plays a major role in athletic competition. "Overhead sports" athletes are those whose primary sport involves much activity with the arm overhead. These sports include, but are not limited to, football, basketball, baseball, tennis, swimming, lacrosse, and gymnastics. These sports place particularly significant stresses and strains on the athlete's shoulder. Baseball pitchers, due to the high energy of the pitch, are a unique group of athletes who place particularly high demands on their dominant shoulder. Swimmers also rely heavily on repetitive exaggerated shoulder motions to swim fast. Shoulder injuries are more common in overhead sports athletes and occur most frequently in baseball pitchers and swimmers.

This entry reviews the anatomy of the shoulder and the types of injury that commonly occur in athletes and explains the surgeries used to repair the affected structures.

Anatomy

The shoulder is a ball-and-socket joint in which the ball is the head of the humerus and the socket is called the *glenoid*. The glenoid socket is directly attached to the scapula, or shoulder blade. Both the ball of the humerus and glenoid socket are covered in smooth cartilage that resembles the shiny white end of a chicken bone. The smooth cartilage allows the ball-and-socket bones to move against each other with minimal friction. The glenoid socket resembles a dish and is surrounded on its edges by a circular rim of rubbery cartilage called the labrum. The labrum can be thought of as an O-ring that attaches to the outer edges of the glenoid socket. The labrum serves to make the glenoid socket deeper and helps keep the ball of the humerus from moving outside the socket. The *shoulder capsule* is made up of strong elastic tissue that surrounds the head of the humerus and glenoid socket. The shoulder capsule prevents the ball of the humerus from moving outside the glenoid socket. The shoulder capsule is reinforced by *ligaments,* or areas of condensed fibrous bands, that run between the head of the humerus and glenoid socket to provide strength to the shoulder capsule.

The rotator cuff is a group of four muscles that lie on top of the shoulder capsule, surrounding the ball of the humerus and the glenoid socket. These muscles sit on top of the shoulder like the cuff of a shirt. Two rotator cuff muscles lie on top of the shoulder and are called the *supraspinatus* and the *infraspinatus*. One rotator cuff muscle sits in front of the shoulder and is called the *subscapularis*. The *teres minor* is the fourth rotator cuff muscle, and it lies in the back of the shoulder. The rotator cuff muscles all form muscle tendons that attach to the head of the humerus. The rotator cuff functions to move the shoulder in all directions. The top muscles (supraspinatus and infraspinatus) work to bring the arm above the head and are most important in overhead sports.

Surrounding the rotator cuff muscles is the *deltoid* muscle. The deltoid muscle begins at the collarbone and shoulder blade and attaches to the humerus. The deltoid muscle helps the rotator cuff move the shoulder. The *biceps* muscle lies in the front of the arm and helps bend the elbow. The biceps muscle in the arm becomes a cordlike *biceps tendon* near the shoulder. In the shoulder, the biceps tendon attaches to the glenoid socket at the top of the labrum. There are also multiple *bursa* around the shoulder. A bursa is a small fluid-filled sac that occurs around tendons and allows the tendons to move without generating friction with nearby bones. The most prominent bursa in the shoulder lies below the deltoid muscle and above the rotator cuff tendons.

Shoulder Joint Function

The ball-and-socket nature of the shoulder allows the shoulder to move more than any other joint in the body. The labrum, capsule, and ligaments of the shoulder must strike a delicate balance between allowing the shoulder to move in all directions and preventing the ball of the humerus from moving out of the glenoid socket. The strength and power of the shoulder come from the rotator cuff muscles and the deltoid muscle. Athletes must develop their shoulders' strength and mobility to accommodate the demands of their sports. Baseball pitchers normally have significantly more strength and different motion ranges in their throwing shoulder as compared with their other shoulder. The best swimmers tend to have loose shoulder joints on both sides, which allows for great shoulder motion. Shoulder injuries can occur when the stress and strain of the sport or activity prevail over the ability of the shoulder to perform its function.

Shoulder Joint Injuries

Most athletic shoulder injuries are muscle strains, tendinitis, or bursitis. Muscle strains represent microscopic muscle tears that occur when the muscle is stretched more than it can withstand. Muscle strains can occur in the rotator cuff, biceps, and deltoid muscles. These injuries are treated with rest and heal on their own over time. Tendinitis occurs when the muscle tendon (the part of the muscle that attaches to the bone) becomes irritated or inflamed. Tendinitis occurs most commonly in the rotator cuff muscle tendons near where they attach to the head of the humerus. Rotator cuff tendinitis is often seen in repetitive overhead sports such as tennis, swimming, and baseball. Many times, a small injury to the rotator cuff tendon is ignored by the athlete, who continues to stress and strain the tendon through playing the sport. Over time, the body responds by sending blood cells to the rotator cuff tendon in an attempt to repair the injury. An inflammatory response is generated by the blood cells, which causes pain and swelling in the area of the rotator cuff tendon. Rotator cuff tendinitis is treated with rest, ice, anti-inflammatory medications (e.g., ibuprofen), and physical therapy focusing on shoulder muscle strengthening. Bursitis is a similar inflammation of a shoulder bursa. This can occur when the nearby tendon is inflamed, as is often the case in rotator cuff tendinitis. Shoulder bursitis is treated like rotator cuff tendinitis. In addition, the physician may elect to inject a corticosteroid (an injectable anti-inflammatory medication) into the shoulder bursa to help decrease inflammation in that area.

The most common shoulder injuries in sports that may require surgery are rotator cuff tendon tears, labrum tears, and shoulder dislocations. Rotator cuff tendon tears occur when the rotator cuff tendon pulls away from its attachment to the humerus. This can occur when a sudden force is placed on the arm, pulling the arm away from the body. Rotator cuff tendon tears can also occur in the setting of rotator cuff tendinitis if the athlete continues to stress the inflamed tendon. Rotator cuff tendon tears most commonly occur in overhead throwing athletes in the supraspinatus tendon at the top of the shoulder. Rotator cuff tears can be diagnosed by a physical exam as the athlete will have weakness with overhead shoulder motion. When a physician suspects a rotator cuff tear, an MRI scan of the shoulder is usually obtained and can be used to diagnose a rotator cuff tear. Rotator cuff tendon tears can be of partial thickness (where only a part of the thickness of the tendon has pulled off its attachment on the humerus) or full thickness (where the entire thickness of a portion of the tendon has pulled off the humerus). Many partial-thickness rotator cuff tendon tears will heal on their own and can be treated without surgery. Full-thickness tendon tears often require surgical repair.

Labral tears are most common in overhead throwing athletes such as baseball pitchers. These injuries usually cause deep pain and popping of the shoulder joint with overhead activities. Labral tears occur in many different forms and sizes. When the labrum tears at the top of the glenoid socket, it is called a SLAP tear (which in medical terms stands for superior labrum anterior-posterior). These labral tears are important because the biceps tendon attaches to the labrum in this region. When the physician suspects a labral tear, an MRI scan is often obtained to evaluate the shoulder labrum. Sometimes dye is injected into the shoulder prior to the MRI scan to help the radiologist identify the labrum and determine if there is a tear. Many labral tears do not require surgery. Surgery is usually reserved for overhead throwing athletes who have deep shoulder pain and popping that does not improve after a period of rest and rehabilitation.

Shoulder dislocations occur when the ball of the humerus slips outside the glenoid socket. Because of its inherent mobility, the shoulder is the joint that is most likely to dislocate in the body. Shoulder dislocations most commonly occur when the ball of the humerus moves outside the glenoid socket and toward the front of the shoulder (an anterior shoulder dislocation). This occurs when the arm is extended and a force pushes the arm backward while levering the head of the humerus forward. When the shoulder dislocates, the head of the humerus must be “reduced” or put back in the glenoid socket. This can sometimes be done on the playing field by the athletic trainer. At other times, shoulder muscle spasms prevent the shoulder from being reduced easily. In these cases, the athlete is usually taken to the emergency room, where medication is used to relax the muscles while a physician manipulates the shoulder back into place.

When the humeral head dislocates out of the glenoid socket toward the front, the shoulder capsule and ligaments, and occasionally the front of the labrum, are usually torn. An MRI scan may be obtained to determine exactly what structures have been injured by the dislocation. Many shoulder dislocations are treated without surgery. The athlete is usually placed in a sling for a period of time before undergoing a course of physical therapy to restrengthen the shoulder. When a shoulder dislocation occurs in a young athlete who participates in overhead contact sports, the chance of the shoulder dislocating again is very high. Also, in patients who have had shoulder dislocations in the past, the chance of having another dislocation is very high. In these and other cases of shoulder instability, surgery may be recommended to repair the torn labrum and to retighten the front of the shoulder capsule and ligaments to prevent future shoulder dislocations.

Surgery: Rotator Cuff Repair

Surgery for a full-thickness rotator cuff tear involves repairing the torn rotator cuff tendon back to where it attached on the humeral head. This surgery can be done through a large incision (open technique) or through multiple tiny incisions with the aid of an arthroscope (arthroscopic technique). The choice of technique depends on the pattern of the tear and the preference of the surgeon. Open techniques require that part of the deltoid muscle be detached and then repaired to allow access to the torn rotator cuff tendon. Recently, arthroscopic equipment and skills have improved considerably, allowing many tears to be repaired using this technique. Arthroscopic rotator cuff repair often results in less pain immediately after surgery, although the overall recovery time and time to tendon healing are not changed.

During rotator cuff repair, in most cases, one or more tiny metal or absorbable anchors are inserted into the bone of the humeral head where the torn rotator cuff is supposed to attach. The anchors are connected to strong suture material that is used to tie the torn rotator cuff back to where it attached on the humeral head. The number of anchors used depends on the size of the tear. After surgery, patients are placed into a sling that is typically worn for approximately the first 3 weeks after surgery. For the first 6 weeks after surgery, no active lifting of the arm over the head is allowed. Full recovery from rotator cuff repair back to sporting activities often takes 4 months or much longer for overhead throwing athletes.

Surgery: Labral Repair

When surgery is necessary for labral tears in the shoulder, an arthroscopic technique is most commonly employed. In these cases, multiple small incisions (termed arthroscopic *portals*) are made around the shoulder. The arthroscope (a small, thin camera) is placed through one of these portals and into the shoulder joint (between the humeral head and glenoid socket). With the arthroscope in the shoulder, the surgeon is able to look at a monitor and identify the labrum (the rubbery O-ring around the glenoid socket) to determine if there is a tear. The surgeon decides how to proceed based on the size, shape, and location of the labral tear.

For smaller tears or tears that are frayed and degenerated, the surgeon may elect to remove only the torn portion of the labrum and leave the rest of the labrum alone. This is done with the aid of a miniature motorized shaver that is placed through an arthroscopic portal. For larger tears or tears that involve the labrum on the top of the shoulder (where the biceps tendon attaches), the surgeon may elect to repair the torn portion of the labrum back to where it belongs on the glenoid socket. This is done by placing tiny metal or absorbable anchors through an arthroscopic portal and into the glenoid socket at the location of the tear. Strong suture material is attached to the anchor, and this suture is then passed around the torn labrum and used to tie the torn labrum back down to the glenoid socket. After labral repair surgery, most patients are kept in a sling for approximately 3 weeks before starting a course of physical therapy. Return to sports takes approximately 3 to 4 months as the repair site has to heal. For baseball pitchers and overhead throwing athletes, return to full throwing can take as long as 9 to 12 months.

Surgery: Shoulder Instability

Surgery for shoulder instability involves repairing the structures that were injured when the head of the humerus dislocated out of the glenoid socket. These injured structures usually include a combination of the shoulder capsule, ligaments, and front part of the labrum. Repair of these structures can be done through one large incision on the front of the shoulder (open technique) or through multiple small incisions around the shoulder (arthroscopic technique). In the past, the open technique has produced the best results, but recent advancements in arthroscopic equipment and skill have made arthroscopic surgery an equal or better alternative in many cases.

The goal of surgery for shoulder instability is to repair the torn structures caused by the dislocation and to tighten the shoulder capsule just enough to prevent the humerus from dislocating again. If the shoulder capsule is overtightened by surgery, some shoulder motion will be lost, and the athlete will have trouble returning to high-level sports. If the shoulder capsule is not tightened enough, the humeral head may dislocate again. Regardless of whether an open or an arthroscopic technique is used, the front part of the labrum is first examined. A tear in the front part of the labrum is often seen and is termed a *Bankart tear* (named after the physician who discovered it). This part of the labrum has the shoulder capsule ligaments attached to it and must be repaired back to the glenoid socket. Repair is usually done by placing tiny metal or bioabsorbable anchors in the front part of the glenoid socket. Strong suture material attached to the anchors is then used to tie the front part of the labrum back to the front part of the glenoid socket (a *Bankart repair*). This helps restore the bumper effect of the front part of the labrum on the glenoid socket, which helps keep the humeral head from coming out of the front of the shoulder. In addition, Bankart labral repair tightens the front shoulder capsule ligaments that are attached to this part of the labrum. If further tightening of the shoulder is necessary, sutures are then placed in the front part of the shoulder capsule to retighten it.

After surgery for shoulder instability, most patients are placed in a sling for 3 to 4 weeks. The arm is kept near the body, and active motion of the arm away from the body is not allowed for the first 6 weeks after surgery. Approximately 3 months of physical therapy is necessary after surgery to restore shoulder motion and strength. Return to sports generally occurs at about 4 to 6 months after surgery.

Shoulder Instability

Glenohumeral instability is a common shoulder disorder, particularly among young athletes. Traditionally, shoulder instability has been divided into two types: those that were initially caused by a traumatic event and those associated with generalized ligamentous laxity.

Peak incidences of traumatic shoulder dislocation occur in a bimodal distribution. Men are at the highest risk of dislocation between 20 and 30 years of age, whereas women more frequently experience dislocation of the shoulder between 61 and 80 years of age. Risk factors for shoulder dislocation include falling on an outstretched arm; a direct blow to the shoulder, as in an automobile accident; force applied to an outstretched arm, as in a football tackle; and forceful throwing, lifting, or hitting. Sports that place an athlete at a higher risk of shoulder dislocation include football, wrestling, and hockey.

Generalized ligamentous laxity can also place an athlete at a higher risk of dislocation. Although ligamentous laxity can be congenital, activities such as swimming, gymnastics, and weight lifting, which frequently subject the shoulder to extremes of glenohumeral motion, can stretch out the capsule and place the shoulder at a higher risk of dislocation.

Anatomy

The glenohumeral joint is made up of a ball-like humeral head rotating on a shallow, dishlike surface, the glenoid. The bony anatomy of the glenohumeral joint allows the shoulder the widest range of motion of any joint in the body. Because of this wide range of motion, the shoulder is very dependent on soft tissue restraints to prevent dislocation.

The soft tissue restraints of the shoulder include the glenoid labrum, the surrounding capsule and ligamentous structures, and the rotator cuff musculature.

The glenoid labrum is a border of soft tissue that surrounds the bone of the glenoid and effectively deepens the glenohumeral articulation. The glenoid labrum may provide stability against humeral head translation.

The capsule extends from the periphery of the glenoid around the humeral head to the periphery of the articular cartilage. The capsule is thickened in three distinct areas. These thickenings make up the glenohumeral ligaments. The ligaments function to stabilize the shoulder by becoming taut in different positions of shoulder motion.

The superior glenohumeral ligament and middle glenohumeral ligament stabilize the shoulder against inferior subluxation or dislocation when the arm is at the patient's side. They also assist in resisting posterior translation. The primary function of the middle glenohumeral ligament is to limit external rotation with the arm at 45° of abduction. The inferior glenohumeral ligament forms a sling with an intervening axillary pouch that tightens anteriorly as the shoulder extends, preventing anterior dislocation, and tightens posteriorly as the shoulder flexes, preventing posterior dislocation.

The surrounding rotator cuff musculature provides dynamic shoulder stabilization. Weakening of the rotator cuff musculature can contribute to shoulder instability.

In 1923, Bankart described a lesion that occurs during a shoulder dislocation and ultimately leads to shoulder instability. The lesion is a detachment of the anterior-inferior portion of the labrum from the rim of the glenoid. The lesion occurs as the labrum is sheared from the glenoid rim during a shoulder dislocation.

In multidirectional instability, the capsule is often enlarged and may be weakened from multiple episodes of subluxation or dislocation.

Causes

It is important to understand the difference between laxity and instability. Laxity refers to the extent to which the humeral head can be translated on the glenoid. Instability is an abnormal increase in glenohumeral motion that causes symptoms such as pain, subluxation, and dislocation and functional symptoms such as catching or locking.

Individuals who have congenitally lax joints are at an increased risk for shoulder instability. Laxity can also be acquired through activities that involve extremes of glenohumeral motion that may stretch out the shoulder capsule, such as swimming, gymnastics, and weight lifting.

The most common direction of traumatic dislocation is anterior. Traumatic anterior dislocation commonly occurs with the arm in a position of abduction/external rotation. Activities that place the shoulder at risk for dislocation and subsequent instability include contact sports, falls on an outstretched arm, direct blows to the shoulder, and forceful throwing, lifting, or hitting. Traumatic dislocations that occur in patients less than 20 years old are at a significant risk for redislocation. A youth or adolescent with a first-time dislocation is at a 70% to 100% risk of dislocating again.

Posterior dislocation occurs when an axial load is placed on a flexed, adducted, internally rotated shoulder. Posterior instability can occur as a result of repetitive episodes of loading the posterior capsule, as is common with an offensive lineman. Other causes of posterior instability include seizures and motor vehicle accidents.

Inferior instability is most commonly associated with multidirectional instability.

Symptoms

An athlete who presents after a traumatic dislocation will often complain of pain that is usually worse with activity or with the arm in certain positions.

The pain is often associated with the direction of the dislocation (i.e., posterior shoulder pain with posterior dislocations). Symptoms may be aggravated by overhead activities, carrying objects at the side, or overuse. Other complaints may include weakness, a sensation of the shoulder slipping out of place, or numbness and tingling of the affected extremity. Nocturnal pain is variable.

As instability worsens, symptoms begin to occur in midranges of glenohumeral motion common to activities of daily living.

Diagnosis

Physical Examination

The physical examination of shoulder instability should begin with an inspection of the shoulder and its surrounding musculature. Findings that may be common with glenohumeral instability include atrophy of the biceps, supraspinatus, or infraspinatus.

The range of motion of the involved shoulder should then be compared with the opposite shoulder. Restrictions to motion as well as hypermobility should be noted.

Special tests for the shoulder include the sulcus sign, the drawer test, the anterior and posterior apprehension test, the relocation and release tests, the load and shift test, and the jerk test.

The drawer test is useful for evaluating increased anterior and posterior shoulder laxity. The examiner performs this test by stabilizing the scapula and clavicle with one hand while gently pushing the humeral head as far forward and then as far back as possible with the other hand. Normal humeral head translation is approximately 50% of its anterior-to-posterior dimension.

Inferior laxity is demonstrated by the sulcus sign. This test is performed with the examiner standing at the patient's side. The patient is encouraged to relax as the examiner grasps the patient's arm just above the elbow and gently pulls distally while observing the lateral acromion. As the humeral head translates inferiorly, a sulcus is formed between the acromion and the humeral head. The size of the sulcus should be compared with the opposite shoulder.

The anterior apprehension test is the classic provocative test for anterior instability. It is performed by placing the arm in 90° abduction, extension, and external rotation with the elbow flexed to 90°. The examiner then progressively externally rotates the shoulder. A patient with anterior instability will complain of pain in the anterior shoulder or apprehension of impending dislocation.

The relocation test increases the specificity of the anterior apprehension test for cases of subtle instability. It is performed by placing the shoulder in a position of apprehension and then applying a posteriorly directed force over the humeral head. A patient with instability will feel decreased pain and reduced apprehension. When the examiner removes the posterior force, the pain and apprehension return (release test).

Anterior and posterior instability can also be tested with the load and shift test. This test is performed with the patient lying on the examination table. The table serves to stabilize the scapula. The patient's arm is slightly abducted from his or her side. The examiner then stabilizes the scapula with one hand and grasps the proximal humeral shaft with the other hand. While slightly compressing the humeral head against the glenoid, the examiner attempts to slide the proximal humerus off the anterior and then the posterior glenoid rim. In the stable shoulder, anterior or posterior translation of approximately half the distance of the humeral head will occur.

The jerk test is an additional test for posterior shoulder instability. It is performed by placing the patient's arm in 90° flexion, adduction, and internal rotation with the elbow flexed to 90°. The examiner applies a posteriorly directed force at the elbow, attempting to push the humeral head posteriorly off the glenoid. A jerk or clunk is felt as the humerus slips over the edge of the posterior glenoid rim.

Imaging

Imaging of the unstable shoulder should include the three standard views: anterior-posterior (AP), scapular Y, and axillary. Although the dislocated shoulder frequently only involves soft tissue injury, as many as 55% of traumatic dislocations have an associated bony injury.

Additional views that may be helpful in visualizing bony injury include the *West Point view* and the Stryker notch view. The West Point view is taken with the patient prone, with the arm abducted to 90° and hanging over the side of the table. The radiograph is taken with the X-ray beam aimed anteriorly and 25° medially. It is most helpful in detecting anterior-inferior glenoid rim fractures (bony Bankart lesions).

The Stryker notch view brings Hill-Sachs lesions (humeral head impaction lesions) into view. The radiograph is taken in an anterior-to-posterior direction, aiming the beam 10° cephalad with the patient supine with his or her hand on top of his or her head with the elbow flexed.

Because instability most commonly involves a soft tissue component, magnetic resonance imaging (MRI) is usually performed for diagnosis and surgical planning. To improve visualization of soft tissue avulsions (labral tears), a dye can be injected into the glenohumeral joint prior to the MRI scan (an MR arthrogram). Recent literature states that the sensitivity of an MRI scan alone in diagnosing a labral tear is 91% to 93%. The addition of dye in the glenohumeral joint (MR arthrogram) improves the sensitivity to 96%.

Treatment

Nonsurgical

Treatment of instability is primarily nonsurgical. Rehabilitation usually begins with a period of activity modification and rest. A short period of immobilization may be required for pain control in a patient with multidirectional instability. After a traumatic dislocation, younger patients (less than 30 years old) should be immobilized in a sling for 3 weeks to allow the tissues to heal prior to exercises to restore strength and motion. Older patients are at greater risk for shoulder stiffness but with a reduced risk of developing recurrent instability. Some physicians therefore have patients begin exercises to restore range of motion after only 1 week of immobilization.

Modalities to help reduce pain such as ice, anti-inflammatory medications, and electrical stimulation can also be of great use. Overhead activities are initially avoided. Once the patient's pain is well controlled, an exercise program is instituted to help restore normal, painfree range of motion. Exercises should include strengthening of the deltoid, periscapular, and surrounding rotator cuff musculature.

Surgical

Arthroscopy

Arthroscopy can be used as an effective tool for both diagnosing and treating shoulder instability. Some of the benefits of shoulder arthroscopy include avoiding the morbidity associated with a large incision and releasing the subscapularis muscle from its attachment site on the proximal humerus required in an open surgical approach.

Arthroscopy is additionally beneficial because it allows the physician to visualize the relationship of the humeral head to the glenoid and the integrity of the ligaments and capsule as the shoulder is taken through a range of motion. The labrum can be inspected and probed for any areas of detachment. The shoulder capsule, which is often enlarged and weakened from multiple dislocations, can also be evaluated.

Shoulder instability is treated by tightening the loose shoulder capsule. This is done by placing plicating stitches in the capsule and typing them through special arthroscopic cannulas. The labrum, if torn from its attachment on the glenoid, can be repaired by placing small anchors along the edge of the glenoid. The anchors have a suture attached to them that allows the surgeon to secure the torn labrum back to the bone while it heals.

Open Treatment of Shoulder Instability

Several methods have been developed to treat shoulder instability through an open (nonarthroscopic) procedure. Some of these involve repairing the capsule in a shortened fashion, while others are meant to limit the patient's external rotation to prevent her or him from getting into a position of potential dislocation.

An open procedure is performed by making a longitudinal incision in the axillary crease. Dissection is carried down through the subcutaneous tissues to an interval between the pectoralis major and the deltoid muscles. The subscapularis muscle is then identified and released from its attachment on the proximal humerus. The capsule is then split. Labral tears, if present, are identified and repaired. The capsule can then be tightened on closure.

After Surgery

As a general rule, the shoulder is protected in a sling for 4 to 6 weeks after surgical repair. The sling should be removed several times each day for elbow and wrist range-of-motion exercises.

During the first 2 weeks after surgery, the patient is allowed to perform pendulum-type exercises with the arm hanging at his or her side while he or she gently swings the arm in small circles.

Formal physical therapy begins after the 2-week postoperative visit. Initially, the patient is allowed to forward-flex his or her shoulder to 90°. External rotation is limited to neutral for the first 6 weeks. At 6 weeks, the patient is allowed to increase the external rotation to 30°. Full external rotation range of motion is allowed at 4 months postoperatively. Progressive strengthening exercises are begun at 6 weeks postoperatively. Return to sports is allowed at 4 months postoperatively once 90% of the strength and a functional range of motion have been regained.

Shoulder Subluxation

The shoulder joint is more complex than other joints because it has a full 360° of motion. This is made possible by the structures making up the joint itself. The joint is made up of the placement of the ball of the humerus on the glenoid portion of the scapula. This can be likened to a "bowling ball sitting on a golf tee," where the top portion of the humerus, or head, is the bowling ball and the smaller glenoid is the tee. Just as the ball is held in place by the rim of the tee, the humerus is held in place by sitting on the glenoid and is supported by a rim of cartilage called the labrum, just as a golf tee has a rim. Because this does not allow much stability, there are numerous soft tissue structures to hold this joint together. Ligaments, with the most important being the inferior glenohumeral ligament, hold the humeral head on the glenoid. A soft tissue capsule holds the structure together. Muscles called the supraspinatus (needed for forward flexion), infraspinatus and teres minor (needed for external rotation), and subscapularis (needed for internal rotation) move the humerus and, thus, allow the humerus to move on the glenoid. In most patients, this is a stable arrangement; however, in some, there can be instability or too much perceived movement. Such instability can be intrinsic to an individual. When the instability produces symptoms, then it becomes pathologic and problematic to the patient. When this instability allows the shoulder to ride up on the labrum, producing feelings in the patient as if the shoulder is going to "pop out" or dislocate, which it does not do, the action of the shoulder is referred to as having undergone a subluxation.

Symptoms

Shoulder subluxation is perceived by the patient as a shoulder that is "moving too much," "moving in ways it should not," or "making noise" during activity. Patients often report that the shoulder *feels* as though it were "popping out" but is not actively dislocating. This is especially evident in shoulder-dependent sports such as swimming or throwing sports. In addition to these "unstable" feelings, patients can also feel pain deep in the glenohumeral joint or sometimes numbness going down the same-sided arm. This can be due to the movement of the humerus on the glenoid and by associated contact of nerves close to the joint by the moving humerus. Often, the subluxation will worsen with each successive motion that places the shoulder in the dependent position. This position has the affected arm in 90° flexion and 90° abduction and external rotation. The shoulder does not necessarily have to be in this position for subluxation to be perceived, but it is the more common position in which to feel the shoulder begin to subluxate. Increasing symptomatology, associated numbness, and a feeling as though the shoulder is going to dislocate often bring patients to the physician's office.

Types of Perceived Instability

It is the physician's job to recognize in which way the patient perceives subluxation and what the underlying cause of the movement is. The most common way that patients feel the shoulder moving is with increasing motion forward, or anterior subluxation. Backward, or posterior, motion is relatively rare. Some patients can feel movement more out of the bottom of the shoulder joint, or inferior. Still others can have multidirectional movement, in which they feel the shoulder move in a combination of all these motions. The reasons for a subluxating shoulder can include a genetic predisposition to abnormally loose cartilage that makes up the supporting soft tissue structures, injury to the joint or its surrounding structures, or a combination of both. Sports with a high demand on the shoulder, such as throwing sports, often make subluxating shoulders worse.

History and Physical Examination

The history is often the most important factor in the diagnosis of shoulder subluxation. This aids the physician in determining in which direction the shoulder is moving to produce the feelings of subluxation. Physical examination is also extremely important. Range of motion and strength are assessed to determine if there is a neuromuscular reason for the subluxation. Certain structures, such as a tear in the rim of the glenoid labrum, are tested physically to see if injury to these structures is the cause of the instability. Finally, the physician manipulates the shoulder in various planes in an effort to reproduce the feeling of subluxation within the patient or actively move the shoulder in a position that can make the patient feel as if the shoulder is about to "come out of joint." Often the physician checks one position at a time for movement or complaints of subluxation.

Diagnostic Testing

Diagnostic testing for shoulder subluxation is often directed at the shoulder structures to determine if they are the cause of the abnormal movement. X-rays can determine if there is damage to the bony structures of the shoulder, leading to subluxation. Computed tomography (CT) is also a good test to examine bone. Magnetic resonance imaging (MRI) with the addition of contrast material, called an *MR arthrogram*, can allow the physician to visualize any damage to soft tissue structures as a possible reason for subluxation.

Treatment

Nonsurgical

Treatment for shoulder subluxation is directed toward stabilizing the shoulder and preventing excess movement. The first and least invasive course of treatment is to perform physical therapy to attempt to have the muscles of the shoulder stabilize the humerus and glenoid tighter within the joint. Assistive braces or harnesses can be used for stabilization of the shoulder by preventing movements that would lend the shoulder to dislocation. These can only be used in sports or positions in certain sports that would not require the arm to be in full forward flexion, full abduction, or full external rotation. Return to play can follow physical therapy, provided that the patient has diminished symptoms, full active range of motion of the shoulder, and full strength within the shoulder.

Surgical

If stability cannot be maintained with physical therapy, surgery is often considered. With surgery, if there is a damaged structure, the physician will attempt to repair the damaged structure. With cases of nontraumatic origin, such as genetically "loose" soft tissue, surgery will be attempted to make the shoulder joint soft tissue tighter to hold the humerus on the glenoid to prevent subluxation. Surgery is usually successful. Return to play after surgery for recurrent subluxation is often possible 4 to 6 months after the procedure and associated physical therapy. There is often the risk of recurrent symptoms within the shoulder if the patient returns to sports, especially one that is very shoulder dependent. This is often seen in swimmers. Athletes who were stable postsurgery often again become unstable because of the high demands placed on the shoulder joint by their sport.

Sickle Cell Disease

Sickle cell disease (SCD) is caused by a mutation in hemoglobin, the oxygen-carrying component of red blood cells (RBCs). This change in hemoglobin causes RBCs to become abnormal. Normally flexible and oval-shaped, RBCs in SCD lose their flexibility and assume a rigid, "sickle" shape. This change in shape hinders the ability of RBCs to travel through vessels. Since the role of RBCs is to carry oxygen throughout the body, sickling prevents oxygen from getting to vital areas, leading to a number of major complications.

Those who receive two sickle cell genes from their parents present with SCD, while those who receive one sickle cell gene and one normal hemoglobin gene are referred to as sickle cell trait (SCT) carriers. Although carriers possess one sickle gene, they often do not present with the major complications seen in those with two genes due to the one normal hemoglobin gene. Both SCD and SCT protect individuals from malaria, making the sickle cell gene predominant in people (or their descendants) in places where malaria is widespread, such as sub-Saharan Africa. An estimated 8% of African Americans are SCT carriers, and other populations with the sickle gene include the Mediterranean, Middle Eastern, Caribbean, Indian, and South and Central American populations.

Impact on Athletes

The majority of people with SCD do not participate in strenuous physical activity due to the increased risk of sickling caused by lower oxygen levels and anemia resulting from RBC destructions. Although most people with the SCT do not experience any symptoms, intense physical activity can produce exertional sickling. The causes of this exertional sickling are low levels of oxygen, metabolic acidosis, overheated muscles, and RBC dehydration. It is most likely to begin after 2 to 3 minutes of any all-out exertion, and as with SCT, the sickling leads to blockage of the blood vessels and eventual muscle breakdown due to the lack of blood supply. This muscle breakdown can threaten the lives of athletes.

Exertional sickling is extremely dangerous to athletes and ranks as the number four cause of nontraumatic sports deaths in high school and college athletes. In the past 40 years alone, exertional sickling has killed at least 15 football players and accounted for 5% of sudden, nontraumatic sports deaths in high school and college athletes in the past decade. When comparing SCT with normal controls, the relative risk of exercise-related death was 30 times greater with SCT. The data show that the more strenuous the activity is, the greater the sickling.

Signs and Symptoms

Sickling collapse due to exertional sickling is often confused with cardiac or heat collapse. However, there are subtle differences. Athletes with sickling collapse do not lose consciousness, and they often experience cramping, not seen with cardiac collapse. Unlike heat collapse, the core temperature in those with exertional sickling is not greatly elevated.

Other signs and symptoms include the following:

- Cramping with no prior muscle twinges
- Pain
- Inability to catch one's breath
- Fatigue
- Generalized muscle weakness

If treated appropriately, sickling players recover quickly.

Safety

Sickling collapse due to exertional sickling is a medical emergency. The athletes should immediately have their vital signs checked and should be administered oxygen. The administration of oxygen often can prevent further worsening of symptoms as the sickling cells will return to their normal shape. If the athlete's condition does not improve, he or she should immediately be brought to the hospital.

Although SCT athletes are at increased risk of sudden death, this should not prevent them from participating in sports. If simple precautions are taken, the risk of exertional sickling greatly decreases. The following are some of these precautions:

- Gradual progressions in training with longer periods of rest
- Stopping participation in the activity if any of the above symptoms present themselves
- Emphasizing hydration
- Avoiding heat stress
- Having supplemental oxygen available
- Educating athletes on the signs and symptoms

Screening

All newborns in the United States are screened for the sickle cell gene. Athletes who are carriers of the trait should inform their coaches as well as trainers of their condition to ensure a safe environment. Screening is inexpensive and reliable. In the absence of screening or if an athlete is unsure of his or her status, screening should be completed prior to any strenuous exercise regimen.

Side Stitch

Side stitches are associated with vigorous physical activities such as walking fast, running, swimming, cycling, and aerobic exercise. The longer medical term—*exercise-related transient abdominal pain*—is both a definition and a description of the symptoms: a painful but temporary condition associated with exercise that affects the lower (right) side of the abdominal wall.

A study conducted by Morton and colleagues (2005) in Australia, and published in the *Journal of Science and Medicine in Sport,* showed that among 848 distance runners, 27% experienced side stitches and 46% felt pain on the right side. Side stitches seem to affect exercisers below the age of 20 more than they do older adults, women more often than men, and those who are not in good physical condition more than well-conditioned individuals. Relatively few major studies have investigated the topic, and while information coming from those studies is relevant, it cannot be considered conclusive.

Causes

Side stitches among runners may be the result of the pumping action of legs putting pressure on the diaphragm from below, with the rapid breathing associated with strenuous physical activity expanding the lungs and placing pressure on the diaphragm from above at the same time. The combined effect is one of pinching the diaphragm, reducing the flow of blood and oxygen, and causing noticeable pain in the side. While this scenario seems plausible, it is a theory that has not been proven by scientific research and one that does not seem to account for side stitches in exercisers who do not walk or run.

When a fitness walker or distance runner pounds his or her legs against the ground while taking rapid breaths, the connective tissue that extends from the diaphragm to the liver can be stretched. That stretched, stressed tissue could also be responsible for causing pain in the side.

The amount and type of food consumed before an exercise session may place an additional stress on the diaphragm, again potentially causing side stitches. Whether the food-exercise association is real, there are ways to minimize the negative effects of foods and beverages on exercise without compromising athletic performance. These strategies are discussed below, in the Prevention section.

Although not warming up adequately before exercise has been mentioned as a possible cause of side stitches, there is no evidence to support that claim. In fact, the Australian study found that the incidence of side pain occurred equally during the first, middle, and latter segments of the 14-kilometer race. If the side stitches had occurred only during the initial part of the race, an inadequate warm-up might have been the cause. That was not the case.

In spite of some logical explanations and a few well-designed studies, the exact cause of side stitches remains an exercise science mystery. Nevertheless, scientists, sports medicine physicians, elite athletes, and weekend exercisers agree that the pain is as real as it is temporary and that the discomfort can be minimized, if not eliminated.

Symptoms

Side stitches have two distinguishing symptoms. The first is a stabbing pain on the lower right side of the abdomen, and the second is pain that subsides almost immediately after the cessation of exercise. Side pain that persists regardless of exercise patterns is not exercise-related transient abdominal pain, and people who have that symptom should seek medical attention.

Treatment

The immediate treatment for side stitches is simply to stop doing whatever causes the pain, wait a couple of minutes, and resume the activity. Some people try to temporarily decrease the pain by stopping, bending forward, and tightening the abdominal muscles. There is no long-term treatment, but there are ways to lessen the probability that the condition will develop in the first place.

Prevention

The measures a person takes to avoid side stitches may be effective for that individual but not necessarily for all exercisers. Ten suggestions for preventing side stitches follow:

1. To focus on breathing patterns that might be associated with side stitches, exhale through pursed lips.
2. Before exercising, stretch by extending the left arm upward and leaning toward the right. Hold for 20 to 30 seconds, and repeat the stretch with the right arm up while leaning to the left.
3. Practice breathing deeply during exercise to stretch the diaphragm.
4. Change patterns of breathing while running or walking. For example, inhale, hold for one second, exhale. Then inhale, hold for 2 seconds, exhale. Next, inhale, hold for 3 seconds, exhale.
5. Change the pace of walking or running during an exercise session.
6. To address potential nutrition-exercise interaction, eat moderately sized, low-fat meals 2 to 3 hours before a training session or event.

7. Experiment with various sources of calories to discover the ones your body can tolerate without developing side stitches. Examples include energy gels, sports drinks, fruits, and grains.
8. Do not test a new or different kind of food or beverage the day of an important event.
9. Eat a familiar, easily digested, low-fat or no-fat snack an hour before a workout. Half a sandwich, a sports drink, fig bars, and granola bars are possible choices.
10. Drink 10 to 16 ounces (oz; 1 oz = 29.57 milliliters) (two cups) of cold fluid approximately 15 to 30 minutes before practice sessions or athletic events, and drink 4 to 8 oz of cold fluid every 10 to 15 minutes during exercise.

Sinusitis in Athletes

Sinusitis (or rhinosinusitis) is the inflammation of the sinus airspaces and epithelial lining within the bones of the face. The symptoms associated with it are responsible for a significant percentage of athletes' visits to training rooms and physicians throughout the year. It can be difficult to differentiate between sinus infections and other upper respiratory infections because the symptoms overlap. Understanding the difference, however, can help an athlete return to play and perform at a normal level more quickly.

Anatomy

The sinuses are air pockets within the skull that include the maxillary sinuses, located within the cheek bones; the ethmoid sinuses, located behind the bridge of the nose; the frontal sinuses, located above the eyes in the center of the eyebrows; and the sphenoid sinus, located behind the ethmoid sinuses and behind the eyes. When the mucus-clearing cilia of the epithelial tissue that lines the sinuses cannot function due to swelling and inflammation, mucus is trapped, and an excellent growth medium for bacteria is provided, resulting in symptoms usually correlating with the location of each sinus. Because the epithelial lining of the sinuses and nasal passage is the same as that seen in much of the respiratory system, sinusitis can also cause problems anywhere in the respiratory tract.

Diagnosis

Although bacteria and viruses account for a majority of cases, allergens, smoke, pollution, and cold air can also cause rhinosinusitis. A careful history can usually elicit the likelihood of the latter diagnoses. Sinusitis is a self-limiting condition 80% to 90% of the time. To avoid unnecessary antibiotic use and expensive testing, clinical prediction rules have been developed on the basis of meta-analyses of numerous studies. According to the Cochrane Database and the Agency for Health Care Research and Quality (AHRQ), the most significant clinical predictors for the diagnosis of sinusitis, regardless of symptom duration, and therefore for the consideration for antibiotics, are unilateral purulence, predominantly unilateral facial pain, bilateral purulence, and the presence of pus in the nasal cavity. When other minor symptoms such as fever, headache, anosmia, facial congestion, fatigue, cough, and dental or ear pain have been present for more than 7 days, antibiotics should also be considered. The use of sinus radiographs and limited computed tomography (CT) scans of the sinuses for the diagnosis of sinusitis should be reserved for recalcitrant cases lasting more than 30 days and/or two antibiotic treatment failures.

Asthma and allergy sufferers can have an allergic rhinosinusitis with symptoms mimicking those of acute sinusitis. If any of the acute sinusitis clinical predictors become evident, then antibiotics should be prescribed. Migraines can often be mistakenly attributed to sinusitis when the main complaint is either sinus pain or headache in the absence of other symptoms. A careful history and physical exam should screen out the athletes with sinusitis.

Treatment

The *Sanford Guide to Antimicrobial Therapy* and most primary care and otolaryngology organizations recommend mucolytics, analgesics, decongestants, and sinus irrigation in the early stages of infection. With athletes who may undergo drug testing, providers should be aware of current banned substances such as pseudoephedrine. A list of these can be found on the U.S. Olympic Committee (USOC) and sports governing board websites. In most cases of uncomplicated acute sinusitis, amoxicillin for 7 to 10 days provides adequate coverage. There is no evidence that non–penicillin-based antibiotics offer any additional benefit over penicillins. In penicillin-allergic patients, sulfa drugs, macrolides such as azithromycin and clarithromycin, cephalosporins, and quinolones are good substitutes, but providers should be aware of the potential tendinopathic side effect of quinolones. In more serious cases or treatment failures, amoxicillin-clavulanic acid for 14 to 21 days is recommended. In athletes diagnosed with sinus infections who have comorbid asthma and allergic rhinitis, nasal steroids may enhance mucociliary clearance and reduce nasal congestion. Aggressive long-term treatment in these athletes with nasal steroids, nonsedating antihistamines, nasal irrigation with saline, and/or leukotriene inhibitors can reduce the frequency of sinus infections and improve lung volumes, fatigue, and overall athletic performance.

Return to Sports

Most athletes with a diagnosis of sinusitis can return to practice immediately. Unless they have a fever, severe fatigue, or a significant symptomatic drop in peak flows, there is no specific reason to hold them out from competition or training. Swimmers and divers with sinusitis, significant eustachian tube dysfunction, serous otitis media, or bilateral facial congestion have increased risk for tympanic membrane rupture and should be watched closely. These athletes also appear to be more susceptible to sinus infections, possibly due to the effect of chlorine as an irritant. A tympanogram to monitor tympanic membrane mobility may be useful in providing clearance to divers with persistent symptoms. Ear plugs are not recommended for water athletes, but nose plugs can be used in athletes susceptible to sinusitis.

Skiing, Injuries in

Skiing, an alpine sport and popular winter pastime, is enjoyed in many countries by millions of people at more than 300 facilities in the world's mountainous regions. The skier slides down a naturally or artificially snow-covered hill on skis attached to the foot through boots and bindings. *Telemark skiing* refers to a skiing style and a specific nomenclature in which the only connection to the ski is through a binding attachment of the ski boot at the toes with the heel being free, as is the case with all cross-country skis. The emergence of new technologies and ski designs as well as skiing techniques and interests have led to the further development of alpine or downhill skiing and its numerous sport disciplines, together with cross-country skiing and, most recently, snowboarding, an alternative form in which both the athlete's feet are placed on a single board. The rapid evolution of these sports has been spurred by the innovation and creativity of sport enthusiasts as well as advances in equipment design and manufacture. New disciplines are continually being introduced as the sport continues to develop over time.

Ski Disciplines

The International Ski Federation (FIS) administers the following sport disciplines:

Alpine Skiing. This includes Downhill (DH), Super-G (SG), Giant Slalom (GS), and Slalom (SL). Downhill is considered to be the showcase sports event, with the longest distance and the greatest speed. Downhill and Super-G are considered the speed events, while Giant Slalom and Slalom are considered the technical events. Slalom is the shortest of the tech events, with a zigzag race across the ski hill carving a path around gates. There is also an event termed the Combined (CO; in Europe, K), composed of the combined efforts of two separate races—the Downhill and Slalom—which are run on courses that are shorter than normal. More recently, an event called the Super Combined (SC) was introduced with a shorter downhill and a single slalom, both run on the same day.

Cross-Country Skiing. This is the original and most popular Nordic ski sport. Initially cross-country skiing meant only one technique, in which a "diagonal stride" was performed in prepared ski tracks. In the 1980s, the "skating" technique was popularized and was considered to be more of a free technique than a "classical" stride, in which skiers today use a trackless course except during tricky turns or transitional sections. Cross-country skiing is a rugged mix of endurance and speed, with a variety of race distances ranging from 800-meter (m) sprints to 50-kilometer (km) events.

Nordic Combined Skiing. This is a combination of the two main elements of Nordic skiing, cross-country skiing and jumping. The traditional competition entailed a 90-m jumping competition followed by 15 km of skiing. Ski jumping is one of the most spectacular winter sports because athletes fly through the air traveling distances greater than a football field down a snowy slope.

Freestyle Skiing. This in its earliest form was named for the creative elements and "free" components of skiing performance, which included ballet, moguls, and an aerial maneuver. In 2000, ballet was dropped, and the disciplines of moguls and aerials flourished. In aerials, skiers are launched 50 feet (17 m) or more into the air off a "kicker" to land on a steep slope while performing intricate twists and flips. Moguls is the pulsating sport event where skiers maneuver through a treacherous course of bumps, with two obligatory air jumps that are scored by the judges along with the speed of the run to determine the winner.

Skiing for the Physically Disabled. This gained momentum in the 1960s and was originally called "handicapped skiing." Disabled skiing began as a rehab and recreational activity for people with mobility impairments. Eventually, it also became a competitive environment with disciplines in alpine races and cross-country events. Disabled skiers are classified according to their disability, which includes 12 basic classes along with 3 blind classifications. The FIS uses a 3-class system: sit-skiers, stand-ups, and blind.

Promoting Safety

The United States Ski and Snowboard Association (USSA) is the national governing body of the United States for Olympic Skiing and Snowboarding and is the parent organization of U.S. Ski Team and U.S. Snowboarding.

The promotion of safety and the enhancement of the overall experience for skiing enthusiasts is undertaken by an association called the National Ski Patrol (NSP), which follows a creed of "service and safety." The NSP was originally organized as a committee of the USSA (formerly known as the National Ski Association) back in 1938. In 1980, this nonprofit organization was recognized with a federal charter by the U.S. Congress to promote safety and health in skiing and other outdoor winter recreational activities. Today, its membership exceeds 26,000, with more than 600 ski patrols throughout the United States. NSP has evolved from its infancy as a service organization to a professional education association responsible for the development of, and education in, safety and emergency care training methods.

Although skiing and snowboarding are commonly depicted as highly dangerous, deaths associated with the sport are rare. During the period from 1991 to 2003, a total of 469 traumatic deaths occurred at ski resorts in the United States. Collisions of all sorts, but chiefly with trees, account for 90% of the fatalities.

The issue of helmet use in skiing and snowboarding continues to be debated. Helmet use is currently accepted by approximately 38% of skiing enthusiasts but has been steadily on the rise at a rate of nearly 4% annually. Although helmet use has been shown to reduce the number of head injuries by 30% to 50%, this is limited to less serious injuries. Non–helmet users' risk of death from head injuries is two times greater than the risk for those involved in accidents while wearing helmets. In very high-speed collisions, helmet use has not resulted in a reduction of fatalities because helmets are not designed to encounter the extreme forces involved at high speeds.

Orthopedic Ski Injuries

The most common injury in skiing is attributed to the knee joint. Injuries to this particular joint are typically identified as soft tissue and ligamentous type injuries, with the anterior cruciate ligament (ACL), the ligament inside the knee joint that prevents anterior displacement, being the most commonly injured tissue. An injury to this ligament is typically the result of a fall that causes a distribution of forces and an increase in the torque absorbed by the knee. The ski itself acts as a lever arm that significantly increases these forces transmitted through the knee during a fall. This is why proper equipment and maintenance of ski bindings are essential. It is important that the binding-release mechanisms activate during a fall to prevent significant injury to the knee.

The medial collateral ligament (MCL), which is the supporting ligamentous structure on the inside aspect of the knee, and the meniscus, the cartilage tissue inside the knee joint, are the next commonly damaged tissues in the lower leg. The ACL and the meniscus are typically repaired with surgical intervention to prevent long-term consequences to the knee joint. MCL injuries are not typically treated surgically but require a rehabilitation intervention strategy for full recovery. The relative frequency of lower leg fractures continues to decline, which can be attributed to better equipment, better binding technology, and shorter skis, particularly the shorter tail on carving skies, which has revolutionized the recreation industry.

Injuries to the head and face are typically the next most common in skiing. Concussions and contusions acquired when a skier falls and comes into contact with the snow surface at significant forces result in a higher frequency of reported trauma. Fractures of the skull and closed-head injuries are the most frequent traumas that result in head-related traumatic deaths. Attention to concussions and any mild traumatic brain injuries is essential to recovery so that the athlete does not return to the sport before proper recovery has been confirmed. Many head injuries are complicated by the fact that they recur over the course of a day or an entire ski trip, leading to complications and long-term consequences. Another frequent injury to the facial region is due to t-bars and poles and accidents that occur while getting on and off lifts. This includes facial cuts, knocked-out teeth, bloody noses, eye injuries, and ear cuts or abrasions following contact with the snow.

Upper extremity injuries in the skiing population occur much less frequently than in the snowboarding population. Most commonly, typical injuries reported in the literature include fractures of the wrist and forearm as a result of falling on an outstretched limb. Shoulder dislocations predominate for the same reason but more typically to an outstretched arm reaching backward. The shoulder essentially becomes unstable and pops out of joint completely. A dislocation is quite different from a shoulder separation because it involves the shoulder joint (known as the *glenohumeral joint,* the articulation of the head of the humerus with the glenoid fossa of the scapula) and requires a much greater traumatic force for injury to occur. A dislocation is different from a subluxation because the joint actually displaces completely—it doesn't just slide to the edge of the rim and return to its normal position. A separation usually involves the *acromioclavicular (AC) joint,* a supporting structure at the end of the clavicle.

The so-called *skier's thumb* is caused by injury that results when a ski pole and, more conspicuously, the wrist strap force the thumb away from the axis of the hand, resulting in a ligamentous injury. There are two common strap grips, the traditional and the saber, resulting in injury because the thumb cannot get out of the way during the fall, causing trauma to the ulnar collateral ligament of the thumb. This ligament connects the bones on the inside aspect of the thumb (more specifically the metacarpal and the proximal phalanx) and is typically the most commonly injured extremity next to the knees, which are sprained. Because it plays a major role in our grasping, pinching, and stabilizing objects in our hand, the injury is often very debilitating. Typical treatment following proper evaluation and diagnosis is immobilization for up to 6 weeks in less traumatic situations. In severe cases, however, surgery is recommended to repair the injured ligament. The best prevention strategy would be to use strapless poles so that one falls on the palm of the hand rather than a thumb-restricted hand with a pole in between. Fractures of the lower arm are also common, including fractures to the radius, the ulna, and the scaphoid bone in the hand.

Spinal injuries are not very common, but they still account for almost 5% of the fatalities that occur on the slopes. Injuries to the cervical spine are the most traumatic. Cervical vertebrae may be fractured as the result of a fall, whether it be due to compression, rotation, or hyperextension. Such injury potentially results in damage to the spinal cord, which is life threatening.

Nonorthopedic Ski Injuries

Other common skiing injuries that are less serious but still debilitating include frostbite, dehydration, and sunburn. Sunburn results from solar ultraviolet (UV) radiation, not from the heat. Sun exposure on cold, snowy days without any protection often results in sunburn, particularly in young children. It is essential that prevention be emphasized while skiing anytime. Hypothermia results when the core body temperature drops below 95 °F. Exposure to cold environments, particularly in the presence of wet, windy conditions, can lead to the loss of body heat very quickly. Recognizing the signs and symptoms, such as confusion, slurred speech, fatigue, exhaustion, shivering, and loss of motor control, necessitates immediate action. The key is to eliminate the exposure and warm the individual. Hypothermia may lead to cardiac arrest; therefore, close observation is extremely important. Frostbite is literally frozen body tissue. Children are at a much greater risk than adults because they lose body heat more rapidly and are reluctant to protect against exposure. Treatment typically includes removing the wet clothing and warming the exposed body parts in warm—not hot—water and prevention from additional exposure. Following an appropriate immediate treatment strategy, medical care is advised.

Preventing Ski Injuries

There are several ways to prevent serious injuries as a skier. This includes maintaining your equipment every season by having a certified ski technician service your skis and bindings every year. Proper binding release and new advances in binding technology are the main reason for ski injuries declining. The skier should always make sure that his or her boots fit properly. Use of protective eyewear and a helmet is recommended. One of the best ways to prepare for the upcoming ski season and to prevent injury on the slopes is to maintain a strength-and-endurance exercise program. Skiing requires aerobic power and strength, even at the beginning of the season; trying to "ski oneself into shape" is not recommended. Some strength exercises that will prove useful are leg presses, squats, hamstring curls, lateral leg raises, and core exercises such as crunches, sit-ups, and side bends. For enhancing aerobic capacity, cycling with the seat adjusted high at >80 revolutions/minute (rpm), running, swimming, and using a jump rope, ski machines, stepping machines, and elliptical trainers are recommended.

Skill Acquisition in Sports

Humans acquire skills, sometimes deliberately, sometimes incidentally, and often by necessity. Skill can be defined as the achievement of an intended outcome repeatedly, with economy of both time and effort (which is logical, given that conservation of energy has been the primary driver in the evolution of most organisms). In sports, acquisition of skill can refer to movement (learning specific ways in which to move in order to achieve a movement goal) or the cognitions associated with movement (e.g., learning when and where to move). In both instances, the "skill" shows improvement as a function of appropriate practice, accompanied by increasingly consistent performance associated with greater persistence and, eventually, adaptable performance in a wide range of situations or contexts.

Our understanding of skill acquisition has its beginnings in work that examined the way in which people acquire telegraphy skills—the ability to transmit and translate the complex dots, dashes, and pauses of Morse code—which was the Internet of the 1800s. The work established that it takes many years of training to become truly skilled, variability of performance decreases over time, and events that disrupt the performance of beginners are less likely to disrupt the performance of experts. The work also suggested that skill acquisition is not necessarily continuous but that plateaus can occur, during which practice does not appear to take effect. Shortly afterward, a universal law of learning was realized. This was the power law of practice, which characterizes skill acquisition as having the greatest rate of change early in practice, with gradual reductions in rate of change occurring as a function of increasing amounts of practice. The role of practice in skill acquisition has received much consideration, not surprisingly given the remarkable feats of skill so often seen in sport. While it is unlikely that there will ever be a definitive clarification of whether those of us who display such high levels of skill are a freak of nature or the function of nurture, there is no doubt that the level of skill that most of us achieve is closely associated with the degree to which we devote time and effort to practice the skill.

Two approaches dominate the study of skill acquisition in sport: information processing approaches and ecological-dynamical approaches.

Information Processing Accounts of Skill Acquisition

The information processing approach to skill acquisition evolved from cognitive psychological characterizations of the human brain as a computer that processes data from the stream of information elicited by the sensory organs and produces an output specific to the "software" that has been loaded. The approach supposes that the flow of information from our senses is of no value until it is converted to symbolic representations that guide movement with commands that are programmed either in advance as some sort of movement plan or schema (open-loop models) or modified on the basis of comparing available afferent information with central representations of the sensory feedback generated by previous successful movements (closed-loop systems).

The approach implies that repetition allows the internal representations to be updated, adapted, and refined (e.g., with knowledge of the results) to produce increasingly efficient movement that progresses from a consciously controlled, cognitive stage of information processing that is rule based, slow, and erratic to an unconsciously controlled, automatic stage that is procedural, fast, and effortless. This fundamental, stages-of-learning distinction is common across the numerous psychological theories of skill acquisition. Recently, it has been argued that the cognitive stage may be superfluous to motor learning and that the learner does not therefore need to progress through such a stage before reaching later autonomous stages that reflect expert performance. It has even been suggested that advantages accrue from avoiding the cognitive stage. By using *implicit* motor learning techniques that prevent the accumulation of explicit or declarative knowledge during the cognitive stages of skill acquisition, researchers have trained people in skills that are more stable under conditions of psychological stress, multitasking, and even fatigue.

Ecological-Dynamical Approaches to Skill Acquisition

An ecological approach to skill acquisition grew out of dissatisfaction with the view that there is a need to process information from the senses before movement can be produced efficiently. In *The Ecological Approach to Visual Perception,* J. J. Gibson (1979) argued that the direct interaction between an organism and its environment specifies *affordances* (the personal possibilities for an action or behavior); information obtained by perception, therefore, does not require elaboration in the manner suggested by information processing accounts, implying that movements can be initiated directly by perception and that perception and action are mutually dependent.

Coupled with the ecological approach, a dynamical systems view of motor behavior has emerged that views biological organisms as capable of dynamically self-organizing in response to constantly interfacing with their environment, much in the way that the study of thermodynamics deals with open systems that self-organize into spatial and temporal patterns that can be defined by one or two specific order parameters.

This view progressed from the work of N. A. Bernstein, who in his book *The Coordination and Regulation of Movement* (1967) suggested that the human body (the motor apparatus) has evolved with an almost limitless array of coordination possibilities to respond with dexterity to the host of motor problems that constantly emerge in the environment. Bernstein viewed skill acquisition as a degrees-of-freedom problem in which the learner must find a way to coordinate the many degrees of freedom available within the motor system. He suggested that this is done by constraining the muscles to act as synergies (i.e., coordinative structures) that can be controlled without cognition. Initially, this requires execution of the movement/skill to be simplified by freezing some of the degrees of freedom (i.e., by locking up various joints) and releasing the degrees of freedom as movement competence proceeds and later by exploiting the energetic forces that exist within the actor-environment interface (e.g., inertia, momentum). This focus on movement constraints within an ecological framework that models the human movement apparatus as a dynamic system attracted to a stable coordination pattern offers an alternative to the traditional information processing approach to skill acquisition in sports.

Skin Conditions in Wrestlers

No other sport is probably more closely associated with skin lesions and infections than the sport of wrestling. Because wrestling involves direct contact, the chances of transmission to an athlete are higher than in most sports. Transmission can occur most obviously by skin-to-skin contact, but can also be spread by contact with objects such as a mat or headgear. While skin infections were once considered a nuisance, they can now be deadly or debilitating, and their proper identification and treatment have never been more important. As discussion of every skin condition seen in wrestling is beyond the scope of this article, the most common conditions seen in the sport are addressed here.

Bacterial Infections

Impetigo

The most common bacterial infection seen in wrestling is impetigo. The bacteria usually responsible are *Staphylococcus* or *Streptococcus*. The bacteria are spread from person to person or by shared equipment or surfaces. The most common place to see impetigo is in areas where the skin is exposed. Honey-crusted lesions that are often seeping fluid characterize the disease. The area around them may be red, and the patient may have itching. The infection is highly contagious. When the condition is discovered, the athlete should be removed immediately from competition. A culture can definitively identify the organism, but diagnosis is often based on the uniqueness of the lesion. Treatment consists of topical antibiotics for small lesions and oral antibiotics for larger patches of lesions. Return to sports is generally after 5 days of antibiotic treatment, and when all the lesions have dried and crusted over. They should also be covered with a gas-permeable bandage.

Folliculitis

Folliculitis is a common term referring to infection of the hair follicles by bacteria. It often occurs after a wrestler suffers an abrasion from the mat or from clothing. Small, pus-filled follicles characterize the infection. Treatment is imperative to prevent secondary infection. Topical antibiotics are often prescribed to treat this infection. A gas-permeable dressing should cover the affected area while the athlete is actively infected. In most instances, athletes do not need to be removed from competition when suffering from folliculitis.

Furunculosis

Furunculosis is a form of folliculitis in which a “boil” develops. The bacteria usually responsible for this infection are *Staphylococcus* or *Streptococcus*. Again, it commonly occurs from an abrasion from the mat or from clothing. It is characterized by a large, red, often pus-filled raised lesion on exposed areas of the skin. Topical and, if warranted, oral antibiotics are used to treat this infection. If pus is present, often physicians will open the lesion and allow it to drain while the patient is being treated with antibiotics. If the lesion can be adequately covered, there is no pus drainage, and the athlete does not have any ill effects from the lesion, then he or she can participate in sports during treatment.

Methicillin-Resistant Staphylococcus Aureus

The emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) has become a great concern in wrestling. These bacteria are resistant to some of the most common antibiotics prescribed for skin infections. MRSA is often believed to start as a lesion that looks like a “spider bite” or boil. It is often a raised, red lesion that may or may not have pus at its center. If not identified and treated quickly, the infection can advance through a limb or disseminate through the body. If this happens, patients may have some of the typical signs of systemic infections, including a fever and chills. Identification of the bacteria can be done via a culture. Treatment includes opening and drainage of the wound followed by antibiotic therapy. More general antibiotics are given first and tailored to drugs that the MRSA is susceptible to once the bacteria are identified and susceptibility to antibiotics is determined via culture. Treatment is begun with a high suspicion of MRSA infection before the cultures are returned. Again, return to sports is allowed when all the lesions have dried and crusted and any systemic symptoms have resolved after antibiotic treatment. Some patients, however, are chronic carriers of MRSA. Doing swabs of the nasal passages, groin, or axillae, where MRSA is known to colonize, often leads to their discovery. These patients are often placed on antibiotics, either topically or orally, to try to definitively eradicate the infection.

Acne Vulgaris

Athletes are not immune to acne vulgaris, one of the most common bacterial infections found in the general population. Acne vulgaris is caused by bacterial growth in the pores of the skin secondary to androgen stimulation that results in unorganized keratinization and irritation of the skin. Stress, both mechanical and emotional, as well as certain drugs, cosmetics, and foods, can make the acne worse. Acne is typified by the blackheads and whiteheads on a red base seen most commonly on the face but also found on any surface of the body. The acne lesions are often characteristic, and no further laboratory work-up is needed to identify the condition. Acne is treated using topical bactericidals, topical and oral antibiotics, topical and oral retinoids, hormonal treatments, phototherapy, or laser therapy. These treatments may be carried out alone or in combination to try to control the outbreaks. It is critical to try to control these outbreaks to prevent secondary bacterial infection in wrestlers with more severe cases of acne. Acne alone is not reason enough to stop a wrestler from competing. Acne can be lessened by wearing clean, dry, loose, cotton clothing in a cool, well-ventilated environment. Wet clothing should be changed as soon as possible. Proper-fitting equipment is also necessary as acne can be made worse by ill-fitting equipment. Scarring from continued irritation of areas of acne is often a complication of this common athletic skin condition.

Viral Infections

Herpes Simplex

The most common viral infection seen in the sport is herpes simplex. In wrestling, this infection is often referred to as herpes gladiatorum. The virus that is often responsible for this disease is herpes simplex I. This virus is spread in the same manner as bacteria, but the infection is not treatable with antibiotics. The lesion from herpes simplex is described as a "blister on a red base." It is often seem in the area of the lips but can appear anywhere on the body. There are often systemic symptoms that occur approximately 1 week before the eruption of the lesions, which include flulike symptoms, malaise, fatigue, and itching or tingling at the site of the infection. The virus can be identified by a culture, but this is usually not performed as the lesions are so specific to this virus. Treatment is often supportive and addresses individual symptoms. If identified early, antiviral medicines can be given that can decrease the symptoms and duration of the outbreak. These drugs work best if given within 72 hours of identification of the virus. Wrestlers with chronic infections are often placed on oral antiviral medications. Return to sports occurs when all the lesions have dried and crusted over. This can take anywhere between 4 and 7 days. The lesions should then be covered with a gas-permeable bandage for competition.

Molluscum Contagiosum

Molluscum contagiosum is another common viral infection seen in wrestlers. It is spread in the same manner as the other viral infections. Wrestlers who are infected should immediately be removed from competition. Raised lesions with a hollow center characterize the disease. They are often seen in clusters and have a waxy appearance. They are often found on exposed areas of the skin. Treatment is by removal of the lesions via modalities such as freezing with liquid nitrogen or scraping off using a specific tool. There are also medications that can treat the disease. Once the lesions are removed and the athlete is free of new lesions, the wrestler can return to activity.

Warts

Warts are caused by the human papillomavirus and can be found on any part of the athlete. They are characterized by raised, scaly lesions and are often characteristic in their appearance. They are spread by direct contact. There is usually no laboratory testing attempted as the lesions themselves are diagnostic. Treatment is via removal of the lesions by substances such as salicylic acid or liquid nitrogen or by direct excision. As long as the lesions are covered, wrestlers need not be removed from competition.

Fungal Infections

Tinea

The most common fungal infection is due to the tinea fungus. Tinea can be found in any location on the body and thrives in a warm, moist environment. Infection in the scalp is referred to as *tinea capitis.* Infection at the foot is referred to as *tinea pedis,* or athlete's foot. Infection in the groin is referred to as *tinea cruris,* or jock itch. Infection on the trunk or extremities is termed *tinea corporis,* or ringworm. The most commonly isolated organism causing infection is *Trichophyton tonsurans.* These infections are spread by skin-to-skin contact and by sharing of equipment, uniforms, or towels.

A ringworm infection is most often recognized on the body by its characteristic ring formation. The fungus generally appears in a red patch that is scaly and has a distinct border with a clear center. This patch generally does not have little "satellite" lesions around it but can appear on other areas of the body. A scraping of the fungal infection can allow its identification when it is observed under a microscope; however, this is rarely done as the lesion often has a characteristic appearance. Athletes discovered with these lesions should be immediately withdrawn from competition as the infection is highly contagious. Tinea lesions are also likely to get secondarily infected with bacteria if left untreated. Treatment is generally by topical antifungal medications. If topical antifungal medications cannot control and treat the infection, then systemic antifungal medications are used. Caution needs to be used when these are prescribed as they may be toxic to the liver. Some athletes who are highly susceptible to tinea and develop chronic infections are often placed on chronic antifungal medications. Return to sports should not be attempted until after approximately 5 days of treatment with antifungal medication and drying of the lesions. These should be covered with a gas-permeable bandage when returning to competition.

Infestations

Scabies

Scabies is caused by an infestation of the body by a small living organism. The living organism burrows itself in the skin, leaving droppings along the burrows, causing persistent itching. The hallmark symptom of infestation is a persistent itch followed by redness of the affected skin. This is often first seen in the skin between the fingers but can also be seen in other areas of the body. The rash is identified by the characteristic burrows. This skin condition is easily spread from person to person. Usually, the athlete is not the only person affected as he or she brings the infection home, causing the infection of other family members. Treatment is washing with a solution that is left on overnight to kill the organism. Treatments are carried out every 3 days until the infection is cleared. Individuals without symptoms are treated twice, with 1 week between treatments. Athletes should be removed from competition at the first signs of infestation and can return to sports the next day after the overnight treatment.

Noninfectious Skin Conditions

Contact Dermatitis

This skin condition is not due to an organism but is due to an allergic reaction to an object such as a headgear. The skin lesion generally begins as a red patch with a border that approximates the size of the item exposed to the skin to which the athlete is allergic. This redness may evolve to scaling and weeping of the area with continued exposure. Small fluid-filled blisters may also appear. There are no lab tests to perform as the skin signs usually alert physicians to the diagnosis. Treatment is by using topical corticosteroids on the affected areas. If the outbreak is significant, oral steroids may be necessary. There is often no reason to withdraw the athlete from competition. The key to treatment is to eliminate that item to which the athlete is allergic, substitute the affected item with an item the athlete is not allergic to, or put a barrier between the irritating item and the athlete's skin.

Prevention

Good hygiene is the key to prevention of common dermatological conditions associated with wrestling. The following rules should be followed:

1. Removal from competition at the first sign of an infectious lesion.
2. Showering after all practice and competition sessions.
3. Thorough drying of all body areas.

4. No sharing of equipment or uniforms.
5. Use of breathable athletic clothing.
6. Consistent laundering of athletic clothing.
7. Consistent cleaning of athletic surfaces.
8. Being aware that body shaving exposes the skin to infection.

Skin Disorders, Metabolic

Metabolic skin disorders include several conditions that may cause discomfort and impaired performance. Conditions such as eczema, psoriasis, and urticaria can affect a significant proportion of the athletic community. The pathophysiology of all these disorders can be traced back to the participant's immune system working abnormally. Although treatment of these skin problems is not difficult, they must be first correctly identified and diagnosed to enable the timely return of the athlete to active participation.

Eczema

Eczema is an extremely common skin condition and has the potential to affect athletic participation. Although *eczema* is often used synonymously with the term *atopic dermatitis,* true eczematous reactions can occur in people with or without other findings of atopy, such as allergic conjunctivitis, bronchial hyperreactivity, or allergic rhinitis. Nonallergic sources account for 10% to 25% of eczematous reactions, and most are associated with atopy. In recent years, the term *atopic eczema/dermatitis syndrome* was coined to encompass several varieties of atopic dermatitis that are clinically related.

The effect that eczema has on athletes is a function of its prevalence in the population. Up to 10% of school-age children in the United States have eczema; furthermore, many school-age children participate in organized athletics. As a result, there is a significant likelihood that school-age children who play sports will also have eczema.

Diagnosis

Diagnosing eczema is a challenging task because of the many noneczematous disorders that mimic its skin lesions and symptoms. In addition, the skin manifestations of eczema itself are varied, appearing erythematous, papular, macular, or pruritic depending on its severity. Milder lesions are characterized by erythematous, maculopapular microvesicles. More severe outbreaks display crusted-over lesions that may or may not weep. Over time, the lesions become increasingly dry and result in lichenification. Regardless of the lesion's severity or chronicity, the hallmark of eczema is the intense pruritus (itching) that accompanies the rash and often results in excoriation due to repetitive scratching.

Eczema is usually localized to the flexor creases of the arms and legs, with occasional distribution to the genitalia and face. However, as the condition becomes more severe, it may spread to any body surface.

Treatment

Most cases of mild eczema will respond to more benign treatments such as topical steroid creams or over-the-counter moisturizing lotions. Caution should be advised with chronic topical steroid use,

Eczema

Source: From DermNet NZ. Reproduced with permission.

since there is risk of pigmentation changes, striae formation, and atrophy of the skin. Because of these complications, treatment with steroid creams around the eyes and face should be avoided. Pruritus that is associated with eczema is usually well controlled with antihistamines.

Newer therapies aimed at suppressing the immune response, such as cyclosporine, have also been used. In recent years, the medication pimecrolimus has been marketed as a first-line agent against mild to moderate eczema. Although this nonsteroidal medication is effective in inhibiting the inflammatory cytokines of eczema, physicians should attempt to use more conventional treatments first, because pimecrolimus suppresses T-cell function and may make individuals more susceptible to viral infections.

Return to Sports

Eczematous eruptions can be a significant impairment for athletes. The discomfort of not only the pruritus but also the physical contact of athletic gear against the affected skin can negatively affect athletic performance. Furthermore, the team physician must recognize the risk of secondary bacterial infection of eczematous skin, usually caused by *Staphylococcus aureus* or Group A beta-hemolytic *Streptococci*. It is this secondary bacterial infection in eczema that may require withholding the athlete from participation, especially in sports that require skin-to-skin contact between competitors.

Return-to-play decisions must be individualized based on a number of considerations. The location of eczematous outbreaks on the body and the feasibility of covering the lesions, clinical improvement with treatment, and the likelihood of physical contact between athletes should all be factors in determining an athlete's return. Because misdiagnosis and/or ineffective treatment of eczema are a common occurrence, habitual return to play after immediate initiation of antibiotics should be discouraged.

Psoriasis

Psoriasis is an autoimmune condition that affects approximately 2% of the U.S. population. It is characterized by erythematous, scaly patches that are sometimes silvery in color. The patches usually have very well-defined edges and often appear symmetrically on the body. As with eczema, the performance of athletes afflicted with this disorder is often impaired because of the discomfort of the rash, the chronic arthritis associated with the condition, or secondary bacterial skin infections, which may preclude participation in sports.

Diagnosis

The key to diagnosing psoriasis is being able to identify its pathognomonic rash from other dermatologic conditions. Psoriatic lesions are usually covered with a silvery white scale as a result of the increased turnover of the skin cells. Although this appearance is unique to psoriasis, it may not always manifest in this way and can easily be misdiagnosed as eczema, dermatophytic infection, or lichen planus.

Athletes with psoriasis may display the Koebner phenomenon, in which psoriatic plaques appear on previously unaffected areas as a result of trauma. This may be especially disabling for athletes if the affected site is the plantar surface of the foot. Although this phenomenon waxes and wanes with athletic activity, it may become uncomfortable enough to discourage an athlete from participating in sports.

Another complication of psoriasis that may affect athletes is psoriatic arthritis. This chronic manifestation affects about 5% of patients with psoriasis. Classically, the axial skeleton and the metacarpophalangeal (MCP) and proximal interphalangeal

Psoriasis

Source: From DermNet NZ. Reproduced with permission.

Notes: The most common ages for psoriasis to first appear are the late teens, but it is possible for children to be affected as well. It affects men and women equally, although among children, girls are more commonly affected than boys. There does appear to be a genetic predisposition to psoriasis, but it is also known to be influenced by many environmental factors. Usual sites of involvement include the scalp, eyebrows, knees, elbows, ears, genitalia, and nails. Psoriatic fingernails can become yellowish in color and display pitting, which can often aid physicians in diagnosis.

(PIP) joints of the hands are involved. On X-ray, erosion of the articular surfaces of the involved joints is observed.

Treatment

There is a wide spectrum of agents used to treat psoriasis. The more traditional methods such as selenium formulations, topical corticosteroids, or coal tar preparations are effective against mild cases of psoriasis.

As the psoriatic outbreak becomes more severe, the use of systemic or newer biologic agents may be indicated. Although quite effective, these newer medications and treatment modalities carry a certain degree of risk. Methotrexate is hepatotoxic and has been shown to interact with nonsteroidal anti-inflammatory drugs (NSAIDs). Cyclosporine combined with psoralen-ultraviolet light treatment (PUVA) increases the risk of squamous cell carcinoma. Oral retinoids have been shown to be highly teratogenic. Thus, the team physician may decide to take the help of other specialists in prescribing these agents and managing more severe cases of psoriasis in athletes.

Return to Sports

Return-to-sports decisions regarding outbreaks of psoriasis are quite similar to those regarding outbreaks of eczema. The risk of secondary bacterial infection is present in psoriasis, and decisions regarding return to play should take into account the same precluding factors as those concerning eczema. Therefore, the team physician should determine the appropriate time for return to competition on a case-by-case basis.

Exercise-Induced Urticaria

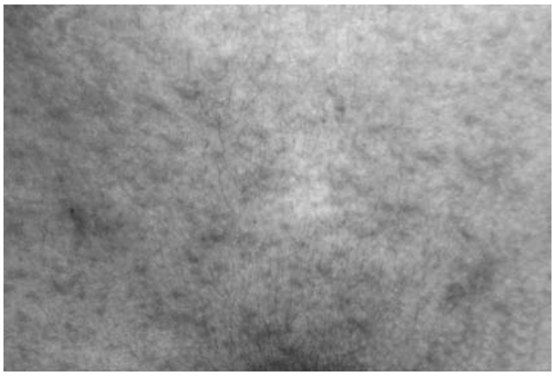
Exercise-induced urticaria, also known as *cholinergic urticaria*, is a physically mediated allergic condition that has been increasingly reported in recent years. This type of reaction occurs much less commonly than those arising from allergen exposure; however, for active individuals and athletes, this disorder may be extremely debilitating.

Diagnosis

The physiologic mechanism underlying exercise-induced urticaria is unknown, although the clinical manifestations appear to arise due to an exaggerated cholinergic response to rapid increases in core body temperature. Acetylcholine release followed by mast cell degranulation and histamine release precede the urticarial response. People with this condition may experience the urticaria not only after exercise but also after hot showers, during times of emotional stress, or when afflicted with a fever.

The classic response is characterized by the development of generalized flushing, coupled with discrete, punctuate, extremely pruritic 2- to 4-mm wheals surrounded by a red flare. Fortunately, vascular collapse is not commonly associated with this condition. Other clinical signs of parasympathetic activation such as lacrimation, salivation, or diarrhea may also aid in diagnosis.

Urticaria usually begins approximately 6 minutes after the onset of exercise and reaches a peak in 12 to 25 minutes. However, recovery may take from 2 to 4 hours. This condition primarily affects young active individuals between the ages of 10



Exercise-induced urticaria

Source: From DermNet NZ. Reproduced with permission.

and 30, although it may recur for many years after initial onset. Although diagnosis is usually made clinically, methacholine skin challenge tests have been used to help confirm the presumed diagnosis.

Treatment

Treatment of cholinergic urticaria consists of withdrawing the precipitating factor and using antihistamine medications/creams to relieve the urticaria. Use of a mast cell–stabilizing medication such as cromolyn sodium or beta blockers such as propranolol has also been reported, but antihistamines such as hydroxyzine are more universally recommended.

Return to Sports

The degree of discomfort and willingness to return to participation dictate the decision to allow an athlete to continue playing. However, if exercise is the essential trigger of the condition, it may be prudent to withhold the player from participation until prophylactic antihistamine medications can be given to help blunt the urticarial response.

Skin Disorders Affecting Sports Participation

Sports-related skin disease is quite common with a wide variety of causes. Broadly categorized as infections, dermatitis, or trauma, several skin disorders directly affect sports participation. Early recognition and treatment are crucial in determining the athlete's ability to return to play and preventing the occurrence of outbreaks among team members.

Infections

Skin infections cause the most disruption to individual and team activities. Many of the skin infections that affect athletes are transmitted by close contact. A variety of other factors contribute, including macerated skin from sweating, abrasions, and occlusion from equipment. These risk factors are present in many sports. The National Federation of State High School Associations Sports Medicine Advisory Committee and the National Collegiate Athletic Association have set specific guidelines for return to sports after a skin infection is diagnosed in wrestlers; these guidelines can help guide treatment and return-to-play decisions for other sports as well. Athletic skin infections can be fungal, bacterial, or viral.

Fungal Infections

Fungal infections of the skin are caused by dermatophytes that invade and reproduce in the outermost layer of the skin, as well as the hair and nails. They cause superficial infections commonly referred to as "ringworm" or *tinea.* Tinea affects the scalp, body, groin, and feet. Fungal infections are easily spread between athletes. Therefore, an athlete should have the affected areas covered and oral or topical antifungal treatment initiated. Wrestlers specifically need to be treated for a minimum of 72 hours for the skin and 2 weeks for the scalp prior to return to play.

Bacterial Infections

Bacterial disease can range from impetigo to cellulitis. Impetigo appears as a honey-colored scab and is caused by *Staphylococcus* or *Streptococcus* bacteria. Treatment should be initiated after soaking the area to remove the lesion's crust. Topical antibacterial agents are then applied for localized disease. Oral antibiotics are considered if the disease is extensive or if methicillin-resistant *Staphylococcus aureus* (MRSA), a serious condition, is suspected.

Boils (abscess) typically begin near the hair follicles. Infection is introduced by skin injury and is typically caused by *Staphylococcus* or *Streptococcus.* Abscesses, typically described as painful, red, soft tissue masses, most commonly occur in moist areas where hair follicles are present, such as the groin, posterior thighs, and face. Athletes at risk include those who are diabetic, are obese, use steroids, or have poor hygiene. Treatment consists of draining the lesion. Oral antibiotics are not typically needed unless there is concern for overlying skin infection (cellulitis) or MRSA. Cellulitis presents as diffuse red, warm, tender, and swollen areas of skin. Cellulitis is particularly dangerous as it may spread rapidly. Athletes with the condition can become quite ill. Antibiotic treatment and close monitoring are crucial until resolution.

Bacterial infections need to be considered "noncontagious" prior to return to play. This requires that no new lesions develop for 2 days. All current lesions should be scabbed over, with no oozing or drainage. An athlete needs to have been on an oral antibiotic for a minimum of 3 days. If new lesions develop or there is continued drainage, a diagnosis of MRSA should be considered, which requires prolonged treatment, defined as a minimum of 10 days, with all lesions scabbed over.

Viral Infections

Viral disease can take many forms, but most frequently, athletes are plagued by the herpes simplex virus (HSV). HSV appears as a cluster of skin blisters with a reddened base. Athletes may have associated symptoms such as a fever, chills, and muscle aches. Patients often notice a tingling or burning sensation before the onset of HSV lesions. Athletes with abrasions or lacerations of the skin are at high risk for transmission. HSV is self-limiting and will spontaneously improve but can recur and is easily spread. Outbreaks can be prevented by keeping athletes out of competition while treatment is initiated. A low index of suspicion and early detection are crucial for preventing spread. Careful inspection of each athlete before practices and competitions is vital to prevention. Prior to returning to play, the athlete should have no new lesions for 2 days, and all current lesions should be scabbed over, with no oozing or drainage. An athlete's first episode of herpes needs to be managed with antiviral treatment for a minimum of 10 days. This should be extended to 14 days if associated symptoms such as a fever, chills, and muscle aches are present at diagnosis. Recurrent episodes require a minimum of 5 days' antiviral treatment prior to return to play. In athletes with a recurrent infection, suppressive treatment should be considered.

Molluscum contagiosum is caused by the poxvirus and is spread by skin-to-skin contact. This infection is typically seen in swimmers, gymnasts, and wrestlers. Molluscum appears as a skin-colored papule with a central dimple, commonly seen on the face, neck, and trunk. These lesions are usually asymptomatic and resolve spontaneously. However, spontaneous resolution can take many months, and most athletes desire to expedite resolution in order to return to play. Molluscum can be removed by scraping, cryotherapy, or local application of medicated creams.

Parasitic Infections

Scabies is caused by *Sarcoptes scabiei.* A scabies infection occurs when a female mite burrows under the skin, leaving eggs in the tract she creates. Scabies infections are characterized by severe nighttime itching that usually occurs between 1 and 4 weeks after infection. Burrows appear as tracts in the skin and are commonly found between the web spaces of the fingers or over the wrists, breasts, axillae, scrotum, penis, or knees. Transmission occurs through close contact for a substantial period of time. Treatment typically involves a topical lotion. The lotion is spread over the entire body, kept on for 8 to 12 hours, and then washed off. A repeat application in 1 week is usually adequate for eradication. The clothing and bedding of the infected individual should be washed and dried at high temperatures. Household contacts of those infected with scabies should also wash their clothing and bedding and be treated as noted above.

Infection Prevention

In athletes, skin infection prevention is crucial. This requires athletes to pay close attention to personal hygiene, such as not sharing personal items or equipment, washing clothes and personal gear regularly, showering immediately after practice and competition, and regular use of shower shoes. Education and skin surveillance are essential for early recognition and treatment and to expedite return to play.

Dermatitis

Allergic or irritant dermatitis can cause significant redness, swelling, and itching of an affected body part. Diagnosis is often readily apparent in individuals on the basis of the distribution of the rash and a history of repeated skin eruptions after exposure. Recognition of environmental irritants and allergens is critical for appropriate treatment.

Trauma

Abrasions need to be cleansed with antibacterial soap, and protective dressings need to be applied. Return to play for lacerations should occur once active bleeding is stopped and the wound is properly dressed. Calluses and blisters occur secondary to shearing forces and perspiration. Frequently due to ill-fitting footwear, treatment of these conditions involves frequent sock changes, antiperspirants, and new, properly fitted shoes. Similarly, jogger's toe is caused by painful bleeding beneath the toenails in an athlete wearing improper shoes. Properly fitted shoes again are the mainstay of treatment.

Skin Infections, Bacterial

Bacterial skin infections are a common occurrence among athletes and range from simple "sweaty-sock syndrome" to potentially life-threatening methicillin-resistant *Staphylococcus aureus* (MRSA) infections. Conditions that favor infection, such as skin abrasions, moist environments, and skin contact with other players, are all present in the athletic environment. This entry discusses some common and some unusual causes of bacterial skin infections among athletes.

MRSA Infections

There is a growing prevalence of this infection in the athletic community, and although deaths are extremely uncommon, they have been reported. The hallmark of these infections is that they do not respond to the antibiotics traditionally used for skin infections and may progress more rapidly than do "normal" skin infections to severe illness requiring hospitalization. It is important to distinguish between hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) and community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA). HA-MRSA has been an issue for many years and affects primarily those in hospitals and nursing homes, those with immune disorders, and those with recent antibiotic usage. CA-MRSA has been of concern only for two decades or so and does not need any of these requirements to infect individuals and thus even causes infections in otherwise healthy athletes.

MRSA can be the pathogen involved in many of the skin conditions described below. Treatment depends on the prevalence of MRSA in the community, the severity of infection, and the type of infection (MRSA is more likely to cause abscesses, although this is not a reliable identification measure). Oral antibiotics such as trimethoprim/sulfamethoxazole, clindamycin, doxycycline, or linezolid may be used to treat these infections, although more severe cases may need hospitalization with intravenous vancomycin. A full discussion of MRSA is found in the encyclopedia entry dedicated to that topic.

Folliculitis

Folliculitis is a superficial infection or irritation of the base of the hair follicles anywhere on the body. Athletes usually complain of mild to moderate tenderness or itchiness and have small pustules located at the base of the hair shafts, usually with a small amount of redness at the base of each pustule. Folliculitis in athletes can be broken down into three types: *Staphylococcus* L (either MRSA or methicillin-sensitive *Staphylococcus aureus* [MSSA]), *Pseudomonas folliculitis,* or *Pseudofolliculitis barbae*.

Staphylococcus folliculitis is the most common type of folliculitis and is usually found on areas of the skin under equipment pads, although it can occur anywhere on the body. Most of these infections are from MSSA strains of organisms, but MRSA can be an issue even in these small lesions. Treatment of these infections should include oral antibiotics and the use of antibacterial soaps to help prevent recurrence. The type of antibiotics given depends on the severity of the infection and the level of concern for MRSA. Treatment is usually for 7 to 10 days.

Pseudomonas folliculitis, also called "hot tub folliculitis," occurs most commonly as clustered lesions under swimming gear. As the name implies, poorly cleaned hot tubs or whirlpools are usually the cause of the infection. This is a self-limiting condition that typically lasts 5 to 7 days and usually does not respond to either topical or oral antibiotics. Appropriate cleaning of whirlpool facilities is essential to prevent infection and transmission.

Pseudofolliculitis barbae is not truly an infection but rather a reaction of the skin to ingrown hairs at sites of shaving. It has a presentation similar to that of true folliculitis but often does not have pustules that are as inflamed as in that condition. Treatment involves using fresh razors, manually releasing ingrown hairs with a sterile needle, or stopping shaving for several days to allow the hairs to grow out. Occasionally, there will be bacterial superinfection, in which case the condition should be treated as a true folliculitis.

Pitted Keratolysis

Also called "sweaty-sock syndrome," this is a condition presenting as sliminess and intense malodor of the feet, with a characteristic pitting of the skin of the foot almost exclusively at the pressure-bearing areas. It is commonly initially misdiagnosed as a fungal infection. Treatment of pitted keratolysis is to ensure a dry environment through the use of synthetic socks and an aluminum chloride antiperspirant (Drysol) and frequent changing of socks and footwear. Persistent lesions should be treated with topical antibiotics such as clindamycin or erythromycin. This is not usually considered a contagious condition, and players do not need to be held back from practice or play.

Erysipelas/Cellulitis

Cellulitis is differentiated from erysipelas by the fact that it involves the subcutaneous tissue, whereas erysipelas is essentially a superficial infection. Both involve redness, swelling, and pain of the involved tissue, and there may be red streaking found extending from the infection (called lymphangitis). In severe cases, there may be a fever, chills, and malaise.

These infections are usually caused by *Streptococcus* and *Staphylococcus* species in athletes, although many different types of bacteria may be responsible. Oral antibiotics are the treatment of choice, and strong consideration should be given to treating for MRSA in regions with a high prevalence or infections involving risky areas such as the groin, hands, and face.

Abscesses

Abscesses are closed pockets of infection within the skin and often underlying tissue. Friction is a high risk factor for developing these lesions, as are warm, moist environments. Unlike cellulitis and erysipelas, there is rarely any fever or chills unless the abscess is extensive or there is significant surrounding cellulitis. Abscesses are almost always caused by *Staphylococcus* species, and MRSA is of particular concern with these types of infections. Incision and drainage of the abscess under sterile conditions is highly recommended in most cases when feasible. Cultures should be obtained from the abscess contents. If the lesion is small, if the patient is otherwise healthy, and if he or she has a close follow-up with a medical provider, this alone may be sufficient treatment. Often, however, oral antibiotics are needed in addition to incision and drainage—particularly if surrounding cellulitis is present.

Erythrasma

Patients with this skin infection complain of discolored, reddish plaques between their toes or in their groin or armpits or between their buttocks. There is little to no pain, and often only mild itching or irritation. People with depressed immune systems, obesity, or excess sweating are more at risk of developing this infection. The diagnosis can be confirmed by shining a special fluorescent (Wood's) lamp on the patches, with a coral-red appearance indicating erythrasma.

The causative bacteria for these infections are *Corynebacterium* species, although there is a high association with concomitant fungal infections. Treatment consists of topical antibiotics, a combination of topical antibiotics and antifungals, or even oral antibiotics. This is a contagious condition, and so players should avoid contact, group showers, or shared footwear if any lesions are present.

Impetigo

One of the most contagious of bacterial skin infections affecting athletes, it is unfortunately also one of the most common. Impetigo can affect any area of skin but is most often found on the face. There are two types: bullous (bubble-forming) and nonbullous. Both types have a classic "honey-crusted" appearance to the lesions, although the lesions can also mimic cold sores, poison ivy, or even simple acne.

For simple cases, treatment can be simply the use of topical mupirocin (Bactroban), an antibiotic cleanser. This cannot penetrate any crust that is present, however, so any crust must be soaked off prior to application. Occasionally, oral antibiotics are needed to treat more severe infections. It is of utmost importance to quarantine any infected individual for at least 2 to 3 days after starting treatment to prevent spread among a team or region.

Mycobacterium Marinum Infections

Caused by bacteria related to those that cause tuberculosis, *Mycobacterium marinum* is a very rare skin condition that aquatic athletes can contract from infected freshwater or saltwater swimming areas. After several days to weeks after exposure, patients may present with nonhealing ulcerated lesions. Treatment is oral antibiotics for up to a year's duration.

Necrotizing fasciitis

Despite being extremely rare, this condition of "flesh-eating bacteria," as it is sometimes referred to in the popular press, is fairly well known. Athletes may present with a mild cellulitis, which can progress rapidly over hours to days to severe infection and death. Any such rapid progression or severe pain out of proportion to the appearance of an infection warrants immediate hospitalization for intravenous antibiotics and surgical debridement of the wound. Even with such precautions, as many as 1 in 4 patients die.

Skin Infections, Viral

Viral infections of the skin are commonly seen in athletes. Excessive sweating, tight clothing, and close skin-to-skin contact may contribute to the occurrence of infection. Because many of these diseases are potentially contagious to other athletes, a rapid diagnosis and initiation of treatment is important to prevent spread to teammates or opponents. Although most of the lesions resolve with no treatment, athletes often do require treatment in view of the high rate of transmission to other athletes if the condition is left untreated. Additionally, to reduce the spread of infection, the major sports organizations have set guidelines that require treatment of the lesion(s) and confirmation of resolution before allowing participation.

Verruca Vulgaris (Warts)

Warts most commonly affect the hands and feet and are caused by a strain of the human papilloma virus. The virus can enter through breaks in the skin, as in the case of an abrasion. The wart infects a superficial layer of the skin (the basal layer) and does not travel into the deep layers. The warts tend to grow slowly over 4 to 6 months. They can be spread either by direct contact with the virus or contact with an object that has come in contact with the virus (i.e., the mat in wrestling). If left alone, a majority of warts tend to resolve after about 2 years.

Treatment of warts focuses on direct destruction or surgical removal. The virus actively replicates at the base of the lesion, and so it may be necessary to remove the superficial layers before treatment is initiated to allow improved success of resolution.

Warts do not require that athletes be restricted from play. However, it will be necessary to have the lesions covered during competition. The National Collegiate Athletic Association (NCAA) rules that lesions should be "adequately covered."

Herpes Simplex Virus

The herpes simplex virus (HSV) is classified into two strains: Type 1 and Type 2. In general, HSV-1 is associated with lesions around the mouth. The lesions are very common in childhood. Occasionally, the lesions are asymptomatic, though they can be very painful and cause significant difficulty with eating. The initial infection often shows up from 1 to 3 weeks after contact with the virus. At the time of the first infection, the person may have a fever, headaches, and muscle aches and feel ill. After the initial infection, the virus lies dormant in the nerves of the face and has the potential to reactivate at a later point in life. Reactivation is often associated with physical or emotional stress, ultraviolet light, or fever (immune system stress). Usually, the person does not feel ill with a recurrent infection.

The infection appears as tiny blisters (called *vesicles*) with clear fluid and redness of the skin. Often, before the skin findings, an infected person may recall a feeling of tingling or burning in the location where the infection has settled. After the vesicle stage, the lesion may form a painful ulcer. Eventually, the lesions scab and dry up and self-resolve after 3 to 5 days. It is generally accepted that high doses of antiviral medications such as acyclovir or valacyclovir may help resolve the lesions. In some cases, a persistent use of the same medication in a lower dose can potentially help prevent recurrence of the infection.

The infection is so common in wrestlers that a particular name has been given to an HSV infection in that subset of athletes: *herpes gladiatorum*. In rugby players, HSV infection is known as scrum pox. It has been reported that 7.6% of college wrestlers and 2.6% of high school wrestlers are infected annually with the disease.

The NCAA has set guidelines for treatment and rules regarding return to play for athletes. Wrestlers who have HSV must be free of signs of infection (fever, muscle aches, feeling ill) for 72 hours and must not have any new lesions for 72 hours; all lesions must be dry, and the athletes should have been treated for at least 120 hours with oral antiviral medications before they can be released to practice or competition. For this reason, many athletes with the condition prefer to continue preventive therapy with antiviral agents throughout their season.

Varicella

Varicella is more commonly known as chicken pox and is part of the Herpesviridae family of viruses. As it is genetically similar to HSV-1 and HSV-2, it tends to produce lesions that are similar in appearance. The virus can grow rapidly and cause many lesions to show up in a short period of time. The entire body can be affected. Prior to the institution of immunization against varicella, it was a very common childhood infection. The lesions show up about 2 weeks after exposure to the virus. The skin rash proceeds in a predictable way—first as red flat spots, then raised spots, then small blisters, and finally a scab. Since the virus reproduces itself so rapidly, it is possible to see all stages of the lesions in an individual person at the same time. The condition is highly contagious and is probably spread most efficiently starting 2 days before the rash starts up until 7 days after the rash has started. Most children infected with varicella improve within a short period of time and have no permanent effects. Varicella is particularly dangerous to pregnant women in their first 5 months because of fetal damage. Adults tend to have a more serious illness at times, resulting in pneumonia or a brain infection.

Herpes Zoster (Shingles)

Once a person has had chicken pox, he or she tends to be protected from a second infection. However, the virus can lie dormant in the nerves of the body and may resurface in times of stress or in the elderly. This resurgence is known as herpes zoster or, more commonly, *shingles*. Shingles returns in a single nerve root and follows the course of the nerve. In many instances, this produces a red rash with small blisters in a line. Often this is seen across the neck, chest, or abdomen. A more serious recurrence can occur in the nerves of the face. With facial involvement, there can be paralysis of the muscles of the face that is usually temporary but can result in permanent deformity. Recently, an immunization against shingles has become available, and it could decrease this risk of recurrence.

Molluscum Contagiosum

Molluscum contagiosum is caused by a virus in the Poxviridae family. It appears as a painless bumpy rash with multiple small lesions. After contact with the virus, it may take from 1 to 6 months for the lesions to develop. The bumps are often of a pearly color and have a center that appears pressed in on itself. Most of the time, there are no symptoms associated with the rash. The infection is particularly common in children and tends to occur on their trunk, thighs, or upper arms. Children tend to pass the virus by direct contact with lesions. Adults can manifest the disease in their genital area, and the condition is often considered sexually transmitted. Most often the lesions regress in about 6 to 9 months. If the lesions are single, they can resolve in as short a period as 2 months. If treatments are recommended, they are focused on directly destroying the lesions by freezing them, chemically destroying them, or cutting them off. There are topical creams that can help resolve the lesions as well, but they tend to take about 1 month to clear the lesions.

The NCAA requires that lesions be removed in some manner before clearance for competition. Localized or solitary lesions can be covered with a dressing and taped. After removal, it is recommended that the athlete be removed from competition for 24 hours.

Skin Infestations, Parasitic

Parasitic skin infestations are infections of the skin caused by small organisms that require human hosts for a portion of their life cycle. These skin infections, including lice and scabies, rarely affect athletes when compared with viral or bacterial infections. Though these infestations are rare, any of them may affect an athlete's ability to participate in practice or competition. Symptoms include intense itching and the development of a rash or bite marks. Diagnosis is based on a clinical exam. The most common treatment for these conditions is topical medications. Scabies and lice are transmitted from person to person, meaning that actively infected athletes cannot be allowed to participate until treatment is complete.

Anatomy

The skin is the largest organ of the body. It covers an area of approximately 2 square yards (yd^2; 1 yd^2 = 0.84 square meters [m^2]). The skin ranges in thickness from 0.5 millimeters (mm) on the eyelid to more than 4 mm on the palms of the hands and soles of the feet. Up to 15% of a person's body weight is made up by the skin.

The skin has several major functions. It plays a major role in regulating the body temperature with a vast network of small blood vessels below the skin surface. The skin helps protect the body from damage, dehydration, and systemic infections. This protection is obtained by having a relatively impervious external layer of skin called the epidermis. Supporting the epidermis is an internal layer called the dermis. The dermis forms the support structure for the external layer.

Organisms that cause parasitic skin infestations have adaptations including special claws and suckers that can aid attachment to the epidermis. Lice exert their clinical effects on the skin surface, whereas scabies organisms burrow into the epidermis itself.

Lice

Causes

Lice are parasitic insects about 2 mm in length that survive by feeding on human blood. Lice infestations are caused by one of three different organisms, named for the human anatomic site that is affected. Pediculosis capitis refers to head lice, pediculosis corporis refers to body lice, and pediculosis pubis refers to genital lice. Transmission of the infection requires close skin-to-skin contact with another infected person. Rarely, the infection can be transmitted from clothing or equipment that was recently used by an infected person. Close skin contact can occur during athletic participation. Lice infestations are classically reported in sports such as wrestling, where there are prolonged periods of skin-to-skin contact. However, lice remain a rare cause of skin problems in the athlete. One-tenth percent of skin infections in college wrestlers are due to lice.

Symptoms

The bites of the lice lead to complaints of itching up to 10 days after exposure. The itching can be severe and is due to a local allergic reaction to the bite. Other symptoms can include a tickling sensation or a sensation of movement on the affected area. Sores can develop from repeated scratching.

Diagnosis

Diagnosis is made by observing the area of concern. The body part affected is examined for live lice or lice eggs, called "nits." Nits are small, white nodules attached at the base of a hair shaft. Nits can be mistaken for dandruff, hair spray droplets, or dirt particles. Use of a fine-toothed comb can facilitate visualization of an affected area. If live lice are seen, then the diagnosis of lice infestation is confirmed.

Treatment

Treatment of an affected athlete involves the use of topical medications to eradicate the infestation or make the skin inhospitable for the lice. Commonly used topical medications include permethrin 5% cream, pyrethrin cream, and lindane shampoo. There are multiple forms of the topical treatments, and each form has individual instructions for application. Some treatments require a doctor's prescription, while others are available over the counter in the pharmacy. Topical medications can typically be repeated 1 week after the initial treatment.

All clothing, hats, sporting equipment, and bedclothes used for 5 days prior to use of the topical medication require special handling. All items should be cleaned in a washing machine set to the hot cycle and dried at a high temperature. Any item that cannot be cleaned in this fashion should be placed in an airtight container for 3 to 5 days. These measures are designed to diminish the risk for reinfestation by an athlete's personal items.

Prevention

Preventing the spread of lice from one athlete to another can be promoted by employing several simple measures. Any athlete who has an active lice infestation should not practice or compete in any sport that requires skin-to-skin contact with other participants. Athletes need to have infestations fully treated before returning to play. The National Collegiate Athletic Association (NCAA) has special rules for wrestlers with skin infections. Collegiate wrestlers with lice are required to be fully treated before they are allowed to compete. At the time of a precompetition skin check, a physician or certified athletic trainer may disqualify a wrestler if there is evidence of active lice infestation.

Scabies

Causes

Scabies is a parasitic infestation caused by small parasitic organisms called *Sarcoptes scabiei* mites. The mite burrows into the epidermal layer of the skin. As the mite burrows into the skin, it deposits its eggs and fecal matter. The fecal matter of the mite is also called *scybala*. Transmission of the infestation is most often through close skin-to-skin contact with another infected person. Rarely, the infection can be transmitted from clothing or equipment that was recently used by an infected person. Scabies infestations are classically reported in wrestling, where there are prolonged periods of skin-to-skin contact during matches or practice. However, scabies remain a rare cause of skin problems in the athlete when compared with bacterial, viral, and fungal infections. Only 0.5% of skin infections in college wrestlers are due to scabies.

Symptoms

Athletes present with complaints of severe itching, especially at night. The affected athlete develops characteristic skin lesions within several weeks of exposure. These skin lesions can occur in the webbing of the fingers or on the hands, arms, legs, trunk, or groin. The lesions are classically thin, linear, red, slightly raised plaques but can also be diffusely spread red bumps or papules. In athletes who have had prior episodes of scabies, the symptoms can appear within a few days of reexposure. This can happen due to the host's immune system being reactivated quickly to the infestation.

Diagnosis

Diagnosis is made by carefully examining the lesions for characteristics of scabies as described earlier. A black speck that can just be seen by the naked eye at the end of a linear lesion represents the burrowing mite.

To confirm the diagnosis, a scabies preparation is performed. This preparation is done by scraping the linear plaques three or four times each with a scalpel blade in the direction of the visible black speck. The scrapings are then placed in a drop of mineral oil on a microscope slide. The slide is then examined with a microscope on a low-magnification setting. The presence of mites, eggs, or scybala is considered a positive result.

Treatment

Treatment of an affected athlete involves the use of topical or oral medications to eradicate the scabies infestation. A commonly used topical medication is permethrin 5% cream, applied to every surface of the body. The cream is left in place overnight and washed off in the morning. The topical medication therapy is typically repeated 1 week after the initial treatment. An alternative treatment is an oral medication called ivermectin. A single dose is given and then repeated 7 to 14 days later. The severe itching typically resolves within 1 or 2 days following the first treatment. However, a topical corticosteroid cream can be applied for cases of persistent severe itching.

All clothing, hats, sporting equipment, and bedclothes used for 5 days prior to the use of the topical medication require special handling. All items should be cleaned in a washing machine set to the hot cycle and dried at a hot temperature. Any item that cannot be cleaned in this fashion should be placed in an airtight container for 3 to 5 days. These measures are designed to diminish the risk for reinfestation by an athlete's personal items.

Prevention

Preventing the spread of scabies from one athlete to another athlete can be promoted by employing several simple measures. Any athlete who has an active scabies infestation should not practice or compete in any sport that requires skin-to-skin contact with other participants. Athletes need to have infestations fully treated before returning to play. The NCAA has special rules for wrestlers with skin infections. Collegiate wrestlers with scabies are required to be fully treated and have a negative scabies preparation before they are allowed to compete. At the time of a precompetition skin check, a physician or certified athletic trainer may disqualify a wrestler if there is evidence of active scabies infestation.

Skull Fracture

Sports and recreation–related head injuries, such as concussions, are relatively common. Fortunately, skull fractures occur very infrequently from athletic participation. With improvements in head gear and protective equipment, it has become rare that enough force is imparted to the skull to result in a fracture during athletic events. When a skull fracture does occur, however, it is important that it be promptly recognized and treated. Skull fractures typically result in injury to the brain, which may require emergent treatment.

Anatomy

The skull consists of a total of 27 bones that constitute two main regions. The first region is the bony covering around the brain (cranium), and the second region is formed by the bones constituting the face (Figure 1). The facial bones consist of the upper portion, which houses and protects the eyes and nose, and the lower portion, which helps form the jaws. This entry focuses on fractures to the first region of the skull, the cranium, which covers the brain.

During growth, the bones of the skull are connected by growth plates, which are also known as "sutures," that eventually fuse together. The bones are named based on their location. As shown in Figure 1, the bones covering the brain include the frontal bones, at the front of the skull; the sphenoid and temporal bones, at the side; the parietal bones, on the top; and the occipital bones, at the back of the skull. The major bones of the face include the nasal bone, forming the nose; the maxilla and the zygomatic bone, forming the upper jaw; and the mandible, forming the lower jaw. The mandible is technically not considered a part of the skull but rather a separate bone that connects to the skull via the temporomandibular joint or TMJ.

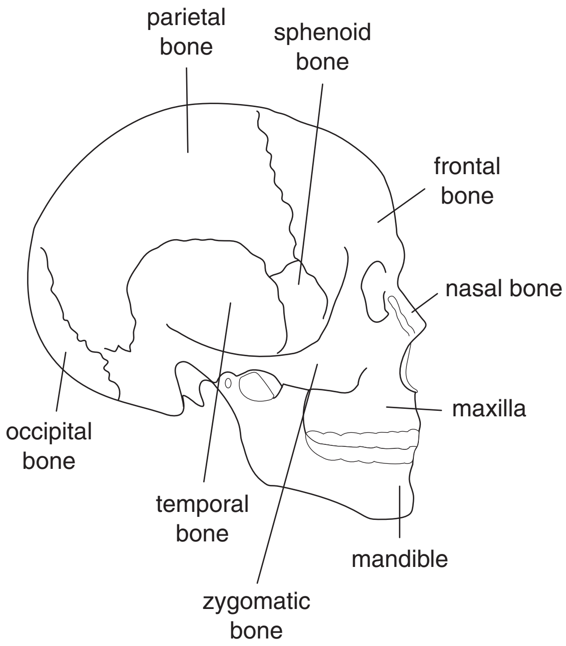

Figure 1 Some of the Major Bones Constituting the Face and Skull

Causes

A skull fracture is simply a break in a skull bone. The majority of skull fractures are not related to sports but result from motor vehicle accidents, falls, or violence. Skull fractures are grouped into four main types: linear, depressed, diastatic, and basilar. Linear skull fractures are the most common, accounting for about 70% of all skull fractures and virtually all fractures resulting from sports activities. With a linear fracture, there is a break in the bone, but the break does not result in any movement of the bone. With a depressed skull fracture, the area of the skull that is broken is pushed inward or appears sunken. This type of fracture has a higher risk of injury to the underlying brain. Diastatic skull fractures are fractures that occur along the growth plates or sutures of the skull. These fractures tend to occur in newborns and infants and are not typically seen after sporting activities. Basilar skull fractures are fractures that occur at the base of the skull or the portion underneath the brain. This type of fracture can occur even with helmet use in high-energy automobile racing accidents.

In sporting activities, fractures to the facial bones occur much more commonly than do fractures to the cranial bones. Improvements in head-and-face protection in sports such as football and hockey have led to a substantial decline in the number of cranial and facial fractures. Even in sports where very high impacts may be imparted to the head, resulting in injury to the brain, such as automobile racing, modern helmets have made the incidence of skull fractures quite low. Sports in which no protection is worn, such as soccer or rugby, actually account for a significant number of facial fractures and occasionally fractures to the cranium. A fracture can be caused by direct contact against another athlete, such as in a head-to-head contact in soccer. Fractures can also result from contact between the head and a piece of athletic equipment, such as the goalpost in soccer, or less commonly from contact against the ground. Fractures at the base of the skull (basilar fracture) can result from high-energy automobile racing accidents due to sudden compression forces imparted to that portion of the skull.

Symptoms

The symptoms resulting from a skull fracture depend on the type of fracture sustained. Athletes who have suffered a depressed skull fracture may be rendered unconscious due to underlying brain injury. With a linear skull fracture, the athlete may not lose consciousness but often will display symptoms consistent with a concussion, such as headache, confusion, and lethargy. Postconcussion symptoms can last for days to weeks and are listed below. Athletes who have suffered a linear skull fracture have pain and tenderness overlying the area of the fracture.

Diagnosis

The diagnosis of a skull fracture begins with a history and physical exam. The history usually reveals a high-energy mechanism, especially if the athlete wears protective headgear, as in auto racing. In some cases the headgear may not have been fit or functioned properly, as with a baseball player hit on the head by a pitch. In rare cases, the athlete may not have worn headgear at all, such as a soccer goalie who contacts the goal post with his

Postconcussion Signs/Symptoms

"Bell rung"	Nausea
Depression	Nervousness
"Dinged"	Numbness/tingling
Dizziness	Poor balance/coordination
Excessive sleeping	Poor concentration, easily distracted
Fatigue	Ringing in the ears
Feeling "in a fog"	Sadness
Feeling "slowed down"	"Seeing stars"
Headache	Sensitivity to light
Inappropriate emotions or personality changes	Sensitivity to noise
Loss of consciousness	Sleep disturbance
Loss of orientation	Vacant stare/glassy eyed
Memory problems	Vomiting

head, resulting in a fracture. Most athletes who have sustained a skull fracture are rendered unconscious from the initial impact to the skull and underlying brain. Although the neurologic injury and other associated injuries take precedence over the skull fracture in initial treatment, diagnosis of the skull fracture is important to minimize potential late complications. Depressed and open skull fractures should be apparent in a physical exam; however, linear skull fractures may not be obvious.

A diagnosis of linear skull fractures and fractures at the base of the skull is typically made on radiographic imaging. Plain radiographs have essentially been supplanted by the computed tomography (CT) scan in the imaging of the skull and brain. The CT scan is much more sensitive in detecting subtle fractures of the skull, especially those at the base of the skull. Unlike plain radiographs, a CT scan also images the brain and will detect bleeding in or around the brain. A magnetic resonance imaging (MRI) scan will also show skull fractures but is best for evaluating the brain for bleeding, contusion, or a shearing-type injury.

Treatment

Nonsurgical Treatment

The initial treatment for an athlete with a skull fracture focuses on the ABCs (airway, breathing, and circulation) of advanced trauma life support. The athlete's cervical spine should be immobilized with a rigid collar until spine injury can be ruled out. The athlete should be transported to a medical center that provides neurosurgical services. In the rare event of an open skull fracture, the wound should be covered with sterile gauze and intravenous antibiotics administered.

Linear skull fractures are typically treated nonoperatively. Ice can be applied to the area of contact to minimize swelling. A computed axial tomography (CAT) scan should be obtained to evaluate the underlying brain tissue for injury or bleeding. The CAT scan also accurately shows the extent of the fracture. Patients should be monitored for at least 24 hours to assess for deterioration in neurologic functioning. Narcotic pain medication should be avoided or given in limited quantities to minimize difficulty in diagnosing changes in neurologic status.

Surgery

Depressed skull fractures require surgery to eliminate pressure on the underlying brain tissue. Open skull fractures also require surgery to wash out the wound, elevate the depressed portion of the skull, and close the wound. These injuries represent surgical emergencies to minimize further brain injury and decrease the risk of infection. Since depressed and open skull fractures tend to result from very high-energy injuries, surgery may also require evacuation of underlying hematoma.

Rehabilitation

Nonsurgical Rehabilitation

Linear skull fractures heal without any surgical intervention. The fractures typically unite by 6 to 8 weeks after the injury. The type and extent of rehabilitation depend mostly on the degree of associated brain injury. Athletes who have sustained a concussion can return to athletic activity once the fracture has healed and all postconcussive symptoms have resolved both at rest and during activity.

After Surgery

Return to athletic competition after a skull fracture that requires surgery is controversial. Whether an athlete attempts to return depends on multiple factors, including the extent of brain injury and the nature of the sport that resulted in the injury. It is not the fracture, which typically heals without incident, but the extent of damage to the brain that is the most important factor in the athlete's long-term prognosis. To even consider returning to athletic competition, the athlete must have a complete neurologic recovery and not be at increased risk for repeat brain injury. Given that this is such a rare occurrence, there are no studies to help guide physicians in managing a patient.

Sleep and Exercise

Exercise has been proposed as offering a safe and healthy means of alleviating insomnia and other sleep disorders. This entry discusses the impact of sleep disorders, reviews the surveys and epidemiologic evidence supporting the benefits of exercise, and discusses the potential mechanisms by which exercise can promote healthy sleep patterns.

In industrialized countries, the annual global incidence of insomnia is approximately 30%. The prevalence of sleep problems increases with age, such that more than 50% of adults over age 60 have some sleep-related complaint.

Insomnia has been associated with physical and mental illness, impaired quality of life, and increased risk of automobile accidents. Moreover, in the United States, the costs associated with the resulting worker absenteeism, declines in work productivity, and increases in health care utilization have been estimated at approximately $14 billion.

Individuals' reactions to disturbed sleep and self-help strategies can often exacerbate and perpetuate insomnia. For example, excessive worry about insomnia and attempts to compensate by spending extra time in bed can lead to a vicious cycle dynamic of further sleep problems.

Many physicians who are untrained in dealing with sleep problems are most inclined to treat patients with sleeping pills. However, sleeping pill use has been associated with daytime sedation, "sleep driving," and impaired cognition; and chronic nightly use has been associated with a mortality risk comparable with that associated with smoking a pack of cigarettes per day.

Hence, there has been an increased interest in cognitive/behavioral treatments for insomnia. There is compelling scientific evidence that these treatments are superior to sleeping pills for chronic treatment of insomnia. However, the treatments are costly and time-consuming, and there are not enough clinicians who are trained to administer these treatments. Thus, other self-administered treatments would be helpful.

Exercise is almost invariably included in both expert and lay recommendations for improving sleep. The expectancy that exercise promotes sleep is centuries old; moreover, the notion that exercise promotes sleep has been consistent with historical theories about the function of sleep. For example, theories that sleep serves an energy conservation or body restitution function naturally led to hypotheses that energy utilization and body tissue breakdown associated with exercise could elicit unique needs for sleep. These theories influenced much of the earlier research on exercise and sleep. However, they have been largely discredited on the basis of evidence, for example, supporting the idea that sleep is associated with only a minimal reduction in oxygen consumption and no particular increase in protein synthesis or replenishment of adenosine triphosphate (ATP) stores.

Undoubtedly, some of the interest in this topic stems from anticipation that exercise could be a very attractive alternative or adjuvant treatment for insomnia. Exercise has profound health benefits and would be a comparatively safe, inexpensive, and simple means of improving sleep. Besides affecting insomnia and sleep quality, there are also theoretical and empirical rationales for expecting that exercise could be a useful alternative or adjuvant treatment for several other sleep disorders, such as sleep apnea, restless legs syndrome, and circadian rhythm sleep disorders.

Insomnia/Sleep Quality

Survey Results

Surveys have consistently shown that exercise promotes sleep. For example, in a National Sleep Foundation poll, people who reported exercising regularly also reported fewer complaints of difficulty falling asleep, difficulty staying asleep, waking up unrefreshed, or daytime sleepiness compared with people who reported exercising less frequently than once per week, and these associations showed a dose-response pattern.

In other population surveys, people have consistently reported that exercise helps them sleep better. For example, Urponen and colleagues studied a random sample (n = 1,090) of people in Tampere, Finland, who were prompted thus: "Please state, in order of importance, three practices, habits, or actions which you have observed to best promote your falling asleep or your quality of sleep." The respondents (men, 33%; women, 30%) reported that exercise was the most important behavior, more important than reading or listening to music (men, 15%; women, 23%), taking a sauna/shower (men, 9%; women, 9%), and psychological factors (men, 8%; women, 9%).

Although these survey results are provocative, it is plausible that they might overestimate the benefits of exercise for sleep. Physically active people tend to have better physical and mental health, which are conducive to sleep, and they tend to engage in other healthy behaviors that are conducive to sleep, such as avoidance of smoking and excessive alcohol consumption.

Moreover, people are not always accurate in their assumptions about sleep. For example, although the "nightcap" is commonly used to promote sleep, it is well established that alcohol actually impairs sleep. Likewise, people might assume that exercise promotes their sleep on the basis of a common, but incorrect, assumption that physical fatigue is synonymous with sleepiness.

Interestingly, survey data have unanimously failed to support the common assumption that late-evening exercise will disrupt sleep. For example, assessing a random sample that includes people who reported exercising after 8 p.m. (n = 320), Vuori and colleagues in Finland found that the majority of these people reported that after exercise, they fell asleep more quickly (65%), had deeper sleep (62%), and woke up feeling better (60%).

Epidemiologic Results

Epidemiologic studies could theoretically provide stronger evidence that exercise promotes sleep because they can statistically control for some of the potential confounds listed above. Epidemiologic studies have consistently found that self-reported exercise is significantly independently associated with less insomnia and other sleep complaints. These associations have been observed across all age-groups and various ethnicities around the world. The association of exercise with better sleep has generally been modest compared with other predictors (e.g., depression and stress/anxiety), but the association has been more consistently established than for perhaps any other behavior. Moreover, if exercise indirectly promotes sleep via its antidepressant/anxiolytic effects, then these studies might underestimate the effect of exercise.

Nonetheless, there are a number of limitations of the epidemiologic studies linking exercise with better sleep. First, with few exceptions, these studies have relied on self-reported measures of exercise and sleep. These measures have often had unknown reliability and validity. Second, as discussed above, causality cannot be definitively inferred from epidemiologic associations. The epidemiologic associations could be explained by external factors, such as incidental outdoor light exposure, which has been associated with better sleep. Moreover, fatigue is a barrier to exercise, so people who sleep better might be more inclined to exercise. Third, the studies often have not adequately measured or controlled for health status and other behaviors that can affect sleep.

Experimental Studies

Acute Exercise

Approximately 50 experimental studies have examined the effects of acute exercise on sleep in comparison with sedentary control treatments. These studies have focused predominantly on laboratory polysomnographic measures. Our meta-analysis of this literature summarized the effect and explored potential moderating factors. The meta-analysis found that acute exercise elicited virtually no effect on how long it took subjects to fall asleep or how much they were awake during the night and that exercise elicited a statistically significant but modest increase in total sleep duration (median 10 minutes), a significant but small increase in slow-wave sleep (SWS) (1.6 minutes), a significant increase in rapid-eye-movement (REM) latency (11.6 minutes), and a significant decrease in total REM duration (6 minutes).

The effect of acute exercise on sleep duration was significantly moderate by exercise duration, with negligible effects for exercise durations of less than 1 hour (2 minutes) and progressively greater effects following exercise of 1 to 2 hours (11 minutes) and more than 2 hours (15 minutes). This finding raises some questions about the practical utility of exercise for promoting sleep since many people are unwilling to exercise for 1 hour. On the other hand, no moderating effects of fitness or exercise intensity were found, which is consistent with survey and experimental evidence that exercise promotes sleep across the population.

Also consistent with surveys, experimental evidence indicates that late-evening exercise does not impair sleep for most individuals. This lack of impairment has been found in sedentary individuals as well as physically active individuals and has been seen even following vigorous exercise of 1 to 3 hours' duration, ending only 30 minutes before bedtime.

In summary, experimental studies have found significant, but quite modest, beneficial effects of acute exercise on sleep. However, there have been a number of limitations of these studies that might explain the modest effects. First, the studies have often had small sample sizes. Second, the studies have typically been limited to one or two nights. Because sleep is sensitive to many factors, more assessment nights might be needed to delineate the effects of exercise. The most important limitation is that the studies have focused almost exclusively on good sleepers, who have little room for improvement. Indeed, it has been shown that acute exercise and sleeping pills have quite comparable effects in good sleepers. Whether exercise will also have an effect similar to sleeping pills in insomniacs is a question worthy of future research.

Chronic Exercise

Chronic exercise studies have also generally revealed only modest beneficial effects of exercise on sleep. However, most of these studies have also been limited to normal sleepers. Several recent studies have examined whether exercise training could improve sleep in older adults, who tend to have worse sleep compared with young adults. In general, the results do not suggest more beneficial effects of chronic exercise in older versus young adults. There is some limited evidence of greater benefits of chronic exercise in older adults with insomnia, as might be expected. However, this evidence is limited mostly to self-reported sleep, which could be confounded by expectancy effects and demand characteristics. Further research involving insomniacs and objective sleep measures is needed.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) affects about 10% of the adult population and has been associated with cardiovascular disease, diabetes, and mortality. The primary treatment for OSA, continuous positive airway pressure (CPAP), has limited efficacy and is associated with dismal compliance. There is recent interest in the notion that exercise could help reduce OSA severity or at least offset some of its hazardous consequences.

Epidemiologic studies have consistently shown an association of exercise with reduced symptoms and diagnoses of OSA. For example, Peppard and Young of the University of Wisconsin-Madison found that the relative risk of polysomnographically determined sleep apnea (>5 events per hour) was 0.62, 0.39, and 0.31 in respondents (n = 1,104) who reported exercising 1 to 2 hours, 3 to 6 hours, and 7 hours or more, compared with 0 hours per week. Although weight loss is an obvious potential mechanism by which exercise could indirectly reduce apnea, the association of exercise with reduced apnea has persisted following control for body mass index and skin fold thickness.

Uncontrolled experimental studies have revealed that exercise training can reduce OSA severity, and these effects were not correlated with weight loss. A recent randomized controlled study found that exercise training significantly reduced central sleep apnea (a rarer type of apnea) in patients with chronic heart failure.

Restless Legs Syndrome

Restless legs syndrome (RLS) is associated with excruciating "creepy-crawly" sensations in the legs, which cause an irresistible urge to move the legs, primarily at night when one is trying to sleep. The presence and severity of RLS has been strongly linked to genetic factors, as well as iron and dopamine deficiencies. Anecdotally, people who suffer from RLS report that moderate daytime exercise can help prevent or reduce the severity of RLS symptoms at night. Moreover, exercise involving the legs is the best remedy for acute RLS symptoms. Epidemiologic research by Phillips and colleagues of the University of Kentucky has also indicated that exercise is associated with reduced RLS. Finally, randomized controlled research has shown that both acute and chronic exercise can reduce the symptoms of RLS. In one study by de Mello and colleagues in Sao Paulo, Brazil, the effects of exercise were comparable with those of L-dopa, one of the primary pharmacologic treatments for RLS.

Mechanisms by Which Exercise Could Promote Sleep

Anxiolytic Effect

Exercise could promote sleep via anxiety reduction. Clearly, anxiety disturbs sleep, and there are dozens of studies that indicate that acute exercise can reduce state anxiety and chronic exercise can reduce trait anxiety. The anxiolytic effect of acute exercise provides some rationale for expecting that the evening might be the best time to exercise since the anxiolytic effects are best established during the first few hours after exercise.

Antidepressant Effect

Since depression is also clearly linked with poor sleep, exercise could also promote sleep, indirectly, via its well-established antidepressant effects. Singh and colleagues at Harvard University conducted a 16-week exercise training study of depressed individuals and found that sleep-promoting effects were significantly correlated with antidepressant effects. Some evidence suggests that the efficacy of antidepressant drugs might be mediated partly by decreases in REM sleep and increases in REM latency, and so it is plausible that the antidepressant effects of chronic exercise might also be partly mediated by the REM changes that have been observed after acute exercise.

Thermogenic Hypothesis

One of the most widely accepted hypotheses in this area is that exercise could promote sleep via body-heating effects. This hypothesis is supported by evidence that the anterior hypothalamus/pre-optic area of the brain is associated with both sleep regulation and body cooling and that passive heating (e.g., in hot tubs) can promote sleep. Most compellingly, Horne and colleagues at Loughborough University in the United Kingdom have shown that experimental blunting of temperature elevation during exercise (via body cooling) can attenuate some of the beneficial effects of exercise on sleep. Chronic exercise could also potentially promote more rapid temperature downregulation at night, which has been linked with sleep onset.

Circadian Phase-Shifting Effect

Exercise could also have a positive effect on sleep via its influence on the circadian system. One of the hallmark features of primary insomnia is an erratic sleep-wake schedule. There is evidence that exercise can help stabilize the circadian system, which could, in turn, stabilize and improve sleep.

Moreover, there is compelling evidence that exercise can shift the circadian system, which could help correct circadian rhythm sleep disorders. Exercise and bright light have also been shown to have additive phase-shifting effects, both in animals and humans. Delayed sleep phase syndrome, which often prevents one from going to sleep before 2 a.m. or arising before 10 a.m., is particularly prevalent in adolescents and young adults. This condition can result in profound sleep deprivation, absenteeism and tardiness, and impaired academic and work performance. The circadian phase–advancing effects of morning exercise could help correct this problem. Conversely, the phase-delaying effects of evening exercise could help treat advanced sleep phase syndrome, which tends to cause one to go to bed before 9 p.m. and wake up before 4 a.m.

About 20% of the U.S. workforce are shift workers. Shift work is associated with chronic sleep problems as well as many other morbidities, including heart disease, cancer, mood disturbance, and gastrointestinal distress. In a randomized, controlled experiment involving a simulated "graveyard shift," we found that nighttime exercise facilitated circadian adjustment to the shift and resulted in a significant reduction in symptoms.

Conclusion

It is commonly assumed that exercise is one of the most important behaviors promoting sleep. Surveys and epidemiologic studies have supported this assumption. Experimental studies have shown more modest effects of acute and chronic exercise on sleep. However, these studies have been limited to good sleepers. More promising results have been found in studies of exercise in people with sleep problems. Further randomized controlled research of this type is needed. Moreover, there should be verification of the exciting evidence that exercise might be an effective treatment for sleep apnea, RLS, and circadian rhythm sleep disorders.

Sleep Loss, Effects on Athletic Performance

Sleep has always been thought of as a critical factor for optimal performance in athletics. Research has established that sleep is an active physiological state and not a passive process and is as complex as wakefulness. Critical cognitive, immunological, and metabolic processes occur during sleep, but its direct relationship to athletic performance is still unproven.

Both sleep and athletic performance are extremely individual activities and are influenced by many factors and variables, making research on this subject difficult to perform. However, scientific evidence is emerging that confirms a connection between sleep and athletic performance.

This entry describes the basic circadian rhythms and stages of sleep; the causes of sleep deprivation; sleep requirements; the effects of sleep deprivation through cognitive, immunological, and metabolic impairment; sleep quality; and recovery.

Circadian Rhythms

Circadian rhythms, or biological rhythms, are physiological parameters that fluctuate in specific ways over a 24-hour cycle. Sleep and wakefulness are among those rhythms. Circadian rhythms are genetically and environmentally determined in humans. Each athlete has a preferred sleep schedule that best suits his or her circadian phase. If a circadian preference and sleep schedule are not harmonized, or get out of phase, it will affect the amount and quality of sleep of the athlete.

Overview of Stages of Sleep

The American Academy of Sleep Medicine (AASM) uses a standardized method for describing sleep. This was revised in 2007. The modified stages of sleep and general outline include the following:

- Sleep is analyzed in 20- to 30-second epochs, with each epoch being assigned a single sleep stage.
- Sleep is subdivided into two general states: rapid eye movement (REM) sleep and non–rapid eye movement (NREM) sleep. NREM sleep is further subdivided into four stages.
    - *REM:* Electroencephalogram (EEG) findings show rapid, low voltage, similar to an active, awake EEG pattern. High-frequency beta waves occur with frequent bursts of REM. Most vivid dreaming occurs during this stage.
    - *NREM:* This accounts for up to 80% of total sleep time in human adults.
        - *Stage 1:* In this stage, the brain transitions from wakefulness to sleep or from alpha waves to theta waves. The muscle tone is lost, and the person loses awareness of the external environment. This stage lasts for only minutes, before the person moves on to the next stage.
        - *Stage 2:* EEG findings are characterized by higher "sleep or theta spindles" and "k-complexes," which are thought to be associated with arousal. This stage accounts for up to 55% of total sleep and lasts only a few minutes.
        - *Stages 3 and 4:* (the new AASM guidelines combine Stages 3 and 4). These are characterized by "deep sleep" or "slow-wave sleep." Delta waves are more pronounced. This is the last and deepest of the sleep stages before REM sleep. If a person is deprived of this stage of sleep, it rebounds once sleep is allowed again, suggesting that this stage is essential to the sleep process.

The true function of REM sleep is uncertain, although some data suggest an important role in memory consolidation. Some data indicate that NREM sleep has an association with the restorative functions of sleep, that is, restoration of alertness and energy. The data indicate that deep sleep is increased in athletes after significant physical effort.

Causes of Sleep Deprivation

Many circumstances can contribute to sleep disturbance and disruption of normal sleep cycles in an athlete. Some of these are work, academic and practice schedules; difference in time zones while traveling; pre-event anxiety or excitement causing early sleep arousal; early start of an event; diet; lifestyle choices; or jet lag.

Though many studies have produced mixed results or show methodological flaws in establishing whether optimal performance is influenced by transmeridian flights, one study showed that an appropriate choice of itinerary and lifestyle did indeed reduce the negative effects of jet lag in athletes.

Sleep Requirements

There is great interest in the ideal sleep requirement for an athlete to "rest and recuperate." Individuals respond differently to workout routines, and sleep deprivation and their sleep need vary.

In a 1994 National Institute of Mental Health study, participants with a "stabilized" sleep pattern averaged 8 hours and 15 minutes—a figure that is often interpreted as the amount of sleep that most adults require. Recent studies show that teenagers need as much, if not more, sleep as younger children (an average of 9.25 hours per night).

Though significant differences exist among individual athletes in their degree of vulnerability and responses to sleep deprivation, eventual negative effects have been shown to be cumulative. Sleep restriction practiced on a chronic basis induces performance deficits of the same order and magnitude as those observed during a large single event of total sleep deprivation. For example, if a person with a usual nightly sleep quota of 8 hours sleeps only 7 hours, there is a 1-hour sleep deficit that is carried over to the next day. A 7-hour sleep debt accrues after 7 days of losing 1 hour of sleep a night, nearly equal to a full night without sleep.

Effects of Sleep Deprivation

Though the direct effects of sleep deprivation on an athlete's performance are unproven, their relationship to the human body's metabolic processes, immunological function, and cognitive processing is more established and is related to a variety of adverse consequences.

Cognitive Impairment

Studies demonstrate a causal relationship among sleep, memory, and performance. Though not related to sports, major catastrophes such as In a 2008 study published in *Neurologic Clinics,* Three Mile Island accident, Chernobyl nuclear plant disaster, Exxon Valdez oil spill, and Space Shuttle Challenger disaster have been attributed to the poor judgment of sleep-deprived workers.

Dr. Charles Samuels cites previous research that has shown that sleep restriction (sleep deprivation) is linked to cognitive impairment with distinct interindividual variability. Cognitive performance (psychomotor vigilance) is directly affected by sleep deprivation. The impact of sleep disturbance on learning and neural plasticity (changes that occur in the brain as a result of experience) has also been established.

Sleep-deprived patients have reported decreased energy levels. They have difficulty with short-term memory, attention, alertness, speed, hand-eye coordination, and decision making—all of which are relevant to optimal athletic performance. These symptoms often disappear when normal sleep is restored.

Immunological Impairment

Chronic reduction in sleep can lead to immunosuppression. The integrity of normal immunological functions is negatively affected by sleep restriction. Studies have shown that partial or total sleep deprivation resulted in increased plasma levels of immune system "messengers" (tumor necrosis factor alpha [TNF-α] and interleukin 6 [IL-6]), which are involved in immune regulation. These "messengers" serve to connect the nervous, endocrine, and immune systems.

According to Samuels, there is a critical relationship between physiological recovery during sleep and an athlete's ability to train at maximum capacity with optimal results. The phenomenon of overtraining syndrome or chronic training fatigue is believed to result chiefly from immunological, neuroendocrinological, and musculoskeletal factors. The athlete's total sleep need and ongoing sleep debt are key factors in postexercise recovery, performance, and susceptibility to overtraining syndrome.

Metabolic Impairment

In a 1999 article published in *Lancet,* K. Spiegel and colleagues showed that sleep-deprived participants metabolized glucose less efficiently, leading to a reduced ability to manage glucose (similar to what is found in the elderly), decreased activity of human growth hormone, and elevated serum cortisol. Theoretically, elevated cortisol levels may interfere with tissue repair and growth and may lead to overtraining and injury.

Other detrimental changes in normal body metabolism due to sleep deprivation have been published, including delay in the healing of wounds, which has been shown in a study of rats with burn wounds. One night of sleep deprivation shows abnormal findings in electrocardiogram (EKG) testing (significant increase in QT max, QTd, cQTd, and P waves) in healthy young adults. These EKG changes can contribute to the development of arrhythmias. The effects of sleep deprivation on P waves may contribute to atrial fibrillation.

Sleep Quality

It is not enough to have an adequate quantity of sleep. An athlete may sleep for 8 hours or more and still be sleepy, secondary to disturbances in sleep quality. Sleep quality is another factor affecting performance in athletes. The full "restorative" benefit of sleep may not be received if sleep is fragmented by recurrent arousal without full awakening or light sleep with recurrent awakening.

Athletes experiencing "nonrestorative sleep" may become more tired from training, which affects performance and recovery. Optimal sleep quality may facilitate optimal athletic performance.

Recovery

When overcoming the effects of sleep deficit, any possible sleep "disturbance" should be minimized to allow normal and full sleep cycles to produce a full restorative benefit.

A positive or mitigating effect of "recovery sleep," that is, strategic napping, has been established as well in sleep deprivation studies, and it helps improve alertness and aspects of physical performance.

A Stanford University study showed that "extra" or extended sleep may boost athletic performance. Subjective reports of improved sprint times, increased free throw percentage, higher energy, and improved mood were obtained in six members of the men's basketball team who were instructed to "get as much sleep as possible" over a 2-week period. Studies with a larger sample may provide more meaningful results.

Conclusion

Determining an athlete's sleep patterns and ideal sleep needs and optimizing opportunities to allow optimal sleep quality so that the full restorative benefit of sleep can be achieved should be the current goal of coaches and athletes.

Coaches and athletes can make reasonable decisions to reduce the negative impact of sleep loss and encourage sleep quality as well as quantity. Traveling athletes can minimize the negative effects of readaptation when traveling over time zones by strategically planning their itinerary and lifestyle choices. Above all, further research must be conducted on the effect of sleep on athletic performance.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is an orthopedic emergency. It must always be considered in an adolescent with hip pain. Any young patient presenting with knee pain should always have his or her hips examined for SCFE. Treatment suggested is primarily surgery to prevent further damage and destruction to the femur (thighbone).

Anatomy

SCFE occurs at the femur in the hip joint. Specifically, the femoral head is the area that is part of the hip joint; the pelvic portion is called the acetabulum. The femoral head has a growth plate or epiphyseal plate, which is wider and weaker than normal bone. The slip is actually a Salter-Harris fracture (the classification for fractures involving the growth plate) that occurs in that growing and weakened area of bone.

Causes

SCFE happens in about 1 to 10 per 100,000 people. It is nearly 2.5 times more common in males than in females. It usually occurs in boys between 10 and 16 years of age and girls between 12 and 14 years. African Americans have a higher incidence of SCFE. About 25% of SCFEs are bilateral or affect both hips.

Obesity is a risk factor, because it increases the shear forces on the growth plate in the femoral head. Genetics may play a role as well. Of the patients with SCFE, 5% to 7% have another family member with the injury.

Metabolic and endocrine disorders also increase the risk of SCFE. Any patient with SCFE who is less than 10 years of age should have a metabolic and endocrine evaluation. These disorders include hypothyroidism, hypopituitary disorders, growth hormone deficiency, hypogonadal syndromes, and renal osteodystrophy. Bilateral SCFE is more common in young patients.

Clinical Evaluation

SCFE should be diagnosed and treated as quickly as possible to decrease the risk of long-term complications.

History

Most patients will complain of hip pain with decreased range of motion and difficulty weight bearing. Some will complain of knee pain (the pain radiates down the obturator nerve, which can confuse the examiner). The duration of symptoms should be obtained. If it is longer than 3 weeks, it is deemed chronic, whereas if it is less than 3 weeks, it is considered acute SCFE. Occasionally, patients will present with hip pain that has lasted longer than 3 weeks along with an acute worsening of pain or limp. This is termed *acute on chronic SCFE.*

It is important to inquire about family history and about symptoms consistent with the metabolic and endocrine disorders mentioned above.

Physical Exam

Some, but not all, patients may be obese. They classically hold the affected leg in external rotation or the foot pointed away from the body. This outward rotation may worsen with forward bending (flexion) of the hip. Testing of hip range of motion will be painful. It should be determined whether they can weight bear. It is always important to examine the opposite hip. Finally, the physical exam should also look for clues to endocrine and metabolic disorders.

Diagnostic Imaging

X-rays should be obtained. It is necessary to obtain X-rays of the opposite hip not only to rule out bilateral disease but also to use it for a comparison with the injured hip. Radiographs should include two views, usually a front-to-back film (AP or anteroposterior) and a "frog leg" view. However, if the patient is known to have SCFE, the frog leg view may potentially worsen the slippage, so a cross-table lateral view should be obtained.

The X-rays should be assessed to classify the amount of slippage and to see if there is other damage to the femoral head.

Blood testing for endocrine and metabolic disorders is necessary only in patients younger than 10 years or patients with other signs or symptoms of the disorders. Magnetic resonance imaging (MRI) and computed tomography (CT) are not helpful with diagnosis.

Source: Kevin D. Walter, M.D., Children's Hospital of Wisconsin.

Patient's right side shows the normal femoral head; the left side shows SCFE.

Source: Kevin D. Walter, M.D., Children's Hospital of Wisconsin.

Classification

There are three ways to classify SCFE. The most important is stable or unstable. A stable SCFE means that the patient is able to weight bear. An unstable patient cannot put any weight on the affected leg because of the pain. An unstable SCFE means that the patient is likely to get progressively worse.

The next classification is based on the duration of symptoms. This includes chronic, which is greater than 3 weeks, and acute, which is less than 3 weeks of symptoms. The term *acute on chronic* refers to greater than 3 weeks' duration of symptoms but with a recent worsening of symptoms.

Finally, the amount of slippage can be determined by looking at the X-rays. Type I is less than 33% displacement. Type II is 33% to 50% displacement. Type III is more than 50% displacement. The larger the degree of displacement, the more likely the patient will have complications.

Treatment

SCFE is an orthopedic emergency. The patient should be non–weight bearing at all times. An orthopedic surgeon should be immediately contacted to evaluate the patient.

The most common treatment is surgery or internal fixation. The surgeon will use screws to fix the femoral head to the femur. This screw goes through the growth plate. The screw will provide stabilization, which can reduce the risk of further slipping. The screw also can cause the growth plate to close earlier than usual, which increases stability.

This procedure is done shortly after diagnosis to reduce the risk of avascular necrosis (AVN) or bone death of the femoral head. The femoral head is supplied by a single blood vessel that runs through the hip joint. As SCFE worsens, there is a chance that the blood flow will be disrupted, which causes AVN. The cartilage on the joint surface of the femur (articular cartilage) can be damaged as well. This is called chondrolysis. These two complications can lead to disability, pain, and early arthritis.

Since the blood vessel that supplies the femoral head is very sensitive, the slipped portion is rarely repositioned in the anatomically correct position. It is usually just fixated in its slipped position, due to fears that repositioning may damage the blood vessel.

Prophylactic bilateral fixation is controversial. Some surgeons feel that the risk of the opposite hip becoming affected is an indication for surgery on both hips. Other surgeons feel that it is not necessary to operate both sides unless the patient is younger or has an endocrine disorder, because both these issues have a higher risk of bilateral involvement.

Casting and other surgical procedures have been done in the past, but they have a high rate of complication, and thus have fallen out of favor.

After Surgery

The surgeon will discuss after-surgery care. Usually, patients are non–weight bearing or partial weight bearing on crutches for about 6 to 8 weeks after the surgery. Rehabilitation exercises after surgery can minimize weakness and improve strength.

X-ray follow-up until the growth plates close is recommended. During this time, leg lengths should be observed as well. Since the goal of surgery is to prematurely close the growth plate in the proximal femur (near the hip), the affected leg may be shorter than the unaffected leg.

There is some controversy about return to sports and contact sports. Some surgeons allow return after the growth plate has closed, some do not allow a return to contact sports, while others may allow return before growth plate closure. This is best discussed on a case-by-case basis with the surgeon.

Of course, if there are concerns for endocrine or metabolic disease, it may be worthwhile to follow up with a primary care provider or an endocrinologist for further evaluation.

Most patients who have a smaller percentage of slippage do quite well with early diagnosis and treatment. However, patients who are diagnosed late, as well as patients with severe slippage, may have more complications. The complications of AVN and chondrolysis may lead to chronic pain and early onset arthritis, both of which can lead to significant disabilities.

Slipped Disk

Spinal pain is a common reason for preventing athletes from participation in sports. The spine is composed of the cervical (neck), thoracic (upper back), and lumbar (low back) vertebrae. Approximately 20% of athletes will experience back pain during a 1-year period. Neck pain will occur in about 10% of athletes overall during this time period. Of course, this will vary from sport to sport. The cyclist will have a much higher prevalence of neck pain, while the gymnast will complain more of low back pain.

The sources of spinal pain are multiple and include the surrounding muscles, the ligaments, the facet joints, and the intervertebral disk. The disk accounts for up to 25% of spinal pain. However, there are a number of pathologic processes that are associated with the disk. It may degenerate with loss of fluid and height. Or the disk may rupture, which is called a *herniated disk* or, in lay terms, a "slipped disk." To prevent and to properly rehabilitate an athlete with this injury, one must understand the biomechanics of both the sport and the individual athlete.

Anatomy

The spinal column descends from the skull to the pelvis with 7 cervical vertebrae, 12 thoracic vertebrae, and 5 lumbar vertebrae. The articulation of the adjacent-level vertebrae occurs via the intervertebral disk in the front and the facet joints in the back (Figure 1). The lumbar vertebrae end on the sacrum, which is a fused V-shaped vertebra that

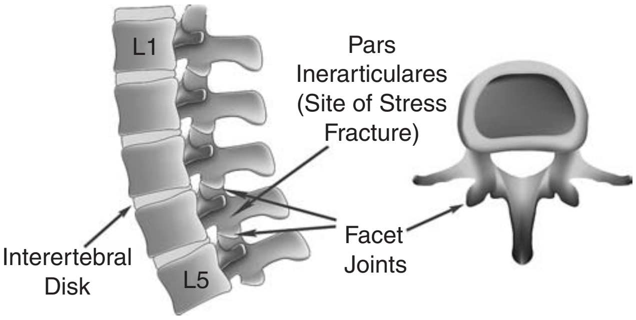

Figure 1 Lumbar Vertebrae (*lateral view*) and Single Vertebra (*top view*)

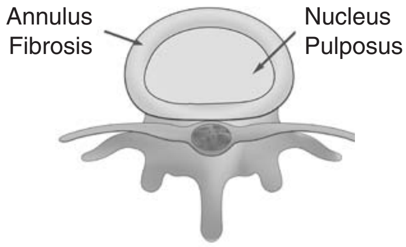

Figure 2 Cutaway View of Intervertebral Disk, Showing the Nucleus Pulposus at the Center, Surrounded by Annular Ligaments

Source: Illustration by Michael d'Hemecourt.

articulates with the pelvis to transfer forces from the trunk to the legs.

The disks become progressively larger from the cervical spine down through the lumbar spine. The disks provide shock absorption to the spine as well as motion. These disks are composed of three basic components: the annular ligaments on the outside (annulus), the colloidal gel (nucleus pulposus) on the inside, and the end plates of the vertebrae above and below. The *annulus* is composed of well-organized ligamentous sheaths (10–20 layers; Figure 2). The *nucleus pulposus* is a hydrous gel with few cells and some inflammatory enzymes. The *end plates* are at the top and bottom of the vertebrae, where the disk attaches. Since there is no blood supply to the disk, the end plate provides the nutrition to the disk by way of hydrostatic pressure during motion. In the child and adolescent athletes, these end plates are composed of soft growth cartilage and are susceptible to injury.

The disks are round and crescent shaped, with the posterior curved away from the posterior spinal column. The one exception is the lowest disk at the lumbar-sacral juncture (L5-S1), which is round. In the adult, the disk has the weakest ligamentous constraints on the posterolateral side, where the nerve roots exit. As such, a rupture here will affect the nerve. Conversely, the child and young adolescent may rupture into the soft end plate growth cartilage.

Etiology

A slipped disk represents a herniation of the nucleus through a tear in the outer annular ligaments. When a small isolated tear occurs, the nucleus stays in place except for mild bulging. This annular tear will appear as an intense white line on some magnetic resonance imaging (MRI) scans. This is called a high-intensity zone (HIZ) and has been correlated with pain.

When the annular tear is more complete, a herniated disk will occur with expression of the nucleus material through the tear in the annulus. The slipped disk may be subdivided into a protrusion, an extrusion, and a sequestration. A protrusion occurs with a partial focal tear of the ligaments, and there is a broad-based disk protrusion of the nuclear gel. An extrusion represents a complete focal annular ligament tear with a more narrow-based gel extrusion, but it remains in contact with the central gel (Figure 3). A sequestration occurs when this extrusion separates from the disk.

Risk Factors

Risk factors include smoking, obesity, genetic factors, lack of core conditioning, hard labor, and sedentary lifestyles. A genetic component is felt to be one of the most important considerations. Certain motions in sports are highly associated with disk involvement due to the biomechanics of the sport. When the spine is loaded in flexion, the disk on the front of the lumbar spine is placed under the greatest pressure. Examples of this loaded flexion include wrestling, power lifting, and crew (catch phase). Cycling can also load the spine in flexion when the fatigued cyclist loses the normal lordosis or sways back and slumps forward.

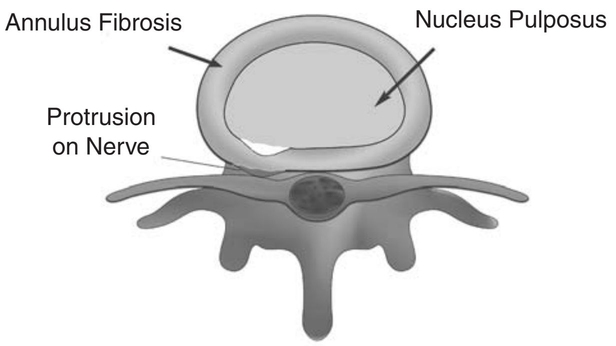

Figure 3 Herniated Disk, Showing Extruded Part of the Nucleus Pulposus Impinging on the Pathway of the Nerve Root

Source: Illustration by Michael d'Hemecourt.

The cervical disk may rupture in the wrestling take-down position. Collision sports such as American football and rugby also have some association to disk rupture due to direct impact and torsional loads. Long-distance cyclists place the spine in extension with a strong shear force, which can also cause disk rupture. Up to 40% of cyclists will complain of neck pain after a week of riding.

Clinical Presentation and Evaluation

The athlete with the disk herniation will present with pain either centrally or peripherally into the extremities. A herniated disk may occur next to the nerve roots. When it affects the nerve roots, pain and weakness of muscle groups in the distribution of the nerve supply may occur. In the neck, this will often produce symptoms along the shoulder, scapular, arms, or hand. In thoracic disk herniation, the symptoms will often distribute to the anterior chest or abdomen. In the lumbar spine, the distribution involves the buttocks, thighs, lower leg, and/or feet. These radiating symptoms are called *radicular symptoms*. They may be secondary to nerve compression from the mechanical bulk of the herniation or simply nerve irritation from leakage of inflammatory enzymes from inside the disk. Conversely, when the disk does not affect the nerve roots, there will be central pain in the neck, upper back, or lower back, depending on the level involved. This is called *axial pain syndrome*.

Disk herniations in the cervical spine mostly occur at the lowest cervical levels: C5-C6 and C6-C7. These levels produce symptoms into the arms and hands. Similarly, the lower lumbar spine is also affected, L5-S1 and L4-L5, which can affect the lower legs and feet. Thoracic disks are very uncommon but usually occur in the lower thoracic spine.

The peripheral pain often far exceeds the central neck or back pain. Certain motions are often provocative of the symptoms, while other motions will relieve the symptoms. Neck pain is often aggravated by activities that place the neck in hyperflexion or hyperextension. Classically, the cyclist or computer worker with the neck extended and chin forward will suffer aggravation of symptoms. Chin retraction may alleviate the symptoms. Lumbar or thoracic pain is often aggravated in the sitting or bending forward posture. In some cases, lumbar extension will relieve the pain.

It is essential to inquire about any worrisome red flags in the athlete that may prompt an immediate imaging evaluation. These would include loss of ability to hold the urine or stool, fever, chills, weight loss, weakness of an extremity, or constant night pain. In the absence of these, full imaging would be warranted if the symptoms last for longer than 6 weeks in the adult or 3 weeks in the young athlete. An MRI scan is usually the most appropriate imaging method to detect disk disease, but a CT scan is useful if the MRI scan is not possible.

Treatment

Treatment is based on the acuity of onset and the level of neurologic involvement. If there are signs of nerve root involvement, the progression is slower but usually follows a specific sequence. During the first few days, there is relative rest with utilization of analgesics. Rest should not exceed more than a few days. As the initial inflammation quiets, the subacute phase of isometric strength is used, where the core muscles or upper trunk muscles, if the neck is involved, are activated without motion. This often involves the use of calisthenic exercises, such as bridges for the lower back. Gradually, more dynamic low-resistance exercises are used, with progression of resistance as tolerated. Finally, as the athlete regains full strength, the sport-specific phase is started, with conditioning aimed at simulating sport-specific motions with attention to proper form. It is important to realize that cervical spine disk involvement typically requires more gradual progression initially as motion is poorly tolerated.

Because the herniated nucleus of the disk includes inflammatory components, an anti-inflammatory medication is very useful along with analgesics. In refractory cases, epidural injections of corticosteroids are very useful in accelerating the recovery phase. The adolescent athlete will often benefit from bracing to allow better rehabilitation.

Finally, surgery may be considered in three situations: (1) progressive muscle weakness, (2) loss of bowel or bladder control (emergent), and (3) refractory symptoms. The latter situation is somewhat subjective. In cases of severe pain, this may be as early as 6 to 8 weeks. In moderate cases, it may be months before surgery is considered. If surgery is needed, the athlete with a simple disk excision may possibly be ready for sports participation in 6 to 8 weeks.

Snapping Hip Syndrome

Coxa saltans, or *snapping hip,* is a condition in which one feels a snapping sensation with movement of the hip. This may be accompanied by an audible pop and sometimes pain. There are three types of coxa saltans: external, internal, and intraarticular. Coxa saltans is common between the ages of 15 and 40 and is more often found in women. It is particularly common in athletes and dancers who undergo repetitive twisting motions about the hip.

Anatomy

The hip joint is the junction between the pelvis and the thighbone. The bony anatomy involves a ball-and-socket joint, with the head of the femur (thighbone) comprising the ball and the socket being formed by a groove in the pelvis called the acetabulum. This groove is deepened by a rubbery structure around the rim, called the *labrum*. The cartilage between these two surfaces serves as a cushion to absorb the stress transmitted between the surfaces.

There are many muscles around the hip that attach on the femur and pelvis. The muscles attach to the bones via ropelike fibrous tissue called *tendons*. Some of these tendons cross over bony prominences, which are normal protrusions in the bone. The natural consistency of healthy tendon fibers allows them to glide over these prominences with joint movement. Between the tendons and the bony prominences, there are sacs of fluid, called *bursae*, which minimize the friction between the bones and the tendons that pass over them.

The *iliotibial* (*IT*) *band* is a fibrous structure that extends from the pelvis to the knee. It functions to flex and rotate the thigh. The *gluteus maximus* is a large muscle that extends across the buttock and rotates the hip. Both the IT band and the gluteus maximus muscle cross over a bony prominence on the femur called the *greater trochanter*. This bony prominence can be easily felt in most people by pushing on the bone over the outer aspect of the thigh. With normal walking motions about the hip, the muscles and tendons glide over the greater trochanter without difficulty.

The hip flexor complex is a set of muscles formed by the iliacus and psoas muscles, which fuse to form the iliopsoas tendon. This connects the spine with the femur and functions to flex the hip. The iliopsoas tendon crosses over the hip joint, near the groin. In doing so, it passes in a groove next to the femoral head (the ball of the hip joint) and over the pelvis at a point called the *iliopectineal eminence*. With hip movement, the tendon slides from one side of the femoral head to the other (see Figure 1).

Causes

Coxa saltans can be divided into three different types. The external and internal types are generally caused by overuse and irritation of the muscle groups, which can lead to snapping of the tendons over the bony prominences. The two types are distinguished by their locations and the groups of muscles and tendons involved. The third type is intraarticular, in which the snapping can originate from within the hip joint itself. This is much less common but tends to be a more serious problem.

The external snapping hip is the most common type. Here, the IT band or the muscle of the gluteus maximus can catch and cause a snapping sound while crossing over the greater trochanter during normal motions of the hip. This may be due to tightening of these structures, caused by lack of flexibility. This can also happen if the greater trochanter protrudes more than normal. If the underlying bursa becomes irritated, one may have pain associated with the snapping as well.

In the internal snapping hip, the snapping occurs in the groin. The iliopsoas tendon becomes irritated due to overuse and can catch or snap while moving over the iliopectineal eminence or the femoral head. Inflammation from overuse of the iliopsoas tendon, called tendinitis, is often found in athletes or dancers who repetitively flex and externally rotate the thigh.

The intraarticular type of snapping hip stems from problems within the hip joint itself. This type is more commonly related to an injury rather than to chronic overuse. One of the more common injuries in this category includes labral tears, which are injuries to the cartilage rim around the joint. Other injuries may cause pieces of the cartilage, termed *loose bodies,* to be entrapped within the hip, causing a clicking noise with movement.

Symptoms

Typically, snapping hip develops over the course of months or years. Patients will describe an audible snap that is often reproducible at the time of the exam. An associated bursitis may cause tenderness or pain accompanying the snapping sensation.

In contrast, patients with intraarticular snapping may note a sudden onset of symptoms, usually

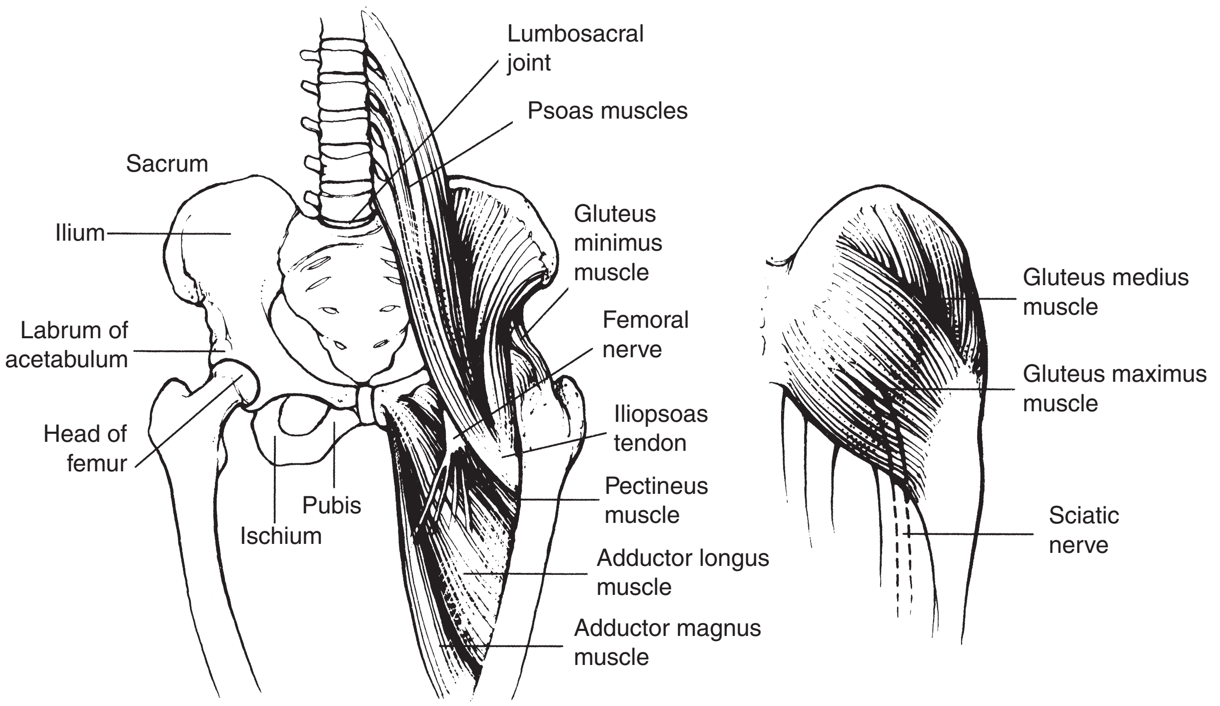

Figure 1 Anatomy of the Hip, Pelvis, and Groin

related to a specific injury. Patients may describe their symptoms as a clicking rather than an audible snapping sound. This type is more likely to be associated with pain and may also include locking or catching sensations while moving the hip.

Diagnosis

The diagnosis of internal and external coxa saltans is typically made by observing the snapping and identifying the area involved. The external type can be diagnosed by feeling the snapping of the IT band over the greater trochanter as the patient flexes and extends the hip. Tightness of the IT band on examination may also point to this diagnosis. Those with internal snapping hip will have similar symptoms near the iliopsoas tendon in the groin.

X-rays are generally not helpful in the diagnosis of snapping hip, as the soft tissues involved cannot be assessed on radiographs. Magnetic resonance imaging (MRI) may be used to rule out injuries to the intraarticular cartilage but are not routinely obtained.

Rarely, internal and external coxa saltans may require diagnostic procedures. An ultrasound test is a noninvasive method of using sound waves to image the hip. Iliopsoas bursography (injecting dye into the bursa) can also be used to diagnose internal coxa saltans. Both techniques can detect abnormal motion of the tendon over the bony prominences, as well as identify any inflamed bursal tissue or tendons.

Treatment

Nonsurgical Treatment

The typical treatment for most cases of internal and external snapping hip is nonoperative, as the snapping motion of the hip is considered normal. If symptoms persist and become painful, then the physician may give a cortisone injection directly into the area that is inflamed. Rest, anti-inflammatory medications, and physical therapy will also help stretch and heal the muscles and tendons that are irritated. Most patients respond well to conservative therapy and are able to resume normal activities within 6 to 12 weeks.

Surgery

Surgical treatment of the internal and external types of snapping hip is rarely indicated, but it may be performed in cases of severe and persistent symptoms. Surgical treatment of external coxa saltans involves removal of the inflamed bursa and lengthening of the IT band. This removes tension from the tendon and allows it to glide over the bony prominences without snapping.

For the internal type, a similar procedure involving lengthening of the iliopsoas tendon is available. This can be done through a small incision in the groin or through a procedure called arthroscopy, which is a minimally invasive method using small incisions and a camera. Both procedures are typically done as outpatient surgeries.

Unlike the internal and external types, intraarticular causes of snapping hip generally require surgery. Many types of disorders contribute to intraarticular snapping, and these require therapies that are specific to the disorder. In cases of injury to the cartilage, surgery may be indicated to either remove or repair the problem. Most procedures of the hip are done with a standard open surgery. However, the advent of arthroscopic surgery has provided a minimally invasive way to address many of these problems.

After Surgery

Physical therapy after surgery depends on the type of surgery that is performed. Tendon-lengthening procedures will cause some hip weakness for several weeks until the muscle begins to heal. The first few weeks of physical therapy should focus on protecting the hip and reducing pain with range-of-motion exercises, as well as exercises to increase control of the leg. At the rate determined by the physician, therapy should later progress to strengthening and gait training, with eventual return to normal activities.

Snowboarding, Injuries in

The origin of snowboarding is somewhat debatable, yet most historians of the sport agree that the first snowboard was made out of a plywood plank in 1929 by M. J. "Jack" Burchett, who strapped the wood to his feet using a clothesline and horse reins. Some historians attribute snowboarding's origins to Sherman Poppen back in 1965, when he tinkered with the invention of a toy called a "snurfer" for his daughter, which consisted of two skis bound together and then tied a rope to the front for steering downhill to mimic the combined components of surf and snow. The early entrepreneurs Jake Burton Carpenter and Demetrije Milovich designed and produced the modern-day version of snowboards. The sport's modest beginning can be traced back to the production of snowboards and bindings back in 1977, although the sport did not really flourish until the 1990s. It made its Winter Olympic Games debut in 1998 in Nagano, Japan, and is today the fastest-growing winter sport with more than 3.4 million participants. There is some speculation that snowboard will take over skiing in popularity by as early as 2015.

The Sport and Its Equipment

The appearance of the snowboard on the scene was initially met with much resistance, for its enthusiasts were characterized as rebellious teenagers in baggy clothing, looking for an outlet that was devoid of respect and etiquette and disrupted the natural flow of skiing. Snowboarding in its infancy appealed to surfers, skateboarders,

Snowboarding is the fastest-growing winter sport, with more than 3.4 million participants.

and backcountry idealists, who were often characterized as overly aggressive youths with a foolhardy attitude that negatively affected safety, although such characterizations might be attributed to age bias.

Snowboarding is typically identified in three major categories according to the particular style of riding or the type of board: (1) freestyle board, (2) freeride (all-mountain) board, and (3) Alpine (carving) board. Each board is uniquely characterized by the specific construction technique, the material of the board, and the unique shape, pattern, and flex for each specialty.

A freestyle snowboard is typically the one a beginner uses because it is more stable, wider, and more forgiving and thus easier to ride. Due to the softer flex and the shape, as well as the uniform symmetry, forward motion can occur in both directions, as is typically seen in the twin tip boards. These boards are meant for performing tricks such as airs, spins, grabs, and fakies (motion in a reverse direction) in terrain parks and half pipes. The contrasting directional freestyle snowboard has a stiffer tail than the nose of the board and is more beneficial when primarily going in one direction with a particular footed dominance.

Freeride (all-mountain) snowboards are typically the most popular type of snowboard, as illustrated by the sheer number of sales of these types of boards. These specialty boards are designed to be used for powder snow conditions and are identified as all-terrain mountain boards because they can be used not only on the hill but also in a terrain park and in a half-pipe. Freeride snowboards have a more directional shape, with a tail that is narrower, shorter, and flatter than the tip of the board. The stance position of these boards also differs in that they are typically offset toward the tail of the board. These boards are soft enough for beginners to maneuver in the snow and stiff enough to carve some turns.

Alpine (carving) snowboards, in contrast, look like larger versions of skis with a shoveled front tip and asymmetric appearance. They are characterized as carving snowboards because of their ability to make sharp, clean turns and their great edging abilities on hard snow for stability and speed. Alpine snowboards are designed for high-speed performance, such as in racing, and for moving in a more uniform direction; therefore, they are much more difficult for beginners to manage and learn due to the advanced body mechanics required to maneuver on harder snow surfaces.

Competition snowboarding includes numerous sporting events that are sanctioned by the International Ski Federation, abbreviated in all languages as FIS. FIS was founded on the eve of the first Olympic Games in 1924 in France with 14 member nations. Today, 107 National Ski Associations constitute the membership of FIS, which oversees the World Cup competitions and the World Championships. The federation organizes a number of disciplines in alpine, parallel giant slalom (PGS), and freestyle, which include subcategories such as half-pipe, snowboard cross, big air, and, more recently, slope style.

Following the collapse of the National Association of Professional Snowboarders in 1990, five nations and 120 athletes established the International Snowboarding Federation (ISF) with the goal of keeping the officiating by riders and for riders. The ISF set the standard for snowboarding competition, which contributed to snowboarding becoming an Olympic sport in 1998. Controversially, the International Olympic Committee did not recognize the ISF as the governing body for snowboarding but recognized FIS as the sport's official governing body. Many snowboarders boycotted the Olympics as a result, concluding that the FIS rules were inappropriate for snowboarding. The FIS has maintained its control over the Olympics, giving credence to the position that snowboarding is a discipline of skiing and not its own, individual sport.

Injuries in Snowboarding

The pattern of injuries in snowboarding differs from that in skiing primarily because of significant differences in sport mechanics. Skiing typically demonstrates a significant number of injuries, from torque-type injuries such as tears of the anterior cruciate ligament (ACL) of the knee to other lower extremity pathologies induced by the free rotation and often uncontrollable trauma of the lower extremities during falls. Snowboarding, in which two feet are planted firmly on the same board, does not demonstrate the same frequency of rotational torque-type injuries. Instead, falls on an outstretched arm typically lead to more injuries of the upper extremity. The wrist is the most commonly injured body part, with wrist fractures accounting for almost half of upper extremity injuries. Wrist sprains and elbow fractures, along with clavicle fractures and shoulder dislocation, contribute to the upper extremity percentages being predictably higher for snowboarders than for skiers.

The use of helmets has reduced the frequency of head injuries to between 30% and 50%. Injuries to the head typically occur as a result of a direct blow to the head when making contact with the hard-packed snow surface. As a result, the injuries that occur are less serious in nature and are limited to head lacerations, contusions to the head, and milder versions of concussions. There continues to be a reduction in the number of fatalities due to increased helmet use, which has been shown to drastically reduce the severity of concussions and minimize the number of skull fractures as well as lessen the likelihood of severe closed-head injuries. The overall rate of injury has increased for snowboarding more recently due to the greater number of beginners who have taken up the sport. The research literature has clearly demonstrated that the highest frequency of injury is typically found in young novice snowboarders. More than 50% of novice skiers have the greatest likelihood of being injured in their first season of snowboarding. Additional contributing factors include failure to wear appropriate protective gear or receive appropriate instruction. Injury prevention is of extreme importance in snowboarding and entails the selection of specific gears such as wrist guards, elbow guards, back protectors, and tailbone butt protection along with helmets and proper boot fitting and equipment maintenance.

Boots and bindings are also of particular interest in snowboarding due to the different types of styles. There are three styles of boots: (1) soft, (2) hard, and (3) hybrid. Most of the boots today are softer in form and function, making it easier to maneuver specific snowboard moves due to the increased flexibility of the boot material. Hard boots are typically used only for racing and are the most common cause of boot type injuries and fractures. Most bindings on snowboards are nonreleasable and are made of plastic molding, with buckles to strap the boots onto the boards. The number of ankle injuries has been reduced due to the advanced technology of boots and bindings, but fractures remain the predominant ankle injury. The most common fracture is the so-called snowboarders' ankle, which is a fracture of the lateral process of the talus and is often undiagnosed on a typical X-ray. Treatment of a nondisplaced fracture typically consists of casting for 6 to 8 weeks. Displaced fractures are usually characterized by a displacement of 2 millimeters and are typically treated by open reduction internal fixation repair of the bone tissue.

Other common injuries in skiing that are less serious but still debilitating include frostbite, dehydration, and sunburn. Sunburn results from ultraviolet radiation and not from heat. Sun exposure on cold snowy days without any protection often results in sunburn, particularly in young children. Sunburn prevention should be practiced when skiing at any time. Hypothermia results when the core body temperature drops below 95 °F. Exposure to cold environments, particularly wet, windy conditions, can lead to rapid loss of body heat. Recognizing the signs and symptoms of hypothermia, such as confusion, slurred speech, fatigue, exhaustion, shivering, and loss of motor control, necessitates immediate action. The key is to eliminate the exposure and warm the individual. Hypothermia can often lead to cardiac arrest, so observation is also of great importance. Frostbite is literally frozen body tissue. Children are at a much greater risk than adults because they lose heat more rapidly and are often reluctant to protect against exposure. Treatment typically includes removing wet clothing, warming the exposed body parts in warm water, and preventing additional exposure. Following an appropriate treatment strategy and medical care are advised.

Soccer, Injuries in

The physical demands of soccer can result in a wide variety of injuries to athletes. Youth and adult soccer players of all skill levels are at risk for both traumatic and overuse injuries. The types of injuries that may occur during soccer participation include sprains, strains, contusions, abrasions, fractures, and head injuries.

Mechanisms of Injury

Both contact and noncontact injuries occur during soccer participation. Contact injuries may result from contact with another player or equipment (i.e., ball, goal post). Noncontact injuries occur due to the high frequency of pivoting, running, and jumping activities performed by soccer players. Contact injuries more commonly occur during games, whereas noncontact injuries are more common during practice. For injuries that result in missed playing time, injury rates for both men and women are higher during games than during practice.

Acute Lower Extremity Injuries

The majority of soccer injuries occur in the lower extremities, with ankle sprains and knee ligament injuries occurring most frequently. Muscle strains of the hip adductors, hamstrings, and quadriceps are also very common. The contact nature of the sport also increases the frequency of contusions and abrasions to the lower extremities.

Ankle

A common ankle injury in soccer is a lateral ankle sprain. The ligament most commonly injured in an ankle sprain is the anterior talofibular ligament; this is caused by forced ankle plantarflexion and inversion. The calcaneofibular ligament is the second most commonly injured ligament in a lateral ankle sprain, followed by the posterotalofibular ligament. When the foot is forced into dorsiflexion and eversion, the deltoid ligament on the medial aspect of the ankle can be injured.

A high ankle sprain is a more severe type of ankle sprain. In this injury, the ligaments above the ankle (the syndesmosis) are torn. A high ankle sprain includes injury to the anterior inferior tibiofibular ligament, posterior talofibular ligament, and interosseous ligament. Pain at the ankle with compression of the tibia and fibula above the ankle (squeeze test) or a Maisonneuve fracture (proximal fibula) are positive findings of a high ankle sprain. High ankle sprains that are determined to be unstable are treated with stabilization of the fibula to the tibia with one or two screws while the injury heals.

When evaluating an athlete with an ankle sprain, the possibility of a Jones fracture (at the base of the fifth metatarsal) must also be considered.

Knee

Knee ligament and meniscal injuries result from pivoting, rapid direction changes, rapid deceleration motions, or contact with another player. Knee ligament injuries can occur with or without meniscal damage. Soccer players, especially women, are at a high risk for noncontact anterior cruciate ligament (ACL) injuries. The ACL is injured when the lower extremity is in a position of femoral internal rotation, genu valgum, and tibial external rotation. A valgus stress to the knee will injure the medial collateral ligament (MCL). Less commonly injured is the lateral collateral ligament (LCL). LCL injuries result from a varus stress to the knee. Multiple ligament knee injuries can occur with higher forces (see Figure 1).

Chronic Lower Extremity Injuries

Excessive amount of running during soccer can lead to chronic, overuse injuries. Achilles and patellar

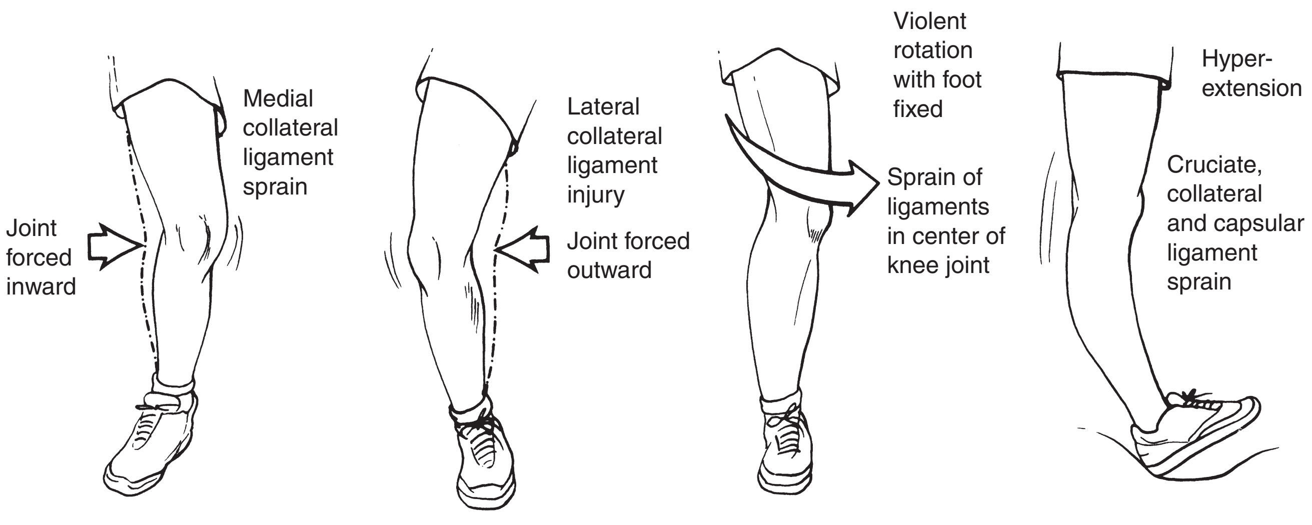

Figure 1 Knee Ligament Injuries

Notes: Which of the knee ligaments are injured depends on how the injury occurs. The most common mechanisms of knee injuries and the specific ligaments that most often get damaged are shown in the figure in each case.

tendinitis are common in adult soccer players. Although rare, stress fractures can develop from factors such as a hard playing surface, poor shoe wear, improper mechanics, and training errors.

Upper Extremity Injuries

Although not as common as lower extremity injuries, upper extremity injuries do occur during soccer. Direct contact with another player or a fall on an outstretched hand can result in upper extremity injuries, including acromioclavicular joint sprains, clavicle fractures, glenohumeral joint dislocations, elbow sprains and dislocations, and wrist sprains.

Injuries to Skeletally Immature Athletes

Year-round training combined with a high number of training hours increase the risk for injury in any sport. In a skeletally immature athlete, the apophysis, an ossification center where a tendon attaches to the bone, can be injured by traction forces or from a sudden muscular contraction. The forceful running and kicking motions during soccer play can cause avulsion fractures of the pelvic apophyses, including the anterior superior iliac spine (ASIS), the anterior inferior iliac spine (AIIS), the ischial tuberosity, and, less commonly, the pubic symphysis and the iliac crest. An avulsion of the ASIS is due to a forceful stretch or contraction of the sartorius muscle, whereas an avulsion of the AIIS is related to the rectus femoris muscle.

In addition to an acute avulsion fracture, overuse-type injuries to the apophysis can also occur from excessive running and jumping in young soccer players. Repetitive traction forces cause inflammation at the apophysis, known as *apophysitis*. Common sites of apophysitis in soccer players include the tibial tuberosity (Osgood-Schlatter disease), calcaneus (Sever disease), inferior pole of the patella (Sinding-Larsen-Johannson), and iliac crest.

Head Injuries

Concussions during soccer play most often result from player-to-player contact but may also occur from contact with the playing surface or goal post. Although there has been some concern that the repetitive low-impact stress of heading the ball may possibly have injurious effects to the brain, there is no conclusive evidence for this. Heading the ball is considered a safe skill when done properly.

Return to Sports After an Injury

Once an athlete has sustained an injury, a qualified health care professional should assess the athlete to determine if he or she is ready to return to play. The athlete should be painfree, have no swelling, have full range of motion, and have normal strength testing done before considering return to sports. Isokinetic strength testing can be used to objectively identify and evaluate smaller strength deficits that are not detectable by manual muscle testing. Sport-specific functional testing also needs to be performed to determine if the athlete is ready to return to sports. Lower extremity functional testing should progress from bilateral to unilateral and from straight-plane activities to multiplanar activities. Examples of functional tests include balance/proprioceptive tests, broad jump, unilateral hop test, triple hop test, crossover hop test, and sport-specific drills (running, lateral movements, pivoting, and cutting maneuvers).

Injury Prevention

Although the risk of contact and noncontact injuries with soccer participation cannot be eliminated, it is possible to decrease the risk of injury. General guidelines to minimize the risk of injury during soccer participation include the following:

- Always perform a proper warm-up (general cardiovascular warm-up, dynamic stretches, sport-specific drills).
- Perform lower extremity stretches to improve muscle flexibility.
- Wear proper shoes.
- Use protective equipment.
- Maintain good field conditions.
- Maintain an adequate fitness level (muscle strength and cardiovascular endurance).
- Have proper hydration and nutrition.
- Enforce game rules.
- Properly supervise young athletes.

Since most soccer injuries occur to the lower extremities, training programs specifically for minimizing the risk of ankle and knee injuries can be beneficial. Training programs may include all or any combination of the following components: warm-up, lower extremity stretching, lower extremity and core strengthening, proprioceptive and neuromuscular training, plyometrics, and sport-specific agility drills.

Speed, Agility, and Speed Endurance Development

The goal of all team and individual sports athletes is to have great speed, agility, and speed endurance to outperform their opponents. To develop these conditioning adaptations to their full potential, the athletes have to be ready for rigorous training and must be disciplined when not training to allow the body to recover properly; otherwise the risk of injury from overtraining is imminent. This entry will provide insight on the necessary training variables to become not only faster but also faster for longer periods and more agile on the court, field, or floor.

Defining Speed, Agility, and Speed Endurance

To develop speed, agility, and speed endurance, it is necessary to assess the needs of the athlete in the sport or position that he or she plays. First, it is important to fully understand each of these terms.

Speed

Speed is the ability of an athlete to create a lot of velocity through recruiting muscles rapidly. Speed must come from all joints and segments of the body working sequentially (see the entry Resistance Training). Pure speed is often seen in sports as straight-line speed, such as the 100-meter (m) sprints or a fastball in baseball. Just as important for the ability to develop speed through the segments of the body is developing the muscles, joints, tendons, and ligaments for the rapid deceleration of the joints once the speed-producing movement is complete. If the body is not able to decelerate itself, then serious injury will occur. For example, if the muscles did not decelerate when throwing a fastball, then the arm would likely dislocate.

Agility

Agility, also known as sports speed, is an athlete's ability to rapidly accelerate, stop, and change directions and accelerate again. Agility training is a priority for sports played on a field in team settings such as soccer, rugby, and American football. The focus of agility training should be on the ability to slow down the body rapidly and accelerate the body as fast as possible in as little time possible. Developing speed for sports requires an immense amount of power coupled with eccentric and concentric strength of the antagonist and agonist musculature.

Speed Endurance

Speed endurance means that the athlete is able to sustain high velocity and able to reproduce the acceleration and deceleration multiple times without a significant drop-off in power output multiple times for more than 6 to 7 seconds. This would mean that the athlete has a high threshold for pyruvate-lactate accumulation. The dominating energy system supporting high-intensity work for durations greater than 10 seconds is the anaerobic glycolysis system.

The rate of force development (RFD) implies how quickly a movement can be produced. This is the measure that will indicate how successful off-season conditioning is for the athletes on the field. To increase the RFD in a movement pattern that ultimately increases speed, agility, and speed endurance, the ratio of fast-twitch glycolytic (Type IIa) muscle fibers and fast-twitch oxidative (Type IIab) muscle fibers to slow-twitch oxidative (Type I) muscle fibers need to increase more on the side of Type IIa.

This will result in an increase in the impulse production, according to Steven Plisk (in *Essentials of Strength Training and Conditioning,* 2000), by generating a greater force in a given time or by improving the RFD.

Speed Technique Development

For an athlete to reach his or her true potential in top-end speed, form, or technique must be developed along with the athlete's muscular strength and power. A needs analysis for the athlete's power profile is necessary before prescribing the correct ratio of volume to intensity of conditioning for the athlete's respective sport or position. The ratio of pure speed drills to strength-speed drills for an offensive lineman in football would be drastically different from that of a wide receiver. Coaches must conduct video analysis of the amount, if any, of contact the athlete has with opposition, how many quick changes in direction the athlete executes in competition, how long it takes for the athlete to decelerate, and the number of times that an athlete performs sprints at maximal effort. To develop the optimal speed endurance program, the strength coaches need to know what the work-to-rest ratio throughout the sporting event typically is. Once the aforementioned data have been collected, the team strength coach and team head coach are able to combine the information on movement and performance with the information on skill of the athlete(s). Having this information all together allows the coaches to develop the best sequence of movement, performance, and skill drills and the best work-to-rest ratio between these types of drill before, during, and after a given competitive season to optimize on-field performance and to decrease the risk of injury.

Sprinting technique drills will teach the athlete the correct form to use when accelerating away from an opponent or when trying to catch or pass an opponent. If the athlete's form is impaired, more energy than is necessary is being expended to produce a movement, ultimately causing fatigue. In the case of sprinting, two variables dictate the forward projection of the athlete's body: stride length and stride frequency. Stride length is the distance between the feet each time a foot makes contact with the ground. If the athlete's stride length is too long or too short, it will take more effort than is necessary. The length of the stride will vary depending on the athlete's height and limb length. Stride frequency is the number of times that the legs can turn over in a maximal sprint. Steven Plisk points out that both stride frequency and length are equally important when an athlete is accelerating; however, the stride rate has the most influence at maximal speed. When the athlete's speed picks up, impulse production becomes more dependent on the ability to create force rapidly.

There are a multitude of techniques that coaches use to develop straight-line speed. Form drills such as "high-knee drills" and "butt-kickers" train the hips and knees in the rapid turnover. Different styles of skipping and bounding help with stride length frequency development. Hill training is another very useful training modality. When athletes run up gradual hills, their leg drive technique is developed; focusing on high knee strikes will develop impulse. Running down gradual hills will assist the athlete in increasing stride frequency and stride rate. It is important to note that the incline/decline of a hill should not be too steep so that the athlete's form is not compromised.

Agility Technique Training

Having great straight-line speed does not necessarily translate into great sports speed. The most important components in developing sports speed are acceleration and deceleration development. Stability and efficiency are essential when training the right body mechanics so that the transitions between stopping, quick change of direction, and acceleration are more balanced. Agility training can be taught through form drills, using set parameters such as cones, lines, or poles. Agility training can also be taught openly through reaction drills such as mirror drills, tag, or reacting to cues from the coaches, such as a whistle or signal indicating a change of direction. Agility must be trained in all plains of motion—sagittal, frontal, and transverse—to provide the athlete with the necessary conditioning for movements that may occur during competition.

Speed and Agility Training Methods

There are several ways to develop an athlete's speed and agility. Hill training is one example. Others include the following:

- Footwork and form drills
- Assisted and resisted sprinting drills
- Resistance training
- Flexibility training

Footwork and Form Drills

Footwork drills and form drills are necessary to conduct at the beginning of training sessions. Examples are ladder drills, crossovers, turns, and cuts using traffic cones. The body is sensitive to neuromuscular feedback and is able to adapt to the detailed drills so that the body keeps the correct form even when it is fatigued.

Assisted and Resisted Sprinting Drills

Hill training is a form of assisted running because the athlete is running with the downward pull of gravity. Another way to train an athlete to run faster is to use stretched rubber tubing with a harness around the athlete's waist or torso to pull him or her forward. Rubber tubing may also be used for resisted running. When the tubing stretches, it creates greater resistance. Parachutes, running uphill, and weighted sleds that are pushed or pulled by the athlete are other tools to provide resistance while running forward, backward, and laterally.

Resistance Training

General total body strength and power training must complement the aforementioned drills. Resistance training must be used to maintain overall kinetic chain symmetry and to prevent overtraining injuries that may occur. (For more information on the proper methods of training and sequencing, see the entries Periodization and Resistance Training.)

Flexibility Training

Strength and conditioning coaches must know the work-to-rest ratio in the sport of the athletes they are training to optimize the adaptations of speed endurance. Sports such as rugby and soccer have different work-to-rest ratios in comparison with American football or ice hockey. Rugby and soccer athletes do not have as much opportunity to rest between high-intensity plays unless play has been stopped due to penalty, injury, or halftime. It is important to note that the energy system that must be trained, and is affected the most by speed-endurance training, is the anaerobic glycolysis system. When repetitive bouts of high-intensity sprints or tackling occur in rapid succession, lactate-pyruvate concentrations increase in the body's cells because the mitochondria (the organelle responsible for cellular respiration) are unable to clear out the by-products produced. Implementing the aforementioned speed and agility drills with little or no rest at submaximal (80–90% of maximal intensity) efforts when the athletes are slightly fatigued will produce a positive adaptation for speed endurance. Having the athletes perform obstacle courses that integrate footwork drills with sprints and low-intensity jogging are popular ways to train athletes for improved speed endurance. (For more information on speed-endurance training, refer to the entry Interval Training/Fartlek.)

Speed Skating, Injuries in

Speed skating is a sport that held its first competition over 300 years ago in the Netherlands. There are two disciplines in speed skating—long track and short track. Short-track skaters race in a pack around a smaller oval, while long-track skaters race in their own lane. All speed skating athletes are at risk of sustaining injuries during training and competition, although the short-track skaters are at higher risk.

History

Ice skating originated thousands of years ago, when Scandinavian men attached animal bones to their footwear to help glide across frozen waterways. The metal blade was invented in the late 1500s. That helped spur the popularity of speed skating. The first world championship was held in the Netherlands, with four events: 500, 1,500, 5,000, and 10,000 meters (m). Short-track speed skating began in the early 1900s.

Olympic long-track speed skating debuted in 1924, at the first Winter Games in Chamonix, France. Short-track speed skating was introduced at the 1988 Winter Games in Calgary, Canada. Both disciplines are governed by the International Skating Union.

Long-Track Speed Skating

Equipment

The body of the ice skate is called the boot. Many elite athletes have custom boots created using the molds of their feet. The boot is constructed with leather and carbon graphite. A long-track boot is cut lower on the ankle than a short-track boot.

The blades are made from carbon steel. They are very flat and thin, allowing long-track skaters to glide in long, straight lines. Most elite skaters use a clap skate. This blade detaches at the heel and has a spring-loaded hinge at the ball of the foot. As the skater lifts his or her foot, the hinged blade remains on the ice longer. This improves speed and traction.

Most skaters wear eye protection to prevent tearing and drying secondary to wind. Many also wear skin-tight clothing with hoods designed to make them more aerodynamic. Long-track speed skaters do not wear helmets.

Events

Long-track speed skaters race counterclockwise on a two-lane, 400-m oval. The winner is the person with the fastest time. The athletes will cross over, or change lanes, every lap on the back stretch. Thus, long-track skaters do not race in the same lane.

The traditional events are the 500, 1,000, 1,500, 3,000, 5,000, and 10,000 m. A 100-m sprint event has been recently added. Team pursuit is also a newer event. In team pursuit, each team begins at opposite points on the track. A team of three or four skaters race in a single-file line, allowing the skater in the back to conserve energy by not having to break the wind. They rotate positions in the single-file line to try to get the fastest time for six to eight laps.

Short-Track Speed Skating

Equipment

The short-track boot rises higher on the ankle than a long-track boot to give more stability with turning.

The blades are made from carbon steel. They are shorter and thicker than long-track skates to withstand the stress of turning. The blades are offset and bent to allow skaters to lean into turns without allowing the boot to contact the ice.

All skaters must wear protective gear. This includes a helmet, a neck protector, cut-resistant gloves, knee pads, and shin guards. Most skaters wear protective eyewear, which also helps prevent tearing. The skaters wear tight-fitting skin suits like the long-track skaters. However, many short-track suits are made of Kevlar, making them cut resistant and safer.

Events

There are normally four to six skaters racing counterclockwise around a 111-m oval. The outcome of the race is not based on time, but the first person to cross the finish line is the winner. The racers all share the same space, so there is great potential for contact between skaters, falls, and subsequent collision into the wall of the rink.

The main events are the 500-, 1,000-, 1,500-, 3,000-, and 5,000-m relay. In relay events, there are usually four teams of four skaters. The skaters must take at least one lap on the track, but there is no set number of laps that each racer must complete.

Injuries

Very few data are available on injury rates in speed skaters. While injuries can occur during training and competition, it is thought that short-track skaters are at higher risk of injury due to the higher risk of collision. There is a higher risk of asthma symptoms due to exposure to cold, dry air. As with all athletes who compete in international events, there is a risk for infectious disorders common to the region hosting the event, as well as common viral syndromes.

Skaters are at risk for overuse injuries, particularly of the lower extremities. This is secondary to the repetitive motions required for the sport. Back pain can be secondary to mechanical and muscular issues, as well as lumbar disk disease. Hip pain is commonly related to iliotibial band tendinopathy and groin strains. Knee pain is frequently secondary to patellofemoral pain syndrome and patellar tendinopathy.

Foot and ankle disorders frequently occur due to irritation from the skate boot. A tightly laced boot can apply pressure to the muscles around the ankle, causing Achilles tendinopathy, as well as "lace bite," which is a common name for tendinitis of the anterior tibialis and toe extensor muscles. Due to the amount of time spent in the skates, athletes may develop athlete's foot or tinea pedis. Interestingly, peroneal tendinopathy is seen much more frequently in short-track speed skaters due to the force required to complete sharp, high-speed crossover turns.

All speed skaters are at risk for arm and wrist injuries such as contusions, fractures, and sprains secondary to falls. Short-track skating carries a higher risk for upper extremity injuries due to the high-speed, pack-style skating format. This leads to a great deal of contact and can precipitate falls. Therefore, injuries such as shoulder dislocations, concussions, and lacerations (from contact with the skate blades) are seen much more frequently in short-track speed skaters.

Injuries can potentially be reduced by ensuring that athletes use proper equipment and maximize their off-ice conditioning. Athletes should also warm up well and remain warm throughout their practice and competition. It is important that they have well-maintained skates that fit properly. The blades should be sharpened frequently to improve traction. Of course, loose clothing that can get caught on the blades should not be worn.

Spinal Cord Injury

Spinal cord injury (SCI) is a rare but potentially devastating occurrence in sports. In the general population, motor vehicle crashes are the most common cause at around 40%. Sports and recreation injuries are responsible for about 12% of

SCI, diving accidents being the most common cause in this category. However, any sport involving speed, contact, or collision presents an environment where SCI can occur. This includes, but is not limited to, ice hockey, football, motor sports, and cycling.

Anatomy

The spinal cord extends from an opening in the base of the skull (the *foramen magnum*) to the second lumbar vertebra in the lower back. Beyond this level, it continues as a bundle of nerve roots called the *cauda equina,* or "horse's tail" because of its appearance. The spinal cord resides in a canal formed within the bony vertebral column of the back, which provides protection for the delicate tissue.

The spinal cord is divided into 31 segments or levels: 8 cervical (neck), 12 thoracic (upper and midback), 5 lumbar (lower back), 5 sacral, and 1 coccygeal. The latter two are so named because the nerve roots for these segments exit the spinal canal via the sacrum and coccyx, which are part of the pelvis. Viewed in cross section, each segment gives rise to motor nerve roots that exit the spinal cord from the front and sensory nerve roots that exit dorsally (from the back). The motor and sensory roots from each segment combine to form a spinal nerve corresponding to that segment, one to the left and one to the right. These spinal nerves carry motor and sensory information from the spinal cord to the periphery and back.

The spinal cord's job is to transmit information from the brain to the body (e.g., coordinating the motions of one's arm and hand to pick up a cup) as well as to transmit feedback from the body to the brain (once one's hand grasps the cup, this sensory information is sent to the brain to let it know that it can proceed with the instructions to lift it from the table).

Etiology

Most injuries to the spinal cord are traumatic in origin. Traumatic SCI frequently occurs in association with dislocation or fracture of the surrounding vertebrae in the neck or back. However, a special consideration in the pediatric population is SCI without radiographic abnormality (SCIWORA), where the increased flexibility of the developing spinal column allows for trauma to be inflicted on the spinal cord in extreme neck flexion or extension without any apparent fracture or dislocation occurring. In such an injury, the spinal cord is contused (bruised) by the impinging vertebrae. Depending on the severity of the impingement and the resulting inflammatory reaction, this injury can be temporary or permanent. The clinical exam will reveal diminished motor or sensory function consistent with the segmental level of injury. However, X-ray and computed tomography (CT) will reveal no bony or ligamentous injury. Magnetic resonance imaging (MRI) may show the cord contusion itself, but diagnosis and management are best guided by the clinical exam.

SCI may also be the result of compression of the cord, without actually cutting or bruising it. This is possible in the case of dislocation of vertebrae, progressive narrowing (stenosis) of the bony spinal canal, bulging of one or more intervertebral disks (the cushions between vertebrae), or several other, more progressive conditions. Spinal cord function is affected by the direct compression and/or by reduced blood flow and nourishment of the cells. Clinically, a patient will have reduced sensory and motor functions consistent with the level affected, which may be progressive over time, starting with an occasional "numbness and tingling" and progressing to complete loss of motor function.

Injury Patterns and Symptoms

SCI is a broad term referring to any injury that either temporarily or permanently prevents the spinal cord from performing its job of transmitting motor and sensory information between the brain and the rest of the body. More specific terms are generally defined by anatomic location of the injury (paraplegia vs. tetraplegia) and its severity (complete vs. incomplete). Paraplegia is an injury to the spinal cord in the thoracic, lumbar, or sacral segments. The most obvious deficit is loss of function of both lower limbs; however, sensation will be affected below the level of the injury (e.g., an injury at T2 would affect sensation from the chest all the way to the feet). Tetraplegia is an injury to the cord in the cervical region, which results in loss of function of all four extremities. In addition, an injury in the cervical region can have profound effects on one's ability to breathe, as motor control of the diaphragm originates from the C3-C5 segments. Both paraplegia and tetraplegia cause varying degrees of loss of bowel and bladder function.

Complete SCI is usually associated with a severe vertebral fracture and/or dislocation, with bony fragments transecting, or cutting, the spinal cord. While paraplegia and tetraplegia are considered complete injuries (as evidenced by loss of both motor and sensory function), it is also possible to have an incomplete injury where only motor or sensory function is lost or where only one side of the body is affected. For example, *anterior cord syndrome* is characterized by loss of motor function but preservation of many sensory functions, which travel primarily in the back of the spinal cord. *Brown-Sequard syndrome* is a unique condition in which the left or right half of the spinal cord is transected. Given the manner in which motor and sensory information cross from right to left at different levels, a person with this injury characteristically presents with loss of position sense and motor function on the same side of the body as the injured side of the cord and loss of pain and temperature sensation on the opposite side.

Treatment

Although research is ongoing, there is little to be done to repair a damaged spinal cord. Therefore, management is directed toward pain control, prevention of worsening of symptoms, and recovery of function where possible. This is done through medication, physical therapy and rehabilitation, and, in some cases, surgery.

Medication is an area of intense debate and research. There is little disagreement regarding pain control. Analgesics ranging from acetaminophen and nonsteroidal anti-inflammatory drugs such as ibuprofen to narcotics such as morphine and hydrocodone are all useful in managing pain. However, care must be taken to prevent development of dependence on these drugs and to avoid side effects associated with overuse.

Steroids have played a role of varying prominence with regard to treatment of SCI. More recent evidence shows that steroids may be helpful in reducing the secondary effects of acute SCI, that is, the inflammatory reaction that occurs after injury and is thought to be responsible for some of the longer-lasting damage. Significant improvements in neurologic outcome have been demonstrated with initiation of steroid administration very soon after injury (within 8 hours). However, more research needs to be done in this area to determine efficacy. Also, steroid administration has side effects that may outweigh the neurologic benefits, such as immune suppression, which makes a patient susceptible to severe infection.

Physical therapy can be very effective in both mild and severe injury. In more mild cases, a therapy regimen that improves flexibility may reduce compressive symptoms, including helping a herniated disk "slide" back into place. Also, strengthening of the core muscles (e.g., abdominal muscles and the muscles that stabilize the spine) may be helpful in reducing symptoms by providing an "assist" to the vertebrae and intervertebral disks. In more severe cases where a lasting motor deficit is present, intensive therapy and rehabilitation can help a patient learn to use different muscle groups to compensate or even help a previously affected muscle group and nerve pathway to "relearn" its function.

Another therapy receiving much attention is the intravenous (IV) infusion of very cold saline solution. Saline with a normality of 0.9% has a similar salt concentration to the water present in the body and is used routinely for IV hydration. With regard to SCI, as well as to prehospital management of trauma patients in general, the infusion of ice-cold saline drops the body's temperature by several degrees, which is thought to reduce the body's oxygen and energy demands and is a way to preserve the delicate and damaged tissue, particularly until more definitive management can be initiated. Cooling is another way to reduce the postinjury inflammatory reaction. However, more research must be done to determine the precise effects that produce benefit as well as the appropriate algorithm for implementation. For example, there is a fine line between enough cooling to preserve tissue and too much cooling that triggers failure of, and damage to, other organs. Also, following injury there is likely to be a time after which the benefit of cooling is lost and the effect is perhaps detrimental.

Surgical repair of the spinal cord itself is not currently possible. However, there are several procedures to treat persistent insults to the spinal cord. Laminectomy is a procedure in which the lamina, part of the vertebra that forms a protective ring around the spinal cord, is removed. This allows swelling of the cord or surrounding the soft tissues to bulge outward and away from the spinal cord rather than compress the cord. The more bone that is removed, the more unstable the spine becomes, increasing the risk for future injury to the spinal cord. As a result, spinal fusion may be required. Supplemental bone tissue (from either the patient or another donor) is used to stimulate the body's own bone building to fuse the adjacent vertebrae and limit their mobility. The goals are decreased pain and risk of further injury but at the expense of overall mobility of the back.

Because of the risks associated with surgery in general and because of the likelihood of reduced function after surgery, decompressive procedures are reserved for cases of severe neurologic compromise (particularly in cases of direct pressure on the spinal cord) or in cases where more conservative therapy provides little or no improvement.

Prognosis

SCI is a potentially devastating injury. Incomplete injuries generally have a better prognosis than complete injuries. Patients with complete injuries have a 5% or less chance of recovery, which drops to nearly 0% at 72 hours postinjury. Preservation of some sensory function indicates a 50% chance of recovering the ability to walk. In terms of long-term survival, the mortality rate has steadily improved over the years, mostly as a result of gains in infection control with early diagnosis and better treatment of conditions such as pneumonia and urinary tract infection.

In general, the sooner the SCI individual receives acute intervention (i.e., decompression, steroids, IV cooling) and is stabilized, the better the prognosis. Acute interventions aimed at curbing the inflammatory response are believed to prevent secondary tissue damage and, therefore, further loss of function.

Regarding return to play following a sports-related SCI, the first consideration is whether the patient is dealing with a permanent deficit and that deficit's implications in sports selection and participation. Second, the patient's injury and functional exam must be stable in the case of a permanent deficit or completely resolved in the case of a temporary deficit.

Splenic Injury

Although the liver is the most frequently injured abdominal organ, the spleen is the most frequently injured organ in sports and the most common cause of death due to abdominal trauma in athletic activity.

Epidemiology and Biomechanics

Injuries to the spleen can result from a direct force to the abdomen, especially the left upper quadrant; from a sudden deceleration when the hilum is torn; or by displacement of lower left rib fractures. Any of these mechanisms are possible in high-speed or contact sports. The mechanism of splenic injury was explored in one study of downhill skiers. In high-velocity or high-impact collisions, for example, with a tree, a chairlift pole, or a snow fence, multiple trauma was always present (fractures or damage to multiple organs). Skiers were unable to move at the scene, and splenectomy resulted in 5 out of 6 cases (83%). With low-velocity or low-impact collisions, often just a single organ was involved. Such injuries resulted from falls on ski trails, on moguls, or on tree stumps or rocks. Presentation in these cases was often delayed for hours while the individual continued skiing. Splenectomy was necessary in 5 of 12 cases (42%). An investigation by Machida and colleagues reported in their 1999 article, published in *Injury,* showed a significantly higher abdominal injury rate in snowboarders than in skiers. Injuries to the kidney, liver, and spleen were seen in both. In snowboarders, riding mistakes after jumping and subsequent falls were responsible for 31.6% of the abdominal traumas. Skiers were more likely to have a collision as the mechanism for their abdominal injury.

Clinical Presentation

Initially, the pain of splenic injury is sharp, followed by a continued dull, left-sided ache. The patient may complain of radiating pain to the left or right shoulder secondary to free intraperitoneal blood irritating the diaphragm. Splenic rupture is associated with abdominal pain, left shoulder pain (the Kehr sign), or periscapular pain.

Physical exam is neither sensitive nor specific for splenic injury. Because the spleen's capsule can contain bleeding, the signs of splenic injury are often delayed, thereby rendering physical examination unreliable and subsequently hindering diagnosis. The abdomen may be distended. Left-upper-quadrant abdominal tenderness may or may not be accompanied by peritoneal signs, such as generalized tenderness, guarding, and rebound tenderness. There may also be tenderness over the left 10th, 11th, and 12th ribs. Indicators of hypovolemia, such as tachycardia and hypotension, are worrisome signs.

Imaging

Patients with an appropriate mechanism or pain should have a computed tomography (CT) scan taken. CT staging of splenic injury does not predict the need for laparotomy, nor does it correlate with clinical outcome; however, it remains the most accurate method of diagnosing initial injury.

Management

The most important determinant of nonoperative management of splenic rupture is hemodynamic stability, including determination of hematocrit. Exploratory laparotomy is indicated if the individual is hemodynamically unstable, and splenectomy is performed if the injury is extensive or the hemorrhage is otherwise uncontrollable.

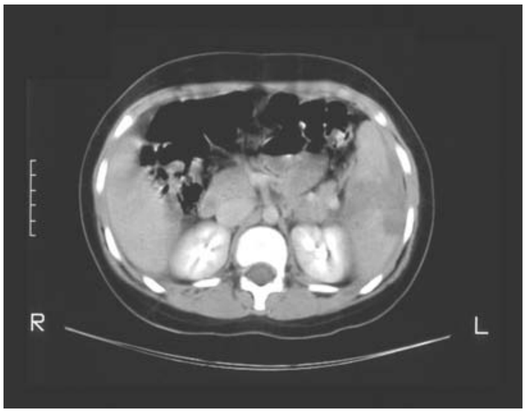
Nonoperative management of splenic injuries consists of careful hemodynamic monitoring, frequent physical and laboratory examination, and, most important, strict bed rest.

In many ways, the management of splenic injury parallels that of the liver. Hemoglobin and hematocrit from a complete blood count can indicate the extent of any blood loss. An elevated leukocyte count may be present if a subcapsular hematoma has developed. Diagnostic peritoneal lavage (DPL) classically is positive if any significant bleeding has occurred from injury to the spleen or other abdominal organ.

Given a stable course, the CT scan should be repeated after 5 to 7 days and should show stabilization or improvement of the injury. Avoidance of contact sports is recommended for up to 4 months after injury. This is determined largely by the severity of the injury seen on a CT scan and its resolution (Figure 1). Most authors recommend at least a 3-month period of physical activity restriction, with the first 3 weeks after hospital discharge spent as "quiet" activity at home. Nonoperative splenic management seems to be more successful in children (90%) than in adults (70%).

Epstein-Barr Virus, Infectious Mononucleosis, and Splenomegaly

By age 30, 90% of the population has been exposed to the Epstein-Barr virus, which causes infectious mononucleosis. This may frequently be unrecognized, particularly in children. From 1% to 3% of college students are affected each year. The peak incidence is in 15- to 24-year-olds. A recent study using physical exam alone reported splenomegaly in 8% of patients with infectious mononucleosis. In comparison, a study using ultrasonography demonstrated that 100% of patients with infectious mononucleosis had an enlarged spleen; physical examination detected the abnormality in less than 20% of the same cases. These studies indicate that physical exam alone is an insensitive tool to diagnose splenomegaly in the setting of infectious mononucleosis.



CT scan illustrating heterogeneous signal indicating splenic fracture. A transverse section is shown at the thoracic level, viewed from below. The spleen is located to the right side, adjacent to the ribcage.

Source: Courtesy of David Mooney, M.D., Children's Hospital Boston.

Infectious mononucleosis causes the splenic architecture to become distorted, making the spleen susceptible to rupture from any increased abdominal pressure, even from sneezing or coughing. Splenic rupture in infectious mononucleosis occurs in 0.1% to 0.2% of cases, with the highest estimate being 0.5%. The timing of this complication is predictable, being noted in the first 3 weeks of the illness. Splenic rupture is unusual beyond 3 weeks from the onset of symptoms (headache, sore throat, and fever). The prodromal period is not considered when determining the onset of the illness.

This complication fortunately is often not fatal. Splenectomy is necessary in some instances, although nonoperative management is often successful. Treatment should be individualized. There is no evidence to suggest that corticosteroids reduce spleen size or shorten the duration of the illness.

Return to Sports

The appropriate time to allow an athlete with infectious mononucleosis to resume his or her activity is determined by the duration of the symptoms, as well as the presence of splenomegaly and the risk of splenic rupture. There is concern that contact trauma may precipitate splenic rupture. In a 1976 survey of college team physicians, the respondents identified 22 cases of splenic rupture. At the time of the trauma, 41% of these were diagnosed with infectious mononucleosis. Seventeen of the student athletes were participating in football. Most splenic ruptures in the setting of infectious mononucleosis, however, are spontaneous and not the result of contact.

Return-to-play recommendations in the literature have been varied. To protect the enlarged spleen, which should probably be assumed to be present in all cases, all strenuous activity should be avoided for the first 21 days. At this point, the athlete may start a graded aerobic program, avoiding contact, if the athlete is asymptomatic, afebrile, and does not have a palpable spleen. At 4 weeks, if the signs are equivocal or the athlete is at a high risk for collision, an imaging study such as an ultrasound should be considered. It should also be noted that normal spleen size has been directly correlated with athlete size; hence, a large athlete with an appropriately sized spleen may be mistakenly diagnosed with splenomegaly if the splenic volume/body mass is not considered.

Spondylolysis and Spondylolisthesis

Spondylolysis is a type of stress fracture in the spine. The fracture occurs in the back of the bone, in an area called the pars interarticularis. The condition is the most common cause of low back pain in adolescent athletes and thought to be an overuse injury that results from repetitive microtrauma to the bone. The term *spondylolysis* originates from the Greek words *spondylo,* meaning "vertebrae" (or bone of the spine), and *lysis,* meaning "to dissolve."

A fracture of the pars interarticularis may become unstable, allowing the vertebrae to slip out of position. This slippage is called *spondylolisthesis*. Typically, the fifth vertebrae shifts forward in relation to the sacrum.

Anatomy

The spinal column consists of 24 bones arranged on top of each other. These bones, separated by fibrocartilaginous disks for cushioning, are called *vertebrae*. The vertebrae provide support and stability for the spinal column and are important for posture and movement.

Facet joints connect the vertebrae and allow them to move freely, resulting in flexibility and movement of the spine. Two other bones—the pedicle and laminae—form the bony ring that surrounds each vertebra. The area of bone that joins the upper and lower facet joints is called the *pars interarticularis*. It is often the weakest link between the pedicle and lamina.

The spinal column consists of three segments, which include 7 cervical vertebrae (in the neck), 12 thoracic vertebrae (in the upper back), and 5 lumbar vertebrae (in the lower back). The lumbar vertebrae are the thickest. The lumbar spine is connected to the pelvis.

Spondylolysis most commonly occurs in the lumbar spine, at the lowest lumbar (L5) vertebral level. Most fractures occur on both sides of the spine and are bilateral; however, they may be unilateral as well.

Causes

Spondylolysis in sports is caused by overtraining and overuse of the spine. Athletes who play sports that involve repetitive hyperextension (bending backward) and rotation of the back have a higher risk of developing spondylolysis than those who do not. Examples of these sports include ballet, gymnastics, diving, and figure skating.

Repetitive hyperextension puts a great deal of stress on the spine. When the spine is overextended, the pars interarticularis is especially vulnerable to these forces, and microtrauma in the bone can result. The body tries to repair these repeated small injuries, but sometimes the repair mechanism is overwhelmed by ongoing damage, leading to a stress fracture (Figure 1).

Sometimes repetitive hyperextension from sports weakens the bone so much that it results in spondylolisthesis. In children and young adults, the most common cause of spondylolisthesis is spondylolysis. Age is a significant risk factor in the development of spondylolysis due to spondylolisthesis.

Symptoms

The most common symptom of spondylolysis in athletes is low back pain that worsens with extension, especially while playing sport(s). Pain may be in one location or spread throughout other areas of the back. It is typically dull and aching, similar to a muscle strain. Symptoms are gradual in onset. Hamstring tightness is often present. Initial rest from sports and medication with nonsteroidal anti-inflammatory drugs (NSAIDs) temporarily reduce pain.

Patients with spondylolisthesis complain of muscle spasms and tightness resulting in difficulty with posture and walking. Muscle weakness, leg pain, and sphincter (a circular muscle that helps maintain constriction of a passage in the body) weakness; loss of feeling in the buttocks; and radiating pain from the spine down the legs may also occur.

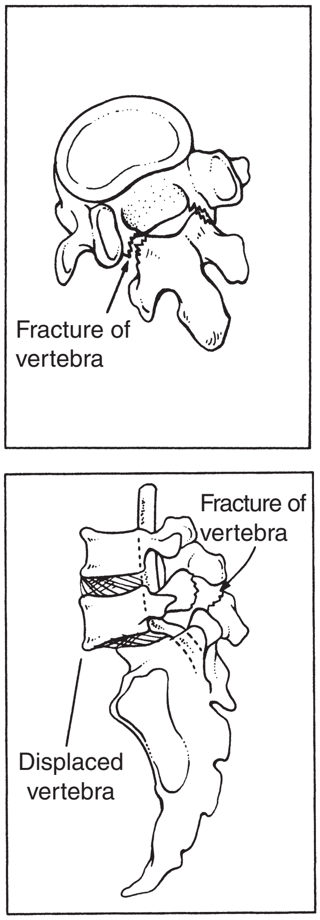

Figure 1 Spondylolysis and Spondylolisthesis

Diagnosis

History

A complete history and physical examination are the first steps in making a diagnosis. A history of the present illness should include the duration of the pain, whether the onset is gradual or sudden, the factors that improve or worsen pain, changes in muscle function, or difficulty with bowel or bladder functions. The presence of night pain may indicate a more serious underlying condition and should be excluded.

It is important to obtain a sport-specific history from the athlete. This includes the maneuvers required for the sport, how long the athlete has been experiencing symptoms, the intensity of the sport, and the level of involvement. Associated factors, such as increased training or growth spurt, should also be considered.

Physical Examination

The spine should be palpated for areas of tenderness, which may indicate the location of the fracture. Tenderness can occur in a part of or throughout the back. It is important to note that an injured athlete's postflexibility should be compared with his or her preinjury flexibility. Range of motion, such as bending forward (flexion) and bending backward (extension), should be tested. In athletes with spondylolysis, this is usually more limited and painful in extension. When the patient stands on one leg and bends backward, the opposite side may be painful. The weight-bearing side is consistent with the painful injured side. Hamstrings are generally tight. An exaggerated curve of the lumbar spine, referred to as *hyperlordosis,* is typical.

Diagnostic Imaging

When the history and physical examination suggest spondylolysis, X-rays are often the first step in imaging. This includes anterior-posterior (AP), oblique (angled), and lateral (side) views. Lateral views show the degree of slip and the angle of slip in spondylolisthesis.

Plain radiographs reveal how the vertebrae are positioned. These are useful in detecting fractures and slippage of the vertebrae. However, X-rays do not always show stress fractures, and more subtle fractures may be missed. In these instances, more advanced diagnostic imaging is necessary. A diagnostic test called a bone scan indicates increased areas of metabolic activity and bone turnover associated with stress fractures. The addition of single-photon emission computed tomography (SPECT) offers an even more sensitive test to detect bone stress. Early fractures not detected on plain radiographs are often shown on SPECT bone scans. When increased areas of bone turnover are present, computed tomography (CT) can be used.

CT identifies bone form and structure. It is used to determine the extent of the fracture as well as its healing potential. Fractures are classified or "staged" as early, progressive, and terminal. Early-stage fractures have the most healing potential.

Magnetic resonance imaging (MRI) offers the advantage of minimizing exposure to radiation while evaluating bony structure and edema (inflammation) in one test. It can also be used to rule out other causes of back pain, including disk problems.

Treatment

The main goal of treatment is complete healing of the fracture and a safe return to sports. Many athletes return to sports with a fibrous union, meaning that although they are asymptomatic, the fracture has not completely healed. This outcome has a favorable short-term prognosis; however, a bilateral bony union is more preferable.

Nonsurgical Treatment

Most athletes with spondylolysis are treated conservatively. Conservative measures include rest from sports, bracing, and physical therapy. It is important to encourage the athlete to be compliant with the treatment plan, particularly rest from sports.

Antilordotic bracing, physical therapy, and modification of activities are often prescribed. Bracing in general remains controversial among practitioners. The purpose of the brace is to reduce the forces on the posterior elements of the spine. Different types of braces are available. Physical therapy includes abdominal strengthening exercises, as well as stretching of the back and hamstring muscles. These exercises strengthen the back and core muscles and help improve lordosis/swayback.

NSAIDs may initially reduce pain. Nonimpact activities such as swimming and the elliptical should be encouraged in the initial treatment phase, as long as the patient does not have discomfort with these activities.

As symptoms improve, activity can be slowly increased. Caution should be taken not to return the athlete to sports too early as this could exacerbate the symptoms and delay fracture healing. The athlete can be slowly weaned from the brace if there is no pain with return to sports or provocative extension maneuvers during clinical follow-up.

In instances where conservative treatment has failed (the fracture has not healed and the athlete is still experiencing pain), electrical stimulation may be prescribed. It is thought that the electrical current stimulates bone cells to grow and divide, which accelerates fracture healing.

At periodical follow-up appointments, the health care professional should ensure that symptoms are improving and that the fracture is healing. The athlete should be painfree by history and with provocative extension maneuvers during the clinical evaluation. Computed tomography (CT) may be used to assess healing of the fracture.

Surgical Treatment

The decision to perform surgery is based on the failure of conservative treatment and the severity of the athlete's symptoms. Surgery is necessary if slippage continues to progress and the pain is so severe that it interferes with activities of daily living.

A spinal fusion is used for surgical stabilization. Bones are surgically fused, allowing them to grow together. This ensures that the bones and joints do not move or slip further. In this procedure, a bony bridge is created between the sacrum at the lower part of the spine and the area of slippage.

Surgery may also be performed to remove bone or other tissue. This takes pressure off the spinal cord or spinal nerve roots and is called *decompression*. A fusion and decompression may be performed together depending on the athlete's symptoms and slippage. After surgery, a brace is used and physical therapy prescribed to strengthen the core muscles. As with conservative treatment, caution should be taken to return the athlete to sports gradually and slowly.

Sport and Exercise Psychology

In the past 30 years, sport psychology has been recognized as a distinct area of study in human behavior. Sport psychology is concerned with the psychological and emotional factors that influence both participation in sports and performance activities and the psychological effects derived from them. There are many dimensions to participation in sports, exercise, and performance activity that are influenced by psychological factors. Sport psychologists study motivation, personality, leadership, team building and cohesion, coaching styles, athletic identity, the psychology of injury rehabilitation, and variables related to achieving optimal performance. Sport psychologists work with individuals, teams, parenting organizations, coaches, and health care providers. The field has grown and has become integrated into the overall development of athletes and performers. Psychological factors are considered to be critical in achieving optimal performance after the talent playing field is leveled. Psychologists also contribute to understanding the effects that participating in physical activity has on psychological development, health, and well-being. While some sport psychologists work exclusively with athletic performance, many focus on the psychological factors involved in exercise—developing strategies to encourage sedentary people to exercise or evaluating the effectiveness of exercise as a treatment for depression. The field has been broadened and is now called *sport and exercise psychology.*

Sport psychology has two primary specialties: (1) clinical sport psychology and (2) educational sport psychology. A significant distinction is made in the field between the two. Clinical sport psychologists have extensive training in clinical and/or counseling psychology and have developed their skills to detect and treat individuals with emotional disorders. Clinical sport psychologists are typically licensed by state boards to practice and have augmented their training to include the subspecialty of sport and exercise psychology and the sports sciences. Educational sport psychology consultants have extensive training in sport and exercise science, physical education, and kinesiology. They also understand the psychology of human movement as it manifests in sport and exercise environments. Educational sport psychology consultants often provide "mental coaching" and psychological skills training. They are often called on to work with teams and individual athletes to teach anxiety management strategies, improve athletic confidence, improve coach-athlete communication, and build team cohesion.

History of Sport Psychology

The first known sport psychology laboratory was established in Germany in 1920. Coleman Griffith has been recognized as the father of this science in the United States. In 1925, he established the first ever sport psychology facility in the nation, the Athletic Research Laboratory. Griffith focused his research on various sport science and psychology issues in 1918, and he introduced the first university-level courses in sport psychology at the University of Illinois in 1923. Coaches showed interest in the psychological aspects of athletic performance in competition even before there was a science called sport psychology. The "pep talk" was highlighted by Knute Rockne—the football coach of the fighting Irish of Notre Dame—in the 1920s. Academic sport psychology was established by the mid-1960s. Physical education had become an academic discipline (now called kinesiology or exercise and sport science), and sport psychology had become a separate component within this discipline. Sport psychologists had also developed the applied side of their field and started to work with athletes and teams.

The field is thriving and vibrant, with many applications in sports, exercise, physical health, and sports medicine. Applied sport psychologists find their skills and application of knowledge helpful in many domains. In coach-training programs, the sport psychologist can help coaches understand the complex relationship between thought, emotions, motivational factors, and behaviors when an athlete is both acquiring a specific sport skill and applying it in athletic situations (with teammates, opponents, officials, and their coaches). Education is provided to help the coach understand the differences between using positive and aversive approaches to influencing behavior—as well as helping coaches use tools to assess their own effectiveness.

In sports medicine, the clinical sport psychologist is called on to treat injured or physically challenged athletes (those with overtraining, eating disorders, burnout, or overuse injuries or on post-surgical rehab) with emotional disorders. In addition, the sport psychologist assists athletes with the psychological process that goes alongside physical rehabilitation from acute and chronic sports injuries. The psychologist assists with the intricate recovery from sports concussions—both in the psychological assessment and in the counseling process. In addition, athletes often face challenges to their athletic identity when confronted with injuries and career-ending situations. The overall adjustment of the athlete is often improved by the specific skill set of a psychologist trained to work with athletes and high performers.

Sport psychology specialists provide consultation, education, and counseling to youth sports organizations. In the United States alone, an estimated 45 million children younger than 18 years are involved in school and extracurricular physical activity programs. Many children are intensively involved in organized sports. On average, youth sports activities require 11 hours weekly in the specific sport for about an 18-week season. Children are offered the opportunity through sports to participate actively in an activity that has meaningful consequences for themselves, their peers, their family, and the community around them. Most children peak in sports around age 12. Developmental psychology has provided the research to help us understand the critical periods for children that have important consequences on their self-esteem, body image, and social development. Hence, the youth sports experience can have important lifelong effects on the personality and psychological development of children. There are few hotter topics in parenting arenas than those surrounding the current challenges and opportunities facing youth sports. The professionalization and early specialization of young athletes have raised important questions about the developmental appropriateness of competition, sports selection, overuse injuries, overscheduled children, and the overzealous coach or parent.

Violence and Aggression in Sports

Another headlining topic that brings in the sport psychology consultant is violence and aggression in sports. Psychologists use the working definition of aggression as "any form of behavior directed toward the goal of harming or injuring another living being who is motivated to avoid such treatment." Psychologists further divide the term into two types of aggression. *Hostile aggression* has as its primary goal the infliction of harm or injury (physically or emotionally). *Instrumental aggression,* on the other hand, occurs as part of a non-harmful goal. A hockey check and a boxer's solid blow to an opponent's head are examples of instrumental aggression. Anger and violence often erupt in sporting situations because the line between instrumental and hostile aggression becomes blurry. Deaths have occurred when a player or spectator has not been able to regulate the aggressive arousal often stirred by high-contact play. The sport psychology consultant provides opportunities for coaches and players to address how to maintain the fine line between instrumental and hostile aggression and develop strategies for dealing with impulsive actions if an athlete, coach, or spectator feels out of control.

College Athletics and Sport Psychology

Many college athletic departments have begun to use and integrate the services of sport psychology consultants. College students and most student-athletes find themselves in a flux of emotionally taxing life transitions—some of which are predictable and result from the athletic commitments made and others that are developmental in nature. Student-athletes are a diverse group of individuals often trying to find their way in a more complex world than that of their predecessors. The commercialization of college athletics has brought new stressors to these athletes and their coaches. Navigating through the complicated National Collegiate Athletic Association (NCAA) rules and contractual obligations of scholarship monies leaves the student-athlete often unprepared for the stressful fallout from such a relished position. The NCAA has come to recognize the significance of counseling and mental health issues in the lives of student-athletes. The sport psychologist is available to assist with performance-based issues in the sports or game situation. He or she is also available to help the athlete balance academic demands, injury, time management, drug and alcohol use, and postcareer planning and transitions.

Professional sports and high-profile competitions such as the Olympics draw attention to the mental side of sports and have made it a "no-brainer" that the mind is often the defining factor in winning and losing. Specific mental skills are honed over time by well-trained and highly competitive athletes—including performing optimally under pressure, with optimal regulation of mood, anxiety, and thought—so that their performance is at a peak. When needed, the sport psychology consultant teaches a range of psychological skills to improve the mental side of the athlete's performance. These skills usually include goal setting, arousal control, self-talk, visualization, imagery, concentration and attention control training, and communication. These skills are used to address and improve performance issues. Sport psychology consultants also help athletes distinguish between performance enhancement and more problematic emotional issues. Depression, anxiety, adjustment disorders, and other mental health issues often affect athletic performance and can be disguised by the athlete or coach's perception that the struggle is performance based.

Exercise and Rehabilitation Psychology

Exercise psychology is an emerging field that separates itself somewhat from applied sport psychology but often shares many of the same underlying principles and tools. Exercise psychology is concerned with the application of psychological principles to the promotion and maintenance of exercise and physical activity and the psychological and emotional consequences of recreational physical activity. A field closely related to exercise psychology is rehabilitation psychology, which deals with the relationship between psychological factors and the physical rehabilitation process. Exercise rehabilitation is broader than recovery from sports injuries. It includes exercise rehabilitation from cardiac events, Type I and Type II diabetes, obesity, spinal cord injuries, and other medical events requiring exercise as a part of rehabilitation. Rehabilitation psychology also addresses the role of physical activity as a complementary strategy for treating disease and disability.

Some of the critical concepts in exercise psychology include studying the psychological antecedents of exercise behavior. While the American College of Sports Medicine recommends being physically active "most" days per week, the rate of exercise adoption and adherence is sluggish. They report that only 20% of adults engage in the minimal recommended amount of activity. Health care professionals frequently recommend exercise regimens as they relate to physical and mental health. However, compliance rates are often low, and adherence is primarily seen as related to psychological factors. In view of the alarming rates of inactivity in most industrialized nations, exercise psychology provides research and intervention strategies to address this epidemic. The U.S. Centers for Disease Control and Prevention have reported that lack of physical activity, along with poor diet, is responsible for at least 300,000 "preventable" deaths per year.

Exercise psychology relies on several theories and models to build understanding and interventions of physical activity behavior. At the core of the predominantly used exercise psychology theories is a common core construct—self-referenced thought. For example, self-determination theory begins with the basic assumption that individuals possess three primary psychosocial needs: (1) the need for self-determination (autonomy, self-dependent behavior), (2) the need to demonstrate competence, and (3) the need for relatedness. They hypothesize that individuals who exercise for reasons related to low self-determination (e.g., improving appearance) would be less likely to adhere to exercise interventions than someone who exercises for the pure pleasure of it. This theory predicts that improvements in intrinsic motivation to exercise would be aimed at enhancing an individual's sense of competence and autonomy in an environment that is supportive of satisfying social interactions. The systematic identification of the relevant psychological variables allows physical educators, trainers, and rehabilitation specialists to design a program making the best use of the strategies that should lead to long-term adoption of and adherence to exercise.

Practitioners and researchers in exercise psychology have extensively addressed questions related to mental health and physical activity. Considerable research has been done on the prevalence of depression, anxiety, and stress and the role that exercise can play in the alleviation of symptoms. Exercise is also studied for its self-esteem benefits and the overall contribution it makes to emotional well-being. Of course, the physical correlates of positive emotional well-being have been documented for decades and extend the value of this field well beyond the mental domain.

Sport Psychology in Sports Medicine

Only very recently has the sport psychologist also become part of an interdisciplinary orthopedic or sports medicine practice. There is a growing interest and need among sports medicine professionals to include the emotional component of the patient in rehabilitation from acute and chronic sports injuries. The sport psychologist works in coordination with sports medicine physicians, orthopedic surgeons, physical therapists, athletic trainers, nutritionists, fellows, and interns in training. Many sports injuries—both acute and overuse—respond well to a sport psychology counseling consultation. Acute injuries that are rather straightforward—broken bones, fractures, sprains, and strains—do not often even make it to the psychologist's office. Patients with recurrent or chronic injuries (e.g., multiple anterior cruciate ligament [ACL] injuries, which require long periods of rehabilitation; chronic back pain; regional pain syndrome) often suffer long periods of frustration, loss, and at times career-ending consequences. Counseling targeting the physical and emotional rehabilitation process often helps with injury recovery and overall adjustment. Children and adults who strongly identify with their sport/performance domain have difficulties making the transition to other activities while injured. As noted earlier, where an ACL repair can take up to 9 months before return to play is possible, athletes find it difficult to manage the unstructured time that is often consistent with being injured. Coordinating care around concussion management is particularly useful, as return-to-play decisions are often based on very subtle symptom recovery, requiring care and supervision from the treating physician or athletic trainer. In families with young athletes with concussions that last more than a few weeks, the psychologist can facilitate the implementation of physician recommendations for brain rest, academic accommodations, and modified physical activity. Based on anecdotal report, many young athletes recover more quickly from concussion symptoms when the treatment includes a psychological consultation.

Many athletes find the line between maintaining a healthy body weight and a strong performance weight to be a challenge. Sports medicine patients who are identified as possibly having nutritional, body image, or eating disorder issues are frequently referred for both nutritional and psychological counseling. The importance of maintaining a healthy body weight is significant for long-term performance issues in both men and women. Female athlete triad is a well-known condition for women who push the line in their athletic pursuits, creating conditions that prevent them from enjoying full physiological health. In many cases, these athletes do not resemble the psychological profile of the clinical eating disorder. In other cases, sports performance–based eating issues can become full-blown cases of anorexia and bulimia and need to be treated as such.

It is not always clear to the medical professional, athletic trainer, or coach as to when an athlete should be referred for counseling or psychotherapy. In much of the performance enhancement literature, most problems in performance are related to competition anxiety, motivational problems, and poor self-talk and concentration. However, sometimes athletes are struggling for reasons related to longer-term emotional issues that need to be identified. As noted at the beginning of this entry, there are sport psychologists who treat performance issues only and others with clinical/counseling training who can facilitate the care of athletes with emotionally based issues. When anxiety generalizes beyond the performance domain, it is usually indicative of issues that extend beyond athletic performance. Other kinds of issues facing athletes who benefit from counseling are identity issues, sexual orientation and homophobia, sexuality and human immunodeficiency virus (HIV)-related issues, eating disorders, alcohol and substance abuse issues, anger and aggression control, and relationship issues.

Sports Biomechanist

This entry provides a brief overview of sports biomechanics and explains the role of the biomechanist in improving performance and understanding sports injuries. Specific examples highlight the importance of integrating sports medicine, biomechanics, and coaching.

Sports Biomechanics

Emerging as a subdiscipline of human movement biomechanics, the evolution of sports biomechanics has been driven by a desire to understand technique in sports performance. Interestingly, some early enquires were related to humans and animals and were based on how these groups organize their biological systems to produce successful performance. These investigations drove the development of theory and technology commonly used today. A famous example comes from the latter part of the 19th century, when the horse racing enthusiast Leland Stanford of California wanted to know if during a trot a horse had a flight phase. Eadweard Muybridge (1830–1904) used early photographic technology to address this question.

In general, the sports biomechanist considers technique from two interrelated perspectives: injury and performance. In the former, scientifically grounded methods are employed to understand and explain the biological responses to load and movement patterns that occur during sports and exercise; this type of biomechanics leads naturally to the clinical applications discussed in the entry Biomechanics in Sports Medicine. Using the same scientifically valid methodologies, the performance perspective presents a number of challenges; including identifying the underlying biomechanical determinants of successful performance, explaining effective and efficient techniques, and ultimately optimizing performance. The research challenge is often complicated by the need to maintain a high level of ecological validity.

In his keynote address at the International Society of Biomechanics in Sports (ISBS) conference in Salzburg, in 2006, former ISBS president Bruce Elliot highlighted the need for biomechanists to conduct research in a "real-world" meaningful environment. Collecting data during training and competition across a diverse range of activities requires flexibility in the methodology used. Fixed-volume analyses maybe used in sports such as gymnastics, where the performance occurs in a small volume, compared with sports such as ski jumping, skiing, and track-and-field events, where panning cameras maybe required. These factors complicate the research design and emphasize the need for innovation while maintaining internal validity, accuracy, and reliability. One result of this is that research has focused on certain sports that lend themselves to fewer complications (e.g., gait analysis compared with kayaking).

The principal ways in which sports biomechanics can help improve performance, develop the coaching process, and explain the most effective ways to train fall into a number of interrelated categories.

Mindset Development

Sports biomechanics can provide coaches with an accurate conceptual understanding of what constitutes successful technique, highlighting the key movement patterns, timings, and phases of the skill. This conceptual model allows the coach to effectively develop technique, strength, and conditioning exercise and preparatory activities. The development of a mindset is the first step in providing an effective coaching-biomechanics interface.

Coach Support

Working alongside the athlete and the coach, the sports biomechanist can provide direct feedback to the coach and/or performer. The feedback can range from basic timings—for example, in sprinting, split times at 5- or 10-meter (m) intervals are very useful—to the more complex kinematic (movement patterns) or kinetic (forces, joint forces) analyses. The important aspect of this feedback is that it is based on key performance variables that are directly related to successful performance. Issues can arise from the use of commercially available qualitative video analysis systems in terms of accuracy and reliability.

Feedback Enhancement

Another topical role that sports biomechanists may play is in the development of innovative technologies, athlete-worn sensors, and motion analysis system technologies that aim to provide meaningful biomechanical feedback to coaches and or performers. These systems are more scientifically grounded than the commercial qualitative video systems and provide precise and relevant information about performance; in addition, the information is presented in a sport-specific effective fashion.

Models of Performance

One important aspect of sports biomechanics is the development of performance or hierarchical models; these were first published by the late James Hay, who was also the former president of both ISBS and ISB (International Society of Biomechanics). These models are based on the underlying laws of human movement and aim to identify the key variables that have a causative effect on success. The models help explain the biomechanical requirements of skill and prevent the arbitrary selection of variables. Different levels of analysis are used within the development of these models, including:

- single-joint analyses,
- intersegmental coordination analyses, and
- joint kinetic analyses (moments, powers, work, energy).

Optimization of Performance

Another approach to understanding and explaining technique is through the use of forward dynamic analyses. Forward dynamics or computer simulation modeling provides a strong and useful tool that allows sports biomechanist to address questions in a completely controlled environment. This approach allows optimal technique to be determined and also predicts what may be possible to perform. Theoretically adapting performance to achieve specific performance criteria allows subject-specific optimal performance to be determined.

Conclusion

The future progression of sports biomechanics, specifically from the performance perspective, rests with the development of the coaching-biomechanics interface (CBI). Increases in effective technology and ecologically valid scientific enquiry will promote the development of the CBI. The integration of sports biomechanics, sports medicine, and sports coaching represents an evolution from a mono- to multidisciplinary research perspective and ultimately to an interdisciplinary approach.

Sports Drinks

Sports drinks are part of a giant multibillion-dollar industry whose products are marketed to the active athletic population. They are a varied group of noncarbonated beverages now widely used to provide energy, to avert fatigue, to enhance concentration, and, most important, to replenish exercise-related fluid, carbohydrate, and electrolyte losses associated with dehydration. The ultimate goal is to optimize athletic and academic performance through the use of sports beverages. However, sports drinks are not universally indicated or needed during exercise, particularly for short-duration, low- to moderate-intensity exercises. The energy derived from sports drink ingestion does provide a nutritive substrate for longer-duration exercise and aids in recovery from high-intensity workouts. Sports drinks must be differentiated from "energy drinks," which typically include nonnutritive stimulants such as caffeine, guarana, taurine, ginseng, carnitine, creatine, and/or glucuoronolactone, with varying amounts of carbohydrate, protein, amino acids, vitamins, sodium, and other minerals.

How Sports Drinks Provide Energy for Exercise

Sports drinks derive their "energy" primarily from carbohydrates, which fuel the metabolic pathways used during exercise, particularly by muscle and brain. Caloric energy comes from sugars such as glucose or fructose. After approximately 20 minutes of aerobic exercise, as the glycogen stores are depleted, blood glucose becomes an increasingly important energy source. Calories (cal; 1 cal = 4.2 joules) in sports drinks range from 10 to 70 per serving (14 grams [g] average per 240 milliliters [ml] or 8 ounces [oz]). There is much greater variability in the caloric content of energy drinks, ranging from 10 to 270 cal per serving. Sports drinks are designed to restore the fluids, carbohydrates, and electrolytes lost during intense physical activity. A carbohydrate sports drink of no more than 6% to 8% is needed to supply the requirements for this nutrient during moderate, prolonged, or strenuous exercise provided that adequate hydration is maintained. A slight rise in insulin is a natural response to ingestion of carbohydrate-containing foods or beverages. The insulin release that follows sports drink ingestion during exercise helps increase the rate of glucose uptake and use by working muscles to prolong the intensity and duration of exercise.

Appropriate Use

Copious ingestion of sports drinks can result in unnecessary or excessive ingestion of carbohydrates. High doses of simple carbohydrates can evoke the greatest insulin responses. For exercise of less than 1-hour duration, most of the energy is readily obtained from the glycogen stores and the metabolic breakdown of protein and fat. Therefore, the primary goal of fluid intake during exercise is to maintain adequate hydration. This should be easily achieved with water ingestion only. Furthermore, sports drinks should not be used during lunch or snacks as a replacement for low-fat milk or water. In this setting, the higher-calorie sports drinks contribute to excessive caloric intake as well as insufficient intake of other essential nutrients, increasing the risk for overweight and obesity in children and adults, not unlike soda ingestion. Low-calorie sports drinks will not contribute to the risk of overweight or obesity and yet do not provide adequate carbohydrates for intense exercise; therefore, their role, if any, in the athlete's diet is yet to be determined.

During prolonged and intense exercise, the body can experience fatigue and impaired sports performance without adequate energy substrates available. A switch from hydration with water only to a carbohydrate-electrolyte beverage after the initial hour of vigorous exercise is appropriate to replenish the calories and electrolytes lost while rehydrating and to maintain exercise intensity. Continued exercise with water intake alone can have negative consequences on the body due to the depletion of the essential nutrients required to maintain the body's energy balance and function. Athletes often prepare for intense exercise by eating a diet high in carbohydrates. But during exercise, eating solid food is usually not an option. Sports drinks provide an easily digested carbohydrate source for the body, thus allowing the athlete to maintain optimum energy levels. Table 1 provides a recipe to prepare your own custom sports drink.

Table 1 Make Your Own Custom Sports Drink

Ingredients
¼ cup sugar
¼ tsp salt
¼ cup water
¼ cup orange juice (not concentrate) or a combination of 100% fruit juices
2 tbsp lemon juice
3½ cups cold water
Directions
1. Dissolve the sugar and salt in the water.
2. Add the juices and the remaining water; chill. Makes four servings.
Caloric Content
Per 8-ounce serving: 50 calories; 12 grams carbohydrate; 110 milligrams sodium

Note: 1 ounce (oz) = 28.35 grams (g); 1 calorie (cal) = 4.2 joules.

Sports Drinks Versus Water

Water is an essential part of our daily diet. During exercise, water is the appropriate choice for hydration for 60 minutes or less of exercise and does not need to be ingested in the form of a sports drink or other beverage. Clothes, diet, medications, illnesses or chronic conditions, fitness level, and acclimatization influence the body's sweat rate and risk of dehydration. Sweat rates vary greatly among individuals but can reach 1 to 3 liters (L)/hour. Environmental conditions such as heat, humidity, intensity, and duration of exercise all affect the quantity of water needed to maintain a euvolemic state. Exercise-induced dehydration is caused by a mismatch of fluid lost in sweat and adequate fluid replacement. Excessive dehydration is associated with premature fatigue, impaired sports performance, and an increased risk of heat-associated illness. Sports drinks offer advantages to promote fluid intake because their flavor, color, and sodium and carbohydrate content all increase the natural tendency to drink during exercise. Offering fluids that are slightly cooled (59–72 °F or 15–22 °C) to athletes also appears to improve their overall fluid intake.

Electrolytes

Sodium and potassium are essential nutrients in our diet. Sodium maintains blood volume and helps preserve the balance of water in the cells. Athletes with low sodium levels may feel nauseated, experience painful muscle cramps, or feel disoriented or confused. Potassium helps regulate muscle control, nerve function, and blood pressure. Potassium works with sodium to keep the body's water in balance. Sweating causes blood sodium levels to rise, which prompts thirst. However, thirst is not generally a sufficient stimulus to maintain fluid balance during exercise in the heat. Therefore, thirst should not be relied on solely as a warning to prevent excessive body water deficits. Athletes should be taught to drink water before, during, and after exercise without waiting for thirst to prompt them; this would reduce the risk of significant dehydration and related heat illness.

For strenuous and endurance activities where large sweat losses are seen, sports drinks are helpful for electrolyte replacement and the prevention of hyponatremia or other electrolyte abnormalities. Several electrolytes, including sodium and potassium, are ingredients of both sports and energy drinks. Sodium content varies from 100 to 200 milligrams (mg) per 240 ml (8 oz), while potassium content ranges from 30 to 90 mg. Too much sodium can cause an excessive feeling of thirst, leading to overdrinking while still overloading the body with salt. Athletes may need as little as 50 mg of sodium per 8 oz. When choosing a beverage, it is important to know its electrolyte content.

Protein, Amino Acids, Vitamins, and Minerals

Many sports and energy drinks contain B vitamins as well as vitamin C. There is no advantage in consuming these vitamins in these drinks as they can be obtained in a well-balanced diet. Protein is an essential part of an athlete's diet. Protein intake should be spread throughout the day. This allows the body opportunity to use the necessary amino acids (AA) throughout the day rather than convert them to fat. Protein ingested shortly before workouts may lead to gastric upset in some individuals. It also may serve as exercise fuel and in small amounts may have a muscle sparing effect preexercise when added to carbohydrates (CHO) in small amounts.

Protein does appear to have an important role in postexercise recovery when combined with carbohydrate. Protein intake provides the necessary amino acids to rebuild muscle broken down during intense exercise and improves muscle hydration. Consumption of CHO + AA (4:1 ratio) after exercising improved postexercise recovery, thus preventing declines in endurance performance in consecutive-day heavy exercise bouts. What research has failed to demonstrate is an actual improvement in exercise performance in endurance athletes following protein or CHO + AA supplementation. Thus, the optimal intake of carbohydrates/protein quantities is likely individual and is influenced by personal tolerance, dietary practices, metabolism, and exercise type as well as duration. Further research is needed to establish optimal carbohydrate/protein types, amounts, and timings of intake with regard to specific types of exercise. Sports drinks containing protein and amino acids can be used for postexercise recovery and rehydration; low-fat milk is another popular option.

Conclusion

Sports drinks have an important but limited role in an athlete's diet. Sports drinks have no significant daily nutritive value in the diet. Their use should be limited to hydration and CHO-E (carbohydrates + electrolytes) supplementation during prolonged, vigorous exercise or CHO-E (±AA) during the immediate postexercise period for rehydration and muscle recovery. Overdrinking can contribute to excessive carbohydrate intake and can contribute to the overweight obesity epidemic in the United States. Sports drinks often contain substances such as vitamins that are better obtained from other dietary sources. The optimal balance of carbohydrates, electrolytes, and water for athletes varies greatly depending on environmental conditions, sweat rates, and the duration and intensity of exercise; therefore, it is difficult to determine the ideal content of a sports drink. Commercially available sports drinks vary greatly in content of carbohydrates, electrolytes, and other substances. An athlete using a sports drink should familiarize himself or herself with the contents of the beverage of his or her choice. It is important to distinguish sports drinks from energy drinks. Energy drinks containing stimulant substances are not recommended for use in children or adolescents and should be avoided in athletes in general. For low to moderate exercise of less than 1-hour duration, water remains the beverage of choice for maintaining an athlete's hydration. Ongoing research continues to add to our knowledge regarding the need for carbohydrates, electrolytes, and protein/amino acids in the athletic population and will likely influence the commercial sports drink industry.

Sports Injuries, Acute

Injuries can be divided into two categories—*acute* and *chronic*. In acute injury, a specific event causes direct trauma to the body and subsequent injury to the tissues involved. Acute injury can vary greatly, from an ankle sprain to a corneal (eye) abrasion and almost everything in between. Acute injury can occur to soft tissue, bone, organs, or nerves. Treatments and duration of healing of acute injuries depend on the severity of trauma and the type of injury. In contrast, chronic injuries are problems that develop over time, often in a predictable manner, and may be the result of repetitive overuse of a region of the body. In sports, the musculoskeletal system, which includes ligaments, tendons, muscles, and bones, represents the primary tissues affected by chronic injury. The treatment of chronic injury also varies based on the type of injury; however, stopping the noxious, repetitive actions is generally required for healing.

Clinical Evaluation

Acute injuries vary in their level of severity. The most common acute injuries involve bruises, sprains, and strains. A mild ankle sprain may require little or no intervention to allow immediate return to play. In contrast, a high-velocity hit to an athlete's abdomen has the potential to cause internal bleeding; a similar blow to the extremities or the spine may cause a fracture. All these can be serious situations that require timely on-site evaluation, stabilization, and transportation to a health care facility. These variations in severity make the clinical evaluation of an acute injury extremely important. Timely assessment is necessary to obtain the most accurate information and exam. Serial exams can reveal clues to a developing serious condition—for example, an intracranial bleed or visceral laceration. Serial exams may also provide reassurance regarding a less worrisome condition that is clinically improving, such as a mild concussion or upper extremity "stinger."

History

The history for an acute injury should be focused and pertinent. The examiner needs to determine when the injury occurred and during what type of movement and what derangements occurred. The timing, character, progression, or improvement of pain and the aggravating or alleviating factors can give helpful clues to the type of injury. Accompanying symptoms of swelling, locking, catching, bruising, bleeding, and neurologic complaints are important for diagnosis. It is also important to know whether the athlete has had any prior injuries, problems, or surgeries, as well as to learn the patient's medical history, for example, chronic illness, medications, and allergies. A thorough, pertinent history can often provide all the clues necessary to make the diagnosis and will at least significantly narrow the differential of diagnosis. The medical history will help determine if the individual has a severe and potentially life-threatening problem that will require more emergent interventions and an escalated level of assistance.

Physical Exam

Physical exams in the setting of acute injury should always follow the American Heart Association guidelines for Basic Life Support. The exam should begin with assessing the athlete's airway, breathing, and circulation (ABCs) and treating problems with these systems before moving to examination of any other body systems or parts, no matter how severe or distracting the injury may appear. Special care and attention needs to be given to any athlete who may have a head or spine injury, and further exam maneuvers need to be done in a way that prevents further injury. For an alert athlete, the exam can focus on the area of injury and first visualize the area of injury, checking for swelling, ecchymosis or bruising, deformity, or skin trauma. Then the area of injury is palpated for tenderness, crepitance, edema (swelling), and, in the case of an abdominal injury, rebound or guarding. More specific exam maneuvers to help better pinpoint the type of injury are then carried out. In the case of a patient with a head injury, who is alert and awake, one would attempt a more complete neurologic exam to include memory, recall, balance, strength, sensation, and coordination. Often, the most accurate physical exam can be obtained immediately following the injury. Serial exams done over the first few minutes to hours after an injury may determine if a condition is deteriorating or improving.

The physical exam may be done at different stages, depending on the nature of the injury and the type of setting in which it is being evaluated. An on-field injury during the course of competition may require a triaged history and focused exam to determine whether the athlete can be safely removed from the field of play. On removal, a more thorough history and physical exam can be performed, either on the sideline or in the locker room. Any athlete, whose injury is deemed to be more severe than can be adequately stabilized and treated on-site should be immediately transported by ambulance to the appropriate health care facility, such as the local emergency room.

Diagnostic Tests

Diagnostic testing may provide helpful clues to the type of injury. Specific tests used and their utility vary. Many injuries require no diagnostic testing at all. Depending on the circumstances, helpful information can be gathered from a variety of diagnostic sources. Computed tomography (CT), magnetic resonance imaging (MRI), and neuropsychological testing may provide information about a head injury. Bone scans, X-rays, ultrasound, compartmental pressure testing, CT scans, and MRI scans can be helpful in musculoskeletal injuries. Laboratory tests, including blood tests and urine tests, as well as some imaging modalities, such as ultrasound or CT scan, can be helpful in chest and abdominal injuries. The type and severity of injury often dictate the need for further diagnostic testing.

Treatment

Treatment of acute injuries varies as widely as the types of acute injuries. Minor scrapes and bruises may require no interventions at all. Intracranial bleeds or abdominal visceral lacerations may require emergency surgeries. Treatment always begins with addressing the basic life support ABCs and when the athlete is stable from a cardiopulmonary standpoint. When the clinician is fully cognizant of any potential spine injuries, further interventions can be done.

A common mnemonic for the treatment of simple, acute musculoskeletal injuries is RICE: *r*est, *i*ce, *c*ompression, and *e*levation. Analgesics may be necessary to control pain in acute injury and rehabilitation settings. Certain injuries may also require casting, bracing, or other form of support or immobilization, and may require nonemergent surgical interventions as well. Physical therapy or other forms of rehabilitation are often used to help an athlete recover from an injury. Occasionally, modalities such as ultrasound, iontophoresis, electrical stimulation, and others can be helpful in getting an injured athlete back to play.

Prevention

The area of injury prevention has become a very important focus of most sports and their governing bodies. It is the reason why protective equipment has been instituted and mandated in many sports. Helmets were introduced into the National Football League and have successfully decreased concussions and head trauma. Mouthguards are now a mainstay in many sports to minimize dental injuries. Contact sports such as lacrosse, field and ice hockey, and football require pads and helmets. People in positions of high risk for contact and injury, such as the catcher in baseball or the goalie in hockey, may be required to wear different safety equipment from others in the same sport at lower risk. Modifications have also been made to playing surfaces in an attempt to minimize injuries, such as the increasingly common synthetic turf in replacement of grass fields or the breakaway bases found on many baseball and softball diamonds. Rules have also been instituted to minimize injuries. For example, head-to-head contact in football is penalized due to safety concerns in allowing this type of collision. Injury prevention will continue to be a focus of all sports, and new equipment, gear, and rules will continue to figure in sports.

Return to Sports

Many acute injuries require little or no intervention and do not prevent athletes from missing any time from their sport. Return to sports is usually dictated by the athletes' ability to recover to the extent that they can function at a level high enough to be productive in their sport and be able to protect themselves from further injury. This means that they must recover full range of motion, sensation, and enough strength to participate without placing themselves or others at higher risk of additional injury. Some acute injuries can be career ending, as many spinal cord–injured athletes have tragically discovered. Other injuries, such as fractures and ligament tears, can have a prolonged recovery period, often with a surgical and postoperative phase with extended rehabilitation, before one can get back to competitive sports. On return, some injuries require further preventive measures, such as bracing or equipment changes, for the athlete to continue to participate.

Sports Injuries, Overuse

Injuries can be broadly divided into two categories: chronic and acute. Chronic injuries are problems that develop over time, often in a predictable manner, and may be the result of repetitive overuse of a region of the body.

The human body is remarkably adaptable to physical stresses. Force loads on tissues cause microtrauma and tears of those tissues. The body reacts to this by rebuilding, reinforcing, and strengthening those tissues as it heals them. An increase in the stress on a bone, such as with initiating a new running program, causes a reactive increase in bone matrix, stability, strength, and integrity. Increases in tensile or shear forces of tendons, ligaments, and muscles cause the body to adapt and strengthen these structures as well. When the balance of microtrauma and repair is disrupted, the tissues are unable to heal adequately because tissue breakdown occurs at a rate greater than healing. Over time, the result is development of pathologic tissue that becomes painful and weak. This can occur from excessive loads placed on normal tissues, normal loads applied abnormally to tissues, or normal loads applied to abnormal tissue. Chronic injuries, such as stress fractures, shin splints, exertional compartment syndromes, and tendinopathies, can then result.

Clinical Evaluation

The number of chronic injuries is on the rise in many of our young athletes as we have seen a transition from the multisport athlete to the year-round, single-sport athlete. This has taken away the variety of physical experiences from participation in multiple sports as well as the relative rest that athletes undergo with the change in sports seasons. The clinical evaluation of chronic injuries is imperative to the diagnosis and the treatment of the injury. Chronic, or overuse, injuries represent a significant portion of injuries in many sports. Early and accurate diagnosis can allow for early intervention and breaking of the overuse cycle. The earlier the diagnosis, the more likely the athlete can return to sports in a timely fashion.

History

History is the most important component to helping an athlete with an injury. The history provides the clues to an accurate diagnosis and can give the clues to why the chronic injury developed in the first place. The history should be approached with two outcomes in mind: First, by determining the type of injury present as accurately as possible; and, second, by determining why this injury has occurred. The primary symptom of an overuse injury is pain. It is important to determine when the pain began initially, as well as the descriptive properties of the pain—sharp, dull, ache, burn, and so on. Associated mechanical symptoms such as locking, clicking, or popping should also be noted. Accompanying symptoms of swelling, bruising, and neurovascular problems are also important. The timing of the pain in relation to the athlete's activities may give clues to the extent of the injury. Most chronic injuries follow a typical pain pattern. Initially, they are often noted as a vague ache or discomfort in the few hours to days after a workout. This may evolve in severity and duration of discomfort as the injury progresses, and limitations begin to occur with minimal activity or even at rest. The timing and quality of the discomfort, as well as any change in these factors especially as they relate to specific activities, can give important clues as to the severity of the chronic injury. A history of similar injuries in the past in the same or different locations can aid one in assessing the risk of injury recurrence.

To answer the question "why" an injury developed requires more of an investigative approach. These injuries can have multiple causes. Repetitive overuse may be from training errors, poor mechanics, strength and flexibility imbalances, nutritional deficiencies, poor or inadequate equipment, underlying systemic disease, poor nutrition, or anatomical malalignments and can all lead to chronic tissue injury.

Physical Exam

The physical exam for a chronic injury should initially focuses on the area of pain or concern. Observe for swelling, bruising, deformity, or other obvious abnormality. Gentle palpation can help localize tenderness, the anatomical structures involved, and any accompanying edema. The affected joint or limb should then be put through its usual passive and ultimately active range of motion for evaluation of limitations of movements and painful movements. Resisted testing of isolated muscles, ligaments, and tendons, as well as provocative maneuvers such as the test for shoulder rotator cuff impingement, may further specify the type of injury and the structures involved. A thorough neurovascular exam of the area should be included, and one should always evaluate the joint above and below a possible injury.

Once the diagnosis has been established by history and exam, the examiner should again change the focus of the exam to the question of "why" the injury developed and, more specifically, the intrinsic causes of the chronic injury. These can include anatomical malalignments and subsequent abnormal tension and stresses across structures. There may also be underlying strength or flexibility imbalances of the affected extremity or of the athlete's core musculature. In the case of adolescent or growing athletes, growth alone can cause increased stress on structures incapable of handling the loads placed on them, such as that found in the pain from Osgood-Schlatter disease of the knee or Little League shoulder or elbow. A thorough physical exam for a chronic injury should include a psychological assessment. Fatigue, depression, and psychological stress can all predispose an athlete to injury, causing an overtraining syndrome, which results in physical and psychological inability to exert at an otherwise normal level, much less a highly competitive level.

A dynamic exam reproducing the repetitive movement may be very revealing. This may help discern an abnormal gait, throwing pattern, or technique.

Diagnostic Tests

With chronic injury, diagnostic tests may help confirm the diagnosis suspected based on the history and physical exam. Radiography (X-ray), magnetic resonance imaging (MRI), computed tomography (CT), or bone scan may confirm a suspected stress fracture or bone problem. Musculoskeletal ultrasound or an MRI scan helps evaluate soft tissue injury such as tendinopathies, bursal problems, or ligamentous injury. Video analysis of an athlete's form can be helpful with the dynamic physical exam to better note the details of the motions and more easily discern potential problems. Diagnostic tests are not required to make most chronic injury diagnoses but can be helpful in the cases where there is a doubt.

Treatment

The ultimate treatment for any chronic, overuse injury is stopping the repetitive movements causing the pathology. These injuries require rest. This allows the time for the body to prepare the injured tissue in the cycle of tissue breakdown and healing to adapt to stress. The time required for this to occur is variable; healing can take weeks to months. The rest is relative, only the excessive stressors to the damaged tissue need to be removed. Not all chronic injuries require immobilization or complete removal from all activity. A marathon runner who develops a fibular stress fracture from overtraining may have to discontinue running for several weeks to allow the fracture to heal; however, he or she may be able to maintain his or her cardiovascular fitness and overall endurance by cross-training with a bike or an elliptical trainer or by swimming.

Additional treatments—such as analgesics to control pain, frequent icing, and occasionally topical, oral, or injected steroids—in a chronic injury may be helpful. It is also imperative to correct the underlying problems that led to the injury in the first place. Clinicians should counsel about appropriate training and escalation of activity when applicable.

Prevention

Chronic injuries develop over a long period of time and have underlying causes that are treatable. Therefore, theoretically these injuries are all preventable. Counseling is the most important component of prevention. Preventing overuse injuries requires appropriate warm-up, stretching, and strengthening, as well as a well-rounded training program that includes aerobic, anaerobic, strength, flexibility, agility, and proprioceptive conditioning, all of which help prevent injury. Equally important is knowing the body's capabilities and limitations and allowing adequate rest for the athletes in the preseason and during the season and an adequate period of complete rest annually. For most athletes, it is recommended that they have 2 to 3 months per year of complete rest from the repetitive physical demands of their sport as well as psychological rest. Teaching and coaching proper technique, and appropriate equipment selection cannot be overemphasized. Worn-out or inappropriately sized equipment can be the causative factor in many chronic injuries.

Return to Sports

The athlete is able to return to sports from a chronic injury when the pain has subsided, full range of motion has been regained, and adequate strength has returned. He or she should not return before the underlying cause of his or her injury is addressed, so as not to cause recurrence. Additionally, the return requires a slow progression because resting the affected tissues causes a relative deconditioning. Not allowing appropriate rest for healing to occur will cause recurrence of the initial injury.

Sports Injuries, Surgery for

With participation in competitive sports increasing throughout society, the number of sports injuries has increased as well. Most sports injuries are treated nonsurgically, with the use of rest, bracing, physical therapy, and rehabilitation. Today, however, more and more sports injuries are being treated with surgery instead. There are many reasons for this. Over time, our knowledge and experience in sports medicine have evolved. Studies have shown that certain injuries, such as anterior cruciate ligament (ACL) tears, recover better if they are treated surgically. In addition, the invention of newer imaging techniques such as magnetic resonance imaging (MRI) has allowed sports medicine physicians to more precisely diagnose torn structures. Advances in surgical instrumentation and technique have made it possible to surgically repair ligaments, tendons, and cartilage and restore native anatomy without damaging the surrounding tissue. Specifically, the advent of arthroscopy, which allows joint surgery to be performed through tiny incisions using miniature instruments, has been the major surgical innovation in the field of sports medicine.

The rapid increase in the number of sports injuries combined with the growing interest among health care professionals to optimize treatment has led to an explosion in the field of sports medicine. This dedication to perfecting the repair and rehabilitation of sports-related injuries is manifested by two prominent professional sports medicine societies.

Professional Sports Medicine Societies

The American Orthopaedic Society for Sports Medicine (AOSSM) is made up of more than 2,000 orthopedic surgeons who are dedicated to the field of sports medicine. Most members are team physicians whose research has advanced our knowledge of sports injuries. The society was founded in 1972 and often works directly with physical therapists, athletic trainers, and other health professionals interested in sports medicine. Each year, an annual meeting is held in which members meet to discuss and present new ideas and techniques in the field. New recommendations for the treatment of various sports injuries and guidelines for prevention are episodically published by the society.

The American College of Sports Medicine (ACSM) includes all health professionals interested in sports medicine. It has more than 20,000 national and international members, including physicians, surgeons, physical therapists, athletic trainers, and other health professionals who are dedicated to the field of sports medicine. Founded in 1954, the stated purpose of this college is to advance health through science, education, and medicine. Presently, it is headquartered in Indianapolis, Indiana. Each year, the college holds meetings, exhibitions, conferences, and team physician courses that educate and integrate scientific research in exercise science and sports medicine.

Sports Injuries

Each individual sport places distinct stresses on specific joints and muscle groups. Injury rates vary between sports, depending on which structures are at risk. Sports in which the athlete constantly uses his or her arms to throw, shoot, block, or bear weight place high demands on the shoulder, elbow, and wrist. Sports in which the athlete has to move quickly and change direction have a high incidence of lower extremity injuries in the hip, knee, and ankle. Baseball pitchers, swimmers, and tennis players have a high rate of shoulder and elbow injuries. Gymnasts often use their arms to walk or push off and have a high incidence of elbow and wrist injuries. Soccer, basketball, and field hockey athletes need to pivot and often get knee and ankle injuries. Hip injuries are common in kicking sports, such as soccer, and also in dancing. Not surprisingly, foot injuries also occur frequently in dancers.

Most sports injuries do not require surgery. Sprains or strains occur when the muscles or ligaments around the joint are stretched more than they can withstand and suffer tiny tears. These injuries usually heal well over time. Tendons and bursae can become irritated and inflamed, leading to tendinitis or bursitis. These are generally overuse injuries and also heal well over time. These sports injuries are commonly treated with a combination of rest, anti-inflammatory medications (e.g., ibuprofen), and physical therapy aimed at stretching and strengthening the appropriate muscle groups.

Certain injuries do not heal well with rest and rehabilitation and generally require surgery. There are various reasons why some injuries require surgery while others do not. In some cases, the injured structure is located in a joint, where its blood supply and capacity to heal on its own is limited. In others cases, repetitive injuries have stretched the structure too thin and compromised its function. Common sports injuries that require surgery in the shoulder joint include tears of the rotator cuff and labrum and a stretched shoulder capsule resulting from multiple shoulder dislocations. In the knee, ACL tears, meniscal tears, cartilage injuries, and loose bodies are common sports injuries best treated with surgery. In the ankle and elbow, stretched ligaments from repetitive sprains may require repair or reconstruction.

Terminology

An understanding of surgery in sports medicine necessitates a familiarity with the terminology of sports medicine procedures. The following is a list of commonly used terms.

Diagnostic Arthroscopy

Arthroscopy is a minimally invasive surgical technique that uses an arthroscope or small camera inserted into a joint. This will be discussed in more detail below. A diagnostic arthroscopy is that part of the procedure where the surgeon examines the entire joint to look for any sources of pain.

Meniscectomy Versus Meniscus Repair

The *meniscus* is a rubbery cushion inside the knee between the thigh and leg bones. A twisting knee injury can cause a tear in the meniscus. *Meniscectomy* is a common knee arthroscopic surgery in which a small tear in the meniscus is removed. The remainder of the meniscus is left alone. *Meniscectomy* differs from *meniscus repair* in which the tear is not removed but is instead sutured back together.

Repair Versus Reconstruction of Tendons and Ligaments

Repair involves using sutures to tighten an injured structure that has stretched. A repair is usually done for injured ligaments or tendons that have a good capacity to heal but are too lax in their present state. Examples include repair of torn ankle ligaments and patellar tendon repair. *Reconstruction* involves replacing an injured tendon or ligament with a separate structure that can perform the function of the injured structure. Reconstruction is usually performed on injured tendons or ligaments that will not heal properly over time. For example, ACL tears in the knee are usually treated with ACL reconstruction, using a hamstring or patellar tendon to replace the function of the torn ACL.

Loose Body

A free-floating piece of bone or cartilage that has broken away and is moving around a joint is referred to as a *loose body*.

Excision

Excision means removal. For example, a loose body in the knee joint is often treated with excision.

Debridement

Debridement is the cutting out of unstable, frayed pieces of a torn structure. The process of debridement smooths the roughened surfaces of the injured structure so that it does not get caught in places during joint motion. For example, a tear in the labrum of the shoulder or hip is often treated with debridement.

Chondroplasty

Chondroplasty is the smoothing of torn cartilage on the joint surface. Chondroplasty is usually done with the aid of an arthroscopic shaver that levels out the cartilage surface by selectively removing torn and unstable fragments.

Microfracture

In *microfracture,* tiny holes are made in the exposed bone in an area of the joint where the full thickness of the cartilage has been completely damaged. Microfracture uses a miniature awl to perforate the exposed bone in a joint. The goal of microfracture is to stimulate the bone to bleed and form a blood clot over itself. Over time, this blood clot can help form a new type of cartilage, called fibrocartilage, over the area of exposed bone.

Arthroscopy

Arthroscopic surgery uses multiple small incisions (1.5 inches [in.; 1 in. = 2.54 cm]) placed around the joint, called *arthroscopic portals*. A long, thin, pencil-sized rotating video camera called an arthroscope is inserted through one of these portals and into the joint in question. The arthroscope is connected to a monitor, and the image obtained by the camera at the end of the arthroscope appears on the monitor. The joint requiring surgery is filled with a saline solution, and the surgery is done within this solution. The surgeon manipulates the camera with one hand while watching the video image of the joint on the monitor. The surgeon's other hand is used to manipulate the arthroscopic instruments to perform the surgery. Alternatively, a surgical assistant may be used to operate the camera or assist with other instrument manipulation.

Arthroscopy is a minimally invasive alternative to many open surgeries, with advantages including less pain, smaller incisions, and faster rehabilitation. Arthroscopy can be performed on many joints, but it is most commonly used in the knee, shoulder, elbow, hip, and ankle. The types of surgeries that can be performed arthroscopically and the joints in which they can be used are constantly expanding. The requirement for arthroscopic treatment is that the structure in question must be within the joint space and in an area that is accessible using arthroscopic tools. One of the primary indications for arthroscopy is diagnosis. In cases where the diagnosis is unclear after physical exam and imaging, some surgeons may opt to perform an arthroscopy to visualize the injured joint and find the problem.

Arthroscopy is done under sterile conditions in the operating room, as with any other surgery. Many surgeons will use specific positioning devices to allow the limb or joint to be in the ideal position for the procedure. Every arthroscopic procedure begins with a diagnostic arthroscopy, which entails looking around the entire joint to either confirm or determine the causes of the patient's symptoms. The joint surface and the ligaments and cartilage in the joint are thoroughly inspected for tears or abnormalities. The recesses, or pockets, of the joint are checked for fragments of bone or cartilage that may also indicate previous injury.

During the arthroscopy, the surgeon may use a variety of instruments. All instruments are long and thin, with a handle that the surgeon manipulates on one end and the active part of the instrument on the other end. A probe, or a small metal hook, is used to feel and move the cartilage and ligaments seen on the camera. An arthroscopic shaver is a tiny motorized instrument that is used to remove torn and injured tissue inside the joint in a controlled manner. The shaver is connected to a suction device that brings loose and torn tissue into the mouth of the shaver. The tissue is cut by the rotation of the cutter blade. By controlling the amount of suction and varying the types of cutter blades used, the surgeon can control how much tissue is removed. Other small instruments that fit through arthroscopic portals act as scissors, graspers, and cutters, to debride or excise loose pieces of cartilage or tears in the meniscus (knee) or labrum (shoulder and hip).

Commonly performed arthroscopic procedures include debridement, repair, excision, chondroplasty, and microfracture. With arthroscopic debridement, the surgeon can smooth the roughened surfaces that may be causing pain or excise any tissues that may be catching on other joint structures and causing painful symptoms. Ligament and tendon repair and cartilage injuries can also be treated with the aid of arthroscopy. Common arthroscopic procedures done in the shoulder include repair of rotator cuff tears, repair or debridement of labral tears, and tightening of a loose shoulder capsule. Knee problems such as ACL tears, meniscus tears, and cartilage injuries can be treated with meniscus repair or meniscectomy, ACL reconstruction, chondroplasty, or microfracture. Smaller joints such as the elbow, wrist, and ankle often require smaller arthroscopic equipment. Cartilage injuries and loose bodies of the ankle and elbow are often treated with arthroscopy.

Arthroscopic surgery has many benefits. When compared with open surgery, in which the joint is opened through a larger incision and the procedure is done under direct visualization, arthroscopy offers a minimally invasive approach. As noted earlier, the arthroscopic procedures use multiple tiny incisions, which result in a better cosmetic appearance. There is less disruption of the tissues under the skin and in the joint, which causes less scarring and stiffness. The smaller incisions also allow a smaller area of the joint to be exposed to the air, decreasing the risk of infection. Because patients have less pain after arthroscopy, they are able to participate in rehabilitation sooner.

Not all diseases or conditions involving a joint can be treated with arthroscopy. Some surgeries require large exposures of the joint, which arthroscopy cannot offer. Complicated arthroscopic cases may require the surgeon to repair the joint under direct visualization, with an open procedure. This most often happens if a structure that needs to be repaired cannot be reached through the small incision without causing injury to other structures or if there is poor visualization within the joint due to bleeding or other factors.

Most arthroscopic surgeries are done as outpatient cases, meaning that the athlete is able to go home on the day of the surgery. The incisions are small and can often be covered with an adhesive bandage strip. Depending on the type and location of the surgery, the surgeon will make recommendations regarding activity limitations. Some procedures will have strict restrictions on how one can use the operative site (e.g., crutches or lifting restrictions), while others may have no restrictions.

Recovery Time and Rehabilitation

Nearly all athletes who undergo arthroscopic surgery will need physical therapy before they can resume their normal sporting activities. Recovery time varies depending on the nature of the procedure. To return to sports, the patient must demonstrate full range of motion and full strength in the affected joint. The initial goal of physical therapy focuses on *regaining full motion* in the affected joint. After motion is gained and the surgical repair has healed sufficiently, the physical therapists will concentrate on *regaining strength*.

For complicated procedures such as knee ACL reconstructions, shoulder rotator cuff repairs, and shoulder labral repairs, full recovery takes 6 months to 1 year after surgery. For knee meniscal repairs and chondroplasty for cartilage injuries, return to sports generally occurs at about 3 months after surgery. For smaller procedures such as diagnostic arthroscopy, joint debridement, and meniscectomy, return to sports takes about 6 to 8 weeks.

Sports Massage Therapist

Sports massage therapy, a specialized branch of traditional massage, is a burgeoning profession worldwide, due to the growing need for it as an adjunct to traditional medical treatment. A 20% increase in demand has been projected over the next decade.

Manual massage (initially called "friction") is performed to improve muscle function and blood circulation via manipulation of the body's soft tissue. Based on the patient's needs and characteristics (e.g., athlete, elderly, pregnant, child), any of several massage treatment techniques or modalities may be used. Each therapist may develop his or her own unique style and may specialize in treating patients with certain diagnoses or conditions.

Sports massage therapy (also known as *manual medicine*) was developed to help athletes recover from an event or workout and to prepare them for top performance. It can be used before, during, and after an event. It is estimated that Americans spend more than $4 billion annually on massage therapy for a variety of reasons, including work, sports, rehabilitation from a motor vehicle accident, and also as a luxurious treat.

In the past few years, referrals for manual medicine have increased significantly and have been integrated into a permanent component of the athlete's training protocol, at all levels—from high school to professional athletic programs. It is a medical preemptive intervention based on the belief that a regimen of massage provides a competitive edge to the athlete. Sports massages are used for athletes as well as for those recovering from an injury. Sports massage is promoted by athletic trainers, team physicians, and sports medicine doctors to assist athletes to prepare their bodies to achieve optimal performance. In a field where a matter of seconds can mean the difference between victory and defeat and where the latest technologies are used to provide an edge over the opponent, sports massage is growing to be an important adjunct.

The reasons to incorporate manual medicine modalities on a regular basis range from aiming to win the gold medal in an Olympic event to assisting in the recovery process of a person with restricted range of motion due to injury. Sports massage is a logical choice, especially if the injury was caused after a sporting event such as a marathon. Preemptive intervention is crucial to prevent injuries. Massage can help promote symmetry and stability of the muscles and joints in the body, thereby avoiding the potential for injury due to abnormal movement or functioning of muscles or fascia.

Massage therapy has become a standard and integral component of athletic training in most sports clinics all over the world. The ultimate goal of a massage therapist is to improve emotional and physical health. The techniques and time spent for each session and the number of sessions may vary based on the physician's massage therapy prescription and goals, as well as the patient's expectations. Massage therapists can specialize in one or more particular techniques based on their interests, community needs, and the market. Currently, there are more than 50 common massage techniques used to promote a healthy mind and body. Each therapist will select a modality that is based on his or her previous experience as well as the needs of the patient.

Some common manual medicine modalities include Swedish massage, deep tissue massage, acupressure, and sports massage. In addition, doctors of osteopathic medicine (DOs) are fully licensed physicians who use various manual medicine techniques, known as *osteopathic manipulative treatment* (OMT), to assist patients toward a return to health. Typically, a massage therapist works along with a physician or athletic team. Most patients seek a massage therapist based on a referral and the specialty of the therapist. There is a wide range in the hours worked per week as well as income earned by massage therapists. One therapist may work 80 hours/week and another in the same area only 15 hours weekly. Income may vary from $30 to $200/hour, based on where the therapist is employed. Variations that may help explain the wide range of salaries include differences in training, which range from 500 to 1,000 hours; knowledge of basic anatomy, physiology, and kinesiology (study of human movement); and practical demonstration of skills. Other factors include interpersonal skills, which affect referrals by other clients, moral character, professionalism, referrals from physicians, attitude, empathy toward the patient, and the ability to engage the patient in a trusting and therapeutic relationship. Prerequisites to become a certified massage therapist include, at the minimum, completion of high school and a desire to assist others. Most massage therapy schools require attendance for at least 6 months and sometimes up to or beyond 12 months, depending on the particular modality specialized in.

In addition to didactic coursework and reading, it is mandatory to obtain experience in the various manual medicine modalities and techniques. It is worth noting that many allopathic medical schools are incorporating several related manual medicine techniques into their curriculum to give their graduates exposure to all forms of manual medicine.

Osteopathic manual therapy is a hands-on form of care. Osteopathic physicians use their hands to diagnose as well as treat injuries and musculoskeletal problems. The first osteopathic medical school was begun in 1892 by Dr. Andrew Taylor Still. Dr. Still was an allopathic physician who was frustrated with aspects of medical care in his time and sought to devise a better way of treating patients.

Most people enjoy getting a massage, and for patients who have been injured during a sporting event and for those who are competitive athletes, seeking the services of a specialist in sports massage therapy may promote speedy recovery, help maintain body shape and symmetry, decrease stiffness and soreness, and reduce the potential for injury.

Sports Socialization

Participation in recreational and competitive sports is widespread in Western cultures. The physical and psychological benefits of physical activity are well known, and most experts agree that everyone should engage in physical activity on a regular basis. Sports participation, including planned physical training and competition, has both positive and negative developmental consequences for participants. Positive benefits from participation include discipline, loyalty, physical development, improved self-esteem, teamwork, sportsmanship, time management, and lifetime patterns of fitness. Conversely, sports participation can also be related to stress, stereotyping, and risk-taking patterns. Sports socialization is the process by which individuals are introduced to sports, taught the physical and behavioral standards, and incorporated into the culture of sports. Parents, coaches, peers, and society all influence the process of socialization into sport.

Process of Socialization

There are numerous theories on the process of sports socialization. Common to most theories is that there is an initial introductory phase where knowledge, cultural norms, and skills of the sports are acquired. Children and adolescents often begin playing the sports that their siblings, friends, and parents find interesting and in which they participate. Depending on individual interests and innate skills, youth self-select the sports in which they would like to continue to participate. Following the introductory phase, individuals further develop their skills, associate with other participants, begin to view themselves as athletes, and are recognized by others as athletes.

Parents have the greatest influence on the sports socialization of their children and adolescents. With the goal of teaching their children positive values and traits, parents introduce their children to sports through game play, television, discussion, and watching as spectators. Parent interaction during sports can also offer opportunities to teach their children lessons regarding desirable morals and social behavior such as sportsmanship, loyalty, teamwork, and determination. It has been shown that children whose parents communicate the importance of sports and foster their training in them find greater enjoyment in sports participation. Surprisingly, parental pressure to succeed has not always been associated with decreased enjoyment.

Sports Goals/Beliefs

Individual motivation and definition of success are personal attributes taught through the socialization process. Two distinct goal orientations have been described: *task* and *ego*. The task-oriented individual describes success in terms of effort and self-improvement, while the ego-oriented individual describes success in terms of comparison with others and demonstrating superiority. Parents and coaches directly influence these two orientations by their actions and their focus on effort, hard work, and collaboration (task) or their focus on winning at all costs, impressing others, and demonstrating superior skills (ego). Similarly, the belief patterns of young athletes can affect their motivation to participate and work hard. Teaching youth that effort should be the focus during participation will foster a pattern of hard work and determination.

Gender Issues in Socialization

The athletic experience is often very different between boys and girls. Competitive males are seen as leaders and deemed role models. Classically male qualities and traits such as intimidation, dominance, insensitivity, and lack of emotional display are often fostered in the realm of sports. These qualities are vastly different from the traits that are often fostered in females during social development (nurturing, sensitivity, and emotionality). Over the past century, women's involvement in competitive sports has become socially accepted and supported. Despite the great strides in equality, female athletes are still expected to possess these dual and often discordant sets of traits.

Burnout and Discontinuation of Sport

A tenet of physical education educators has been to socialize children to sports as a means of beginning a life of physical activity. The idea that involvement in sports as a youth will continue into physical activity as an adult is a common belief; however, it is well documented that individuals tend to discontinue sports participation with increasing age. Research has demonstrated that a pattern of physical activity as a youth can lead to a lifelong engagement in physical activity, but even more consistent is the observation that a pattern of inactivity as a youth leads to inactivity as an adult. Athletes decide to discontinue sports for many reasons, including burnout, changing interests, and changing life situations (work, school, and parenthood).

Burnout among athletes is a phenomenon seen in youth who have been very involved in sports suddenly losing interest in continuing participation and competition. This is seen more often in individual-sport athletes whose lives are consumed by participation in their sports. These athletes often describe a lack of social interaction and a sense of being a one-dimensional individual. Focusing on developing skills outside the sports arena and being involved in more than one sport may decrease the likelihood of burnout and desocialization from sports.

Static Stretching

Static stretching is a form of stretching that slowly elongates the muscle. This can be done actively or passively. In the active form, the person stretches the desired muscle or muscle group to the point of discomfort and holds this for a period of time. The passive form involves a second person (usually a physical therapist or athletic trainer) who assists in stretching the desired muscle or muscle group. Whether active or passive, the goal of the static stretch is to desensitize tension sensors in muscles. Once this occurs, the muscle is able to take on more force before it becomes damaged. A long-standing belief is that this leads to a reduction of injuries as the muscle is more compliant.

Uses

Static stretching has been used as a treatment modality in injury rehabilitation. After a muscle injury, the torn muscle fibers heal in a contracted pattern. Therapists can use static stretching to restore the muscle to its normal length. This helps improve the range of motion in the affected body area. This is usually done in the subacute phase of injury recovery. It can also be used for rehabilitation of certain joint injuries. A common example is stretching the shoulder capsule. Improper mobility following a shoulder injury may result in a frozen shoulder or adhesive capsulitis. The therapist may use static stretches (both active and passive) to improve the shoulder range of motion.

Static stretching has long been used in "warm-up" routines by those engaging in sports activity. The common thought is that loose muscles are less likely to be injured. Multiple studies show that static stretching before an athletic contest may cause small tears in the muscle and make the muscle more prone to injury.

A recent critical review of the literature showed that after a single bout of static stretching, muscle force and torque as well as jump height were diminished. However, when the static stretching was repeated over days to weeks, there seemed to be an increase in muscle force and torque. There was a positive effect of a single bout of static stretching on running economy but not on running speed. Based on these results, it is considered beneficial to perform regular static stretching but not immediately before an athletic contest. Muscles should be warmed by other types of stretching—mainly dynamic stretching.

Examples

An example of a static stretch is the *seated hamstring stretch*. This is performed by sitting on the floor with one leg straight out while the other is bent at the knee with the foot touching the opposite thigh. Then, while keeping the back straight, reach forward with the arms by bending at the waist. A slight stretch should be felt in the hamstring. This is held for 15 to 30 seconds. It may be repeated two to three times.

Another example of a static stretch is the *butterfly stretch*. In the seated position, the knees are bent with the soles of the feet touching. The elbows are used to direct a downward force on the legs. This should cause a slight stretch in the adductor muscles (groin). This is held for 10 to 30 seconds. It may be repeated two to three times.

Sternal Fracture

Sternal fractures are rare yet potentially serious injuries in athletes. Few sports have a high risk of blunt trauma to the anterior chest wall, the main cause of most sternal fractures. Rapid deceleration injuries fall into this category, often resulting from motor vehicle accidents with the patient restrained. Such injuries are primarily seen in the trauma and emergency department setting, but the sports medicine physician should be aware of suspicious patient complaints associated with chest trauma. Awareness concerning sternal injuries may prevent missed diagnoses, unnecessary and expensive work-ups, and frustration for the athlete.

Sternal and stress fractures have been reported in golfers, weight lifters, and athletes involved in other contact and noncontact sports. Injuries have been reported in repetitive hyperflexion of the torso, such as in exercises that involve sit-up postures. Athletes involved in high-speed sports, high-altitude sports, and high-energy contact sports are theoretically at risk. Other patients at risk are those with osteoporosis or osteopenia, those with severe thoracic kyphosis, and any patient subjected to cardiopulmonary resuscitation.

Anatomy

With direct chest wall trauma, the sternum may fracture at any point. The sternum consists of three parts: (1) the manubrium; (2) the body, or corpus; and (3) the xiphoid process. The xiphoid process forms the distal tip of the sternum. The joint between the manubrium and the body, the manubriosternal joint, forms the sternal angle at the second rib. The manubrium is found at the third and fourth thoracic vertebrae. The superior border is formed by the suprasternal notch. The clavicle and first rib articulate with the manubrium. The sternal head of the sternocleidomastoid muscle inserts at the anterior of the manubrium, along with the sternocostal head of the pectoralis major. The sternohyoid and sternothyroid muscles attach to the posterior surface of the manubrium. The rectus abdominus attaches to the distal xiphoid process.

Symptoms

The patient's history may reveal an abrupt stop or direct chest wall trauma during an athletic event. Initial symptoms of a sternal fracture include acute sternal pain and tenderness with palpation directly over the sternum. There may be soft tissue swelling and bruising but usually not a palpable deformity as most fractures will be nondisplaced. The examining physician should keep in mind the cause of the injury, should influence the acuity of the assessment, and should plan for the patient. For example, sternal fractures related to motor vehicle seat belt injuries are not associated with thoracic vascular injuries or spinal cord injuries and are, therefore, not associated with a significant mortality risk. With more serious traumatic injuries, there may be signs of respiratory compromise, including retractions, tachypnea, and cyanosis. Other conditions associated with direct trauma include rib fractures, pulmonary and cardiac contusion, and intrathoracic vascular trauma, including aortic rupture, cardiac tamponade, flail chest, pneumothorax, hemothorax, spine fractures, spinal cord injuries, diaphragmatic rupture, tracheobronchial rupture, and esophageal rupture.

Diagnosis

The American College of Surgeons provided guidelines in the Advanced Trauma and Life Support algorithms for the management of chest trauma (see the list of recommended readings). Any patient seen initially who has sustained blunt thoracic trauma should have a primary survey for potentially life-threatening conditions, including a complete history and physical exam. Initial studies and labs may include complete blood count, electrolytes, coagulation panel, type and screen, arterial blood gas, and electrocardiogram (EKG). Initial radiographs of the sternum should include a lateral view and a frontal view, with the patient prone and slightly rotated away from the midline. These views have a reported sensitivity of greater than 90%. X-ray (radiographs) may also diagnose other potentially serious injuries, including rib fractures, hemothorax, pneumothorax, and pulmonary contusion.

Radiographs remain the initial gold standard for the evaluation of sternal injury. A frontal view and a lateral view should be obtained, as any displacement usually occurs in the sagittal plane. Any evidence of more serious diagnoses such as arrhythmias, hemodynamic instability, or a widened mediastinum should be evaluated with echocardiography and, possibly, computed tomography scans. The body, or corpus, of the sternum is the area most frequently injured. Ultrasound may be slightly more sensitive in diagnosing fractures, but most experts still consider radiographs to be the first initial choice.

Treatment

After the initial work-up, and after potentially life-threatening injuries have been excluded, further course of treatment involves pain management, usually with oral analgesics. There should be a period of relative rest, especially from contact sports or the offending activity. The patient should be encouraged to perform deep-breathing exercises, as with rib fractures, to prevent atelectasis and pneumonia.

Rehabilitation and Return to Sports

The athlete should be encouraged to maintain cardiovascular fitness if unable to participate in practice or contact drills. Otherwise, the decision to return to play should be made on the basis of whether the athlete can compete painfree in his or her event. The literature on rehabilitation is scanty, but therapy for similar injuries includes early rest and lower extremity exercises, followed by range-of-motion exercises, and eventually chest- and core-strengthening exercises. The time required for complete resolution of pain varies; pain can persist from a few months up to a year or longer.

Sternoclavicular (SC) Joint, Separation of

The *sternoclavicular joint* (SCJ) is located on the anterior chest where the clavicle (collarbone) meets with the sternum (breastbone). Separation of the SCJ is relatively uncommon in athletes and is usually caused by significant trauma to the area resulting from high-velocity injuries, such as those incurred in contact sports or motor vehicle accidents. Separation of the SCJ may be life threatening because of the large blood vessels that run just underneath the clavicle. The practitioner must have a high level of suspicion for these injuries to recognize them when they occur.

Anatomy

The SCJ is a two-sided joint and provides the only true joint connection between the trunk and the upper extremity. The SCJ has an inherent instability, with less than one half of the inner clavicle bone articulating with the upper angle of the sternum. This bony articulation of the joint is inherently unstable. Several ligaments help stabilize the bony anatomy of the joint. These include the weaker anterior and the stronger posterior sternoclavicular and interclavicular ligaments, as well as the costoclavicular ligament. Because of the bony instability, the ligaments are at increased stress and are more susceptible to injury (sprain or disruption) (Figure 1).

Important structures lie in direct proximity to the SCJ. Major vascular structures such as the internal thoracic artery and vein, and the brachiocephalic and subclavian veins travel just underneath the clavicle. Deeper important structures in the SCJ and clavicle include the subclavian and brachiocephalic arteries, the trachea (wind pipe), the esophagus, and the brachial plexus (a major group of nerves that innervate the upper extremity). Injuries to these structures are the main concern following an SCJ separation.

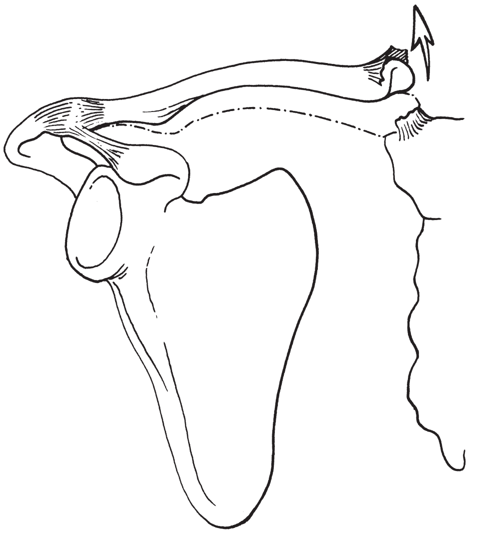

Figure 1 Sternoclavicular Joint Separation

Note: Sternoclavicular joint (SCJ) separation is a sprain of the ligaments of the SCJ, which connects the sternum, or breastbone, with the clavicle (collarbone).

Causes

The most common cause of SCJ separation is vehicular accidents; the second is an injury sustained during participation in sports. This usually involves an athlete falling on one side with an opposing force to the top of the opposite shoulder, such as a pile-up in football or rugby.

The most common mechanism of injury is a blow to the outer aspect of the shoulder, such as a fall on the shoulder. This most commonly levers the medial clavicle (the portion of the clavicle closest to the sternum) anteriorly, increasing the strain on the supporting ligaments and potentially leading to separation of the SCJ. Less commonly, the injury may be caused by a direct blow to the clavicle at its junction with the sternum.

Injuries to the SCJ ligaments fall into three categories. Grades I and II are mild or moderate sprains with minimal displacement of the bony elements of the joint. Grade III injuries are severe and involve complete ligament disruption and significant joint displacement. SCJ separations can occur in both anterior and posterior directions. Anterior SCJ dislocations are more common and less threatening than posterior dislocations. Posterior SCJ dislocations may be life threatening due to the potential damage to vascular structures deep to the SCJ and clavicle. Prompt diagnosis is paramount with posterior dislocations to avoid these serious potential complications.

Diagnosis

Patients generally present with pain and swelling in the area of the SCJ following a history of an acute injury. However, as a result of the significant force needed to cause injury to the SCJ, the patient may have other traumatic injuries that distract both the patient and the examiner from the SCJ injury. The patient may have other life-threatening injuries that warrant immediate attention. A high index of suspicion is required in trauma situations to detect SCJ injuries. Conversely, when an SCJ injury is suspected (especially a posterior dislocation), patient stability should take priority by first assessing the patient's airway, breathing, and circulatory status.

The patient with an injury to the SCJ often has severe pain at the joint that is increased with any movement of the arm, particularly when the shoulders are pressed together by a lateral force. The patient usually supports the injured arm across the trunk with the unaffected arm. The affected shoulder appears to be shortened and thrust forward when compared with the normal shoulder. The head may be tilted toward the side of the dislocated joint. The patient's discomfort increases when he or she is placed in the supine position, at which time the involved shoulder will not lie back flat on the table.

Any injury to the SCJ is difficult to assess with standard X-ray films; however, there are several specialized views, such as the *Heinig view* and *Hobbs axial or serendipity view,* that can make assessment easier. Many experts agree that computed tomography (CT) is the ideal method to image the SCJ. CT is much better at distinguishing separation of the joint from fracture. Additionally, a chest CT with contrast material can also assess the major important structures that run underneath the SCJ.

Based on the degree of injury to the SCJ, injuries are classified as Grades I, II, and III. With Grade I sprains, there is stretching and partial tearing of the SC ligaments. The costoclavicular ligament is usually not involved. With Grade II SC sprains, there is complete tear of the SC ligaments and the SC capsule. The costoclavicular ligament may be stretched or have partial tearing. Instability of the SCJ is present with possible subluxation. Grade III sprains involve a dislocation of the SCJ either anteriorly or posteriorly, with complete tearing of the SC and costoclavicular ligaments.

Treatment

Treatment of SCJ separation depends on the severity of injury. Mild ligamentous sprains (Grade I) are stable and are always treated conservatively. Ice is recommended initially to reduce the inflammation. The involved extremity is immobilized in a sling for 1 to 2 weeks, followed by early range-of-motion exercises.

Grade II sprains differ from Grade I sprains in that a joint subluxation has occurred. The capsule, intraarticular disk, and costoclavicular ligaments may be partially disrupted. The sprained SCJ is stable and can be painful. These injuries can usually be reduced satisfactorily by drawing the shoulders backward as if reducing and holding a fracture of the clavicle. A clavicle strap can be used to hold the reduction. A sling and swath is used to hold up the shoulder and to prevent motion of the arm. The patient should be protected from further injury for 4 to 6 weeks.

SCJ dislocations (Grade III sprain) are the most severe in the continuum of SCJ injuries. This is considered an unstable injury, and if posterior dislocation occurs, the underlying structures can become compressed and may be life threatening. The treatment of choice is a closed reduction restoring the normal bony anatomy of the joint. Techniques for this type of reduction depend on the type of dislocation and should be performed as quickly as possible. If an anterior dislocation has occurred, the patient should be informed that these injuries have a high incidence of recurrent instability but that the symptoms rarely limit normal activities. This avoids misunderstandings later in the treatment course.

Return to Sports

The return-to-play decision must be made with the athlete's well-being as the single most important deciding factor. Consideration should be given to the athlete's ability to move the arm through a full range of motion. Strength is vitally important so that athletes can both protect themselves and be effective in their sport. Special custom padding (or shoulder pads) can be worn to protect the top of the shoulder or the front of the sternum. Even after return to play, it is not unusual for the athlete to experience periods of discomfort for up to several months.

Stimulants

Athletes have been known to use stimulants in and out of competition. Most stimulants are banned by the World Anti-Doping Agency (WADA), but a few stimulants, such as caffeine, are monitored and allowed up to certain levels in the urine.

Stimulants are substances that activate the sympathetic nervous system. This is the part of human physiology that gives us the “fright, fight, or flight” response. The sympathetic nervous system is what gives a person the burst of energy, power, and alertness to deal effectively with a threat or stressor. In the wild, it is the response we would have if we were threatened by a hungry predator. Similarly, it is the response we feel with the stress of public speaking or the excitement of competition. Physiologic effects include increased heart and breathing rates, dilation of the pupils, and sweating. A person would also feel a burst of energy, a heightened state of alertness, and possibly improved concentration or even euphoria. Stimulation of the sympathetic nervous system also inhibits gastric motility (activity in the intestine), stimulates piloerection (goose bumps, or hair standing on end), and liberates nutrients in the body for muscle action.

There are many different types of stimulants, and they come in different forms and strengths. Amphetamines, nicotine, and even cocaine all fall into the category of stimulants. The most commonly used stimulant is caffeine. This is found in different concentrations in *coffee,* tea, soft drinks, and energy drinks. A typical cup of coffee (8 ounces [oz; 1 oz = 28.34 grams]) generally has approximately 100 milligrams (mg) of caffeine (although larger sizes of stronger brewed coffee may have up to 150 mg). Tea usually has around 50 mg per cup (8 oz), and soft drinks have between 50 and 65 mg per 12-oz serving. Energy drinks may have up to 150 mg of caffeine per serving. Soft drinks are required by the Food and Drug Administration (FDA) to keep caffeine levels below 65 mg per 12-oz serving. This rule does not apply to energy drinks, and they often come in serving sizes larger than 12 oz. Some energy drinks containing more than 300 mg of caffeine have been marketed. In addition, energy drinks or dietary supplements may also contain other ingredients that have benign- or exotic-sounding names but still have stimulant properties. Common examples of these lesser-known stimulants include guarana, ma huang, and yohimbe.

Caffeine is also available in a concentrated tablet form, and it is used to increase alertness, energy, and mood. Stimulants such as caffeine also have an appetite-suppressive effect, and they have been used to aid in weight loss. Stimulants do have a performance-enhancing effect in some sports. They have been used by athletes to increase the utilization of body fat for energy and to decrease perceived effort, particularly during intense endurance training.

Caffeine in particular has an interesting history when it comes to sports. In the 1980s and 1990s, caffeine was a banned substance, and several athletes were banned for positive tests. Before January 2004, caffeine levels over 12 micrograms/milliliter (μg/ml) in the urine were unacceptable. Since that time, caffeine has been removed from the list of banned substances by WADA. It is still considered a restricted substance with the National Collegiate Athletic Association (NCAA; the governing body for college sports). If the concentration of caffeine in the urine exceeds 15 μg/ml, the athlete can be disqualified. Urine concentration levels vary per individual, but, in general, to exceed this level, an athlete would have to ingest around 500 mg of caffeine 2 to 3 hours prior to the test.

Cathine and ephedrine are still restricted by WADA. Cathine is a stimulant related to amphetamines and is found in the khat plant. It is a Schedule IV drug in the United States (prescription medication) and is used as an appetite suppressant and decongestant. Cathine is prohibited by WADA when its concentration in urine exceeds 5 μg/ml. Ephedrine is commonly found in over-the-counter cold remedies, antihistamine products, energy drinks, and dietary supplements. Ephedrine and methylephedrine are prohibited by WADA when their concentration in urine exceeds 10 μg/ml. Athletes are responsible for knowing all the contents, effects, and consequences of any product that they ingest, and they are responsible for the product's effect on their test results.

The stimulant epinephrine (adrenaline) is included with some local injectable or transdermal anesthetic agents such as lidocaine or novocaine. Use of small amounts of epinephrine in this form is not prohibited.

The stimulants amphetamine and dextroamphetamine have been used as a treatment for attention deficit disorder (ADD). Increase in the concentration of these medications makes them beneficial.

Anyone who takes stimulants should be aware of their potential side effects. Because there is an increase in heart rate and blood pressure, heart attack or stroke is possible. They can temporarily raise blood sugar levels in patients with diabetes and contribute to insomnia. Overdose or long-term abuse of stimulants can cause paranoia, depression, and psychosis. Stimulants such as caffeine can cause stomach cramps, dizziness, or tremor. Athletes ingesting stimulants such as caffeine must take this into account before training or competing, particularly in endurance events or events that require a steady hand such as archery. Possession of certain outlawed stimulants such as cocaine, ephedra, or MDMA (3,4-methylenedioxy-*N*-methamphetamine; found, among other chemicals, in the recreational drug of abuse ecstasy) also has legal consequences.

Strains, Muscle

Strains often occur in muscles that move two joints, for example, the hamstring muscles that flex the knee and extend the hip joint. These are caused by overstretching or eccentric overload and are located in the muscle-tendon junction. These ruptures occur as a result of the intrinsic force generated in the athlete's muscles, often in the change between eccentric and concentric traction, which is common in high-speed sports and accounts for 10% to 40% of injuries in soccer, Australian Rules football, and American football. When the demand made on a muscle exceeds its innate strength, rupture may occur—for example, in overload during eccentric muscle traction.

Muscle and tendon strains are caused by an abnormally high tensile force that causes rupturing of the tissue and subsequent hemorrhage and swelling. The likelihood of injury depends on the magnitude of the force acting and the structure's cross-sectional area. The greater the cross-sectional area of muscle, the greater its strength, meaning the more force it can produce and the more force that is translated to the attached tendon. The muscle portion of the musculotendinous unit usually ruptures first because tendons, by virtue of their collagenous composition, are about twice as strong as the muscles to which they attach. Muscle strains are rated according to the extent to which associated motion is impaired.

Strains can be classified by the degree of rupture: First- and second-degree strains are partial ruptures, and third-degree strains are complete ruptures or disruptions. A first-degree, or mild, strain describes an overstretching of the muscle with a rupture of less than 5% of the muscle fibers. A second-degree moderate strain involves a more significant but less than complete tear of the muscle. The pain will be worsened by contracting the muscle. A third-degree, or severe, strain involves complete disruption of the muscle.

Abdominal Muscle Strains

Muscular strains are caused by direct trauma, sudden twisting or extension of the spine, or the Valsalva maneuver during weight lifting. The rectus abdominis is the most commonly affected muscle. Pain and spasm in the injured muscle may evoke muscle pain, and any attempt to do a sit-up, straight leg raise, or hyperextension of the back significantly increases muscle pain.

Elbow Strains

Injury of the elbow flexors will result in point tenderness on the anterior distal arm. Pain increases with resisted elbow flexion. With a triceps strain, resisted elbow extension produces discomfort. Strains to the common wrist flexor group result in pain on resisted wrist flexion, whereas strains to the wrist extensors produce pain with wrist extension.

Wrist and Finger Strains

In the hand, muscle strains involving the finger flexors or extensors tend to be more serious. These injuries may involve avulsing the tendon from the bone.

Jersey finger: A jersey finger typically occurs when an individual grips an opponent who simultaneously twists and turns to get away. The ring finger is more commonly involved.

Mallet finger: Mallet finger occurs when an object hits the end of the finger while the extensor tendon is taut, such as when catching a ball.

Cervical Strains

Usually, the sternocleidomastoid or upper trapezius is involved. Strains typically occur at the extremes of motion or in association with a strenuous muscle contraction, an external force, or weakness caused by poor posture.

Pectoralis Major Muscle Strains

The strain may be caused by sudden violent deceleration movements. The frequent underlying reason is abuse of anabolic steroid. The mechanism for this strain may be inappropriate muscle hypertrophy and an increase in power without a concomitant increase in tendon size.

Strains of the Hip and Thigh

Strains of the hip and thigh are encountered in many sports or exercise activities with repetitive motions. Signs and symptoms include a local sharp pain, edema, weakness, and difficulties to contract against resistance.

Hamstring Strain

Ballistic action or a violent stretch may cause this injury. Risk factors are poor flexibility and posture, muscle imbalance, improper preparation, muscle fatigue, lack of neuromuscular control, previous injury, overuse, and improper training technique.

Chronic Muscle Strains

A chronic muscle injury can be defined as an injury that is characterized by disruption of muscle fibers that results in muscle dysfunction. Chronic muscle strain injuries account for 10% to 20% of all muscle strain injuries. These injuries are frequently not recognized and can cause considerable disability, particularly in athletes without any preparedness. Aggressive rehabilitation aiming to restore muscle strength, flexibility, and neuromuscular control is a treatment of choice. Deep transverse friction, stretching of the fibrotic muscle area, and conditioning of the affected muscle with concentric isotonic or isokinetic exercises to eccentric exercises is recommended. Muscle endurance exercises must also be added early in the program.

Repetitive Strain Injuries

These injuries develop following repetitive or sustained submaximal work of the soft tissue structures (i.e., muscles, tendons, ligaments, and nerves). The number of repetitions, duration and intensity of the exercise, and ergonomics of the activity contribute to this damage. Management should include careful review of the exercise program and modification of the inciting repetitive loads. Surgery is reserved for those with no response to conservative therapy.

A history of muscle strain and muscle weakness is a risk factor for muscle strains. Muscle-strengthening programs with an eccentric loading to specific muscle groups create a risk for injuries. Injury-prone athletes should be addressed with appropriate interventions to reduce the incidence of muscle strains.

Strength Training for the Female Athlete

Since the inception of Title IX of the Educational Amendments of 1972, female participation in sports activities has increased dramatically. The desire to become stronger and thereby improve performance has also risen. Women who use strength training to improve performance range from high school athletes, to the postmenopausal age-group, to those pursuing strength training sports such as bodybuilding and power lifting. Strength training is defined as the use of barbells, dumbbells, machines, and other resistive methods to increase one's ability to exert or resist a force. *Strength training* and *resistance training* are often used synonymously. Strength training has many known benefits, including cardiovascular fitness, good body composition, better bone health, lowering of cholesterol, and better mental health. The female athlete may also benefit from the improved attitude and body image that strength training often provides.

The Gender Difference

It is well documented that the response of muscle tissue to strength training by both males and females is similar. Anatomic differences, however, influence the absolute changes females are able to make in their physique with strength training. Males have a longer growth period than females, resulting in the average adult man being larger than the average adult woman. For women, this results in a lower center of gravity and better balance compared with men. Men also weigh about 11 kilograms (kg) more than women but have about 11% less fat than women. Women have narrower shoulders and wider hips. Females have less muscle mass compared with an equally trained male. This accounts for a male's ability to jump higher, run faster, and lift heavier weights compared with an equally trained female. Hormonal differences (lower levels of testosterone) in females will prevent them from becoming too bulky or large. These differences still allow males and females to strength train the same way. However, a training program should be tailored to the individual.

Nutritional Aspects

While males and females may strength train the same way, their nutritional needs are different. Males tend to use glycogen (stored glucose) for energy during exercise, whereas females tend to use more intramuscular (within the muscle) fat. The popular idea of a higher–carbohydrate, low-fat diet for a female who is strength training may not yield the strength gains that a diet higher in healthy fats would. The common practice of females withholding calories to lose weight will further impair the benefits of strength training. The diet of a strength-training female athlete should still consist of carbohydrates, protein, and fat. Carbohydrates should have a low glycemic index (produce small fluctuations in blood glucose levels) and include fruits, vegetables, brown rice, enriched whole-grain breads, whole-grain prepared cereals, rolled oats, beans, legumes, and sweet potatoes. Protein consumption should be 1.4 to 1.8 grams (g)/kg daily. The optimal anabolic (muscle growth) environment would be one of several portions of high-quality, rapidly digested protein with carbohydrate throughout the course of a day. Appropriate sources of protein would include lean pork and beef, poultry, fish, eggs, and low-fat dairy products. These are also excellent sources of micronutrients such as vitamin B_{12} and D, thiamine, riboflavin, calcium, phosphorus, iron, and zinc. Vegetarianism limits the amount of protein in the diet, and these females are at risk for iron-deficiency anemia.

Healthy fat intake is often a difficult concept for females using strength training to improve their physique. Fat has more readily available energy per gram than any other food source. It is necessary for the production of endogenous (made by the body) hormones such as estrogen and testosterone. When fat is withheld from the diet, menstrual disturbances and compromises to bone health may occur. Healthy fat sources include nuts, seeds, nut butters, fatty fish (salmon and trout), fish oil supplements, flaxseed oil, sunflower oil, canola oil, avocados, and egg yolks.

The Preadolescent and Adolescent Female

Controversy has surrounded strength training by children. For many years, children and adolescents have been discouraged from strength training because of concerns about damage to the growth plate from shear forces. However, it is now accepted that strength training is a viable method of improving performance and decreasing risk of injury in young athletes.

The age at which strength training should begin has not been determined. It has been found though that strength training of sufficient intensity and duration can enhance strength beyond what is considered normal for a particular age. A child or adolescent is likely ready for strength training when he or she is emotionally mature, follows instructions, and understands the risks and benefits. The American College of Sports Medicine recommends that children strength train two to three times weekly on nonconsecutive days. By allowing for adequate recovery time, overuse injuries should be prevented. In this population of athletes, greater strength gains have been found in moderate-weight, higher-repetition exercises than vice versa.

The mode of training can be a challenge for this population. Adult-sized machines may be too large, and child-sized weight machines are expensive and difficult to find. Free weights are a good option, because they are readily available and inexpensive. It is imperative that proper supervision is provided. Barbells are often preferred over dumbbells as they promote better form. In children and adolescents, much of the emphasis during strength training should be on core (low back, abdomen, and hips) strength.

A strength program should consider the goals, level of experience, and sports activity both current and past. Training should not take up more than 20 hours a week. A session should include warm-up (5–10 minutes of aerobic activity and stretching), aerobic activity, and then resistance training. One to three sets of 13 to 15 repetitions of many different exercises would be ideal.

The Older Female

The older female strength trains for slightly different reasons from younger females. The cardiovascular, bone, and cholesterol benefits are still attained. The difference is that strength training in the older female aims at increasing muscle mass and avoiding disability. In large part, the goal of strength training in this population is to maintain independence. A fall inducing a hip fracture is most serious for older women, due to the resultant permanent alterations in activity and long hospitals stays. Prevention of hip fracture has an obviously huge impact on the feasibility of independence in older women. The normal process of aging leads to a tremendous amount of atrophy and weakness that can be avoided with strength training. High-intensity training has been found to be more beneficial than low-intensity training in the older female.

Conclusion

Strength training is an excellent way to promote long-term health and increase muscle mass for females. While males and females have many anatomical differences, the effect or strength training on muscle tissue is quite similar. Special dietary considerations with adequate amounts of fat, protein, and carbohydrate should be included. The continued increase of females in athletics will most likely coincide with a continued increase in strength training by females. As noted earlier, strength training programs should be tailored to each individual. The goals of the female should dictate the choice of exercises, intensity, repetitions, and rest period combinations. This individual approach will likely result in long-term benefits from strength training.

Strength Training for the Young Athlete

Strength training refers to a specialized method of physical conditioning that involves the progressive use of a wide range of resistive loads and a variety of training modalities designed to enhance or maintain muscular fitness. Despite the traditional concern that strength training is potentially injurious to the developing musculoskeletal system of children and adolescents, research studies and clinical observations indicate that participation in strength-building activities can be safe, effective, and enjoyable for children and adolescents. Because muscular fitness is required for success in most sports, a growing number of young athletes now strength train in school-based programs and sports training centers.

Potential Benefits of Youth Strength Training

Well-designed youth strength training programs may offer observable health and fitness value to children and adolescents. In addition to increasing muscular strength, muscular power, and local muscular endurance, regular participation in a youth strength training program has the potential to positively influence aerobic fitness, body composition, bone mineral density, and selected psychological measures. Moreover, carefully planned youth strength training programs may enhance motor performance skills, such as jumping and sprinting, and improve sports performance.

Another important benefit of youth strength training is its ability to improve the preparedness of young athletes for the demands of sports practice and competition. A growing number of aspiring young athletes are ill-prepared for the demands of sports training due to their sedentary lifestyle. While factors such as growth, improper footwear, and hard playing surfaces have been implicated as risk factors for overuse injuries in young athletes, the background physical activity level of boys and girls must also be considered. A significant number of injuries sustained by youth while playing sports could be prevented if more emphasis was placed on enhancing musculoskeletal strength and improving skill-related fitness abilities such as agility, balance, and coordination prior to sports participation. Preseason conditioning programs that included strength training have resulted in decreased injury rates in adolescent athletes, and it seems likely that this type of conditioning could offer a similar protective effect in children.

Risks and Concerns

The belief that strength training is unsafe for young athletes is not consistent with the needs of children and adolescents and the documented risks associated with this type of training. While the unsupervised and improper use of strength training equipment may be injurious, there is no scientific evidence to suggest that the risks and concerns associated with supervised and sensibly progressed youth strength training programs are greater than those arising from other sports and recreational activities in which children and adolescents regularly participate.

A long-established concern associated with youth strength training involves the potential for injury to the epiphyseal plate or growth cartilage. Although young athletes are susceptible to epiphyseal plate fractures, this type of injury has not been reported in any prospective youth strength training study. Furthermore, strength training will not negatively affect growth or maturation during childhood and adolescence. It appears that the greatest concern for young athletes who strength train is the risk of overuse soft tissue injuries, particularly to the lower back.

To reduce the risk of injury, youth strength training programs must be well designed and supervised by qualified professionals who should be careful to match the strength training program to the needs, interests, and abilities of each child. This is particularly important for untrained youth, who often overestimate their physical abilities and may not be aware of the inherent risks associated with strength training equipment. Special care is also needed when children and adolescents use exercise equipment at home, where they may be more likely to strength train without supervision or engage in unsafe behavior. Professionals must be aware of the inherent risk associated with strength training and should attempt to decrease this risk by following established training guidelines. Youth should not strength train on their own without guidance from qualified professionals.

Program Design Considerations

Although there is no minimum age for participating in a youth strength training program, children should have the emotional maturity to accept and follow directions and should appreciate the benefits and concerns associated with this mode of exercise. If a child is ready for participation in some type of sports activity (generally at age 7 or 8), then he or she may be ready to strength train. It is important that young athletes begin strength training at a level that is commensurate with their physical and cognitive abilities. Prescribing a program that exceeds a child's capabilities not only increases the risk of injury but may also undermine the enjoyment of the strength training experience. While the long-term goals of youth and adult strength training programs may be the same, the focus of youth programs should be on skill development and having fun.

A variety of strength training programs have been developed and recommended for children and adolescents. Various combination sets and repetitions and different types of equipment, including weight machines, free weights (barbells and dumbbells), medicine balls, elastic tubing, and body weight exercises, have proven to be safe and effective. Factors such as cost, proper fit, weight stack increments, and quality of instruction should be considered when evaluating strength training equipment for youth. Since most children are too small for adult-sized weight machines, child-size weight machines or other less expensive types of equipment can be used. If equipment is not available, a circuit of body weight exercises can be developed.

In general, it has been recommended that children and adolescents strength train 2 or 3 days per week on nonconsecutive days and perform one to three sets of 6 to 15 repetitions on 8 to 12 exercises that focus on the upper body, lower body, and midsection. It is reasonable to begin strength training with one or two sets of 10 to 15 repetitions with a light to moderate weight of basic exercises. As youths gain confidence in their abilities to perform these exercises with proper technique, heavier weights and more advanced multijoint movements can be incorporated into the strength training program. However, when learning any new exercise, youths must first learn how to perform each exercise correctly with a light weight and then gradually increase the training weight without compromising on exercise technique. This approach will not only allow for positive changes in muscle function but also provide an opportunity for participants to gain confidence in their abilities to perform strength exercise.

Over time, continual gains can be made by changing the exercise choice, exercise order, training weight, number of repetitions, number of sets, or training frequency. On average, a 5% to 10% increase in training weight is appropriate for most exercises. Since training-induced strength gains are impermanent and tend to regress toward the pretraining values once the training stops, program variation is needed to optimize training adaptations, reduce boredom, and promote exercise adherence. Planned variation in the strength training program can also help prevent training plateaus, which are not uncommon after the first 2 to 3 months of strength training.

Basic education on proper exercise technique, fitness training, and realistic outcomes should be part of all youth strength training programs. Professionals who work with youth need to listen to each child's concerns and monitor progress. Some youths with poor levels of fitness may not be able to tolerate the same amount of exercise as some of their peers in the same training program. This is where the art and science of developing a strength training program come into play, because the principles of training specificity and progressive overload need to be balanced with individual needs, goals, and abilities.

Youth strength training requires qualified supervision, appropriate overload, gradual progression, and adequate recovery between exercise sessions. When designing strength training programs for young athletes, the goal of the program should not be limited to increasing muscular fitness. Teaching youth about their bodies, promoting safe training procedures, and providing a stimulating program that gives participants a more positive attitude toward strength training and physical activity are equally important. Strength training should be recommended to young athletes as part of a total fitness program that should include a variety of physical activities and sports pursuits.

Stress Fractures

Stress fractures are overuse injuries of bones. They are common in both competitive and recreational athletes who participate in repetitive activities such as running, jumping, marching, and skating. Stress fractures were first described as "march fractures" in military recruits who had recently increased their level of impact activities. These injuries are true overuse injuries that result from an accumulation of microdamage during exercise, exceeding the body's natural ability to repair this damage. This accumulation of microdamage can cause pain, weaken the bone, and lead to stress fracture. The majority (95%) of stress fractures occur in the lower extremity and most commonly involve the tibia, fibula, metatarsals, or navicular bone. Treatment of stress fractures depends on both the site and the severity of injury.

Etiology

During repetitive loading cycles, bones are exposed to mechanical stresses that can lead to microdamage or microscopic cracks. Fortunately, when given adequate time for recovery, the body has the ability to heal and further strengthen bones through remodeling and repair mechanisms. These healing mechanisms depend on many factors, including hormonal, nutritional, and genetic factors. Unfortunately, under certain conditions, such as starting a new training program or increasing the volume of a current program, the damage to bones is enough to overwhelm the body's ability to repair. In these circumstances, there can be an accumulation of cracks and inflammation that leaves the bones at risk of fatiguing and fracturing. This fatigue failure event is termed the stress fracture. The severity of the injury is determined by the location of the stress fracture and the extent to which the fracture propagates across the involved bone.

Diagnosis

History and physical examination are fundamental for the practitioner in making the diagnosis promptly. Patients typically present with an insidious onset of localized pain at or around the site of the injury. Initially, the pain from a stress fracture is only experienced during strenuous activities such as running and jumping. However, as the injury worsens, pain may be present during activities of daily living, such as walking or even sitting. Physical examination classically reveals a focal area of bony tenderness at the site of the fracture. Soreness in the surrounding joint and muscle is common, and in severe cases, palpable changes to the bone at the site of injury may be present.

Multiple modalities of imaging are routinely used in diagnosing stress fractures. Plain radiography (X-rays) is the most commonly used test to diagnose a stress fracture, but within the first few weeks of injury, X-rays often will not reveal the presence of the fracture. Bone scans, a nuclear-enhanced image modality, have classically been used in the evaluation of stress fracture and have proven to be very sensitive. In recent years, magnetic resonance imaging (MRI) has become the diagnostic test of choice for many physicians because of its superior availability, shorter exam time, earlier fracture detection, and image quality and because it can show damage to other structures such as muscles or ligaments, which conventional X-rays do not.

Classification

Stress fractures can be classified as high- or low-risk injuries based on their location. This classification allows a practitioner to quickly implement treatment for each stress fracture. Low-risk sites include the medial tibias (shin), femoral shafts (thigh), first four metatarsals (foot), and ribs. These locations tend to heal and have a lower likelihood of recurrence, progression to nonunion (not healing), or completion (worsening) of the fracture. Conversely, high-risk stress fracture sites have a higher complication rate and require prolonged recovery or surgery before the athlete can return to participation. Common high-risk sites include the femoral neck (hip), anterior tibia, medial malleolus (ankle), patella (kneecap), navicular (ankle), sesamoids (foot), and proximal fifth metatarsal.

Treatment

The treatment of stress fractures will vary with the location of the injury, severity of injury, and treatment goals. Low-risk stress fractures generally heal faster and with a lower incidence of poor outcomes than high-risk stress fractures. Depending on the particular injury, treatment may include discontinuation of the precipitating activity only, discontinuing all training activities, or, for more serious injuries, crutches or surgery. For minor injuries, healing may take as little as 3 to 6 weeks of avoiding the precipitating activity with continued cross-training followed by a gradual return to the pre-injury level of participation. More severe injuries often take 2 to 3 months or more of aggressive treatment. While treating the stress fracture, it is important to evaluate and modify risk factors that may predispose the athlete to future injuries, including anatomic abnormalities, biomechanical forces, hormonal imbalances, and nutritional deficiencies. Returning to play after a stress fracture usually is granted once the athlete is painfree with activities, is nontender to palpation, and, for high-risk sites, shows evidence of healing on imaging.

Stretching and Warming Up

From time immemorial, stretching and warm-ups have been a part of athletic training and competition. These routines are purported to improve performance and to reduce injury and postexercise soreness. Perhaps surprisingly, although research supports the position that warming up is critical, the evidence is tenuous that stretching itself is beneficial. In fact, some stretching evidently predisposes to injury and reduces performance. A long-term program of stretching after exercise probably reduces injuries or postexercise soreness, but this is also controversial. Thus, there is a major shift occurring in the practice of stretching. This entry describes what, why, and how we should stretch and then reviews what role stretching should play in warm-ups.

What to Stretch

Stretching affects the ligaments that provide joint stability, the tendons that connect muscle to bone, and/or the muscle that produces power. Stretching has been discovered to induce changes in the nervous system as well. Ligament stretching is generally not desirable, as described below. Tendon stretching is difficult and of limited benefit. It is in the muscle that most stretching occurs.

Muscles have elastic properties, which means that if stretched, they will tend to return to their original length. They also have viscous and plastic properties, which means that if stretched for long enough (repeatedly for about 30 seconds), they tend to remain lengthened and only slowly return to their original length. The viscoelastic changes that occur with stretching have been considered the reason why the muscle lengthens. But some of the changes turn out to be the result of decreased pain thresholds or decreased muscle strength, which have as many detrimental effects as good ones.

Why Stretch?

The traditional reasons to stretch are to increase range of motion (ROM) around a joint, to increase flexibility of the muscle, and to warm up the body in preparation for intense exercise. We will deal with each of these putative attributes in turn.

Range of Motion

ROM is the arc through which a joint can move. Some sports such as gymnastics require large ROM. But simply increasing ROM around a joint is not necessarily useful. An increased range must be accompanied by sufficient muscle strength to protect the ligaments, tendons, and muscles from injury. This muscle strength is also necessary to allow use of the body in that new ROM, or it has little purpose. For instance, the ability of a backstroke swimmer to externally rotate the arm so that the hand is above and behind the head is only useful if the ROM is also accompanied by strength and power of the muscles to produce faster swimming. Much of the stretching we have traditionally done produces increased ROM by stretching the ligaments, which may already be too loose, and actually decreases the power of the muscles for a short time.

For example, a stretching exercise sometimes used by swimmers to increase shoulder external rotation is having a partner pull the arms back as far as possible. The anterior ligaments of the shoulder that limit this motion are rarely tight because most swimming motions stretch them daily. Stretching these ligaments may adversely affect joint stability. Tightness in the front of the shoulder arises when muscles such as the pectoralis get short. If we are to increase ROM, it must be done under control, preferably with the athlete's own muscles, so that strength and power increase in coordination with flexibility of all the related muscles.

Ligaments hold joints in precise positions throughout the ROM, and usually they are best left alone to do what they were marvelously designed to do. But occasionally they do need stretching. One example is the ligaments in the posterior part of the shoulder, which often *are* tight, but the muscles are long and weak. Here, it is important to stretch the ligaments but not the muscles. An exercise intended to stretch these tight posterior ligaments is where the upper arm is forced across the chest. But more often it actually only stretches the scapular stabilizer muscles, which may already be too long. An athletic trainer or physical therapist will need to ensure that the athlete does stretches very precisely to stretch the right thing without damaging something else.

Flexibility

Flexibility is the ability of a muscle to work over a full ROM—in a short length and a long one. What has been perhaps better appreciated in recent years is that flexibility cannot be created in an isolated muscle. A related property is stiffness, which is the amount of force needed to elongate a muscle. Stiffness is not necessarily bad, but muscle stiffness must be balanced. Often, it is a balance of the flexibility and stiffness of opposing muscles that needs to be corrected, not just a change of one muscle group. We have come to realize that there is such a thing as too much flexibility.

Using the above shoulder example, even if the pectoralis muscle is carefully stretched without damaging the ligaments (i.e., it becomes more flexible), this new elongated status may only last a few minutes. One common reason is that many athletes have a rounded shoulder posture from hours of computer keyboarding, which is what really caused the pectoralis to become short in the first place. Unless the long and weak posterior rotator cuff muscles and scapular stabilizers are corrected, it will be virtually impossible to maintain an elongated pectoralis. The longer-term solution is to stretch the pectoralis by stiffening (strengthening and shortening) the posterior muscles. When your mother told you to sit up straight with your shoulders back, this is what she was intuitively trying to accomplish.

Warm-Up

Studies have clearly shown that warming up muscles before exercise improves performance and prevents injuries. Stretching has been an important part of "warming up" for exercise, but the benefits of warming up have been inappropriately attributed to stretching. Research is showing that traditional stretching is not the best way to warm up. The actual temperature of the muscle is probably the most important factor, and so sitting in a hot tub is almost as effective; warming muscles with moderate dynamic activity is the best. Dynamic movements effectively prepare the muscles for powerful action throughout the needed ROM.

Therefore, we need to reassess how to stretch to get the benefits of a useful increase in balanced ROM, flexibility, and warm-up, without the potential drawbacks or wasted time.

How to Stretch

Stretching can be *static,* where an athlete assumes the stretching position using his or her own opposing muscles. Stretching can also be *passive,* where the force for achieving the stretching position is provided by a partner. In both cases, we seek to stretch to a point of mild discomfort in a muscle for about 30 seconds. While these actions do elongate the muscle, there is increasing evidence that they actually decrease power and speed, at least for several minutes. One study showed that the time for a 600-meter (m) run was improved by 2.4% if athletes had routinely done dynamic exercises, whereas it worsened by 2.5% in the athletes who had done a static stretching routine. Ballistic stretching, which involves swinging a body part to force the joint into an extreme ROM, overactivates some neurological reflexes and may increase the risk of muscle damage.

Dynamic stretching is the currently recommended technique. This involves dynamic movements as opposed to static positions and thus may not appear to be stretching in the former sense. Overload movements such as jumping with weights show even more promise. This activates the nervous system, while static stretching inhibits it. As mentioned above, ballistic stretching also activates the nervous system but probably in a deleterious way. Passive stretching usually stretches more ligaments than muscles and must be used very carefully, if at all.

To show how these various kinds of stretching might be used, let's see how we might approach tight hamstrings. An example of passive stretching would be to have the athlete sit with legs extended and have a partner push on that athlete's back. There is a danger that this will increase ROM, but by stretching back the ligaments, which increases predisposition to back pain, there is little improvement of tight hamstrings. An example of passive stretching would be to have the athlete sit in the same legs-extended position and hold his or her head on the knees. If done correctly, this will result in increased hamstring length but at the cost of short-term decreased strength and power of the hamstrings. Standing on one leg and swinging the other one to the limit of ROM would be ballistic stretching. This may cause tears, again without significantly increasing flexibility of the muscle. Dynamic stretching would involve active movements such as striding, lunging, or whole-body movements similar to the sport itself, all the while maintaining a stable lower back and pelvis. Tai chi, yoga, and pilates often include this type of movement. It is also the essence of "core" training that is critical to all musculoskeletal health.

Dynamic stretching results in a durable rebalancing of muscle strength, flexibility, and stiffness and does not damage the ligaments.

An example of how stretching is related to core strength is what one well-known physical therapist calls the "tail wagging the dog." Athletes with strong legs may produce undesired motions and pain in the back and pelvis, because the back and pelvis (core) are not strong enough to stabilize the leg motion. In this situation, the core muscles are less stiff (more flexible) than the leg muscles. The long-term solution to stretch the "tight" leg muscles is to "stiffen" the core muscles. Doing such rebalancing with isolated stretching of the leg muscles is virtually impossible, while real-world movements of dynamic stretching done with proper form will create a practical balance of flexibility.

Conclusion

In summary, warming up before exercise continues to be very important, but stretching, at least passive or static stretching, has little to no function in a pre-exercise routine. It may have limited benefit after exercise, where at least it has little deleterious effect. Warming up should be done with moderate activity similar to the sport to be undertaken. Muscle flexibility and ROM are best improved with a careful long-term training program. Muscle strength and power, working from a strong core, are developed gradually over the needed ROM. This usually entails sportlike activities done with more attention to form than force.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage occurs when there is bleeding into the space between the two innermost protective coverings surrounding the brain, the pia mater and the arachnoid mater. A subarachnoid hemorrhage most often occurs as the result of significant head trauma and is usually seen in the setting of skull fractures or injuries to the brain itself. In this setting, the presence of a subarachnoid hemorrhage has been linked to significantly worse outcomes, although it is unclear whether the presence of the blood in the subarachnoid space is directly responsible or whether it is just a marker for a very serious injury. In either case, a subarachnoid hemorrhage is typically symptomatic, with headache and an alteration of consciousness being common. Once identified, the subarachnoid hemorrhage requires immediate medical attention, and quick intervention is necessary to improve the chance of a positive outcome.

Anatomy

The brain is protected inside the skull by three separate layers of tissue (meninges). The innermost layer, the *pia mater*, is a thin and delicate membrane that lies on the surface of the brain. The second layer, the *arachnoid mater*, covers the brain and pia mater but does not follow the contour of the involutions of the brain. The outermost layer, the *dura mater*, provides a thicker and tougher layer of protection.

These layers define three potential spaces for blood to collect. The *epidural space,* between the skull and the dura; the *subdural space,* between the dura and the arachnoid layer; and the *subarachnoid space,* between the arachnoid and pia layers—each having their own potential sources of hemorrhage. The pia mater is too closely adhered to the brain and too fragile to act as a barrier for blood, and therefore, there is no potential space between the pia and the brain for a hemorrhage to form. A subarachnoid hemorrhage is simply defined as the presence of blood in the subarachnoid space.

Mechanism of Injury

The subarachnoid space is prone to blood collection whenever there is damage to any of the cerebral blood vessels that travel beneath the arachnoid layer, in close proximity to the surface of the brain. Subarachnoid hemorrhage can also occur when there is a substantial injury to the brain tissue itself. In either case, this type of hemorrhage is most often the result of a significant mechanical force applied to the skull. Accompanying skull fractures are common, as are other types of bleeding such as epidural and intracerebral hematomas. This mechanism is relatively rare in sports, especially in those that require the use of a helmet, as long as the helmet is used properly. It is still possible in any sport, however, and more likely when there has been a significant force applied directly to the skull.

Subarachnoid hemorrhages can also occur spontaneously. In these cases, approximately 85% of the hemorrhages are the result of a ruptured cerebral aneurysm. Other causes of spontaneous subarachnoid hemorrhage include arteriovenous malformations, anticoagulation therapy such as coumadin, and the use of certain illicit drugs such as cocaine.

Risk Factors

In the case of the subarachnoid hemorrhage that is caused by an athletic injury, the baseline risk is primarily a function of the type of sport being played, the equipment being used, and the playing technique of the athlete. Additional risk, although hard to quantify, likely exists for athletes who have abnormal vascular anatomy, such as an aneurysm or arteriovenous malformation. Otherwise, the risk of developing a subarachnoid hemorrhage is defined by the nature of the injury and the severity of the impact. Certain sports that involve high velocities and little, if any, protective equipment, such as soccer and field hockey, may also pose additional risk.

In the case of most spontaneous subarachnoid hemorrhages, the risk is determined mainly by the size and location of any vascular abnormality. Although it can be difficult to accurately define the risk of any one aneurysm rupturing, a general rule is to take a conservative approach of repeat neuroimaging for any aneurysm 10 millimeters (mm) in diameter or less. The size and location of aneurysms larger than 10 mm should be carefully considered before undergoing a procedure designed to prevent rupture in the future.

Signs and Symptoms

When a subarachnoid hemorrhage is secondary to head trauma, there is typically a constellation of symptoms similar to that seen in all serious head injuries that includes confusion or loss of consciousness, memory loss, dizziness or unsteadiness, lack of coordination, nausea and/or vomiting, or sleepiness. If the patient is lucid enough to describe symptoms, he or she will typically describe an extremely severe headache. While the subarachnoid hemorrhage may not be directly responsible for neurological deficits such as numbness or weakness on one side of the body, these signs may be present as a result of concurrent injury to the brain.

In the setting of a spontaneous subarachnoid hemorrhage, the hallmark symptom is known as the "thunderclap headache." This headache occurs quite suddenly and is severe. It is often described by patients as feeling like somebody hit them on the head with a blunt object. The sudden nature and severity of this headache are distinct and should always warrant consideration of a subarachnoid hemorrhage as the cause.

Clinical Evaluation

With any athletic head injury, care should be taken on the field to first assess the "ABCs" (airway-breathing-circulation) and evaluate the possibility of cervical spine trauma, instituting cervical immobilization when appropriate. The level of consciousness should then be noted using the Glasgow Coma Scale. Any language, memory, or orientation abnormalities should also be noted. A physical examination should then be performed to evaluate for skull fracture or any focal neurologic abnormality, including pupillary, visual field, and funduscopic examinations, followed by a careful assessment of strength, sensation, reflexes, coordination, and gait. Any evidence of fracture or focal neurologic abnormality warrants activation of emergency medical services.

Following the on-field assessment, appropriate monitoring and serial examinations should be performed to document any changes in signs or symptoms. If the situation gets worse, the patient should be further evaluated in a hospital setting. Care should be taken to establish an accurate timeline of events, and the accurate documentation of findings will help clarify the athlete's postinjury course.

Diagnostic Tests

The presence of a subarachnoid hemorrhage is usually confirmed with a computed tomography (CT) scan of the head. Magnetic resonance imaging (MRI) of the brain can also be used. While MRI may provide more information regarding damage to the brain itself, it is more expensive, requires more time, and is not available at every medical facility. The initial diagnosis, therefore, is typically made with a CT scan. If the clinical suspicion is high enough but the CT of the head is normal, a lumbar puncture can be performed as an alternative method to establish the diagnosis. If a subarachnoid hemorrhage is present, the cerebrospinal fluid that is obtained via the spinal tap will almost always have evidence of blood or blood products. In the case of spontaneous subarachnoid hemorrhages, an intravenous, catheter-based procedure, a cerebral angiogram, is the most useful test for establishing the source of the bleed.

Management

Once the "ABCs" have been addressed, the patient is in the appropriate medical facility, and the patient is medically stable, the next step should be to establish the source of the hemorrhage. Further management depends on the identified cause. In the setting of sports trauma, the cause is likely known (a direct force to the skull). In these cases, there are likely concurrent injuries that need attention, such as a skull fracture. Neurosurgical consultation is required to determine the next steps in management, which could include a catheter-based procedure, surgery, or the placement of a device to monitor the pressure inside the skull. Blood in the subarachnoid space can cause the surrounding arteries to spasm, increasing the chances of further damage to the brain. Medicines can be used to help prevent this phenomenon, and further diagnostic tests can help monitor the cerebral vasculature.

Prevention

As with the prevention of other head injuries in athletics, proper technique, well-fitted and certified equipment, and adherence to the rules of play are paramount. The prevention of spontaneous subarachnoid hemorrhages is applicable only in very specific situations. If an athlete has two or more first-degree relatives (father, mother, siblings), some studies have shown that screening for aneurysms is warranted. If an aneurysm is identified, it may then be evaluated further for the possibility of performing a procedure to reduce the risk of rupture in the future. These decisions are best made carefully and after direct consultation with a vascular neurosurgeon.

Return to Sports

No athlete should return to participation in contact sports as long as he or she is still symptomatic from any head injury. In the case of a subarachnoid hemorrhage, the decision to return to sporting activity should be made very carefully and with the mechanism of the hemorrhage in mind.

Subdural Hematoma

Subdural hematomas are a type of head injury that involves bleeding into the space between the brain and its outermost protective covering, the dura. They typically result when a traumatic force applied to the head creates significant fast-changing velocities of the contents inside the skull. The expanding hemorrhage can increase the pressure inside the skull and compress the underlying brain tissue. While subdural hematomas are relatively uncommon in sports, they are very serious injuries that can lead to significant disability or death. Early recognition of the warning signs and quick medical attention are paramount to a good outcome.

Anatomy

The brain is protected inside the skull by three separate layers of tissue (meninges). The innermost layer, the *pia mater*, is a thin and delicate membrane that lies on the surface of the brain. The second layer, the *arachnoid mater*, covers the brain and pia mater but does not follow the contour of the involutions of the brain. The outermost layer, the *dura mater*, provides a thicker and tougher layer of protection.

These layers define three potential spaces for blood to collect. The *epidural space,* between the skull and the dura; the *subdural space,* between the dura and the arachnoid layer; and the *subarachnoid space,* between the arachnoid and pia layers—each with their own potential sources of hemorrhage. The pia mater is too closely adhered to the brain and too fragile to act as a barrier for blood, and therefore, there is no potential space between the pia and the brain for a hemorrhage to form.

Mechanism of Injury

A network of veins traverses the space between the surface of the brain and the dura. These veins, the *bridging veins*, can tear if the contents of the skull experience sudden changes in velocity. Blood leaking from the bridging veins then collects in the subdural space, creating a hematoma. The size of the hematoma and the speed with which it expands depend primarily on the number and size of the tears in the bridging veins. Given that the blood in the bridging veins is coming from the venous side of the circulatory system and is therefore under less pressure, subdural hematomas typically expand at a much lower rate than hematomas that are formed from arterial blood, such as epidural hematomas. The expanding subdural hematoma increases the intracranial pressure and can lead to damage of the underlying brain.

Subtypes

Subdural hematomas are often classified based on their acuity into *acute, subacute,* and *chronic* subtypes. Acute subdural hematomas are extremely dangerous and frequently lethal without quick surgical intervention. Symptoms develop quickly, and mortality rates are estimated between 60% and 80%. Subacute subdural hematomas become symptomatic over several hours to days and carry a better prognosis. Chronic subdural hematomas develop over days to several weeks and are common in elderly individuals. Frequently, they are only mildly symptomatic or without symptoms completely. In these cases, the bleeding is self-limited, and no surgery or acute intervention is required. In the athletic population, a subdural hematoma caused by a physical impact is more likely to present as an acute or subacute subtype.

Risk Factors

Any process that increases the distance that the bridging veins must travel to cross the subdural space increases the risk of tearing and, therefore, of hematoma formation. Brain atrophy is probably the biggest contributor of increased risk. Subdural hematomas, therefore, become more common as people age and the brain undergoes the natural process of age-related atrophy. Processes that increase brain atrophy, such as Alzheimer disease or chronic alcohol exposure, can increase the risk even further.

While brain atrophy increases the risk of developing a subdural hematoma, it also decreases the speed and severity of the related symptoms. This is due to the fact that brain atrophy provides more space for the hematoma to expand before it begins to increase intracranial pressure and interfere with brain function. Conversely, younger patients, without atrophy, will typically develop symptoms over a shorter period of time.

Signs and Symptoms

As mentioned above, the signs and symptoms of subdural hematoma typically have a slower onset than those seen in epidural hematomas. Depending on the particular subtype, symptoms can develop within the first 24 hours or may be delayed in onset by several days or weeks. The speed with which the majority of symptoms develop depends mainly on the degree of tearing of the bridging veins and the amount of space available for the hematoma to occupy before intracranial pressures begin to increase. Headache, either constant or fluctuating, can certainly occur during any stage of the process. Other common signs or symptoms that may occur as the result of a subdural hematoma include, but are not limited to, the following:

- Loss of consciousness
- Numbness
- Decrease in consciousness
- Seizure
- Amnesia
- Lethargy
- Disorientation
- Slurred speech
- Blurry vision
- Dizziness
- Nausea or vomiting
- Weakness
- Balance difficulty
- Personality changes

It should be noted that the presenting signs and symptoms of subdural hematoma are similar to those of other head injuries, including concussion. Oftentimes, the main difference is in the time course of symptoms. If any athlete develops new symptoms several minutes after a witnessed impact or if there is any perceived clinical worsening, emergency medical services should be notified.

Clinical Evaluation

As with any athletic head injury, care should be taken on the field to first assess the "ABCs" (airway-breathing-circulation) and evaluate the possibility of cervical spine trauma, instituting cervical immobilization when appropriate. The level of consciousness should then be noted using the Glasgow Coma Scale. Any language, memory, or orientation abnormalities should also be noted. A physical examination should then be performed to evaluate for any focal neurologic abnormality, including pupillary, visual field, and funduscopic examinations, followed by a careful assessment of strength, sensation, reflexes, coordination, and gait. Any focal neurologic abnormality warrants activation of emergency medical services.

Following the on-field assessment, appropriate monitoring and serial examinations should be established to document any changes in signs or symptoms. If the situation gets worse, the patient should be further evaluated in a hospital setting. Care should be taken to establish an accurate timeline of events, and accurate documentation of findings will help clarify the athlete's postinjury course.

Diagnostic Tests

The presence of a subdural hematoma is usually confirmed with a computed tomography (CT) scan of the head. Magnetic resonance imaging (MRI) of the brain can also be used. While the MRI scan may provide more information regarding damage to the brain itself, it requires more time for image acquisition and is not available at every medical facility. The initial diagnosis, therefore, is typically made with a CT scan.

Management

The management of a patient with a subdural hematoma will depend greatly on the extent of the bleed, its location, and the overall clinical status. Small, asymptomatic subdural hematomas can be managed conservatively with serial CT scans of the head to assess for any interval change in hemorrhage size. Larger hemorrhages, or those that are producing a more significant clinical compromise, should be emergently evaluated for surgical decompression.

Prevention

As with other head injuries in athletics, proper technique, well-fitted and certified equipment, and adherence to the rules of play are paramount in preventing a subdural hematoma.

Return to Sports

No athlete should return to participation in contact sports as long as he or she is still symptomatic from any head injury. In the case of a subdural hematoma, if surgical intervention was required, contact sports should be avoided indefinitely. For smaller, less complicated hemorrhages, there are no clear return-to-play guidelines, but a conservative approach is encouraged.

Sudden Cardiac Death

Sudden cardiac death (SCD) in athletes has recently generated much discussion as well as some controversy in the field of sport and exercise medicine. The possibility that an athlete who epitomizes health and longevity could suddenly die in the midst of athletic competition or practice is highly unnerving and unsettling. It is difficult for all of us, health professionals and the lay public alike, to fathom this apparent paradox, often leading to increased scrutiny and attention when a tragic death does occur within a community and to question whether something more can or should be done to prevent this from occurring in the first place.

It is important to remember that sports activity itself is not lethal, but rather it may be the trigger for sudden cardiac arrest (SCA) in an athlete whose susceptibility is increased due to an underlying, silent cardiac condition. It is not unusual for the athlete to not have any symptoms, or perhaps not have recognized them, before the actual episode leading to SCA and death.

Causes

Fundamentally, the heart is a muscle, and its function is to contract and pump blood, carrying oxygen to the body. Unlike other muscles, the heart has an elaborate electrical conduction system that regulates or signals its own activity.

The most common cause of sudden cardiac death in the United States in those above 35 years of age is hypertrophic cardiomyopathy (HCM). In adults above 35 years of age, the number one cause of SCD is atherosclerotic coronary artery disease.

Hypertrophic Cardiomyopathy

In HCM, the heart is thickened abnormally, and usually asymmetrically, and is at risk for abnormal function. There is a genetic basis for this condition; however, the physical expression of the condition is variable. There are much fewer cases of diagnosed HCM than people with the genetic defect, which is believed to be about 1 in 500 people. It is not clear what other factors contribute to an athlete actually being diagnosed with HCM.

Diagnosing HCM, as with other cardiac conditions that cause SCD, starts with having a low threshold of suspicion for findings in the athlete's history, physical exam, and electrocardiogram (EKG; a tracing of the electrical activity of the heart). Listening to the heart with a stethoscope (cardiac auscultation), a certain type of heart murmur consistent with turbulent blood flow within the heart may be detected in an athlete with HCM. There are, however, a number of types of heart murmurs, and the presence of a murmur can be normal or benign. An echocardiogram may be obtained to help confirm the presence of HCM.

It is worth noting that there are normal physiologic adaptations of the heart in response to exercise. The condition of "athlete's heart" encompasses normal cardiac responses to exercise, including heart muscle hypertrophy and electrical changes as evidenced on an EKG. Because of the clinical overlap in findings between an athletic heart and one with HCM, the diagnosis of one versus the other can sometimes be challenging.

Coronary Atherosclerotic Disease

In adults above 35 years of age, coronary atherosclerotic disease (CAD) can lead to sudden death in exercising individuals. Over time, susceptible individuals will build up fatty plaque within the arteries, which causes significant narrowing. As exertion increases, as during exercise, the heart requires more oxygen; the narrowed artery can limit the amount of blood flow that can get to the heart. The oxygen demand can outpace the supply, causing heart muscle ischemia; this in turn can disrupt the electrical signal, throwing the heart into a lethal rhythm, as in ventricular fibrillation. The atherosclerotic plaques may also break off, especially during times of high demand or stress on the heart; the plaque can then limit or cut off blood flow distal to the blockage, causing heart muscle ischemia and tissue death. Diagnosis of CAD can be supported indirectly with a variety of cardiac stress tests and directly with invasive cardiac catheterization. Of note, changes of CAD have been found in people in their 20s and younger and so may contribute to some cases of SCD in this age-group as well.

Other Causes

Other, less common causes of SCD in young people include structural and electrical abnormalities such as, but not limited to, congenital anomalies of the coronary arteries, arrhythmogenic right ventricular dysplasia (ARVD), myocarditis, and conduction abnormalities such as long QT syndrome.

Congenital coronary artery anomalies are normal anatomic variants. In certain alternate locations, the coronary artery can pass between structures such as the back of the heart and aorta, which can in turn cause the compression of the artery and thereby limit flow, especially during exercise. The consequence is similar to what occurs in coronary artery disease in that the decreased flow leads to myocardial ischemia, heart muscle death, and fatal arrhythmia. Diagnosis is difficult, and this condition is typically diagnosed at the autopsy after an SCD event; a cardiac CT (computed tomography) angiogram or cardiac catheterization may be helpful if clinically suspected.

In ARVD, the heart muscle is affected, undergoing changes that replace the normal healthy cardiac muscle tissue in the right ventricle with abnormal, irregular, disorganized, nonfunctioning fibrofatty connective tissue. Fibrofatty tissue can be thought of as scar tissue except that unlike with typical scar tissue formation, there is no precipitating injury or damage to the muscle in patients with ARVD. Family history, and thus a genetic component, may be contributing factors. The mechanism that leads to SCD is likely the result of arrhythmia that occurs as the conduction system tries and fails to work properly in tissue that is abnormal and in disarray. An EKG may raise clinical suspicion, and further imaging with echocardiogram or possibly cardiac MRI may be indicated for confirmation.

Myocarditis is an acute illness that causes inflammation of the heart muscle as a result of infection with a virus or bacteria. The athlete may experience chest pain, palpitations, and shortness of breath, along with associated systemic signs of fever, myalgia, and fatigue. While there is considerable overlap in the symptoms of myocarditis with severe viral illness such as the "flu," a rapid pulse out of proportion to other features should alert the physician to this possibility. Consider holding the athlete from return to play for several months after the acute illness resolves as the heart muscle may continue to be at risk for a period of time during recovery.

Prolonged QT syndrome describes a certain electrical conduction abnormality within the heart that predisposes the athlete to SCD. There may be a family history of SCA or SCD, and there are at least six genetic variants that have been identified thus far. Diagnosis is confirmed by EKG. There is no cure per se for this, though the risk for SCD may be reduced with appropriate risk stratification and medical management.

Management

Acute

The mechanism by which most cardiac conditions are thought to cause sudden death during exercise pertains to structural changes in the heart that disrupt normal electrical conduction or rhythm. Typically, in SCD, the final lethal heart rhythm resulting in an irregular, chaotic rhythm is due to *ventricular fibrillation.*

Once ventricular fibrillation occurs, an electrical shock delivered by a defibrillator (e.g., an automated electronic defibrillator, or AED, which can be used by a lay person with little to no prior training) must be provided quickly; otherwise, this rhythm is usually fatal. The success of defibrillation declines rapidly by the minute once the heart is in ventricular fibrillation. If successful, the defibrillator shock will restore a normal electrical rhythm to the heart and restore normal blood flow through the body. At the very least, basic resuscitation efforts including calling for help and beginning CPR (cardiopulmonary resuscitation) with regular breaths and chest compressions should be initiated immediately for the fallen athlete with no detectable pulse.

Follow-Up

If an athlete is found to have any of these conditions, he or she may be disqualified from competing in most, but not necessarily all, sports for some period of time. Some conditions are amenable to medical management, including medications, activity modification, and possibly an implanted defibrillator. Treatment may depend on whether the athletes have previously had an event of SCA and survived, whether they have any symptoms related to their cardiac condition, or whether they have any close family members with the same condition who have had an SCA event. None of the medical interventions, however, guarantees the athlete a return to the same low level of risk for SCD that an athlete without any of these conditions has. All these heart conditions place the athlete at increased risk for SCD, and all these athletes need close medical follow-up and monitoring.

Regardless of management, careful consideration should still be given to the athlete's diagnosis, condition, and expected level of function and sports, and the risks and benefits of sports participation should be carefully weighed on an individual or a case-by-case basis.

Prevention

Though SCD is fortunately rare (annual incidence is 1 in 200,000), prevention of SCA and SCD events is the best and optimal approach. Many physicians currently rely on the sports preparticipation screening history and examination to help identify at-risk athletes. (For all 12 elements of the American Heart Association–recommended preparticipation cardiovascular screening steps in athletes, refer to the 2007 article by B. J. Maron et al., published in *Circulation*.) Some of the essential questions that should be asked at all preparticipation physicals include the following:

1. Have you ever passed out while exercising?
2. Have you ever had chest pain, palpitations (rapid or irregular heartbeats), or shortness of breath while exercising?
3. Has there been a sudden, possibly unexplained, death in an apparently healthy, otherwise young relative?

Utilization of the screening EKG in preventing SCA and SCD is currently controversial. The discussion on whether to perform screening EKGs for all athletes is complicated to say the least, and it is beyond the scope of this entry. Factors to consider in the controversy involving EKG screening are the accuracy of the EKGs, the potentially significant number of false-positives (i.e., normal hearts that would look abnormal on EKG), and the effectiveness and financial impact of large-scale mandatory EKG screening (as well as the impact of further testing and subspecialty consultations that the EKG screening would necessitate). This could be very burdensome to an already strained health care system, not to mention the individual athlete and his or her family having to undergo further mandated evaluation prior to participating in sports.

Sunburn

Sunburn is characterized by skin redness, swelling, tenderness, and blistering in response to sunlight exposure. Given the number of athletes who play outdoor sports, prevention of the negative short- and long-term health effects of sunburn is important.

Sunlight

Sunlight is divided into visible light, infrared radiation, and ultraviolet radiation (UVR). UVR is categorized further into UVA (320- to 400-nanometer [nm] wavelength), UVB (290–320 nm), and UVC (<290 nm) radiation. UVB radiation can lead to the acute skin changes seen in sunburn. It has the ability to directly damage DNA, causing genetic mutations and cancer. UVA radiation is associated with skin wrinkling and may also contribute to some skin cancers. UVC does not contribute to sunburns.

Environmental factors play a role in determining UVR exposure. The stratosphere contains ozone, which absorbs all UVC, high amounts of UVB, and a small amount of UVA radiation. Ozone concentrations vary with temperature, weather, altitude, and latitude. UVB radiation increases by 3% per degree of latitude, and UVR intensity has been found to increase by 4% for every 300 meters (m) of elevation. Midday sunlight passes through less of the atmosphere than at any other point in the day, leading to more UVR exposure during midday hours. Clouds, fog, and haze can decrease UVR by 10% to 90% but never fully block it out. Snow and sand can reflect up to 90% of UVR. Even under water, UVR can penetrate to a depth of 1 m.

Skin Changes

The *epidermis* forms the protective, outermost layer of the skin. The deepest layer of the epidermis is constantly repopulated by new keratinocytes (cells composed of keratin), which migrate superficially, replacing the older keratinocytes and turning over the entire epidermal layer in approximately 28 days. *Melanocytes* (cells that produce melanin) are located in the deepest layer of the epidermis. The melanin is stored in melanosomes, which can be transferred to the keratinocytes. Skin color is influenced by the number and size of melanosomes, the type of melanin they contain, and the rate at which melanin is broken down.

Sunburn occurs as the skin tries to protect itself by absorbing UVR. UVA radiation is partially absorbed by melanin, which produces a darkening of the skin as the melanin is transferred to the keratinocytes. The resulting tan appears immediately after exposure and lasts for a few hours but does not protect the skin against future damage from sun exposure. UVB radiation is responsible for the redness, swelling, tenderness, and blistering that appears 6 to 12 hours after exposure and peaks in effect around 24 hours. These changes are caused by the release of inflammatory mediators, leading to dilation of the blood vessels and increased vascular permeability. In response to the damage, melanocytes accelerate the production of melanin and its transfer to keratinocytes. This results in a darkening of the skin that appears 2 to 3 days after sunlight exposure, persists for days to weeks, and reduces the skin's sensitivity to UVR by two- to threefold.

Risk Factors

Athletes with more melanin, and darker skin, are at lower risk for sunburn, while fair-skinned athletes are more likely to sunburn. But UVR still penetrates the skin and causes damage in people with dark skin. People living at higher altitudes or locations with predominantly sunny climates have an increased risk due to more exposure to sunlight. Sweating has also been found to increase the photosensitivity of the skin and to increase the risk of sunburn.

Signs and Symptoms of Sunburn

Sunburn is characterized by skin that feels hot or warm to the touch along with the development of red or pink skin after exposure to even a brief period of sunlight or other source of UVR. There will likely be discomfort in the affected area and possibly swelling. Fluid-filled blisters may develop on the skin. Headache, fever, and fatigue may also go along with sunburn. Sunburned eyes have a gritty, painful feeling. A few days after sunburn appears, the skin will begin to become flaky and peel.

Most sunburns do not require assessment by a medical provider. However, the following findings with sunburn require evaluation:

- High fever, intense pain, vomiting, diarrhea, or confusion
- Blistering that covers a large part of the body
- Signs of a skin infection (drainage of yellow pus from the area or increased pain or swelling in an affected area)
- Pain that is not adequately controlled with home treatments

Long-Term Complications

Skin photoaging, actinic keratoses (rough, scaly patches of skin), and skin cancer are some of the long-term effects of sun exposure. Over time, sun exposure causes the connective tissues of the skin to weaken, leading to dryer, rougher skin with deep wrinkling. Large brown macules, called solar lentigines (liver spots), can appear on sun-exposed areas. Actinic keratoses are usually white, pink, flesh-colored, or brown patches that commonly develop on the face, ears, lower arms, and backs of the hands. Actinic keratoses occur mainly in fair-skinned individuals who have had a large amount of sun exposure. They are considered precancerous, and they can develop into squamous cell skin cancer. Exposure to UVR, especially UVB radiation, is thought to be the main determinant in the development of basal and squamous cell skin cancers and is also thought to play a role in the development of cutaneous malignant melanoma. An increased prevalence of either precancerous or cancerous skin lesions has been found in professional mountaineers, surfers, marathon runners, and other athletes who practice outdoors.

Prevention

Avoidance of the sun's rays when they are the strongest, generally between 10 a.m. and 4 p.m., is the best recommendation to avoid sunburn. As this is not always possible, protection in the form of clothing, sunglasses, hats, and sunscreen should be used. The sun protection factor (SPF) is a ratio used to indicate the amount of protection against UVB radiation afforded by a given skin protectant compared with unprotected, sun-exposed skin. An SPF of 15 indicates that a person who normally has skin redness after 10 minutes of sun exposure could go in the sun with sunscreen for up to 150 minutes without experiencing the same skin effect.

There are many different agents used in sunscreens. These chemicals protect the skin by both reflecting and dispersing UVR (zinc oxide, titanium dioxide) or absorbing UVR (benzophenones, cinnamates, salicylates, and numerous other compounds). All types of sunscreen should be applied 30 minutes prior to sun exposure and reapplied at least every 2 hours for best protection. Clothing is also an important part of skin protection. Clothes that are tightly woven, loose fitting, dry, unbleached, and made of thicker fabrics increase the UVR protection. Light-colored, cotton, wet, or loosely woven fabrics all offer lower levels of protection. It is also important to wear a broad-brimmed hat and sunglasses that fit close to the face and block out UVR.

Treatment

Once sunburn occurs, skin damage is already present. Treatments are targeted toward symptom relief but do not decrease any of the long-term risks associated with sunlight exposure. It is very important to rule out heat illness in an athlete with acute sunburn. Cool compresses or baths can provide immediate relief. Skin-moisturizing creams, aloe vera lotion, and other over-the-counter emollients containing combinations of menthol, camphor, pramoxine, calamine, or lidocaine can be used to keep the sunburned skin moist and ease some of the tenderness. Oral pain medication such as ibuprofen or other nonsteroidal anti-inflammatory drugs (NSAIDs) have been found to be most beneficial if taken immediately after the signs of sunburn begin to appear. Oral and topical corticosteroids have been found to have minimal impact on sunburn. If blistering appears, it is best to leave the blisters intact to decrease the risk of skin infection. Eventually, the skin will begin to peel as the body removes the damaged cells from its top layers. Moisturizing creams are recommended during this process.

Sunburn and Skin Cancers

The incidence of skin cancer has been increasing in the general population for the past several years, and the amount of sun exposure remains the most important risk factor. Athletes should be taught basic prevention measures, such as avoiding sunburn by using sunscreen and protective clothing as well as avoiding sun exposure during peak ultraviolet B (UVB) hours. Sunburn is the painful, erythematous reaction of the skin in response to excessive sun exposure that often afflicts athletes who spend many hours training outdoors. In the United States, 30% to 40% of adults and 70% to 85% of children and adolescents have reported at least one occurrence of sunburn in the previous year. Sunburns not only cause acute discomfort after sun exposure but may ultimately lead to skin cancer.

Anatomy

The skin is the body's largest organ, covering the entire outside of the body and weighing about 6 pounds (lb; 1 lb = 0.45 kilogram). In addition to serving as a protective shield against infection, the skin also regulates body temperature and stores water, fat, and vitamin D. The skin is made up of three layers, each of which has a specific function: (1) the *epidermis*, which provides a barrier to infection; (2) the *dermis*, which is made of connective tissue that cushions the body from stress and strain; and (3) the *hypodermis* layer, which is mainly for fat storage.

Causes

Sunburn is a burn on the skin caused by UV radiation. The damaging effects of UV radiation can occur after as few as 15 minutes of sun exposure for light-skinned persons. The symptoms of sunburn do not begin until 2 to 4 hours after the damage has occurred. Minor sunburn is a first-degree burn that turns the skin pink or red. Prolonged sun exposure can cause blistering and is described as a second-degree burn. Sunburn never causes a third-degree burn or scarring.

Frequent sun exposure and suntans can also cause premature aging of the skin (wrinkling, sagging, and brown sunspots). Also, repeated sunburns increase the risk of skin cancer in the damaged areas. Each episode of blistering sunburn doubles the risk of developing *malignant melanoma,* which is the most serious type of skin cancer.

Symptoms

Mild and uncomplicated cases of sunburn usually result in minor skin redness and irritation. Initially, the skin turns red between 2 to 4 hours after exposure and feels irritated. The peak effects are noted at 12 to 24 hours. Other common symptoms of sunburn involve flulike symptoms, including fever, chills, nausea, and vomiting. More severe cases have complications such as severe skin burning and blistering, massive fluid loss, electrolyte imbalance, and infection.

Symptoms of skin cancer may vary from a melanocytic lesion that is completely asymptomatic to a painful bleeding erosion characteristic of squamous cell carcinoma. Routine skin evaluation by a medical provider has been recommended, because most skin cancers are asymptomatic and are found on routine screening examinations.

Diagnosis

Diagnosis of sunburn is usually not difficult and could be made based on symptomatology and a recent history of sun exposure. The appearance of a characteristic reaction on sun-exposed skin with sparing of skin that was covered or shaded is usually sufficient to diagnose sunburn.

The first step in detecting skin cancer begins with each individual. It is recommended that each person examine his or her skin once a month for any suspicious changes, such as moles that have changed in color, size, and/or surface texture. Also, sores that do not heal may also indicate cancerous or precancerous conditions of the skin that need attention.

Actinic keratoses are precancerous conditions that typically occur in individuals with a long history of sun-damaged skin. Lesions appear as rough, crusty bumps on the back of the hands, lips, face, scalp, or neck that may itch or feel tender. If untreated, these bumps may develop into skin cancer.

Basal cell carcinomas show up as flat, firm, pale areas or as small raised pink or red pearly bumps that may appear anywhere on the body that is regularly exposed to the sun, such as the head and neck. They grow slowly and rarely spread to other parts of the body.

Squamous cell carcinomas appear as nodules or as red, scaly patches, typically on the ear, face, lips, and mouth. These patches eventually develop into large masses. This type of skin cancer is more likely to spread to other parts of the body than basal cell carcinoma. Squamous cell carcinomas are highly treatable, with a 95% cure rate.

Melanoma can develop from a preexisting mole or on clear, smooth skin. Unlike a noncancerous mole, melanoma is irregularly shaped or has irregular borders and is black, brown, or tan. The leg is the most common site where melanoma is found in women, and the trunk is the most common site in men. Early diagnosis is the most important factor to improve the prognosis in this potentially fatal disease.

Treatment

A number of treatments aimed at altering the course of sunburn have been prescribed, but none will immediately reverse the damage from sunburn. These treatments include nonsteroidal anti-inflammatory drugs (both topical and oral), cold compresses, aloe vera gel, and topical anesthetics such as benzocaine. Currently, treatment of sunburn is only symptomatic, and athletes should avoid further sun exposure until the symptoms resolve.

There are many treatments for skin cancer, which vary depending on the type of skin lesion. Cryotherapy is commonly used on actinic keratosis. This treatment includes applying liquid nitrogen to the lesion for 3 to 5 seconds, which causes the lesion to slough off within a few days. Another common method for treating all other skin cancers is surgical excision of the affected area of skin. The physician cuts out or excises the cancerous tissue and a surrounding margin of healthy skin. A wide excision of skin is often used to ensure that no malignant cells remain.

Laser therapy may be used to produce a precise, intense beam of light to vaporize growths. Generally, this will cause little damage to the surrounding tissue and minimal bleeding, swelling, and scarring. Mohs surgery is a procedure for large, recurring, or difficult-to-treat skin cancers, which may include both basal and squamous cell carcinomas. The surgeon removes the skin growth layer by layer, examining each layer under the microscope until no abnormal cells remain. This procedure allows cancerous cells to be removed while leaving as much surrounding healthy skin as possible.

Curettage and electrodesiccation are a procedure in which, after removing most of the growth, the doctor scrapes away layers of cancer cells using a circular blade called a *curet*. An electric needle destroys any remaining cancer cells. This procedure is common in treating small or thin basal cell cancers and leaves only a small, flat, white scar.

Radiation therapy may be used to destroy basal and squamous cell carcinomas if surgery is not an option. Systemic chemotherapy can be used to treat skin cancers that have spread to other parts of the body. Photodynamic therapy (PDT) is a treatment that destroys skin cancer cells with a combination of laser light and drugs that makes cancer cells sensitive to light. Photodynamic therapy for precancerous skin lesions is currently available by prescription.

Prevention

Limiting sun exposure is the most important part of preventing sunburn; when avoiding exposure is not possible, proper use of sunscreen and protective clothing is vital. Routine self-examination followed by regular skin checks by your health care provider is the best way to detect any skin abnormalities that could be diagnosed as skin cancer. The American Academy of Dermatology has developed an easy-to-use method to evaluate your skin for melanoma, titled the "ABCDs of melanoma." Look for the following:

*A*symmetry: One half of the spot is not shaped like the other half.

*B*order irregularity: The border is poorly defined, ragged, blurred, notched, or "scalloped."

*C*olor: Across the mole, there are various shades of tan, brown, black, and sometimes red, white, and blue.

*D*iameter: The mole is greater than 6 millimeters.

Superficial Heat

Application of superficial heat is an adjunct to a therapeutic treatment program in the rehabilitation of an injury. Superficial heat is a modality that provides pain control, promotes muscle relaxation, and increases blood flow to the area. Types of superficial heat include fluidotherapy, hot packs, and paraffin. Indications for use are joint stiffness, muscle spasm, pain, and weakness. The normal responses to application of superficial heat are decreased pain, swelling, and muscle spasm; an increase in circulation; and mild redness of the skin. The abnormal responses to superficial heat are increased pain, fainting, bleeding, and prolonged skin redness and/or blistering.

Fluidotherapy

Fluidotherapy is a modality that uses air-fluidized solids called Cellex (particles made from corn cobs), which are placed into a container. Heated air is then blown into the enclosure, causing the Cellex to circulate. An arm or leg can be inserted into the container, and the warmed, moving Cellex flows around the injured arm or leg. Fluidotherapy provides localized heat while the patient completes active or passive range-of-motion exercises.

Contraindications include respiratory distress, skin disorder, corn allergy, circulatory obstruction, arterial occlusion, blood clots, lymph occlusion, acquired immune deficiency syndrome (AIDS), poor sensation, hepatitis, chicken pox, typhoid, paratyphoid, sepsis, and/or other infectious diseases.

Precautions should be taken in the case of an open wound or poor mental status.

Hot Packs

Hot packs provide superficial moist heat via conduction. They are applied to the injured area for 15 to 20 minutes. Hot packs are usually made of canvas covers filled with bentonite, hydrophilic silicate, and other heat-retaining substances. Some hot packs are stored in water with a controlled temperature of approximately 160 °F (71.1 °C). Contraindications include fever, acute inflammatory conditions, active bleeding, long-term steroid therapy, blood clots, and malignancy. Precautions are necessary in case of pregnancy, sensory or circulatory impairments, older age, and the inability to stay still for 15 to 20 minutes. A thick protective barrier must be placed between the hot pack and the skin to avoid burning.

Paraffin

Paraffin application is a method of applying superficial heat that uses conduction through a mixture of paraffin wax and mineral oil in a 6:1 or 7:1 ratio. The heating container should maintain the temperature of the paraffin at 118 to 130 °F (47–54.4 °C).

Contraindications include open wounds, skin lesions, fever, acute inflammatory conditions, active bleeding, long-term steroid therapy, and blood clots. Precautions should be taken in case of poor mental status, age, sensory loss, and newly healed skin.

Superior Labrum From Anterior to Posterior (SLAP) Lesions

A *SLAP* (superior labrum from anterior to posterior) *lesion* is a tear in the superior part of the shoulder joint lining (glenoid labrum) in an anterior-posterior direction. Typical causes of this tear include, but are not limited to, the following:

1. Sports: particularly activities that induce compressive forces on the shoulder, such as baseball, volleyball, and tennis
2. Overuse: doing too much at one time (e.g., overhead activity) coupled with severe tension on the biceps muscle tendon
3. A sudden increase in activity, such as lifting a very heavy barbell
4. A fall onto an outstretched arm.
5. An imbalance between the muscles and ligaments that provide stability to the shoulder joint

To understand the mechanism of the injury, a basic understanding of the anatomy of the involved structures is necessary.

Basic Anatomy

The shoulder is a ball-and-socket joint; the glenoid fossa (cavity) of the scapula (shoulder blade) is the socket and is composed of bone at the base and lined with cartilage. It is surrounded with additional lining at the circular rim by the *glenoid labrum* (from the Latin meaning "upper lip"), which is composed of cartilage, providing a cushion. It also makes the socket deeper and provides more stability to the joint, permitting easier movement with minimal friction. The ball of the joint is the proximal part of the humerus (upper arm bone) that is embedded in the glenoid fossa and surrounded by the glenoid labrum.

Several muscles and ligaments help with movement by initiating, maintaining, and balancing the forces that enable the ball to remain in the joint. The major muscles involved include the deltoid, biceps, and supraspinatus. The glenohumeral ligaments attach to the lesser tubercle of the humerus and the lateral part of the scapula. The semicircular ligament runs side to side, which is very important for stability. Synchronous motion of the ligaments and muscles provides stability and strength to the shoulder. Major motions include abduction (motion away from the body), adduction (motion toward the body), and internal and external rotation.

The main muscles are as follows:

- The *deltoid muscle* covers the shoulder joint and provides a smooth contour of the shoulder. It acts as abductor of the arm and is innervated by the axillary nerve. Any injury to this nerve will affect this function of the deltoid muscle. It originates from the humerus and inserts into the shoulder joint, covering the joint from three surfaces.
- The *biceps muscle* acts to flex and supinate (turn up) the arm. It originates at the elbow and inserts into the glenoid labrum superiorly by its tendon (a band of dense fibrous tissue that unites muscle to bone). The muscle is innervated by musculocutaneous nerve.

The word *tendon* comes from the Latin word meaning "to stretch." The tendon transmits force when the muscles contract. Ligaments are similar, but they originate in bone and insert to bone.

Injuries can occur in a variety of ways—if a patient tries to lift a heavy weight, a lot of force will be exerted on the tendon and its area of insertion (in this case, the glenoid labrum). Two possible injuries could occur. The tendon could get inflamed and begin to tear from the area of insertion or, in the worst case, avulse (snap off), possibly taking a part of the glenoid labrum (cartilage) as well, causing a SLAP tear.

The supraspinatus is part of the rotator cuff muscles, which also include the infraspinatus, teres minor, and subscapularis. The supraspinatus originates at the scapula, or wing bone, passing under the acromion and inserting into the ball of the humerus, and is innervated by the suprascapular nerve. It causes abduction of the arms and is the most commonly injured among the rotator cuff muscles, especially with eccentric repetitive load applied to the muscle.

The infraspinatus originates at the shoulder blade and inserts at the humeral head, which is encapsulated under the coracoacromial arch. It laterally rotates the arm and is innervated by the suprascapular nerve.

Because the muscle tendons pass through a very narrow area, they are very susceptible to injuries. In addition, any buildup of calcification (bone spurs) may also cause problems.

The shoulder has two sets of muscles and ligaments, both with differing functions. Some hold the joint in place, whereas the others permit free motion of the shoulder and upper arm in all directions with ease and without any limitation.

Many factors come into play to ensure good shoulder movement.

The mechanism of injury is not fully understood; however, one scenario is that a sudden contraction of the biceps muscle causes stress on the tendon that is attached to the labrum, and to prevent dislocation of the shoulder, the labrum will tear.

As an example, throwing a ball in a sport such as baseball can cause shoulder injury. The technique of throwing has six phases, each of which can induce certain stresses on the shoulder. In the SLAP tear injury, the late cocking and deceleration phases are the primary contributors of injury in baseball players.

Phase 1: Wind-up is the phase during which there is minimal stress to the shoulder.

Phase 2: Early cocking is a slight-load phase, where the shoulder moves into abduction (away from the center of the body).

Phase 3: Late cocking begins with the stride leg being planted and ends with the shoulder in maximum external rotation, up to 180°. Muscle activity reaches its maximal stress in this phase.

Phase 4: Acceleration rotates the shoulder to the ball release point of 90° rotation, maintaining shoulder abduction.

Phase 5: Deceleration is the most harmful phase of the throwing cycle, where maximal eccentric contractions occur in several muscles to prevent rotation of the arm.

Phase 6: The follow-through is the phase where the body is rebalancing, and the body moves forward until the motion stops and returns to resting levels.

The entire throwing motion, through all six phases, will take less than 2 seconds.

Diagnosis

The patient's history is the key to the diagnosis, and a typical patient may present with complaints that include the following:

- General weakness
- Anterior-lateral sharp pain that gets worse with lifting items
- A perception of the shoulder being unstable
- Diminished arm range of motion
- Feeling as if the joint needs lubrication, due to the consciousness of internal friction
- An increase in pain when trying to do activities that require the arm to be up and behind
- A history of overuse and repetitive activities
- Trauma such as falling on an outstretched arm, which may force the biceps and other shoulder muscles to contract or stretch in unsynchronized actions that may cause a tear

The patient may often be an athlete, especially one involved in sports that require contraction of the biceps, such as swimming, racquetball, football, and so on.

Diagnosis of a SLAP Lesion

Physical Exam

The patient's history is the primary key to the diagnosis, along with the physical exam. The physical exam should include the following:

- Observe the patient for any swelling, deformity, or color changes.

- Evaluate active range of motion: The patient moves his or her shoulder and arms in all directions without assistance from the examiner.
- Evaluate passive range of motion: The examiner moves the shoulder and arms in all directions without the patient's help.
- Evaluate for isometric resistance and muscle strength of the shoulder joint: The patient moves the shoulder or the arm while the examiner tries to prevent the movement by applying force.
- Palpate the joint of the patient for tenderness.
- Evaluate the shoulder and upper arm for sensory deficit.
- Evaluate the blood flow by palpating the pulse at the biceps area.
- Evaluate for osteopathic somatic dysfunction, incorporating manual medicine to evaluate the joint for any restrictions of movement.
- Incorporate special tests that primarily stress the shoulder joint, muscles, and tendons:
  - *Speed test:* The patient flexes the forearm against resistance from the examiner. Pain will increase at the area where the biceps tendon passes to the joint.
  - *Yergason test:* The patient flexes the forearm toward the body while the examiner resists, leading to an increase in pain.

Radiologic studies are not always helpful as an X-ray will not help establish a diagnosis.

For a clinically suspected tear, the orthopedic surgeon can obtain an arthrogram by injecting dye into the joint and obtaining an X-ray to make the lesion more visible. Arthroscopy may also be done, which involves using a small fiber-optic camera to evaluate the lesion.

There is no single physical exam test to diagnose a SLAP lesion. The aforementioned special tests aid, along with the patient's history, in establishing the diagnosis.

Nonsurgical Interventions

Some nonsurgical interventions are listed below:

- The patient has to decrease those activities that cause the symptoms.
- Anti-inflammatory medication as tolerated is administered.
- Physical therapy to regain range of motion is advised.
- Surgical repair is suggested if all the above fail.

Surgical Intervention

Based on the extent of the injury, the surgeon will either reattach or possibly trim the excess tissue.

Postsurgical Intervention

Ensure that physical therapy (shoulder rehabilitation exercises) is initiated as soon as possible, based on the type of injury sustained. Typically, patients need to rest for a month and then increase activities as tolerated.

In summary, this lesion is not very common, but once it occurs, it can be very debilitating, affecting activities of daily living and participation in sports. Prevention is the key. The athlete is advised to start slowly and increase the activity level gradually as tolerated. At the first sign of the symptoms discussed, a visit to the physician is recommended.

Athletes with this shoulder injury should refrain from participation in sports pending clearance from their physician to prevent further damage to the shoulder.

Surfing, Injuries in

Surfboard riding (surfing) is a sport practiced in coastal areas around the world. For the purposes of this entry, surfing will describe the sport whereby the participant engages waves in the water while standing on a surfboard. This is in contradistinction to many other wave and board sports, ranging from bodysurfing to boogie boarding to kite boarding and other activities.

Surfing is a sport that is practiced in increasing numbers: It is estimated that 1.7 million people in the United States and more than 18 million people worldwide participate in this sport.

Overview of the Sport

The sport began centuries ago in the South Pacific. Westerners first encountered surfing in the 18th century when exploring the Pacific islands. In Hawaii, for instance, it was considered the sport of the royalty. It is reported that missionaries actively suppressed the practice in the European settlements, and the sport continued to decline until the 20th century.

The resurgence of the sport in the 20th century began with Duke Kahanamoku, a Hawaiian Olympic swimmer who performed surfing exhibitions in America and Australia. In the mid 20th century, a nexus of factors contributed to the rise in the popularity of surfing: Advances in surfboard design allowed for mass production of lighter-weight boards using materials such as balsa wood, foam, and fiberglass, and cultural changes, including increased emigration to the warm coastal zones and the rise of a "beach culture," saw markedly increased numbers of people take up the sport. By the turn of the millennia, surfing had grown into a worldwide participatory sport and a big business: 195 million surfboards were sold worldwide in 1995.

Surfing is primarily a recreational sport, though worldwide there are increasing numbers of competitions and attempts at forming surfing associations. The Association of Surfing Professionals (ASP) organizes regular competitions at the professional level. On the local level, there are an ever-increasing number of amateur and school-based competitions. There are contests also that center on "big-wave" riding, with its inherently higher risk of injury; "Mavericks" in Northern California is perhaps the most famous.

The vast majority of participants, however, will mostly take to the water to have fun and will be under no formal regulations or requirements. On some level, all that is needed to participate in the sport is a board and access to waves. Surfers can be of all ages and both genders, though many authors have noted a preponderance of male surfers: In many studies, the ratio of male to female surfers is on the order of 9:1. This too, as in many sports, appears to be changing, and increasing numbers of women are taking up the sport.

A final note should be made about the distinct difference between *longboards* and *shortboards,* which represent the two principal types of boards a surfer might use. Each uses a slightly different style. Longboards are typically greater than 2.2 meters (m) in length and are characterized by a rounded nose with one to three fins. They are marked by being more buoyant, more stable, and less maneuverable than shortboards. Shortboards are 2.2 m or less in length, typically have a pointed nose and three fins, and are very light. Shortboard riders often aim to perform more dynamic moves on the waves, including cutbacks, 360° rotations, and "aerials" (launching into the air off a wave). Neophyte surfers typically learn on longboards; more expert surfers may choose either type of board, depending on the wave conditions and the goals for any particular surf session.

Most boards also include a leash attached to the surfer's ankle, enabling the surfer and his or her board to be in somewhat close proximity after the inevitable wipeout. Using a leash can also prevent one's board from flying into a neighbor on the water, but the device is not without risk, as will be discussed subsequently.

Demands of the Sport

Real-time analysis has found that surfing is an intermittent sport in which paddling accounts for

A surfer wiping out on Hawaii's Bonzai Pipeline. Surfers are prone to injuries related to environmental exposure as well as acute and repetitive stress injuries.

Source: Jan Tyler/iStockphoto.

50% of the activity and waiting for suitable waves while on the board accounts for another 40%; only 5% to 10% of a surf session is actually spent riding a wave. A large amount of the time in the water, then, a surfer will be paddling prone, with his or her back in hyperextension. When "catching a wave," the surfer will then pop up from a prone to a standing position as he or she descends the face of the wave. Executing subsequent maneuvers, ranging from turning at the bottom of the wave to cutting back up the face of the wave to still more (see www.riptionary.com), will require an extraordinary amount of balance and lower body strength.

The unique demands of the sport require that the surfer possess a decent amount of both aerobic and anaerobic fitness. Paddling out to a surf break and negotiating obstacles (ranging from waves to other surfers) requires high levels of upper body strength, especially in the shoulders, and a good deal of upper body fitness. Studies have shown that elite surfers will have peak oxygen uptake characteristics similar to other elite upper body athletes (e.g., kayakers) and anaerobic power capacities similar to rugby players.

Injuries

Surfers are prone to *acute* injuries; chronic, repetitive motion injuries; and injuries related to environmental exposure. The reported injury rate has been 4 per 1,000 hours of play (comparatively, the injury rate among National Collegiate Athletic Association [NCAA] male soccer players is 18 per 1,000 hours of play). Some caution should be used, however, in interpreting these numbers, as the novice participation rate in the sport is ever increasing and it is likely that the studies reflect some underreporting in injury rates. Likewise, injuries are thought to be on the rise with increased crowding in the water leading to more likely collisions between surfers and other people and objects in the water. Overall, however, surfing appears to be a relatively safe activity.

Soft tissue injuries such as contusions and abrasions are among the most frequent injuries a surfer will sustain, with lacerations being the most common, representing 42% of all acute injuries. Injury surveillance studies note that the surfer's face is the most common area for lacerations, and the culprit is typically the surfer's own board. The board leash is implicated in many of these injuries, as the board can easily recoil into the surfer after a wipeout. Minor wounds are typically treated in the usual manner, with particular attention to thorough irrigation and exploration to remove retained foreign bodies. Major wounds oftentimes require consideration of delayed primary closure and/or prophylaxis against infection from common marine pathogens, including *Vibrio* species—fluoroquinolones or third-generation cephalosporins. Ruling out an associated open fracture is also important, and consideration should be given to appropriate imaging if indicated.

There are a great number of musculoskeletal conditions that can plague the surfer. Given the great amount of paddling a surfer will do, it is not surprising that shoulder problems are common. Overuse injuries such as impingement, rotator cuff tendinitis, and acquired acromioclavicular (AC) joint arthropathies are seen. Acute injuries, such as shoulder dislocations, can give rise to acquired instability and labral pathology. The back knee of the surfer (farthest away from the board's nose) is another joint at risk, as many maneuvers will require the surfer to put this knee into acute valgus position, courting potential disaster to the medial collateral ligament and meniscus as well as the anterior cruciate ligament (ACL). The front knee, conversely, is oftentimes at risk of hyperextension injuries, including hamstring strains.

Paddling requires the surfer to be in a hyperextended position for prolonged periods of time, and this leads to some special injury patterns. Simple low back strain is common. The typical surfer needs to pay special attention to core and abdominal strength, as well as flexibility of the back, hamstrings, and hip flexors. Over time, isometric hyperextension, repetitive torquing of the lower spine from various maneuvers, and acquired trauma from waves and the like can give rise to spondylolysis and spondylolisthesis. Older surfers often develop degenerative disk disease of the lumbosacral spine.

A unique condition is being increasingly reported in novice surfers: *surfer's myelopathy*. A nontraumatic, usually temporary, paraplegia can develop and appears to be the result of ischemia to the lower thoracic spinal cord caused by the prolonged hyperextension seen when board paddling. Signs and symptoms include lower extremity sensory changes and weakness, new-onset mid to low back pain, and urinary retention. Treatment protocols are still being developed.

Cervical spine trauma is a possibility, as waves can break on reefs, on sand bars, and near fixed objects such as jetties. Aging surfers with preexisting, acquired spondylolysis are at particular risk of catastrophic injury from forced neck hyperextension.

Head, eyes, ears, nose, and throat (HEENT) issues are seen frequently in surfers. Recoil of a board, for instance, can cause much more damage than lacerations. Concussions, oral and maxillofacial injuries, orbital fractures, ruptured globes, and a detached retina have all been seen as a result of trauma sustained during surfing. There is an increasing awareness of the danger to the eye courted by surfers, and there are increasing attempts to encourage use of eye protection when in the surf.

Less severe, but oftentimes more troubling to the surfers because of their frequency and ability to keep them out of the water, are acute conditions such as otitis externa, ruptured tympanic membrane, and the chronic condition known as "surfer's ear." Otitis externa should be treated in the usual manner. Prophylaxis can be achieved by using ear plugs and after a surf session instilling a 50:50 mix of white vinegar and alcohol. A ruptured tympanic membrane will usually spontaneously heal after approximately 2 weeks, and the surfer should not be allowed to enter the water until that time. Close follow-up is indicated.

Surfer's ear is a term applied to external auditory exostoses that develop over years of participation in the sport. The external ear canal develops a reactive hyperemia on exposure to water, particularly cold water; chronically, the reaction can proceed to development of exostoses in the canal. These growths can cause a progressive, albeit reversible, obstructive hearing loss and can also predispose the surfer to recurrent external ear infections. Studies have demonstrated that the longer one surfs and the more the surfer exposes himself or herself to cold water, the higher the chance of developing this condition: A male surfer who has surfed regularly for more than 20 years has a one in two chance of developing this condition. Treatment is surgical, but this is an eminently preventable condition with regular use of ear plugs.

Finally, this is a sport in which the environment affects the participant in a much more direct and significant way than seen in many other sports. Surfers are at high risk for acute and chronic sun damage to the skin and eyes: Sunburns, skin cancers, actinic conjunctivitis, and pterygiums are seen frequently in the surfing population. As ever, prevention can play a significant role here. Regular and frequent use of a waterproof sunblock is encouraged. There are also commercial eye protection devices that can provide ultraviolet protection as well as protection against trauma; it remains to be seen how often a surfer might use these.

The "big risks" of being in marine environments, such as shark attacks, get a lot of media attention but are very rare. More common are marine envenomations from coelenterates (jellyfish and related organisms), stingrays, sea urchins, and coral reef lacerations. Treatment for these injuries can be found in the recommended readings. Drowning, as in all water sports, is a risk every surfer takes. The best prevention of this catastrophe is prudence. At all times, the surfer should be aware of environmental conditions, avoid concomitant use of mind-altering substances, surf with a "buddy," and avoid surfing if conditions exceed one's ability.

Swimming, Injuries in

Swimming is a highly popular sport involving participants of all ages, various body types, and both genders. People take up the sport for leisure and cardiovascular exercise as well as competition. Swimming can be broadly defined as nearly any movement an individual can do in the water. For the purposes of this entry, the concept of *swimming* will be restricted to what is generally considered supervised lap swimming, using defined stroke techniques. There will also be some discussion of open-water swimming, which is a sport pursued in its own right as well as one component of the triathlon event. (Serious and catastrophic cervical spine injuries that may occur when diving into a pool or open water are not discussed in this entry.)

Most swimmers will train in pools, which are typically set up as "short course" (25 meters [m] in length) or "long course" (50 m in length). Open-water swimming refers to swimming in lakes, ocean, or other bodies of water; the distances involved here sometimes are measured in miles.

The four principal competitive strokes are the front crawl, breaststroke, backstroke, and butterfly. Over the years, there have been some modifications in the forms, techniques, and regulations pertaining to each stroke. The recommended reading section gives a fuller treatment of each stroke. The term *freestyle* is sometimes used synonymously with the front crawl but more accurately means *any style* for individual distances and *any style but breaststroke, butterfly, and backstroke* for the medley events.

Some authors have argued that swimming possibly provides the most balanced form of exercise. Use of different strokes and variation in technique emphasize at different times the upper extremities and the lower extremities. The swimmer can develop endurance, power, agility, and coordination in the entire body. Swimmers attest to the psychological benefits of the sport. In competition, the athlete can perform both as an individual and as a team member, especially in relay events. The sport can, therefore, appeal both to the loner and to those who socialize. Equipment is minimal. Perhaps, the only drawbacks are the obvious need for access to water and the fact that swimming does not involve full-body weight-bearing impact on the skeleton and hence does not enhance bone density.

Swimming is particularly suited to the developing athlete. Acquiring good fundamentals as a youth can lead to mastering an activity that can be carried forth through one's geriatric years. Studies have demonstrated an exceptionally low acute injury rate. Compared with age-matched nonathlete controls of ages 13 to 19, young swimmers have been found to demonstrate enhanced physical, cardiovascular, mental, and social skills.

A final note should be made about equipment. At the most basic level, a swimsuit is all that is needed. Goggles are typically worn to prevent irritation to the eyes from the chlorine often used to clean pools. There are many different devices used by coaches and athletes for stroke work or overload training. The most common are fins, kickboards, pull buoys (a flotation device put between the legs of the swimmer to move without the use of the legs), and hand paddles. At times, these devices can be involved both in the development and in the treatment of injuries, as is discussed below.

Injury Patterns

General Principles

From an orthopedic perspective, overuse conditions predominate as the type of injuries that swimmers will encounter. It is estimated that the average collegiate swimmer performs 1 to 2 million strokes annually with each arm. Periodicity is sometimes less than ideal: Swimming for many participants is a year-round activity, often involving two practice sessions daily. During these sessions, the athlete may swim extraordinary distances: 10,000 to 15,000 m/day of training is not uncommon at the college level. Additionally, the swimmer may engage in "dry-land" weight training and stretching activities, some of which may actually increase the risk of injury.

Besides overuse, technique can also expose the swimmer to injury. Poor stroke mechanics applied in the front crawl are frequently implicated in the development of shoulder problems. The arm pull in the butterfly stroke and breaststroke, and less frequently the freestyle, can cause stress syndromes of the elbow. The breaststroke, with its specialized kick, can cause a similar stress injury to the knee. Though swimming, especially the front crawl, is often an exercise prescribed for the treatment of back pain, the unique movements of some strokes expose the back to some risk. The breaststroke can induce an exaggerated lordotic posture of the lower back, causing extension-based back problems. The butterfly stroke has been implicated in the development and exacerbation of Scheuermann kyphosis.

Given this involvement of overuse and technique, most orthopedic issues seen in swimmers, after an accurate diagnosis has been made, will respond to rest, targeted physical therapy, and attention to appropriate modification of technique.

As a final note, though management of most swimming injuries will require rest, it is important to minimize the swimmer's time out of the water not only to avoid deconditioning but also to enhance compliance. Intelligent use of other strokes and/or equipment can often allow the swimmer to rest the affected body part while still being in the pool.

Shoulder

The upper extremity is frequently injured as a result of overuse in the competitive swimmer, and of the involved joints, the shoulder is, far and away, the most frequently implicated: It has been reported that 90% of the complaints by swimmers that bring them to a doctor are related to shoulder problems.

Swimmer's shoulder is the most common injury seen. This is an inflammatory condition of the supraspinatus and biceps tendons, resulting from overuse, glenohumeral instability, and, at times, improper stroke technique. All three contributory causes should be addressed in the diagnosis and treatment of the condition.

The glenohumeral instability seen in this condition is often acquired. Many elite swimmers have inherent ligamentous laxity and often will have multidirectional shoulder instability. However, all swimmers will overdevelop the adductor and internal rotator muscles of the shoulder simply by performing their stroke. The relative weakness of the external rotators and scapular stabilizers of the shoulder results in a humeral head that can migrate anteriorly and superiorly during the front crawl and also the butterfly stroke. Related to overuse, technique, training style (e.g., pull buoys, paddles), and acquired muscular imbalances, the adductors and internal rotators become overdeveloped and the anterior capsule more lax.

The patient will typically present with diffuse shoulder pain and aching that have gradually increased with training. At times, the pain will be localized to the posterior or anterior shoulder, corresponding to the location of the supraspinatus and the biceps tendon. Physical examination generally reveals weakness of the rotator cuff muscles. Maneuvers designed to assess impingement, including the Neer and Hawkins tests, will oftentimes be positive. So too, maneuvers assessing the biceps tendon, such as the Speed and Yergason tests, can be positive. The patient will oftentimes have generalized ligamentous laxity, and the shoulder will often be found to be exceptionally lax or even unstable; occasionally, anterior apprehension and anterior subluxation of the shoulder can be seen on exam.

Imaging is usually not indicated in swimmer's shoulder and should be reserved for recalcitrant cases, atypical presentations, or at times initially for the older swimmer.

Treatment will begin with relative rest. Typically, the front crawl will need to be avoided. If the patient's symptoms are unilateral, they may be allowed to do the one-armed butterfly stroke. Breaststroke and backstrokes are often forgiving. Kick drills can be done, but kick boards (which tend to forward flex the shoulder and aggravate impingement) should be avoided. Paddles and pull buoys, which often contribute to the problem in the first place, should be entirely avoided.

A coach should look at the swimmer's mechanics. In a properly performed front crawl technique, the elbow remains well above the hand when the arm is out of the water, during the recovery phase of the stroke, and as the hand enters the water, during the "catch" phase. Swimmers who allow their elbows to drop may irritate the rotator cuff muscles.

Rehabilitation should focus on stretching the posterior capsule; strengthening the scapular stabilizers as well as the rotator cuff muscles, especially the infraspinatus and teres minor; and occasionally addressing core stability weakness. Exercises in the initial phase should exclude movements that abduct or flex the shoulder beyond 90°.

True rotator cuff tendinitis and bicipital tendinitis can be seen and should be treated accordingly. Degenerative diseases of the shoulder are typically seen in masters-level swimmers. Acromioclavicular and glenohumeral joint arthritis are found in this population, as well as true bony impingement. The geriatric patient may present with a frank, degenerative tear of the rotator cuff tendon. The clinician should have a low threshold for obtaining plain-film radiography, and possibly advanced imaging, in swimmers above the age of 35 years. Treatment would initially be similar to that described above for swimmer's shoulder, but in degenerative cases, more aggressive treatment, including referral to orthopedic surgery, is often indicated. The details of this treatment are beyond the scope of this entry and are found elsewhere in this encyclopedia.

Knee

Knee injuries in swimmers are almost exclusively seen in breaststrokers and are related to the use of the whip kick in that stroke. A study reviewing knee pain in breaststrokers demonstrated an association between more frequent knee pain and higher age of the swimmer, increasing years of competition, increase in training distance, and decrease in warm-up. Nevertheless, the very biomechanics of the stroke can put any breaststroker at risk.

The whip kick itself does not use the flexion and extension patterns seen in the flutter and butterfly kicks, which are natural motions for the knee joint. Rather, the motion applies a significant valgus strain to the joint, resulting in three recognized injury patterns: (1) medial collateral ligament (MCL) stress syndrome, (2) patellofemoral syndrome (PTFS), and (3) medial synovial plica syndrome.

The clinician can diagnose MCL stress syndrome by taking a careful history. Pain is typically activity related, insidious in onset, and localized at the medial aspect of the knee. Palpation over the course of the MCL, from the adductor tubercle of the femur to the insertion on the medial tibia, typically reveals tenderness. Applying a valgus stress to the knee with the leg in external rotation causes pain. The clinical findings of PTFS present no differently in the swimmer than in other athletes. Medial synovial plica syndrome typically presents with complaints of pain experienced at the extension phase of the whip kick. The medial synovial plica is a fold of synovium, which can become irritated; physical examination can frequently reveal a tender, thickened plica crossing the medial femoral condyle. There is typically no pain with a valgus stress.

Treatment for these conditions is typically one of relative rest and the use of anti-inflammatory medications. Occasionally, training can continue by performing strokes other than the breaststroke but only if the swimmer is painfree. Ice and nonsteroidal anti-inflammatory drugs (NSAIDs) are helpful in controlling the inflammation. Addressing stroke mechanics is imperative for all three conditions.

MCL stress syndrome by its nature can persist and can be difficult to treat; it occasionally necessitates changing over to other strokes indefinitely. PTFS is amenable to classic physical therapy techniques addressing patellar tracking. Medial plicae can cause persistent trouble and may require steroid injections or surgical excision.

Foot and Ankle

The most common injury seen in swimmers is tendinitis of the extensor tendons at the extensor retinaculum of the dorsal foot. In this area, the tendons of the extrinsic foot dorsiflexors are encased in their tendon sheaths and are prone to irritation.

In both the flutter kick of the front crawl and the dolphin kick of the butterfly stroke, the foot and ankle are carried through extreme plantarflexion back to neutral position, setting up a situation where the extensor tendons can become inflamed.

Diagnosis is usually straightforward. There can be swelling and tenderness over the extensor retinaculum. Passive range of motion of the ankle typically elicits crepitus in the tendons; having the patient dorsiflex the foot against resistance can evoke pain.

Treatment involves the use of modalities such as ice and ultrasound; NSAIDs may be used to help decrease the inflammation as well. Relative rest is indicated. The patient may swim using a pull buoy to avoid kicking. A program of gentle, pre-exercise stretching of the extensor tendons should commence. Return to full swimming with normal kicking should progress in a graduated fashion.

Elbow

Stress syndromes of the elbow are seen in the arm pull, particularly in the butterfly strokes and breaststrokes. Occasionally, lateral epicondylitis can be seen. Treatment would include relative rest, attention to stroke mechanics, and eccentric strengthening of the wrist extensors.

Wrist and Hand

Less commonly, de Quervain tenosynovitis can be seen, especially in the older swimmer. Frequently, the inciting cause is poor technique. Diagnosis and treatment are the same as in other athletes with these symptoms. Thoracic outlet syndrome, discussed elsewhere in this text, is occasionally seen in swimmers as well. Presenting complaints include paresthesias radiating down the shoulder and arm into the hand, especially over the small finger, complaints of weakness and aching of the arm, and weakness of the hand grip.

Back

As discussed previously, extension-based back pain, including mechanical low back stress, spondylolysis, and spondylolisthesis, can be seen in the breaststroke and, occasionally, the butterfly stroke, especially when the latter stroke is poorly executed. Scheuermann kyphosis can be seen in the butterfly stroke specialist. Degenerative disease of the cervical spine is occasionally seen in the masters-level swimmer. The clinician should attempt to make a precise and accurate diagnosis and treat accordingly. The specifics of treatment for each condition are elaborated elsewhere in this encyclopedia.

Medical (Nonorthopedic) Issues

Asthma is not infrequently seen in swimmers. Some of those suffering from asthma have positively embraced swimming and have noticed that the warm, humid environment of an indoor pool makes their breathing easier. Others will find that an enclosed environment with chlorine fumes may exacerbate the problem. Clinicians caring for swimmers should be conversant with the management of asthma.

Skin and hair problems are seen in swimmers. Viruses and fungi can be transmitted from pool decks and locker room floors, giving rise to plantar warts and athlete's foot. As ever, prevention (including in this case the use of sandals) beats treatment, which would be done in the usual fashion. Swimmers occasionally will shave their bodies prior to meets, giving rise to folliculitis. Pseudomonas as well as *Staphylococcus* infections are often implicated. Topical antibiotics may be used, but occasionally, oral antibiotics will be required for severe or resistant cases. Chlorine and other chemicals used in the treatment of pool water can affect a swimmer's hair, giving rise to color changes. The most effective treatment is, again, prevention: the use of swim caps and frequent shampooing.

Not surprisingly, otitis externa is seen commonly in swimmers. Prevention is best achieved by wearing a tight-fitting swim cap that covers the ears. Alternatively, commercial products containing vinegar and alcohol can be instilled in the ears after swimming to "dry" the ear canal out. If the patient becomes symptomatic, the use of prescription antibiotic/antifungal/anti-inflammatory eardrops and a period of scrupulous avoidance of water are recommended. Out-of-pool time can last as long as 7 days, but if the patient is asymptomatic after 2 to 3 days, he or she may be allowed back in the pool while continuing treatment.

Eating Disorders

Though more definite data are needed, swimming is recognized, along with cross-country running, gymnastics, and diving, as one of the sports in which female athletes especially will have higher rates of eating disorders, including bulimia, anorexia, and other disordered eating behaviors. In one study, 15% of college female athletes had some form of subclinical eating disorder; this is a higher rate than is seen in the general population. Olympic swimmer Dara Torres has publicly shared her struggle with bulimia as a young swimmer. Swimmers often will pursue disordered eating behaviors in the misguided belief that they will help them swim faster or in pursuit of a more idealized body image. Since a principal hallmark of these illnesses is denial, it is incumbent on coaches, trainers, clinicians, and parents to have a high degree of suspicion when addressing the problem in their athletes.

Drowning

As with any event associated with water, swimming exposes the athlete to the risks of drowning. The danger is greater for the open-water swimmer. It is recommended that an athlete always train in a supervised pool setting (i.e., with a coach or lifeguard) or train with a "buddy," either in the pool or in the open water.

T

Tailbone (Coccyx) Injuries

The tailbone, or *coccyx,* projects below the pelvic bone, first curving backward and then curving forward at the tip. There are three to five segments dividing the coccyx. Between these segments are joints, much like those seen between the bones of the spine. However, these may be fused in the coccyx. Injuries to the region of the coccyx can result when the fused joints are repeatedly forced out of their normal positions with regular activities, causing inflammation of the tissues surrounding it.

When a person is sitting, the coccyx, along with the two prominent regions of the pelvic bone, called the *ischial tuberosities*, bears the weight. When a person leans back in a seated position, the weight load on the coccyx increases. The birth canal in women is defined posteriorly by the coccyx. The muscles responsible for the voluntary control of bowel movement attach onto the coccyx.

Mechanisms of Injury

The coccyx is easily exposed to blunt trauma. A fall backward into a seated position is the most common cause of injury. Direct trauma can occur from a kick, using a trampoline, falling from a horse, or a skiing mishap, causing the coccyx to be bruised, broken, or dislocated. Poor posture while sitting for a prolonged period of time, such as while traveling in a car or plane, or sitting on a hard surface can result in trauma as well. Injuries can be encountered as a result of repetitive pressure on the coccyx, as in cycling and rowing. Prolonged sitting, even on a soft seat (i.e., office workers and students), has been documented on patient history as a reason for coccyx tenderness. Anal intercourse has been implicated in injury to the coccyx.

Because the birth canal is bounded by the coccyx at the back, pressure exerted during childbirth can instigate injury. The coccyx is literally "in the way" during childbirth. The resulting pain can involve the muscles used in bowel movement as well as the muscles of the buttocks.

Signs and Symptoms

The coccyx will be painful and often markedly tender, especially while sitting in a leaning-back position. Pain may also be felt on standing from a seated position, with bowel movements, and during sexual intercourse. The adjacent structures may not be tender.

It is important that spinal and pelvic conditions are ruled out, as these may cause pain over the coccyx area. Disk disease may be misinterpreted as injury to the coccyx. However, the coccyx will usually not be tender if only the spine is involved, and the examiner should consider other diagnoses.

Other possible causes of pain that may be misinterpreted as injury to the coccyx include the following:

- Pain of the pyriformis muscles
- Injury to the pudendal nerve, especially in bikers who sit for prolonged periods of time
- Pilonidal cysts, Tarlov cysts, or meningeal cysts

- Obesity, which leads to excess pressure on the coccyx when sitting
- A bursitis-like condition in slim people, who have little fat padding in their buttocks, causing the tip of the coccyx to constantly rub against the subcutaneous tissues

A rectal and pelvic examination may also be performed to rule out other conditions.

Imaging

Management of the condition often does not change with findings on X-rays, so there is often no need to obtain them, unless the examiner finds the results of a physical examination to be inconclusive. X-rays usually include a lateral view of the coccyx. Lateral views may be taken while standing and sitting to measure coccygeal mobility. X-rays of the coccyx reveal four different types. Most people have a Type I coccyx, which curves slightly forward. The Type II coccyx curves forward, with its tip almost pointing straight forward. The Type III coccyx sharply angles to the front. The Type IV coccyx shows movement of the usually fixed joints within the sacrum or within the coccyx itself. The coccyx can move up to 22° when a person repositions from standing to sitting. Subtle backward movement of the coccyx can be noted by taking a sitting lateral X-ray and comparing it with a standing film to check the amount of translation. Mild displacement is defined as more than 25% movement of the coccyx from the standing to the sitting view. In dynamic X-ray imaging, abnormally increased movement of the coccyx is defined as more than 25° of forward movement on a lateral X-ray. Measurement of the angle formed between the first and last segments of the coccyx can provide an objective measurement of forward movement of the coccyx. Computed tomography (CT) scans and magnetic resonance imaging (MRI) scans often do not add significant information to standing and sitting dynamic views. However, an MRI can be helpful if a tumor or infection is suspected.

Repetitive stretching of the surrounding ligaments and muscles attached to the coccyx may result in inflammation of these tissues, causing pain and soreness when sitting or with straining. Continued movement may prevent healing of this injury, resulting in further damage and perpetuation of the cycle. In such cases, X-rays and MRI scans may be required. Abnormal movement of the coccyx may be due to partial dislocation, and this may be noted on patient X-rays taken in the standing and sitting positions.

Treatment

Relief from pain caused by coccyx injuries may take weeks or even months. Pain in the coccyx after an injury may become chronic in some patients. Referral to a specialist is usually unnecessary; however, referral to pain specialists, medication, rehabilitation, anesthesiology, or orthopedic surgery may be needed for patients who develop chronic pain in the coccyx. Pain due to trauma to the coccyx usually resolves on its own with protection of the bone from further injury. Pain medications, heat, or ice can bring relief. Leaning forward while sitting protects the coccyx, as weight is mainly borne on the ischial tuberosities with this position. Weight may be distributed away from the coccyx by using "doughnut" cushions or pillows with a central hole. "Wedge" cushions or pillows with a wedge-shaped section cut out of the back may also be used. These may be purchased or made quite easily. Hot or cold compresses appear to work in selective cases. Pain relief may be obtained with nonsteroidal anti-inflammatory medications. Narcotic painkillers should be avoided unless the pain is severe.

Specialists may inject a local anesthetic, with or without corticosteroids, using X-rays for guidance. Positive results have been noted in some studies with this treatment, although pain relief has been shown to last only for a few weeks.

Specialists are able to manipulate the coccyx through the rectum. The purposes of this treatment are to massage the muscles attached to the coccyx, as they are often spasmodic, or to mobilize the fascia surrounding the coccyx. Several studies have shown modest improvement with these manipulation techniques.

In chronic cases, antidepressants or antiepileptic medications may be helpful. Acupuncture may be a reasonable option, although it is not known whether modalities such as ultrasound or transcutaneous nerve stimulation actually work to relieve pain due to coccyx injury.

Surgical removal of the coccyx is the last resort. Pain relief obtained after this procedure has been studied, with varied results, mostly leading to the conclusion that surgery does provide pain relief for most patients. However, it is important to note that complications such as infection, injury to the rectum, and problems with bowel movement may occur following this procedure.

Taping

The application of tape in sports plays a significant role in today's athletic performance arena. In professional or collegiate sports, the Olympic Games, or local youth league games, a wide array of taping as well as bracing applications are used to enable athletes to enhance their performance, correct minor functional abnormalities, and participate in sports while recovering from injury.

In 1895, what is now known as the *closed basket weave* was described by V. P. Gibney. This original ankle taping was first known by the name "Gibney boot" and was an imitation of a procedure performed by army medics in England. Since that first taping application, not only has the practice of taping expanded dramatically, but also the taping and bracing industry has undergone considerable growth; currently, there are more than 10 major tape manufacturers, providing a wide variety of padding, braces, adhesives, and tapes for use by practitioners.

In the field of sports medicine, taping techniques are currently taught in a variety of courses for specialists. For Certified Athletic Trainers, taping and bracing is a curriculum requirement mandated by the Board of Certification. Although it is not a mandatory class for those seeking certification as a Licensed Physical Therapist, there are various continuing education and undergraduate elective courses that candidates can take to gain this knowledge and skill. A sound understanding of the mechanisms of injury, detailed knowledge of anatomy, and continuous practice of effective methods are the keys to learning how to tape and brace correctly. Once the basic skills are learned, they can then be adapted to a variety of real-life situations and applications.

Appendix A provides detailed information on the materials and clear, step-by-step explanations, accompanied by photographs, of the taping and wrapping methods and techniques most commonly used by specialists.

Target Heart Rate

The premise of aerobic exercise is to exercise at an intensity that will challenge the aerobic energy system while minimizing the risks of adverse health consequences. One way of remaining cognizant of the intensity at which one is exercising is to monitor the heart rate. Heart rate increases in a predictable fashion as exercise intensity increases from light to moderate to vigorous. There is a linear relationship between the heart rate and exercise intensity, and the heart rate is generally accepted as an accurate means of assessing and monitoring relative exercise intensity.

This relationship is a function of the heart's greater demand to pump blood and oxygen to skeletal muscle at higher intensities. The other parameter that increases the heart's ability to pump blood is an increase in "stroke volume," or the volume of blood pumped during each heartbeat. The extent to which these parameters increase is primarily determined by training status: Untrained individuals rely more on increasing the heart rate, whereas trained athletes have a greater ability to increase stroke volume and thus rely less on heart rate at the same exercise intensity.

Individual athletes have a maximum heart rate often predicted by the simple equation "220 minus age," which reflects the physiological ceiling below which the system operates. Younger athletes tend to have higher maximum heart rates; this maximum declines with age. There is also a difference between the sexes; the equation described above has an error of ±10 beats/minute.

Exercising at intensities close to maximum heart rate has theoretical risks. There is slightly increased incidence of adverse coronary events when the heart is maximally challenged, likely a consequence of relative ischemia (or lack of oxygen supply) to areas of heart muscle, particularly in male athletes younger than 35 years. This ischemia can result in a myocardial infarction or an abnormal heart rhythm, such as ventricular tachycardia, both of which can result in sudden death. This risk is multifactorial and slight and does not preclude athletes around the world from competing at intensities close to the maximum. However, when developing guidelines for the general population to perform aerobic exercise, attention has been focused on encouraging exercise at intensities <85% of the maximum.

Determining the exercise intensity, and hence heart rate, most effective for achieving one's exercise goals depends on what those goals are. Aerobic exercise at lower (light) intensities tends to rely on the oxidation of fatty acids for fuel and hence is a suitable intensity for those attempting to achieve weight loss by "burning" adipose tissue or fat stores.

Athletes hoping to improve aerobic performance seek to optimally challenge the aerobic system at vigorous intensities close to a zone termed the *anaerobic threshold* or *lactate threshold*. This is the intensity of exercise during which the skeletal muscle involved in the activity transitions from mostly aerobic energy production (using oxygen) to energy production incorporating *anaerobic* systems, which do not need oxygen. Stimulation of the anaerobic system results in lactate production and a rise in blood lactate that can be detected at this threshold. Athletes exercising above the anaerobic threshold develop fatigue more rapidly than when solely relying on their aerobic system. Different strategies can be used to account for this, such as exercising just below the anaerobic threshold or exercising using *interval training*, where an athlete raises his or her exercise intensity above the anaerobic threshold for a short period of time, then dips back below the threshold and continues exercising.

Monitoring the heart rate is easily accomplished by counting the pulse rate, either at the wrist (radial pulse) or at the neck (carotid pulse). Typically, counting the pulse for 15 seconds (and multiplying the total by 4) or 30 seconds (and multiplying the result by 2) is sufficient to obtain an accurate representation of the frequency of beats per minute. The exercise industry also now markets heart rate monitors, usually incorporating a strap that is worn around the chest and a monitor that can be worn at the wrist like a watch.

The ease and low cost of monitoring the heart rate has led to its widespread use as a gauge of relative exercise intensity. Nonetheless, there is some concern regarding the use of heart rate to monitor exercise intensity due to a phenomenon known as *cardiovascular drift*. This phenomenon describes an increase in heart rate with prolonged exercise (greater than 10 minutes) despite the exercise continuing at the same intensity. Cardiovascular drift is likely to be related to the sympathetic nervous system and catecholamine control of the sinus node, where the heartbeat originates. It should be noted that factors other than exercise intensity also affect the heart rate, such as ambient temperature and caffeine intake.

Research has recently focused more on heart rate variability (HRV). Evidence suggests that trained individuals have higher HRV than untrained individuals. Most research shows that during graded exercise, HRV decreases progressively up to moderate intensities, after which it stabilizes. HRV could potentially play a role in the prevention and detection of overtraining. This is currently an area of great research interest, with mixed results reported in the scientific literature. Measuring HRV overnight, in supine sleeping athletes during training camps, has been the most widely reported method. High HRV is associated with high $\dot{V}O_2$max (peak oxygen uptake) values, while it has been found that low HRV is associated with increased mortality, the incidence of new cardiac events, and the risk of sudden cardiac death in asymptomatic patients.

Team and Group Dynamics in Sports

Shortly before the 2008 Olympic Games, Mike Krzyzewski, coach of the U.S. men's basketball team, remarked:

> From Athens [where the team finished third] we learned we need time to develop camaraderie. We have to be committed to one another before we can be committed to the team. We're developing a program, not "selecting a team." No one ever "selects a team"; you select people and hope they become a team.

Several weeks later, the U.S. basketball team went on to win the gold medal in Beijing and were noted for the high level of cohesion displayed by the team members during both training and tournament play. Indeed, this example illustrates that while it is clearly important to select the right personnel when creating a team, hard work is required to forge a collection of players into a highly integrated, cohesive, and effective team.

Group Dynamics

The study of *group dynamics* is concerned with understanding the various psychological processes that occur within and between groups. The term *group dynamics* can be traced back to the prominent social and organizational psychologist Kurt Lewin (1890–1947). In the context of group dynamics in sports, considerable attention has been given to identifying the factors that influence team functioning. Among these factors, *cohesion* represents one of the most extensively studied psychological constructs. Cohesion can be thought of as the glue that acts to attract and retain members within groups. The attention given to cohesion among sport psychology researchers is perhaps not surprising given that cohesion has consistently been found to predict team performance, across both highly *interactive* (e.g., soccer) as well as *coacting* (e.g., golf) team sports settings. According to the prominent Canadian sport psychologist Albert Carron, cohesion is multidimensional in nature, consisting of task as well as social dimensions, plus individual-level and group-level orientations. Specifically, cohesion involves the extent to which team members are attracted to the team's task and social activities, as well as the extent to which members perceive the group as a whole to be integrated around these task and social activities. Although research evidence suggests that increasing a team's level of cohesion will lead to increased performance, it is worthy of note that the relationship between cohesion and performance is actually bidirectional in nature. That is, teams also tend to become more cohesive when they perform well.

Role Conflict, Role Ambiguity, and Performance

Beyond performance, cohesion is also influenced by a variety of other factors, such as the types of roles that are performed by team members, the group norms and goals that members establish, the behaviors of those in leadership positions, as well as members' perceptions of their team's capabilities. From the perspective of team roles, athletes are typically expected to perform a range of responsibilities with the team's task-related objectives in mind. When athletes are unclear about their various role responsibilities, they are said to experience role ambiguity. This can lead to greater precompetition anxiety, less satisfaction, and diminished levels of performance. While reducing role ambiguity is vital within sports teams, it is also important to curtail any role conflict that athletes might experience. Role conflict occurs when athletes receive conflicting information and/or expectations about what is required of them. When athletes experience role conflict, they tend to perceive greater role ambiguity and report reduced role-related confidence. Although minimizing role ambiguity and conflict has many benefits for member and team functioning, one must also consider the degree of role acceptance among team members when attempting to maximize performance. Sir Clive Woodward, coach of the 2003 World Cup winning English rugby team, was known to emphasize the importance of selecting and developing a team of "energizers," who bought into the team concept, accepted their prescribed roles, and contributed to team cohesion. If some athletes, who he described as "energy sappers," did not accept their roles and could not be turned into energizers, his recommended strategy was to remove them from the team before they destabilized team chemistry and debilitated the team's level of cohesion.

Team Norms and Group Cohesion

Norms correspond to the accepted standards of behavior that exist for members within teams. Team norms are usually unconnected from the position-specific roles prescribed by a team's coach. These norms are often unwritten and evolve through the course of ongoing group development. While those responsible for developing teams, such as coaches, can allow team norms to evolve naturally, several benefits are associated with formalizing appropriate team norms. This can be accomplished by encouraging team members to contribute to and decide on their own set of expectations for off-field and/or on-field interpersonal engagement (i.e., in the form of an athlete "charter"). Such an approach can foster athlete autonomy and is more likely to result in athletes committing to these rules than if the rules are directly prescribed by a coach or a manager. This, in turn, can facilitate a sense of cohesion among team members. The use of goal-setting strategies has also been found to positively influence team cohesion. In particular, when athletes are involved in setting out their own process- and performance-oriented goals (rather than having these goals prescribed to them), they tend to be more committed to the group's endeavors, thus resulting in improved group integration.

While team cohesion, to a large extent, depends on the quality of interpersonal relations among athletes within a team, the coach can also play a prominent role in fostering group cohesion and a healthy team culture. For example, a growing body of evidence from various organizational settings has found that when leaders display transformational behaviors (see the entry Leadership in Sports), their teams tend to be more cohesive. Transformational leaders motivate followers to go beyond their self-interests for the good of the group and give group members the confidence to exceed minimally accepted standards. In sports teams, when coaches display transformational leadership behaviors, their athletes have been found to display more self-determined forms of motivation (e.g., intrinsic motivation) and also tend to perform better than athletes who are coached by nontransformational leaders.

In the field of sport psychology, a vast amount of research attention has been directed at understanding the determinants and consequences of athletes' self-efficacy beliefs. Self-efficacy refers to a situation-specific form of self-confidence and has been found to be positively related to outcomes such as athlete persistence, effort, and task performance.

While numerous studies have examined the factors that contribute to athletes becoming more efficacious in their *own* abilities to perform specific skills, researchers have also sought to examine the role of collective efficacy beliefs in sports teams. Collective efficacy refers to members' perceptions about their team's conjoint tasks, and in a variety of team sports settings, these beliefs have been found to influence team functioning. Interestingly, collective efficacy has also been found to be both predictive of and predicted by team cohesion. That is, the relationship is reciprocal, whereby team members can become more confident in each other when the team is more cohesive and, conversely, the team can also become more cohesive when members develop confidence in each other.

In light of the various correlates of group cohesion in sports, a burgeoning area of enquiry has centered on developing and testing effective team-building interventions. *Team building* is the umbrella term given to the process of developing cohesion within groups. As the research described above would suggest, team building does not represent a singular unitary process and may involve a range of processes that can be applied to meet the team's specific needs. Team-building interventions in sports tend to be either *direct* or *indirect* in nature. With direct interventions, the interventionist (e.g., the sport psychology consultant) intervenes directly with the target population. In comparison, indirect interventions involve the psychologist working with a proxy agent (i.e., a third party), such as a coach, who then leads the intervention with his or her athletes. Although the direct approach has been found to be effective in a variety of team sports settings, one of the benefits of the indirect approach is that coaches are given the requisite skills and are empowered to attend to the team's needs on a day-to-day basis and are not reliant on external personnel in facilitating behavioral change.

In summary, a considerable amount of human behavior in sports settings occurs within groups of one kind or another, and in light of the fact that the psychological processes that occur within groups have been found to predict important personal and group-level outcomes, the study of group dynamics in sports continues to represent a vibrant area of enquiry.

Team Physician

The team physician occupies an important position in the public consciousness. News reports about injuries to specific players on sports teams inevitably include interviews with or references to the team physician. In fact, sports physicians—and then team physicians—have enjoyed a high-profile role throughout history.

Historical Perspective

Historians note that battle physicians in ancient times were deemed a necessity. Galen (131–201 CE), a Roman physician of Greek origin, is considered by many to be the epitome of sports medicine practitioners. His voluminous writings reveal that he performed anatomical research and studied physiology, neurology, and wound care. He was appointed physician to the gladiators and was a teacher and a private surgical practitioner. Galen's qualifications to care for athletes and nobles need to be emulated.

Even though there was a marked increase in basic scientific and biological knowledge over the next centuries, there does not appear to have been a similar increase in athletic care and injury reduction in the United States. One possible exception was Edward Hitchcock, MD, who as a school physician at Amherst College in 1854 introduced swimming and gymnastics, emphasized baseball and basketball, and penned a book on athletes and medicine. With the increased popularity of sports participation, the injury rate also escalated. Because severe and often career-ending injuries were occurring so numerously, Harvard University appointed an orthopedic team surgeon in 1890. Other large eastern schools soon followed with similar appointments.

In 1904, the Germans were the first to use the term *sports physician,* and then they proceeded to hold a sports physicians' congress in 1912. This impetus evolved into the Fédération Internationale de Médecine Sportive (FIMS; International Federation of Sports Medicine) in 1933, with the primary goal being to facilitate clinical and scientific research in cooperation with Olympic federations. In 1938, Augustus Thorndike, MD, published a monograph depicting his experiences and knowledge as a team surgeon. His writings, which included much of the scientific knowledge in sports medicine, served as a primary source of pertinent sports medicine information in the 1960s.

A distinct change in sports medicine care of the high school and college athlete occurred when Dr. Jack Hughston (1917–2004) developed team coverage in the early 1950s. He and his orthopedic group and trainers began to "cover" high school football games on Friday night and college games on Saturday. During the week, his crew visited colleges and schools, noted injuries, arranged rehabilitation, and helped decide return to practice and refer, if necessary, back to clinic. This entire program was enacted with the cooperation of the local physician, who was a specialist or generalist, to maintain rapport. This program was not readily accepted until approved by the Georgia State High School Coaches Association. Adjacent states quickly followed this system of sideline and midweek team coverage that persists nationwide to this writing.

In the period after World War II in the United States, there was an exuberance expressed in physical activity and the formation of team sports. Physicians returning home from active duty restarting or starting up a practice often were ushered into a position as a team physician. Most had no sports medical experience, but used good medical knowledge quite successfully. Predominately, these physicians were generalists in the high school and junior college settings. In contrast, the larger colleges, universities, and professional teams tended to select an orthopedist as the primary team physician. While this selection arrangement was transpiring, research and teaching organizations came on the scene such as the American College of Sports Medicine (ACSM), American Orthopaedic Society for Sports Medicine (AOSSM), American Medical Society for Sports Medicine (AMSSM), and the National Athletic Trainers' Association (NATA). Of even greater significance to the practice of sports medicine was the establishment of orthopedic and general sports medicine fellowships. These board-eligible candidates were elected to take an additional year of specialized, sport-centered training under qualified individuals. These mentors used current therapy and ancillary techniques, the most salient of which was the development of the Watanabe arthroscope. This instrument revolutionized the practice of orthopedics and initiated visual understanding of injuries to the knee, shoulder, and elbow.

Even after a fellowship at an accredited institution and after the formal academic process is completed, there are major concerns that must be addressed prior to undertaking the position of a sports medicine physician. No less than for Galen in the ancient world, the essence of practice for Dr. Don O'Donoghue (1917–2004), often referred to as the father of modern sports medicine, was the skillful restoration of the injured patient back to participation status as expeditiously as possible. Times, therapy techniques, and teachings have changed, and certain personal and professional criteria have evolved for both orthopedic and medical sports physicians to contemplate and emulate.

General Criteria

Optimally, to embark successfully into the field of sports medicine as a physician, certain attributes are mandatory. Personal integrity, the athlete's welfare, and the sanctity of the doctor-patient relationship are paramount. Love of sports necessitates considerable time spent at games, practices, and examinations and in the consulting room, so family interaction needs to be facilitated. To function well, the team doctor must possess a working knowledge of a broad range of medical and orthopedic topics and the confidence to make accurate decisions. The measure of a solid team physician is being adept at diagnosing accurately a case of appendicitis as well as an anterior cruciate ligament (ACL) deficiency.

It is imperative that the team physician formulate a program to maintain official standings in state and local academic boards and societies. The physician should join and participate in scientific organizations, cooperate in research protocols, keep abreast of current literature and techniques, and attend sports medicine–related courses and seminars. Since the implementation of Title IX (1974), the team physician must become proficient in caring for the female athlete. Another one of the many important relationships that need to be fostered by the doctor is camaraderie with the head trainer and the staff. Mutual trust and true friendships are to be cultivated.

Another important entity in forming a sound musculoskeletal performance base is the experienced physical therapist. This person needs to be trained in rehabilitation techniques, should be compliant with the wishes of the head trainer and medical personnel, and yet be skilled enough to judge the capacity of the athlete to return to full activity.

The role of the strength coach is integral to this functional group. This person is responsible for personal and team strength improvement and must be certified in the profession. He or she, therefore, knows sports and is capable of enhancing effective playing strength and reducing the risk of injury in the athletes. Strength coaches must respond to the position team coaches and develop programs accordingly.

The head coach of each sport and the subordinates constitute the foundational element in the operational unit that is responsible for caring for the athlete. In addition to mental and physical preparation of the athletes, the head coach determines each athlete's ability, judges what areas need to be improved, and integrates all within the practice schedule. His or her interaction with the players is as important as daily meetings with the other members of the foundational unit (team doctor, trainer, physical therapist, strength coach, and coaches). The coach must communicate freely with the athlete, set a mutual goal, and care for the well-being of the athlete. Additional members of this foundational unit may become involved as the level or caliber of the sport necessitates.

Sports Medicine Physician

Level I

Having complied with state and national stipulations of licensure and satisfactorily completed a sanctioned sports medicine fellowship as an MD or DO in orthopedic or general sports medicine, the team doctor enters into private practice alone or in a small multispecialty group and is legally advertised as a sports medicine physician. In the office, the physician cares for the injuries and illnesses of all caliber of athletes and gratefully accepts insurance. Soon, his or her positive successes bring in parents and then others. The local middle school seeks the doctor's services for all of its sports. When the high school officially recognizes this doctor, then truly he or she is a team physician. The new stipulation requires the team physician to become aligned with radiological, surgical, and medical specialists. To maintain an office practice, a nonwritten agreement with the school officials is mandatory. This official arrangement, which indicates the team physician's scheduled coverage of sports, preparticipation physical examinations, and relationship with high school personnel, is sealed with a handshake. At this stage of the doctor's career, he or she has become the team physician not only of that school but also of the entire area and its active population.

Level II

Officially, the doctor is offered the position of team physician to a fully accredited Division II college in his or her general area with at least 12 different teams. The verbal agreement, witnessed by notables, will allow the doctor to maintain his or her office sports medicine practice, and the school will provide a certified athletic trainer and an office in the school for his or her half-day doctor's visit. It is agreed that the trainer would prepare the athletic field and sidelines and have emergency equipment available. As the sports medicine physician, the doctor would carry a personal sideline kit that contains emergency paraphernalia, oral and injectable medications, the medical history of the players participating, and necessary home and emergency phone numbers. Also, he or she would provide sideline coverage for home football games. For away games, the physician would call his or her counterpart at the other school and secure backup coverage and obtain a hospital contact. The physician would reciprocate when that team plays at his or her school. This new relationship demands more commitment on the sports medicine physician's part. Procedures, routine and pre- and postgame schedules, handling of injuries, and explicit review of emergency protocols and documentation in keeping with National Collegiate Athletic Association (NCAA) rules and regulations are an absolute necessity. It behooves the physician to become a friend, companion, and confidant of the trainer in order to outline rehabilitation and help determine return to play, as well as to be the liaison between coaches, school officials, and parents. When friendship is firmly established, the trainer knows the athletes, their personalities, and their demeanor and is more apt to be aware of abnormal behavior or activity. As noted previously in Level I, establishing consultants in many specialties is deemed necessary in referrals, for preparticipation examinations, and especially with drug testing screening. Any specific problem that is beyond the physician's orthopedic or general medical expertise often requires the athlete, with his or her records, to be examined off campus. Hence, it is an absolute necessity to establish contacts with specialists early in the practice of sports medicine.

Level III

The sports medicine physician accepts a salaried appointment to the state university that holds a membership in a Division I conference. There are eight men's and women's teams with a playoff in each to determine the bowl candidate. Academically, the physician's rank equals that of a full professor and entails comparable perks, including health insurance and prestige, but his or her take-home pay is noticeably less than in office practice. Yet he or she does not have any office expenses since the university provides a fully supplied office, medicines, and travel expenses and allows for state and national license fees. Personal malpractice insurance premiums may be covered in the universities' umbrella policy. Athletic trainers function efficiently as office nurses. Computer and record-keeping facilities are provided and maintained. Since the physician has gratefully experienced and pleasantly succeeded in a sports medicine practice and upheld its qualifications and definitions, this change of venue appears quite inviting to him or her and his or her family.

As in any successful office practice, many functional details persist. An amicable relationship between the trainer, student trainers, physical therapists, and the athlete is mandatory. Duties allocated to the staff with regard to equipment and supplies must be supervised. As in routine office practice, the well-being of the athlete is paramount and requires perfected communication with the individual, parents, and coaches. Previous experience in severe musculoskeletal injuries, surgical cases, diabetic problems, infections, and rashes needs to be supplemented by referrals to competent physicians. On the other hand, newer obligations are to be undertaken. The proper techniques, rules and regulations, and probable injury patterns in each sport must become firsthand knowledge. Why don't women lacrosse players wear masks as men lacrosse players are required to wear? Is the skin eruption on the wrestler similar to that seen on the women gymnast from a floor mat? These and similar problems provoke serious contemplation and research.

The sports medicine physician is indeed fortunate to have an accredited curriculum of athletic training at this university, where athletic training fundamentals are taught and meshed with practiced applications. After the senior year, the student athletic trainer is properly prepared to pass the written, practical, and now computer examinations of the NATA. He or she is obligated to teach this curriculum and partner with the designated department head to determine the course content. These endeavors supplement the one-on-one demonstrations of the diagnostic maneuvers used in musculoskeletal injuries.

A typical week begins with sick call for those athletes who are unable to attend class or those in for recheck to determine their level of function. The history is obtained and documented in the chart by the head trainer. The sports medicine physician's physical examination clarifies the diagnosis and determines the disposition, such as to continue medications and return to class, to arrange for care in the infirmary, or to send to the hospital. In each instance, coaches and parents need to be informed. Parental permission is previously obtained and signed with the athletic department's full documentation on the NCAA identification of eligibility.

Follow-up evaluation of postsurgical care and games/practice injuries is conducted with input from the head trainer, physical therapists, and surgeons. The progress of the rehabilitation protocol is documented, and the coaches are informed. The ultimate outcome of the athlete's situation must be determined— whether he or she is able to return to sports or is to be disqualified for the season, or possibly to file for a "red-shirt" exemption. Orthopedic consultation is obligatory and is welcomed in musculoskeletal problems.

Before the hospital rounds, in consultation with the hospital-based physicians and nurses, the X-rays, computed tomography scans, electrocardiograms, and magnetic resonance imaging scans are reviewed and discussed as a teaching element with the trainers, physical therapist, and staff. This endeavor requires maintaining high-level expertise in radiological disciplines.

Afternoons in season are spent at football practice with the head trainer and his or her staff. The sideline material necessary for routine care of injuries is evaluated, the emergency setup with transportation is alerted and kept in readiness, cell phones are charged, and pertinent numbers are placed in the pockets of trainers. Personnel assignments for the practice are dispensed in concert with the published itinerary for the sanctioned practice. While conversing with the coaches, athletes are scrutinized as to characteristic walk and run, the knowledge of which will be profitable later when returning from injury or surgery. Dehydration, fatigue, and cramps should be urgently treated. Injuries are triaged as to disposition—either to the training room or to the hospital. Those not needing special procedures or consultation are evaluated and tested, and rehabilitation is instituted on the sideline.

Travel with the football team to all away games and to the championships of other sports, when requested by the president of the university, requires considerable preparation with the coaches, trainers, and staff. Consultation and cooperation with the home institution, its facility staff, their physicians, and the hospital for referrals when necessary is the obligation of the team physician. Travel sideline preparations are under the domain of the head trainer but are ratified by the team physician. There is close contact with the players, staff, and medical personnel, so that potential problems can be alleviated early. Team meetings, dining, recreational activities, and bedtime checks all are included in the team physician's itinerary. Occasionally, a member of the traveling academic staff, the athlete's parent, or an eminent supporter may require a visit from the team physician at an inopportune time.

Pregame or practice at home and away involves consideration of each player for play ability, proper taping and protective gear, dehydration prevention, and the issue of medication orally or by injection.

Before spring practice, coordination of and participation in preparticipation screening examinations are absolutely necessary. Usually performed at multiple stations, these screening examinations require many physicians, nurses, trainers, and secretary personnel to record basic information and to review parental signed history forms, as well as technicians to perform blood pressure, visual acuity, and special blood and urine tests. The NCAA manual requires an initial thorough history and an examination that includes cardiovascular and orthopedic evaluations and referral when deemed necessary. Annually, an appraisal of the athletes' records is made, a pertinent history is obtained, and new problems are addressed. A yearly, formal, complete physical exam is not required by the NCAA. Some programs in Division I do obtain more elaborate yearly evaluations.

Recently, it has become a policy for universities to perform an exit evaluation of all athletes, which elaborates the significant medical and surgical history and the final appraisal by the medical and orthopedic team physicians. In the form of a legal document, the head trainer, the team physicians, and the athlete sign a statement indicating the condition of the athlete at the completion of eligibility. Such documentation relieves the university of inappropriate and costly future repercussions.

It is quite common for universities to have high school outreach programs in which trainers and physicians actually attend games of contact sports, as well as hold intraweek injury evaluations. A group of these high schools with established relationships with the university often request assistance in their preparticipation evaluations. As with the university preparticipation examination, a convenient time and location at the university are used. At a scheduled time, a busload of high school athletes with previously signed permission and histories are processed in compliance with the university protocol. The aim of the examination is to enhance medical awareness, determine cardiovascular or medically abnormal conditions, and initiate solutions so that the young athlete can safely continue in the program. Significant findings that require disqualification are documented, the teacher/coach and the patient are informed immediately, and written suggestions are given for a physician's follow-up.

Unfortunately, the perils of narcotics and other banned substances in society permeate into athletics in the university setting. In-house testing of each team is done under the supervision of the team physician. Positive results require evaluation by a certified counselor. In an attempt to obviate this dangerous situation, the NCAA requires each student-athlete to attend talks concerning drug education and the pitfalls of using illegal and forbidden substances.

An ancillary, but extremely important, role for the team physician is related to the weight of the individual athlete. Certain sports require maintaining bulk and strength, while others demand a trim physique. Each athlete needs to be monitored in keeping with the position coach's and the athlete's personal goals. Unauthorized supplements of unknown content taken to gain weight may lead to abnormal symptoms. Excessive weight loss may be indicative of anorexia nervosa or bulimia and may result in myriad physical and mental complications. Initially, private consultation with the athlete may be helpful, but often referrals are indicated. The physician needs to eat in the student cafeteria or its equivalent frequently and notice the display, kind, and array of foods, as well as what foods are usually eaten by the athletes. A working friendship with the school dietitian or the food supervisor may facilitate alteration in the menu and variety. Control of eating problems, as suggested by the team physician and enforced by the head coach's orders, is partially enhanced by making breakfast mandatory for the teams in season.

In the university setting, the woman athlete presents a diverse array of circumstances for the team physician to contemplate. By nature, a woman is hyperelastic in essentially all her joints. With regard to the glenohumeral joint, she may subluxate and spontaneously relocate with minimal labral pathology. Unfortunately, her shoulder subluxation may become recurrent just with walking down the stairs. Rehabilitation may not be completely successful, and subsequently, either open or arthroscopically assisted tightening, because of the texture of the rotator cuff, may be less than optimal even with an appropriate surgical technique.

Hyperelasticity allows women gymnasts to perform outstanding maneuvers that are enjoyed by spectators. However, their popularity leads them to attempt more difficult routines. School and conference competitions encourage more recklessness and higher pyramids. Falls produce bizarre injuries, fractures, and central nervous system mishaps.

The woman athlete, because of a lower center of gravity, anteversion of the hips, and a large quadriceps angle while being quadriceps dominant and with tibial torsion, tends to land after jumping with knees adducted and the trunk upright. This sequence of events may produce patellofemoral symptoms, shin splints, or avulsion of the ACL from its attachment to the femur. Research has shown that with torso (core) strengthening, learning to land bent forward, and better leg muscle control, the incidence of ACL tears can be reduced significantly. It is the team physician's obligation to institute these preventative methods into the training program.

In the era of the resurgence of good health through fitness and sports activity, the team physician must be acutely aware that extremes invariably tend to be manifest and moderation becomes socially unacceptable. The philosophy of being the best in any endeavor and winning at any cost becomes a way of life, initially brought about by the use of performance-enhancing drugs. Drug testing has partially alleviated this problem, but even more sinister elements prevail. The ideology of perfection permeates players, coaches, administrators, and almost all parents. To gain an edge, youngsters are started at a young age to excel in one sport year-round. This methodology is encouraged by specialty coaches, tournament administrators, camps, and television and newspaper coverage. A family vacation may consist of watching one of their youngsters in a competition in another state. Emotionally, family life can suffer, as can musculoskeletal growth and maturation. There is a harmful fallacy that exists that to be bigger, stronger, and faster, as adult athletes are today, the young athlete must become one-dimensional. Forgotten are the facts of heritage, supervised good health, and medical care in infancy and childhood on which organized sports is grounded. Young teenage girls are also involved in this push to excel at a very tender age. The phenomenon is especially noted in gymnastics, cheerleading, racquet sports, swimming/diving, and ball sports. In young girls, overuse or abuse often results in shoulder pathology after repeatedly pitching windmill style for four games in a weekend tournament. Preteen boys who throw excessively at home and in games, even under recent guidelines, are at jeopardy, especially when trying to throw a curve ball instead of developing consistency and a changeup. Orthopedic sports medicine centers are evaluating more and more young boys with medial elbow pathology—formerly seen only in seasoned adult pitchers—that requires surgical intervention. Biomechanical studies have found that faulty mechanics with overpitching and throwing curves in the muscularly immature athlete favors the development of ulnar collateral ligament (UCL) weakness, followed by tearing. Reducing total pitch count in an inning, per game week, or at home is a significant measure in the prevention of painful elbow symptoms and UCL pathology.

Published guidelines for parents and coaches are standards to be adhered to with regard to pitch count totals for fast balls and changeups. Whether to use the skeletal or the clinical age to determine when to learn to throw the curve balls is a matter of controversy. One sage orthopedic team physician stated that optimally the best age for throwing the curve balls is when the athlete is old enough to shave. It behooves the sports medicine physician to vigorously encourage an educational program directed at parents, coaches, and school administrators that outlines the factors that must be ameliorated to reduce the incidences of premature medial elbow pathology.

Level IV

The orthopedic team physician, who has served as the primary orthopedic surgeon, director, and consultant to a Division I athletic department, maintains a specialty practice in a metropolitan setting, either in a multicentered hospital or in a building on the campus of the medical school. Because of clinical success, surgical prowess, and skill in treating professional athletes, recreational sports enthusiasts, and others with shoulder, elbow, and knee musculoskeletal pathology, the surgeon's renown in sports circles has escalated. Continued success is due to the orthopedic team physician's proficiency in using the arthroscope and the greatly improved, accurate diagnostic capabilities with radiological interpretation. Intra-operative local and general anesthesia, control of postoperative pain, early mobilization, and a proficient rehabilitation unit are salient features of a successful orthopedic sports medicine practice. This entire entity is now delineated as a center. Soon the sports medicine center becomes identified in that geographic area with the principal orthopedist. In time, another center comes up, and competition for fellows and for identification with a prominent athletic program ensues.

Although the sports orthopedist has been trained by prominent orthopedists and is perfectly capable of performing essentially all musculoskeletal operations, he or she soon realizes the need for other specialists in the group whose interests are primarily hand, neck-back, foot-ankle, and general trauma.

Along with the rapid growth and popularity of sports activity in all ages, there evolved the need to determine the etiology of many of these musculoskeletal injuries. Hence, biomechanical facilities came of age. Initially, characteristic motions of elite athletes were filmed—for example, pitching, passing, and hitting a golf ball. From this information, angles, vectors, and acceleration of joint motions were determined and used as basic information on which other athletes were judged for form variations that may need to be altered. The biomechanics laboratory plays a diagnostic role for the sports orthopedist as a marker to strive for in alteration of motion, if possible, or the level to attain after definitive surgery and rehabilitation.

In the United States, about the time orthopedic fellowships became operational, there was a spirited movement also to create general sports medical fellowships. These selected individuals were board-eligible from essentially all nonsurgical medical residency programs. Characteristically, each man or woman had a keen interest in sports, accepted the guidelines of conduct and regulations imposed by state and national organizations, and demonstrated practice of his or her basic specialty successfully.

Within the orthopedic sports medicine group, these generalists would continue to have a formal practice in their specialty in order to satisfy their board requirements while rotating in the clinic in association with orthopedic fellows who are under the supervision of the team orthopedists or the medical sports–trained counterpart. Orthopedic and general sports medicine fellows tend to complement each other socially and share each others' views, experiences, and knowledge.

In addition, while the orthopedic fellows are in the operating room, the medical sports fellows triage new patients, provide care to others who do not need to be seen orthopedically, follow those in rehabilitation, and make scheduled visits to assigned high schools or colleges. In most established orthopedic team physicians' offices, the preadmission physical examination is performed by outside internal medicine sources, so that the general sports medicine fellow usually is not primarily responsible for that duty.

Both orthopedic and general medicine fellows are given research projects to be completed, if possible, within the year. A formal presentation by each fellow is made to the entire staff and families, and monetary awards are given for excellence and merit. The completed research manuscripts must be designed to comply with the criteria outlined by the referred journals. Ancillary services provided by the orthopedic medical center for the fellows include a staffed library, available secretarial assistance, patients' history files, and available sports-oriented biomechanics. Each fellow is expected to report accurately and succinctly every patient contact, as well as the formal medical opinions expressed by the attending staff member.

Biweekly scientific seminars on assigned topics are delivered initially by fellows' clinical mentors and later by the fellows on specific subjects and on their research progress. Attendance is essential. Usually, monthly journal clubs are convened at a staff member's home or a comparable facility, where discussion of the assigned articles is led by the fellows' clinical mentors.

The fundamental aims of each fellow are to endeavor to increase general knowledge and to develop skills. Also, each must generate an awareness of sport injuries and their diagnoses, treatment, rehabilitation, and prevention. Learning and applying this information mutually results in confidence and accuracy of diagnosis.

Each sports medicine orthopedist or medical center develops a relationship with a school or university to cover that school's sports program. All fellows participate in preparticipation examinations. In addition, each fellow is assigned to a high school and a college team to visit weekly and attend football games. Because of the operating duties of the orthopedist fellows, much of this coverage falls on the general sports medicine fellows. Another practical learning session occurs in the special emergency room area for injury coverage on Friday nights after football games in the orthopedic center's locality. In season, players, cheerleaders, coaches, and officials are brought to a portion of the emergency room and initially examined by the team physician and the general sports medicine fellow, along with backup from the orthopedic fellow. Decisions are made, treatment is instituted, and rehabilitation is begun by the centers' assigned trainers, and office visits are scheduled.

The continued success of an orthopedic center potentially depends on referrals from schools that have established a sideline and midweek coverage relationship. Other noncovered schools and junior colleges in the surrounding area served by the orthopedic center may request preparticipation physical examinations. The general sports medicine fellows will use this experience profitably by suggesting care, treatment, and rehabilitation and arranging orthopedic consultations.

The orthopedic fellows, while in the operating room under expert tutelage, must avail themselves of the opportunities to improve their operative techniques, to visualize new surgical procedures, and to observe the proper postoperative care designed for that particular operation. Rounds of postsurgical patients are characterized by a blend of the previous experience of the fellows and that of the staff orthopedist. Absorption of this experience plus that gained on outpatient follow-up evaluation is essential. Initially, the fellow checks the chart, obtains the history, examines the surgical site, and then presents the information to the staff orthopedist. General sports medicine fellows who are rotating through the orthopedic service are often included in postsurgical, outpatient rounds. This exposure is priceless, fundamentally, but the interplay of both categories of fellows is bilaterally profitable at that time and also in the future when in practice.

Toward the end of this fellowship, the fellows prepare to make significant future plans. Some plans were begun back in residency and some after contacts when attending professional organizational meetings. A few are referred by staff personnel and pertain to specific situations. A very few fellows will sign a contract to go to a foreign country for a lucrative fee to help pay their education bills. It is noteworthy that most fellows going out into practice have not considered a short-term medical or orthopedic missionary trip. The vast majority of fellows already have engaged a lawyer to include certain aspects of insurance, coverage, promotions to partners, percentage of profits and overhead, and area of noncompetition. Family input into decisions is desired, and when this is lacking, it may lead to unhappiness and separation.

Level V

It is extremely rare for a fellow who has recently completed his or her fellowship to step into the position of head team physician of a professional team. Should the new partner be fortunate to come on board and learn that the senior orthopedic partner currently is firmly entrenched as team physician of a professional American football team, a wonderful opportunity ensues to learn what the senior partner has seen and experienced over the years! Equipment has improved, research has brought about rule changes, treatment is now scientifically based, and surgical procedures are more advanced. In recent years, the National Football League (NFL) has instituted a pre-affiliation screening of recently graduated college players for athletic ability, as well as for identifying orthopedic or medical problems. This evaluation process is called a "combine" because all the professional football teams' orthopedic team physicians are eligible to participate. Also, other team physician specialists' services are used when expert opinions are needed for unusual cardiac, pulmonary, psychological, hematological, neurological, and radiological situations.

By now, the professional team physician, the orthopedist, and the generalist have gained a broad base of experience outside their primary specialty. After a specific plan of action is determined for a specific entity, the player, the team, coaches, and agents must be informed and an agreement reached. The action must be recognized by code number for insurance purposes. The effectiveness of rehabilitation has to be determined to accurately predict return to play. History of the players' dependability, substance participation, and psychological makeup may determine long-range surgical success. Follow-up arrangements with trainers and physiotherapists to use published protocols are mandatory.

It would be wise for the team physicians who aspire to a professional association to visit the U.S. Olympic training center in Colorado Springs, Colorado. Essentially, every Olympic sports federation trains there, so that contacts can be established and training facilities and methods critiqued. Each federation, although somewhat political in nature, benefits by engaging an enthusiastic and knowledgeable team physician. The experiences are rewarding and mutually beneficial.

In addition to the examples of the NFL and Olympic teams, there is an abundance of professional and semiprofessional sports teams in the United States and Europe whose longevity depends on the competence of their team physicians in routine preparticipation evaluations, treatment of orthopedic and medical situations, and preventative care. Also, professional companies of performers, such as the circus or a theatrical group, or entertainment troops depend on orthopedic and sports medicine coverage to maintain a rigorous schedule. In these instances, the orthopedist is the primary physician with a sports medical backup. In others, the reverse may be noted. Cooperation is paramount to successful interplay.

Industry uses fellowship-trained sports physicians to evaluate workers' abilities to perform certain physical tasks as well as to ascertain the merit of worker's compensation cases. Many large manufacturers provide the doctor with an office and staff support within the plant to determine applicants' capabilities with regard to job requirements, introduce new safety features, treat injuries and illnesses, determine the percentage of disability, and promote good health habits among employees. Problems do occur with lawyers and union officials when employment termination is needed.

Sports physicians, both orthopedists and medical generalists, at times are openly solicited by pharmaceutical corporations. These recruited physicians are extremely valuable in evaluating clinical trials, especially those related to musculoskeletal effects. Writing a prospectus or a protocol and developing clinical results for publication often reflect fellowship training and personal inclinations. Being engulfed in medicine and clinical outcomes is exciting and an adjunct to clinical practice. To those scientifically inclined, the application of stem cells in the treatment of ligamentous and tendinous pathology would be intriguing.

There are qualified sports physicians employed by international steamship lines not only to examine and care for the crew, but also to hold sick call in order to determine the extent of illness or injury and ascertain the need for removal from ship. Paramedical personnel are provided, and the ports of call are very interesting.

In summer, coaches tend to schedule sports camps for high school and college students at their own university or at a convenient site that is easily accessible. The camps may vary depending on the sport, level of expertise, and position. A full complement of coaches, therapists, trainers, and emergency personnel are housed on campus or at a hotel for a 7- to 10-day period. The qualified sports medicine physician, orthopedist, or generalist signs up or volunteers for previous or future gratuities and enjoys the change of venue and a vacation.

Before entering into a professional relationship as a qualified sport physician to an entity, group, or physical situation, considerable investigation, contemplation, and consultation with an attorney who is knowledgeable in that particular environment are required for the subsequent contract to be mutually gratifying.

Temperature and Humidity, Effects on Exercise

Different environmental conditions, such as temperature and humidity, affect exercise tolerance and capacity in many ways. It is important for athletes to maintain their body temperature at or near 98.6 °F. Environmental conditions, in particular air temperature and humidity, determine the rate at which heat is lost or gained for the exercising athlete.

The body is able to regulate core temperature within a narrow range and must be able to manage heat transfer by convection, conduction, or evaporation. When the outside temperature is cooler than an athlete's body temperature, heat will be lost from the skin to the environment through conduction. The rate at which this heat is lost will be determined by the temperature difference between the environment and the athlete's body. Continual replacement of the warmer air near the body by cooler air from the environment causes loss of heat from the body by means of convection. Convective heat loss is determined by the speed at which air flows across the body. Evaporation is the most effective way in which the body loses heat. However, with high humidity, sweat loss by evaporation is reduced.

At rest, athletes regulate their body temperature around 98.6 °F. Muscles produce more heat during exercise than at rest. The thermoregulation system of the body must compensate for this increase in heat production, and inability to do so could lead to hyperthermia. External factors such as extreme temperatures and humidity also contribute to the development of both hyperthermia and hypothermia.

Hypothermia

When environmental conditions are particularly cold, there is a risk that the athlete will lose heat faster than he or she can produce it. Under these conditions, the body may be unable to maintain a safe temperature, leading to *hypothermia*. Swimmers are particularly at risk because cold water is an excellent conductor of heat, approximately 30 times more effective than air, and the body may be unable to produce heat as rapidly as it is lost by conduction to the surrounding water.

Hypothermia Prevention

There is a high rate of heat production during exercise, but once an athlete stops exercising, this rate falls sharply, and the risk of hypothermia rises significantly. Wearing proper clothing and gear is important in preventing hypothermia. Air is a poor conductor of heat but makes a good insulator. In contrast, water is a very poor insulator but a great conductor; therefore, a thin layer of air trapped next to the skin by specialized clothing creates a layer of insulation, thereby lessening the likelihood of developing hypothermia.

Hypothermia Diagnosis and Treatment

Hypothermia can be diagnosed when an athlete has been exercising in a cold environment, his or her core temperature is low, and he or she has fatigue, disorientation, muscle weakness, or loss of coordination. The treatment of hypothermia begins with removal of the athlete from the cold environment and applying dry clothing and external heating methods, such as convective heat, hot water bottles in the groin and axilla, or heated intravenous fluids.

Hyperthermia

Hyperthermia is described as an increase in body temperature above the normal resting upper limit. Elevated body temperatures occur with exercise because athletes produce heat when exercising, and this exceeds the capacity of the hot environment to absorb that heat. The humidity of the air determines the extent to which heat can be transferred from the body to the environment in the form of sweat. Sweat evaporates from the skin surface, involving a phase change from liquid to gas, which cools the surface of the skin. However, as the humidity of the air rises, the efficiency of heat loss by evaporation falls, and the body may be unable to balance heat production and heat loss.

Hyperthermia Diagnosis and Treatment

The most important aspect of diagnosing heat illness is to recognize the early signs, before the athlete has progressed to the later stages of the illness. Evaluate the athlete's core temperature, amount of sweating, and thirst. If heat illness is suspected, a thorough musculoskeletal and neurologic examination should be performed, noting any confusion, dizziness, or nausea, as well as noting core temperature, all of which could lead to early diagnosis, treatment, and prevention of the progression of heat illness.

Heat cramps can be treated on the field, and once cramping has ceased, return to play is allowed after ensuring proper hydration and electrolyte supplementation. With heat exhaustion and heat stroke, the primary goal should be to return the athlete's core temperature to normal. Cooling the athlete should be the first and most important action taken. Different facilities will have different methods available, including immersion in cool water, misting fans, and cooling vests.

Hyperthermia Prevention

There are many steps that can be taken to reduce the chances of heat illness. Avoid exercising in the middle of the day, when temperature and humidity are at their highest; ensure appropriate fluid and electrolyte replacement; be aware of the signs and symptoms of heat illness; and act according to the limitations of one's body. Have sufficient cooling methods and appropriate fluids on the sidelines of games to ensure that if athletes begin to struggle with heat illness, proper treatments are available. It is also important to note that once an athlete has suffered from heat exhaustion or heat stroke, he or she is at risk for recurrence. Heat illnesses are avoidable if the proper precautions are taken and if the signs and symptoms of the earlier stages are recognized and treated appropriately.

Tendinitis, Tendinosis

Tendons are vital components of the musculoskeletal system as they serve to attach the contractile units of the body (muscles) to the levers (bones). They are thereby responsible for the transmission of the forces required to produce movement. The cross-sectional areas of tendons are small in relation to their attached muscles, and therefore, the stress (force per unit area) they are exposed to is substantial during activity. It is perhaps no surprise, therefore, that they are subject to inflammatory and degenerative pathology. Tendon injuries are reported to account for up to 30% of all running-related injuries and can result in considerable morbidity lasting several months despite appropriate management.

Tendon Structure

Macroscopically healthy tendons are white in color and are found in a variety of forms, from rounded cords to flattened ribbons, depending on their function and anatomical site. Normal adult tendon fibers are composed predominantly of large Type I collagen fibrils (65–80% of the dry mass) arranged in a ropelike configuration with smaller amounts of Type III collagen, proteoglycans, and elastic fibers (2%). The predominant cells found within the tendon structure are tenocytes and tenoblasts (immature tenocytes), which account for 90% to 95% of the cell population. These cells lie between the collagen fibers along the long axis of the tendon. The remaining cells include chondrocytes at the tendon insertion sites, the synovial cells of the tendon sheath, and vascular cells. The endotenon, a thin retinacular structure, invests each tendon fiber. The epitenon surrounds the tendon and contains the vascular, lymphatic, and nerve supply and is in turn surrounded superficially by the paratenon. Synovial tendon sheaths, consisting of an outer fibrotic sheath and an inner synovial sheath, may be found in areas subject to increased mechanical stress, where efficient lubrication is required. The inner sheath produces synovial fluid by a process of ultrafiltration. At the myotendinous junction, the weakest point of the musculotendinous unit, collagen fibrils of the tendon insert into deep recesses formed by the myocytes of the associated muscle. The osteotendinous junction is composed of four zones (dense tendon zone, fibrocartilage, mineralized fibrocartilage, and bone). The blood supply of tendons originates from intrinsic systems at the myotendinous and osseotendinous junctions and an extrinsic system through the paratenon or synovial sheath.

Contrary to traditional beliefs, tendons are metabolically active. Tenocytes have a low metabolic rate and a well-developed anaerobic energy generation capacity that allows them to resist load and maintain tension for prolonged periods. Animal studies suggest that the physical properties of tendons (tensile strength, stiffness, collagen content, and cross-sectional area) are all enhanced with physical activity. Type I collagen synthesis in particular depends on overall protein synthesis and on tensile loading and is thought to occur in a nonuniform way throughout the tendon structure.

Pathophysiology

The relationship between *tendinosis* (degeneration without inflammation) and *tendinitis* (inflammation) is unclear. The terms are often used interchangeably, leading to confusion. The best generic descriptive term for clinical conditions arising in and around tendons is *tendinopathy*. The low metabolic rate that makes the cells of the tendon suitably adapted for their role in load bearing also, however, results in delayed healing following injury. Tendinopathies tend to occur with greater frequency in the older athlete, and it is perhaps not surprising that with increasing age the metabolic pathways of tenocytes shift from aerobic to more anaerobic energy production. In addition, tendon vascularity is compromised at the junctional zones between the intrinsic and extrinsic systems or where there is localized torsion, friction, or compression. A good example of this is seen in the Achilles tendon, where there is a zone of hypovascularity 2 to 7 centimeters (cm) proximal to the tendon insertion, a common site of rupture. It is important to note that tendon blood flow also decreases with increasing age and mechanical loading.

Tendinopathy

Despite the relative frequency of tendon overuse injuries in sports medicine practice, the etiology of tendinosis and tendinitis remain unclear. The processes are multifactorial but on a local level are thought to be one of accumulated trauma as a result of repetitive mechanical loading. Tenocyte damage may occur as a result of localized hypoxia or as a result of free radicals produced during reperfusion after relaxation, which may be compounded by hyperthermia within the tendon produced by repeated or prolonged bouts of exercise. On a macroscopic level, there may be a combination of intrinsic factors such as malalignment, inflexibility, and muscle weakness or imbalance. Biomechanical faults, in particular hyperpronation of the foot, are reported to play a causative role in two thirds of Achilles tendon disorders in athletes. These may be exacerbated by age-related degeneration and diminished vascular supply. Tendons loaded beyond their physiological threshold respond by inflammation of their sheath (synovitis/tendinitis), degeneration of their body (tendinosis), or a combination of the two processes. Macroscopically, the diseased tendons look gray-brown and amorphous, and they may be thickened. Histological examination of tendons in symptomatic patients reveals disordered healing and noninflammatory degeneration. The fibers are thin and disorganized with scattered vascular in-growth. Inflammatory lesions and granulation tissue are infrequent in the chronic situation. Pain may result from a number of mechanical and biomechanical factors. Chemical irritants implicated in the production of pain include glutamate and Substance P.

Sites

Common sites of tendinopathies include the ankle (Achilles tendon/tibialis posterior), knee (patellar tendon), shoulder (supraspinatus tendon/bicipital tendon), and elbow ("tennis" elbow/"golfer's" elbow).

Diagnosis

The diagnosis of tendinopathy or tendinitis depends on the acquisition of a detailed history and a thorough examination. The patient generally complains of pain on loading the affected structure. There has often been a change in the frequency or intensity of activity prior to the onset of symptoms. Examination may reveal localized pain on deep palpation or thickening of the affected structure. Significant loss of function or the presence of a palpable defect should alert the examiner to the possibility of partial or complete tendon rupture. Magnetic resonance imaging (MRI) or ultrasound scanning with Doppler may be useful to identify changes within the tendon substance, including the increased blood flow associated with neovascularization.

Treatment

It is important at the outset to identify whether the problem is an acute episode with an inflammatory component or a chronic condition. Tendinopathies may require lengthy multimodal management, and patients often respond poorly to treatment. The mainstay of treatment is generally conservative. As in most conditions, the keystone of successful treatment lies in the accurate assessment of the factors contributing to the problem. These must then be systematically addressed during the treatment phase. Training patterns and the equipment used by the athlete should be assessed, preferably in conjunction with the coaching staff. Poor technique and "training errors" should be avoided, and where possible, biomechanical factors should be corrected. There is little convincing evidence for the use of nonsteroidal anti-inflammatory drugs (NSAIDs) in chronic tendinopathy, although they may be useful in the acute situation. It is important to recognize that in many sites, there is little evidence of a lasting benefit from the peritendinous injection of corticosteroids. If there is an inflammatory component such as a tenosynovitis or bursitis, these agents may be used to address any associated inflammation, and cautious use of locally applied ice may be helpful in providing pain relief. The degree of tendon loading that should be applied to promote healing is a matter of debate. Prolonged immobilization of tendons is detrimental, leading to tendon atrophy and reduced tensile strength. Controlled stretching is likely to increase collagen synthesis and improve the quality of the regenerate tendon.

Many physical therapies have been proposed for the treatment of tendinopathies, with little good-quality evidence for their efficacy. There is evidence from animal models of the usefulness of extracorporeal shock wave therapy (ESWT) in improving experimentally produced tendinopathy, but the results of clinical trials in humans are conflicting. Other treatments have included the use of pulsed magnetic fields, laser therapy, and radiofrequency coblation, again with variable results. There is good support for the use of an eccentric training program in short-term symptom relief in Achilles and patella tendinopathies. Other modalities used with conflicting evidence include dry needling, the image-guided injection of sclerosants, and the use of glyceryl trinitrate (GTN) patches. Surgical debridement of the macroscopically unhealthy tissue can be considered in cases resistant to other treatment modalities.

Future therapies may involve the use of cytokines and growth factors, gene transfer, or the implantation of mesenchymal stem cells to modify the healing environment.

Conclusion

The assessment and management of tendinopathies is one of the key skills required in the sports medicine practitioner. Further research and scientific evaluation of the available literature are required before evidence-based management protocols can be instituted.

Tendinopathy

Overuse or exercise-related tendon injuries are common in competitive and recreational athletes, as well as in manual laborers. *Tendinopathy*, the term used to describe an overuse tendon injury or disorder, usually presents as pain in the region of the involved tendon. Tendinopathy usually results from chronic repetitive overuse or subclinical injury rather than a single acute injury. Under the Bonar classification, tendinopathy includes tendinosis (degenerative change of the tendon), tendinitis (inflammation of the tendon) with tendinosis, paratenonitis (inflammation of the tendon outer covering), and tendinosis with paratenonitis (see Table 1). Some examples of common tendinopathies are listed in Table 2.

While there is some overlap in the symptoms and physical findings of patients with different causes of tendon pain, the patient's symptom history provides important clues to help in correctly diagnosing and treating the underlying tendon injury. In addition to guiding appropriate treatment, proper diagnosis also provides the ability to properly educate patients about the expected course of their tendon problem. One important clinical distinction in tendinopathy is between acute, inflammatory conditions (tendinitis, paratenonitis), and chronic, degenerative conditions (tendinosis). While inflammatory tendon conditions are usually self-limited and respond well to anti-inflammatory treatments, degenerative tendon changes, since they are usually chronic, typically require a more robust, long-term treatment plan focused on reversing the degenerative process. Furthermore, because inflammatory and degenerative conditions often coexist, both must be considered in developing an appropriate short- and long-term treatment plan.

Anatomy

Tendons are predominately Type I collagen, which consists of tropocollagen chains grouped in a triple helix arrangement. These triple helices are very closely grouped longitudinally in the tendon, with each level of organization being surrounded by an outer covering. The entire tendon is also surrounded by an external covering called the *paratenon*. In areas where tendons bend at acute angles (e.g., the flexor tendons of the fingers) over bone, the paratenon is usually thicker and lined with synovium, which not only provides mechanical resistance to shearing forces but also produces synovial fluid, lubricating the tendon to decrease frictional injury. This is also commonly referred to as the tendon sheath. It is in these areas that the inflammation can commonly occur, causing synovial fluid production and associated swelling (e.g., intersection syndrome). In the remaining tendon areas, the paratenon is thinner and not lined with synovium.

Causes

As mentioned previously, tendinopathy usually results from chronic overuse microtrauma to a tendon. The precise pathogenesis of tendinopathy is still unknown, but general causative mechanisms

Table 1 Classification of Tendinopathies

Tendon Condition	*Formerly Used Terms*	*Macroscopic Appearance/Pathology*
Normal tendon		White, glistening, firm
Tendinosis	Tendinitis	Dull, slightly brown, soft; intratendinous degeneration
Tendinitis with tendinosis	Tendinitis	Intratendinous inflammation (repair response) superimposed on tendinosis
Paratenonitis	Tenosynovitis, tenovaginitis, peritendinitis	Inflammation of the outer tendon layer
Paratenonitis with tendinosis	Tendinitis	Combined degenerative changes of paratenonitis with degenerative changes of tendinosis

Table 2 Common Tendinopathies

Tendon	*Paratenon Synovial Lining?*	*Common Tendinopathy*
Rotator cuff tendons		
Supraspinatus	No	Supraspinatus tendinosis (due to subacromial impingement)
Infraspinatus	No	Rotator cuff tendinosis
Teres minor	No	Rotator cuff tendinosis
Subscapularis	No	Rotator cuff tendinosis
Biceps brachii	Yes (long head in intertubercular groove)	Biceps paratenonitis (long head), biceps tendinosis (long head) ± paratenonitis
Common wrist extensor	No	Medial epicondylosis
Common wrist flexor	No	Lateral epicondylosis
Flexor digitorum tendons (superficial and deep)	Yes (over carpal bones)	Flexor digitorum paratenonitis, Flexor digitorum tendinosis ± paratenonitis
Abductor pollicis longus (APL), Extensor pollicis brevis (EPB), Extensor carpi radialis longus (ECRL), Extensor carpi radialis brevis (ECRB)	Yes (over carpal bones)	APL/EPB paratenonitis (de Quervain), APL/EPB/ECRL/ECRB paratenonitis (intersection syndrome)
Patella	No	Patellar tendinosis
Achilles	No	Achilles tendinosis
Posterior tibialis	Yes	Posterior tibialis paratenonitis, Posterior tibialis tendinosis ± paratenonitis

are becoming more clearly understood. Other than paratenonitis, all other categories of tendinopathy have a component of tendinosis or degenerative tendon changes. It is now understood that these changes can occur as early as 3 weeks after the start of the overuse injury.

While general aging and tendon underuse can contribute to degenerative tendon changes, most tendinopathy is caused by any combination of excessive repetition, anatomic abnormality (e.g., limb length discrepancy), malalignment (e.g., hyperpronation), muscle imbalance or weakness, improper technique, improper equipment, and incomplete recovery after overuse. These etiologies hold true for competitive and recreational athletes as well as for recreational and vocational laborers.

Clinical Evaluation

History

While a patient complaint of pain over a tendon clearly causes one to consider tendinopathy, the clinical history is very important in helping distinguish among the types of tendinopathy. A patient with only paratenonitis will usually complain of a recent increase in his or her activity level or intensity, such as a soccer athlete with ankle hyperpronation who complains of posterior tibialis pain and swelling 1 week after starting preseason conditioning. Of note, pain from paratenonitis will usually be constant and proportional to activity level.

A patient with tendinosis will usually have a prior history of overuse, such as playing competitive tennis in a patient with supraspinatus tendinosis or playing competitive basketball in a patient with patellar tendinosis. Furthermore, tendon pain from tendinosis will typically start during the warm-up phase and, in less advanced disease, decrease during activity and increase during the warm-down and recovery phases. Additionally, pain from tendinosis is usually sharp and more intense early and becomes duller and more achy later in the disease process.

In the evaluation of tendon pain, it is also important to rule out other causes of the patient's pain. Most patients with tendinopathy should not have associated paresthesia, weakness, radiation of pain, blunt trauma, fever, and overlying skin changes. Furthermore, pain from tendinopathy should not persist with relative rest and should not cause night symptoms.

Physical Examination

Physical examination is useful to distinguish inflammatory from noninflammatory tendinopathy. Patients with tendinopathy will have pain with palpation of a tendon under strain using manual muscle testing. As with most inflammatory conditions, patients with paratenonitis or tendinitis complicating tendinosis will often have associated swelling and increased temperature over the affected area of the tendon. Additionally, patients with these conditions can have crepitus with passive joint range of motion, moving the tendon back and forth.

Imaging

Clinical assessment is usually sufficient for the diagnosis and classification of tendinopathy. However, magnetic resonance imaging (MRI) and ultrasound can be helpful adjuncts in assessing tendinopathy. Areas of tendinosis will be most visible as hypoechoic regions on an ultrasound scan and increased signal on T2 and STIR (short T1 inversion recovery) sequences on an MRI scan. However, imaging can also complicate the clinical picture because a high percentage of asymptomatic patients can have evidence of tendinosis on imaging, especially of the rotator cuff in older patients.

Treatment

The mainstay of tendinopathy treatment has been conservative therapy relying on relative rest, ice, and nonsteroidal anti-inflammatory medications (NSAIDs). While modalities to decrease inflammation, such as steroid anti-inflammatory medications (either local or systemic), may be of benefit in proven cases of paratenonitis or tendinitis complicating tendinosis, these medications do not treat the underlying pathology of tendinosis when present. Furthermore, because NSAIDs mostly have analgesic properties, if not coupled with reversal of the causative factors and relative rest, further injury may ensue.

The most widely accepted treatment modality for reforming degenerative tendon has been eccentric muscle strengthening of the affected muscle-tendon unit. There has been some suggestion that eccentric strengthening following soft tissue mobilization has further benefit, but this has not been borne out in the literature. Some other treatment modalities, such as topical nitric oxide and shock wave therapy, have been used but still remain experimental.

In rare cases of tendinosis that do not respond to a prolonged course of conservative treatment options, surgical treatment to remove a section of degenerative tendon may be indicated. Athletes must understand that surgery will not hasten their return to sports and often will guarantee a 6- to 12-month hiatus from full competition.

The most important part of any treatment plan for tendinopathy includes correction of the underlying cause. If the patient has a muscular insufficiency or imbalance, proper identification and physical therapy are essential. If errors in technique or training schedules are identified and corrected as part of the treatment, the patient will often see long-term benefit.

Conclusion

Tendinopathy is a common condition affecting athletes, resulting from overuse injury to the tendon.

Inflammatory conditions of the tendon do occur but predominately involve inflammation of the outer covering of the tendon, or paratenon. More commonly, patients have underlying tendon degeneration, or tendinosis. These patients require a robust treatment plan, including eccentric strengthening exercises and correction of modifiable risk factors, such as muscle imbalances and training errors.

Tennis and Racquet Sports, Injuries in

Injuries are common in players of racquet sports. A retrospective analysis of sports injuries in 2000 showed squash injuries to be more frequent than tennis and badminton injuries, with more men injured overall than women and with persons over age 25 more vulnerable to injuries. The higher proportion of squash injuries were attributed to greater physical stress and more contact. Acute traumatic injuries were seen especially in squash players, most often affecting the knee, lumbar region, and ankle. The most common tennis injuries were lateral epicondylitis, patellofemoral pain, and lumbar disk prolapse. The badminton injury pattern overlapped the others. Lower limb injuries predominated in all racquet sports. Detailed assessment of 106 cases showed many to be new, infrequent, social players. Poor warm-up was a common factor in both new and established players.

Typically, injuries in racquet sports are overuse injuries. These result from repetitive stresses and minor traumatic events, such as the effect on the shoulder of serving thousands of times or the influence on the knee of playing hundreds of points with pivots, twist, and aggressive stops and starts.

Tennis injuries may be categorized as either acute or chronic. *Acute injury* describes a new injury or complaint from the time it occurs and for the short time following the start of injury (e.g., ankle sprain). A *chronic injury* typically recurs or repeats itself due to continued tennis play or lack of proper rehabilitation (e.g., tennis elbow).

Among elite junior tennis players, injuries in descending order of frequency were as follows: back, 24%; shoulder, 21%; foot, 19%; knee, 15%; elbow, 12%; and ankle, 12%.

Head Injury

Although head injuries are uncommon in tennis, they sometimes occur, particularly in doubles play, where the bodies or racquets of two partners may come into contact.

Bruises and Cuts

Bruises are usually caused by being hit by the ball on a smash shot. It's more common in doubles play because the player at the net has less time to react. Being hit by the partner's racquet may also cause a bruise.

Bruises can usually be treated by icing them to reduce swelling and control pain. If the skin is broken, it is cleaned with soap and water, and an antiseptic spray or cream may be applied. Nonsteroidal anti-inflammatory drugs (NSAIDs) may provide pain relief. If a blow causes loss of concussion or memory, or disorientation, the player should be seen promptly by a physician.

Broken Nose

A blow to the nose by a racquet or ball can fracture the nasal bones or injure the cartilage of the septum—the structure that separates the two nostrils.

Any nose suspected to be broken should be iced down to limit swelling and bruising. The athlete should be seen by a physician, and radiographs should be taken. Once fixed, the nose is usually protected with a splint until it heals completely, which can take 4 to 6 weeks.

Eye Injuries

Most eye injuries in racquet sports are caused by being struck in the eye with the ball or, rarely, a blow from a partner's racquet. Eye injuries may cause bleeding into the orbit and surrounding tissues, scratch the cornea, cause bleeding inside the eye, or even cause a detached retina. Any injury to the eye should be examined promptly by an ophthalmologist.

Blowout Fracture

A blow to the eye or cheek from the racquet can fracture the orbital bones surrounding the eyeball. As with any fracture, an athlete who suffers a suspected blowout fracture must see a physician for treatment, which may include surgery.

Neck Injury

Along with the head, the neck area is affected in many racquet sports injuries. The neck is tremendously mobile to allow the head to swivel, so the range of motion between the vertebrae in the neck is greater than in the lower spine.

Pinched Nerve

An injury that initially may seem like a sprain but is actually more complex is a pinched nerve; this happens when a cervical disk ruptures or degenerates.

Tennis players, who may make fairly violent neck motions, are prone to pinched nerves. The problem usually responds to some form of cervical traction (neck brace) for 2 to 6 weeks, with accompanying physical therapy to reduce muscle spasm. However, if severe symptoms persist, particularly in the arm and the hand, surgery may be required to repair damage to the offending intervertebral disk.

Neck Muscle Injuries

Wryneck, or *spastic torticollis,* is due to a pulled muscle, or muscle spasm. The athlete who looks up and serves or hits an overhead smash may feel pain on one side of the neck, and the neck may be pulled over slightly to that side.

The proper treatment is to apply ice for 20 minutes at a time and gently stretch the neck. If the pain is severe, the athlete may need medication, such as a muscle relaxant or anti-inflammatory agent, and physical therapy.

Perhaps the best way to prevent neck injury is to strengthen the neck muscles. Every tennis player should work on improving neck strength. Basic exercises include applying resistance against oneself or by working with a partner.

Shoulder Injury

The shoulder is one of the most commonly injured joints among tennis players, particularly among junior elite players.

Rotator Cuff Injury

The *rotator cuff* is a group of muscles that work together to provide the shoulder joint with dynamic stability, helping to control the joint during rotation. The rotator cuff muscles include the supraspinatus, infraspinatus, teres minor, and subscapularis.

Due to the function of these muscles, sports that involve a lot of shoulder rotation—for example, tennis—often put the rotator cuff muscles under considerable stress. Rotator cuff injuries may range from an impingement to a complete tear. The impingement causes the nerves under the shoulder to fire and shoot pain down through the tendons of the shoulder into their connecting muscles. Tennis players feel the pain particularly in the long head of the biceps. Tennis players with this injury may be able to hit ground strokes effortlessly, but when they try to hit an overhead or serve, they experience shoulder pain.

Treatment for shoulder impingement may include a series of lifting and stretching exercises to strengthen the rotator cuff muscles and increase range of motion.

Shoulder Muscle Strain

A muscle strain can happen to almost any muscle in the body; the shoulder is particularly subject to such strains, or "pulls," which occur when a sudden, severe force is applied to the muscle and the fibers are stretched beyond their capacity. If only some of the fibers tear, it is called a muscle strain. If most of the fibers tear, it is called a muscle tear.

Common treatment for a muscle strain is a rest period, about 3 to 7 days, followed by stretching and then strengthening exercises.

Tennis Elbow

Lateral epicondylitis, or *tennis elbow*, is probably the most common of all upper extremity injuries in racquet sports. This term refers to the overuse injury resulting from repetitive trauma to the tendons that control wrist and forearm movement. Tennis elbow usually results from improper technique during backhands.

The single biggest factor in preventing tennis elbow is using a proper biomechanical tennis stroke technique. Rubber tubing exercises are used effectively to strengthen these muscles.

Treating tennis elbow requires an exercise program to increase the strength and flexibility of the forearm muscles and tendon.

Players with a history of tennis elbow or the athlete who feels elbow pain after play should wait at least half an hour after a match and then ice the elbow down, keeping the elbow cool for up to 30 to 40 minutes.

Grip size of the tennis racquet is important. The correct grip size is the distance from the proximal transverse palmar crease to the tip of the ring finger. An appropriate brace or splint for the forearm, applied distally to the elbow, is believed to dampen some of the shock that contributes to epicondylitis. Adequate warm-up, muscle stretching, and cooldown are always advisable. A physiological heat retainer may also be very useful and should be worn as often as possible.

Formerly, the standard treatment for tennis elbow was local cortisone injection. This form of therapy is no longer in wide use, especially as long-term treatment, because of reports of cortisone injections causing irreparable damage to the tendon.

Another type of tennis elbow causes pain on the inner side of the elbow (the medial epicondyle). This pain involves inflammation of the muscles and tendon that the palm faces down. Prevention and treatment measures are the same as for the first type of tennis elbow.

Torn Biceps

A sudden, severe movement of the arm can tear the biceps muscle. One head of the biceps can be literally torn in half. This is usually seen in an older tennis player who hits a hard forehand smash.

Treatment involves allowing the torn muscle to rest for 2 or 3 weeks while it heals. This is followed by a training program to strengthen the other head of the biceps so that it can take over the full function of the muscle. Arm curls are the best exercise to strengthen the biceps muscle.

Wrist Injuries

Racquetball and squash especially require a snapping motion of the wrist. Thus, the tendons and ligaments of the wrist are frequently injured.

Sprained Wrist

The most common injury to the wrist is a sprain. Strength and flexibility exercise of the muscles that cross the wrist helps protect the wrist and the ligaments that keep the wrist together.

Broken Wrist

A wrist usually fractures from a fall. Any severe wrist pain following a fall or a blow to wrist should be seen by a physician and X-rayed because of the possibility of fracture.

If the bone does not reknit, it probably will need to be fixed surgically.

Racquet Wrist

Tennis players may develop pain at the base of the hand, below the pinky finger. This usually occurs because the racquet butt is too large for the player's hand.

If the pain is severe, the athlete should see a physician. The little hook of bone at this location might be broken. If it is, then it will need to be treated as a fracture.

Tendinopathy

Overuse of the wrist in sports causes irritation of the finger tendons attached to these forearm muscles. This results in swelling, pain, and limited function in one or more of the fingers.

Treatment involves resting and icing the tendon in the wrist, followed by taking anti-inflammatory agents and immobilizing the thumb and wrist to reduce the inflammation. Appropriate strengthening exercises (e.g., ball squeezing) may be prescribed.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is a painful disorder of the wrist and hand. The carpal tunnel is a narrow structure formed by the bones and other tissues of the wrist. This tunnel protects the median nerve, which gives feeling in the thumb, index, middle, and ring fingers. When surrounding tissues, such as ligaments and tendons, become swollen or inflamed, they press against the median nerve, causing pain or numbness. Anyone who tightly grips something while exercising, such as a tennis racquet, may suffer carpal tunnel syndrome.

The treatment is to rest the affected wrist and apply ice. In some cases, surgery is needed for relief of symptoms. Postoperatively, physical therapy with wrist and finger exercises is important to ensure good recovery and return to full function.

Arm Injuries

How equipment is used can affect the athlete's arm. String tension of the racquet is one important factor. Decreasing the racquet's string tension by a few (2–4) pounds (lb; 1 lb = 0.45 kilograms) is recommended for players who are experiencing shoulder, elbow, or wrist pain.

Research suggests that vibration dampeners have no affect on the arm itself; these dampeners do affect high-frequency vibration, such as that coming off the strings.

Knee Injuries

Knee injuries may occur in any racquet sport, but they are of particular concern in racquetball and squash, in which nearly every type of knee injury can occur.

Patellar pain syndrome may be the most frequently encountered condition in persons playing racquetball or squash. The syndrome usually has an insidious onset and is characterized by dull, aching, poorly localized pain that occasionally radiates to the sides and back of the knee. Initially, patellar pain syndrome occurs after activity; however, it can worsen to the extent that the knee is painful throughout the day. Swelling is rare.

Tennis obviously places a great deal of stress on the knee joint from bending, quick starts and stops, and explosive acceleration. Because tennis is a noncontact sport, the bone-crushing knee injuries we equate with football or skiing are not prevalent. With repeated stress to the legs, such as tennis play, and without sufficient strength and endurance of the thigh muscles, the kneecap can become irritated. This repeated irritation can wear down the back side of the kneecap and produce significant pain.

Preventing knee injuries in tennis focuses on two strategies: Strength and flexibility exercises, with proper biomechanics, form the platform for an injury prevention program.

Ankle and Foot Injuries

Acute ankle sprains are another of the most frequent injuries in racquetball and squash players. Most sprains are first degree and are treated in the usual fashion. Ice and elevation, combined with graded exercises, are recommended. Some trainers recommend extra support for the first 6 weeks after play is resumed.

Achilles tendon problems are also frequently encountered. Chronic Achilles tendinitis is characterized by gradually increasing pain that is aggravated by activity and relieved by rest. Rest is most important in the treatment of acute injury. Once pain subsides, gradual stretching of the tendon, along with calf strengthening, should be done.

Less common, and most dreaded, is rupture of the Achilles tendon. Usually, the player is trying to push back from a drop shot at the front of the court and hears a sudden snap, followed by immediate pain. In the Thompson "squeeze" test, the patient lies prone, and the examiner squeezes the calf muscle. An intact Achilles tendon will cause the foot to plantarflex, representing a negative test. The test is positive if this response is absent, due to a ruptured tendon. A tender, palpable swelling may be detected. Palpable or visible defects can also be found, although they may be obscured by bleeding. The patient walks flatfooted with a limp, not pushing off the toes. Treatment may be operative or nonoperative, and the decision is best left to an orthopedic surgeon.

The most common foot problems are related to blisters and calluses. Traditional treatment of blisters includes releasing the fluid, thereby allowing the underlying skin to harden. Some physicians prefer not to drain blisters, so as to avoid creating a portal for possible infection. If the patient wishes to continue playing while the blister heals, a small, doughnut-shaped dressing can alleviate pressure to allow healing. To prevent underlying blister formation, calluses should be smoothed with an emery board or pumice stone.

Plantar fasciitis is the most commonly seen orthopedic condition of the foot in racquet sports enthusiasts. It is characterized by pain at the medial tubercle of the os calcis, where the plantar fascia attaches. The pain may also radiate distally toward the toes or, more commonly, proximally. Most patients complain of pain that begins as they get out of bed, subsides after walking, and recurs later in the day or during a game. Shortening the amount of time spent playing racquet sports or ceasing play altogether is most helpful. This decrease in activity should be followed by the use of orthotics, heel cups, or corrective athletic shoes with good midfoot support.

Tennis Elbow

Tennis elbow, or *lateral epicondylitis*, is characterized by pain at the lateral (outer) aspect of the elbow. The patient may also complain of tenderness on palpation of the area of concern, usually the dominant arm. This entity was first described in a scientific article in 1873, and since that time, the mechanism of injury, pathophysiology, and treatment of this condition have been much debated.

The disorder is due to overuse of the extensor carpi radialis brevis (ECRB) muscle, which originates at the lateral epicondylar region of the distal humerus. Tennis elbow can also be classified as *tendinitis,* indicating inflammation of the tendon, or *tendinosis,* indicating tissue damage to the tendon.

The most common cause of lateral epicondylitis is, as the common name suggests, tennis. It is estimated that tennis elbow occurs in 50% of tennis players. However, this condition is caused not only by tennis but also by any activity associated with repetitive extension (bending back) of the wrist. The activity initiates contraction of the muscles that cause the hand to extend (bend back). There is a significant increased risk of overuse injury if playing for more than 2 hours/week and more than two to four times per week. In players older than 40 years, the risk increases two- to threefold. Significant risk factors have been identified and include improper technique and the size and weight of the racquet.

Anatomy and Mechanism of Injury

To understand the mechanism of injury of this condition, knowledge of some basic anatomy of the elbow is helpful. The elbow is a hinge joint—a junction between two bones primarily connected to each other by ligaments and tendons from the muscles near the humerus. The humerus is a long bone originating from the shoulder and extending to the elbow. It has two bumps called *epicondyles*—one on the medial (closest to the body) side and one on the lateral (farthest from the body) side. The radius and ulna are the bones in the forearm. The tendon (connecting tissue) at the medial epicondyle attaches to a muscle that causes the forearm and wrist to bend forward. Similarly, there is a tendon that attaches to the extensor muscle (ECRB) at the lateral aspect of the elbow, which when contracted, causes the forearm and wrist to bend backward (extend). At this junction at the elbow, inflammation at the area of bone attachment (enthesopathy) can occur with repeated stress, which in turn, causes a biochemical change in the tendon at the lateral epicondyle area. Classically, this is caused by overexertion of the extensor muscle while performing a backhand stroke in a game of tennis or other activity causing repetitive forearm muscle contractions (see Figure 1).

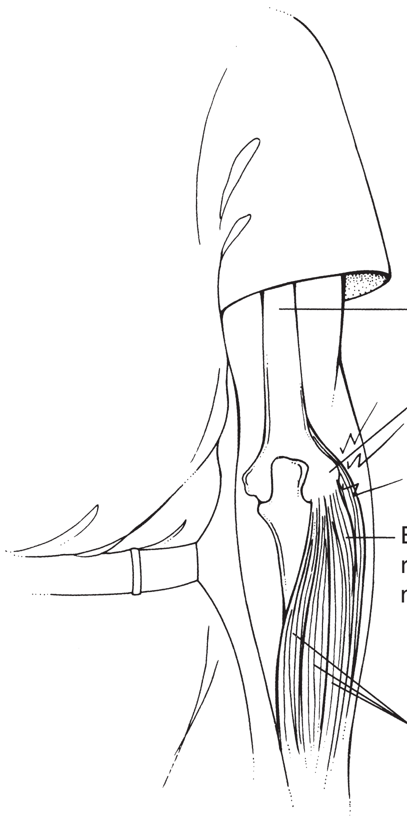

Figure 1 Tennis Elbow

Notes: Among the most common of overuse injuries, tennis elbow is caused by repetitive stress to the forearm muscles. This stress transmits to where the extensor muscle inserts into the lateral epicondyle of the humerus.

The pathophysiology of the condition involves inflammatory processes of the radial humeral bursa (fluid-filled sac) and nearby ligaments. This is caused by microscopic tearing with formation of scar tissue at the area of origin of the ECRB muscle tendon, so these small tears and subsequent repair in response may lead to larger tearing and eventual structural failure. Nirschl categorized this into four progressive stages:

Stage 1: Reversible inflammatory changes

Stage 2: Nonreversible pathologic changes

Stage 3: Rupture of ECRB muscle tendon origin

Stage 4: Tissue fibrosis or calcification noted as a secondary change

The patient may have one or more of the following complaints:

- A steadily increasing pain on the lateral part of the elbow.
- Pain that worsens with recreational activities such as playing tennis or gardening or with occupational activities such as painting walls.
- Pain that worsens when strongly squeezing the hand, shaking hands, or turning doorknobs.
- Pain that worsens with moving the wrist against resistance in any direction.
- Pain with handling a knife and fork and opening jars and, at times, even when driving or placing the hands and wrists in an extended position.
- Pain that may begin to occur at night and at rest without any activity.

The physical exam should include the following:

- Inspection of the area for any signs of trauma, swelling, erythema (redness), and deformity, as well as evaluation for asymmetry of the affected side versus the unaffected side.
- Evaluation of range of motion by the patient (actively) and by the examiner (passively).

- Palpation of the affected area to localize the area of tenderness as well as any nodules (bumps). It is worth noting that in some cases the etiology of pain at this location may be related to another condition called bursitis, which is inflammation of the bursa (a fluid-filled sac), which acts like a cushion; this may get irritated as well as infected. Typically, this area will be red, swollen, tender to the touch, and warm. Management could include rest, anti-inflammatory medication, and antibiotics in case of bacterial infection. So proper evaluation is crucial.
- Special stress testing to test whether resistance of the motion initiated by the patient (bending back the wrist while resisted by the examiner) will reproduce or worsen the pain. This would indicate a positive screening test.

Imaging Studies and Electrical Stimulation Study

Radiographs can help in ruling out other disorders or concomitant intraarticular pathology—for example, osteochondral loose body, posterior osteophytes (bone spurs). Calcification in the degenerative tissue of the ECRB muscle origin can be seen in chronic cases.

If indicated, magnetic resonance imaging (MRI) can confirm the presence of degenerative tissue in the ECRB muscle origin and can help diagnose concomitant pathology; however, it is very rarely needed and is usually expensive.

If clinical examination indicates a possible neural involvement with the patient's symptoms, electromyography (EMG) can be used to exclude posterior interosseous nerve compression syndrome (compression of the nerve).

Diagnostic procedures other than the common standards test may include a localized anesthetic injection into the area of concern, which is both diagnostic and therapeutic if the patient experiences relief from his or her symptoms.

Management

Nonsurgical

Generally, early, nonsurgical intervention is sufficient for the management of tennis elbow. Surgical intervention is not readily done due to the potential for scarring and for complications developing during and after the surgery.

Phase 1: Decrease or stop activity for 2 weeks

- Apply ice on the painful area 10 minutes on, 2 hours off for a day.
- Take ibuprofen for 10 days as prescribed, along with topical pain medication.
- Wear a wrist counterforce brace or splint to keep the wrist straight and avoid extension of the wrist or near the elbow to decrease tension on the muscle.

Usually, the symptoms will improve in 2 to 4 weeks.

Phase 2: If the above interventions do not help decrease the symptoms partially or completely, then consider an injection of corticosteroid in combination with a fast-acting anesthetic. These injections are fairly effective; however, chronic and repetitive use (more than two to three times) in the specific area of injection may cause further degeneration of the tendon. Also, a corticosteroid injection may cause wasting of the fatty tissue just below the skin.

Phase 3: Surgery is used only as a last method of intervention, after all other methods of treatment have been tried without improvement for 6 months. Even then, patients should consider surgery only when the symptoms have worsened to the extent of impairing function and activities of daily living due to pain. The surgery can be performed either arthroscopically (using a fiberoptic scope) through a tiny opening in the elbow (which creates a small scar) or by traditional open incision method (which causes a slightly bigger scar). Neither method has an advantage in postsurgical rehabilitation or functionality over the other method; the choice of technique is based on the surgeon's preference and experience, as well as the patient's preference.

Postsurgical Rehabilitation

1. After surgery, the elbow will be placed in a brace and the patient will be sent home with some pain medications as well as a directive to keep the area of incision clean and dry.
2. The patient will return in 5 to 7 days for a follow-up visit, and if the wound is healing well, the sutures will be removed.

3. If everything goes well, the brace will also be removed. Light stretching will be started, along with mild and gentle restoration of range of motion.
4. After 2 months, strength rehabilitation is started lightly and gradually as tolerated.

At this time, the physician will permit resumption of normal and recreational activities as appropriate. About 80% of the time, surgical intervention will be successful; however, one should allocate 4 to 6 months for complete recovery.

Prevention is the key to avoiding progression to surgical treatment. Patients should not delay seeking medical consultation at the earliest onset of symptoms.

Testicle, Undescended or Solitary

Diseases, congenital anomalies, cryptorchidism (the undescended testicle), trauma, and their treatment may leave a child with a solitary testicle. When these youths come to the office for clearance to play sports, especially contact-collision sports, their reproductive future is at stake. A decision must be made as to whether it is safe to allow them to play.

Evidence from multiple pediatric trauma registries and thousands of contact-collision sports exposures suggests that the risk to the solitary testicle is not significant. In the injury surveillance data gathered from team sports at high school and collegiate levels, there is no evidence showing that these males have a significantly increased risk. For example, the National Pediatric Trauma Registry studied injuries in classic contact-collision sports over a 10-year period. There was only one testicle injury. The testicles are freely mobile, which may protect them from crush injury and disruption. Given a slight hypothetical risk, the recommendation by numerous sports medicine societies, including Medical the American Academy of Pediatrics, is unrestricted full clearance to play in contact-collision sports using a cup, after discussion of the potential risks. In other countries, the clearance-to-play recommendation is not so clear. In Australian rugby, there were 14 injuries, 11 with complete testicle loss, in a group of 15- to 19-year-olds from 1980 to 1993. Finally, the athletes should be given the option of sperm banking, if that is appropriate for their situation.

Cryptorchidism has a prevalence of 2% to 4% in babies weighing more than 2,500 grams (g), which decreases to 0.7% to 1% by the time these children reach 1 year of age. The obvious risk of an undescended testicle is testicular cancer. This risk increases concomitantly with the duration of the cryptorchidism. Most males have already had orchiopexy by the time they reach middle school and have no increased risk of cancer. Unfortunately, undescended testicles are still found in teenagers and in as many as 1% of U.S. military recruits.

The preparticipation exam offers an opportune occasion to find undescended testicles before they pose an increased risk of cancer. Several states now require early periodic screening, diagnosis, and treatment physicals (i.e., well-child exams) at the same time as sports physicals for seventh and ninth graders. This is an excellent time when the physician can perform a comprehensive physical and directly reduce the risk of testicular cancer in individuals found to have cryptorchidism. If an undescended testicle is discovered, the physician should make an immediate referral to a urologist to remove the testicle and repair the inguinal hernia that usually coexists with it.

Therapeutic Exercise

Therapeutic exercise is the systematic application of movement to joints and muscles to assist in the recovery from illness or injury. Therapeutic exercises are usually of a lower intensity and shorter duration than exercises used for conditioning healthy athletes. An individualized therapeutic exercise program is established after a rehabilitation professional obtains a full history and performs a comprehensive evaluation of the athlete.

The overall goal of a therapeutic exercise program in sports medicine is to return the athletes to their baseline level of function in their sport. This process can take a few days to several months depending on the injury. As the athlete advances through the stages of recovery, the exercise program is revised to progressively challenge the neuromusculoskeletal system in a safe manner. The components of a therapeutic exercise program will be discussed in this entry.

Exercise Parameters

Exercise parameters are an integral part of the therapeutic program and should be determined for each exercise. Parameters include frequency, intensity, duration, repetitions, sets, and rest. *Frequency* refers to how often each aspect of the exercise program is performed. *Intensity* refers to the difficulty of the activity. The unit of measurement varies for different types of exercise. *Duration* refers to the length of time an exercise is performed in a given session. *Repetitions* are the number of times an exercise is performed in one set. A *set* is a fixed number of repetitions of an exercise performed without rest. *Rest* refers to the length of time of resting between sets.

Types of Muscle Contraction

Muscles can contract *isometrically* or *isotonically*. Isometric contractions generate muscle force, but no joint movement occurs, such as holding a squat for 10 seconds. Isotonic contractions occur when the muscle contracts and joint movement occurs. There are two types of isotonic contractions. Concentric contractions occur when the muscle fibers shorten as the muscle contracts, such as the lifting phase of a biceps curl. Eccentric contractions occur when the muscle fibers lengthen, such as the lowering phase of a biceps curl.

Position of the Exercise

The body or segment can be positioned in relation to gravity to change the demands of the exercise. Antigravity exercises are performed in an upward direction, or against gravity. Gravity-eliminated exercises are performed in a horizontal plane, which is perpendicular to the force of gravity. Gravity-assisted exercises are performed in a downward direction, or in the same direction as the force of gravity. Exercises can be performed with the affected part in a weight-bearing or closed-chain position or in a non–weight bearing or open-chain position. Push-ups are an example of a closed-chain exercise. Biceps curls are an open-chain exercise.

Types of Exercise

Range-of-Motion Exercises

Passive range of motion involves no active contraction of the muscle. The joint is moved through a range of motion by another person or by an outside force. This type of exercise is often used to increase joint or muscular flexibility or to promote muscle relaxation. Active-assistive range of motion is performed with the assistance of a second person. The athlete uses muscle activity to move the part but is assisted by the practitioner. This type of exercise is often used when the athlete is unable to perform the exercise independently because of an injury or when independent exercise is contraindicated. Active range of motion is performed entirely by the athlete's own muscle power, with no assistance or resistance. This type of exercise can be used to increase the range of motion or for strengthening when resistance is not indicated. Active-resistive range of motion or strengthening is performed against resistance.

Strengthening

Strength is defined as the maximum amount of weight a muscle can move. Strengthening exercises employ resistance to increase the strength. *Resistance* is an outside force applied in a direction opposite to the motion of the body segment being exercised. The amount of resistance can be fixed or varied throughout the range or applied isometrically. Resistance can be applied in a variety of ways. The weight of the body or body segment can be used as resistance in an open- or closed-chain manner. Free weights, dumbbells, bar bells, cuff weights, and medicine balls provide a fixed amount of resistance in small increments. Elastic tubing or bands come in a range of levels of resistance that is somewhat variable through the range as the band is stretched. Manual resistance is provided by the contact of the practitioner's hand against the body segment.

Resistance can be provided by machines or weight stations. Weight increments are often larger than those available with other types of resistance. Weight can be fixed throughout the range of motion, or some systems attempt to vary the resistance throughout the range. *Progressive resistive exercise* (PRE) is a method of strengthening muscles used in rehabilitation settings, in which the resistance is added in selected increments in one session.

Isokinetic exercise is a type of strengthening exercise. Special equipment is required for this. The speed at which the exercise is performed is fixed, and the resistance varies throughout the range of motion.

Plyometrics are activities designed to develop explosive power in muscles, which is a component of strength in athletic activities. The muscle undergoes a repetitive, rapid, eccentric, or lengthening contraction, quickly followed by a rapid, concentric, or shortening contraction, such as jumping in place.

Flexibility

Flexibility refers to the amount of motion allowed by joint structures and the muscle tendon unit. Stretching exercises are usually done passively, with no activity in the muscle or muscle group being stretched. The muscle is placed in a position of stretch or elongation, and the position is maintained. This is called *static stretching*. Thirty seconds is the generally accepted time for holding the stretch to achieve maximum benefit. Bouncing or ballistic stretching is not recommended because it is not effective and may cause further injury. Rehabilitation professionals may employ a technique in which the muscle to be stretched performs an isometric or isotonic contraction first, followed by a stretch of the same muscle or group of muscles to increase flexibility.

Muscular Endurance

Muscular endurance is the ability of a muscle or a group of muscles to perform continuous activity without fatigue. Exercises are directed to specific muscles or muscle groups using low resistance and high repetitions.

Aerobic and Anaerobic Exercise

Cardiovascular endurance can be trained through aerobic activities, such as distance running. Aerobic exercise improves oxygen consumption of the body and typically involves repetitive exercise performed at a moderate intensity for an extended period of time. Guidelines usually suggest a total duration of 30 minutes. Intensity is defined as the target heart rate (THR). A lower THR is used for lower levels of fitness. THR is calculated by the following equations:

$$\text{Maximum heart rate} = 220 - \text{Age of athlete}$$

$$\text{THR} = 60\text{–}85\% \times \text{Maximum heart rate.}$$

The injured athlete can often engage in selected aerobic activities to avoid stress on the injured area and maintain cardiovascular endurance. Anaerobic exercises are performed at a higher intensity but for a much shorter duration than aerobic exercises—up to 2 minutes—and do not improve cardiovascular endurance.

Joint Stability and Balance

Joint stability refers to the ability of the various joint structures and the muscle-tendon unit to resist forces and therefore prevent injury. Proprioceptors are sensory receptors in the muscle-tendon unit and joint structures that provide information to the brain about the position of the limbs and body in space. These receptors, which can become faulty after an athletic injury, provide feedback to the brain, which then controls the response of the muscle to the force.

Balance refers to the static and dynamic components of movement. Many systems are involved with balance, including the proprioceptive, visual, and vestibular systems. Proprioceptive and balance activities include balancing with the eyes open or closed, using a progressively smaller base of support or using an unstable surface. Equipment includes foam surfaces or wobble boards.

Proprioceptive neuromuscular facilitation (PNF) is an example of an exercise technique used to enhance joint stability. PNF uses specific patterns of movement of entire limbs or body segments through a range of motion and may incorporate manual resistance.

Neuromuscular Coordination and Retraining

Neuromuscular training is used at all levels of rehabilitation. The process involves developing correct timing of muscle activation to produce correct execution of sports activities.

Sports-Specific Activities

Sports-specific activities are introduced during the latter stages of the rehabilitation process. Activities include drills that mimic the movements or activities involved in the sport. Gradual return to competition is recommended to allow time to recondition the athlete to the activity and prevent recurrence of the injury.

Thigh Contusion

An injury to the front part of the thigh, usually from a direct blow to that area, is common in contact sports and should be recognized early. If the muscle trauma is severe enough, it can develop into a compartment syndrome, and if untreated, it can lead to muscle necrosis, fibrosis, and calcification (myositis ossificans). Treatment involves the use of the RICE principles (*r*est, *i*ce, *c*ompression, and *e*levation) and physical therapy. Recovery depends on the severity of the contusion but can take from days to weeks.

Anatomy

The *quadriceps* are a group of muscles on the front part of the thigh. They include four different muscles: (1) rectus femoris, (2) vastus lateralis, (3) vastus medialis, and (4) vastus interomedialis. Their main function is the extension of the knee (straightening of the leg).

History

A quadriceps contusion develops after a direct blow to the thigh. This can be seen in many contact sports (football, rugby, soccer, mixed martial arts). A *contusion* (bruising) is formed by the rupture or breaking of the blood vessels within the muscle

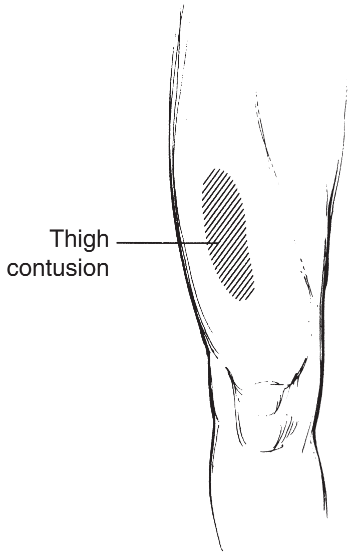

Figure 1 Thigh Contusion

Notes: A thigh contusion is caused by trauma and involves bleeding into the muscle fibers. Unlike strains, which affect the superficial muscles, such contusions occur deep inside the muscle, close to the bone.

(Figure 1). If the bleeding is severe enough, it can cause elevated pressure, which can compress the nerves and other blood vessels within that muscle compartment. This compression of nerves and blood vessels causes tissue death and is otherwise known as *compartment syndrome*. Compartment syndrome is rare in the thigh, but it does occur sometimes, so if this condition is suspected, the patient needs to be examined by a surgeon immediately.

Calcification of the muscle (*myositis ossificans*) can also occur if the athlete tries to rehabilitate a severe contusion too quickly. In this case, the bruised muscle grows bone instead of new muscle cells. Early recognition is the key to preventing this condition.

Symptoms

There will be tenderness at the site of the injury, as well as pain with knee flexion. There may or may not be swelling such that there is an increased circumference of the affected thigh. Sensation should be normal in the lower leg. If this not the case, then compartment syndrome should be considered. Contusions are categorized in three levels: Grade 1, Grade 2, and Grade 3 (most severe). Severity depends mainly on the degree of limited knee flexion (straightening) and on gait abnormalities (limping). Grading of the contusion is important to apply the appropriate treatment.

Imaging

Imaging studies are usually not needed initially for the diagnosis of quadriceps contusions. A diagnosis can usually be made by history and physical exam alone. X-rays are beneficial to look for any fractures of the femur (thighbone) or patella (kneecap), or bone formation in the muscle (myositis ossificans). Ultrasound is a good, inexpensive tool to look for complete muscle tears, but it is not as good for partial tear diagnoses. Magnetic resonance imaging (MRI) is considered the best imaging tool for soft tissue pathology.

Treatment

As soon as a quadriceps contusion is recognized, the athlete should be put into 120° of flexion (knee bent) for at least the first 10 minutes but should not sustain that position for more than 24 hours. This position helps in many ways: It limits the amount of muscle spasm and bleeding into the muscle, decreases the risk of developing bone formation in the muscle, and decreases the amount of pain experienced at that time. Crutches may be necessary early on if walking generates pain. The general RICE principles are applied: *r*est, *i*ce 15 to 20 minutes every 2 to 3 hours, *c*ompression of the thigh with an elastic wrap as needed for swelling, and *e*levation of the leg to decrease swelling. Applying heat should be avoided because this can cause an increase in swelling. Once the pain has been resolved, the athlete should work on stretching, strengthening, and increasing range of motion of the quadriceps and hamstrings (a group of muscles on the back portion of the thigh). Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen are often recommended initially for the first few days after onset of injury along with the RICE therapy. They help not only with pain control but also with swelling.

If compartment syndrome does occur, the athlete must be evaluated by a surgeon immediately. A fasciotomy (opening of the compartment) is necessary for treatment. If this is left untreated, the muscle tissue breaks down, which can lead to muscle contractures.

Myositis ossificans can occur in up to 9% of quadriceps contusions. This condition does not develop acutely and usually occurs approximately 3 months after the injury. Initial treatment includes conservative measures such as oral anti-inflammatories, massage, and stretching. If severe pain persists months after this onset, then surgery is recommended.

Prognosis

The athlete's return to play varies depending on the severity of the quadriceps injury. The athlete may resume play once 120° of flexion is achieved painlessly and there is no evidence of quadriceps weakness or atrophy. Protective padding is recommended for the injured area for the rest of the season.

Thigh Injuries

Injuries to the anterior and posterior thigh are fairly common in sports, particularly in running and jumping sports. Particularly common are *muscle strains* and *contusions*. Quadriceps strains are common in running, jumping, and kicking sports, such as track-and-field events, basketball, and soccer. Hamstring strains occur frequently in sports involving high-speed running and kicking, such as sprints, hurdles, long jump, football, and field hockey. In Australian football, hamstring injuries account for 15% of all injuries and are the most common and prevalent injury. Likewise, in British soccer, hamstring injuries constitute 12% of all injuries. These injuries also have the highest recurrence rate (34% in Australian football, 12% in British soccer). Quadriceps contusions, commonly known as a "charley horse," are extremely common in contact sports such as football and basketball and in ball/puck sports such as hockey, lacrosse, and cricket.

Anatomy

The femur is the only bone in the thigh. The quadriceps muscle group in the anterior thigh contains the rectus femoris, vastus lateralis, vastus medialis obliquus, and sartorius. They are the strongest muscles in the anterior thigh and function to extend the knee. The hamstring muscle group in the posterior thigh consists of the biceps femoris, the semimembranosus, and the semitendinosus. The biceps femoris has two heads. The short head acts only on the knee and is innervated by the common peroneal nerve, whereas the long head is innervated by the tibial portion of the sciatic nerve. The hamstrings cross two joints and are responsible for hip extension and knee flexion. The semitendinosus, the semimembranosus, and the long head of the biceps originate on the ischial tuberosity.

The adductor magnus functions in hip extension and adduction and is innervated by the tibial portion of the sciatic nerve, like most of the hamstring muscles. The posterior part of the adductor magnus is sometimes considered functionally to be part of the hamstring group because of its anatomical position.

Evaluation of Injuries

Details of Injury

The exact location of pain and the mechanism of injury in the setting of a thigh injury can help in diagnosis. In the case of contusions (bruises) or muscle strain, the site of pain is usually well localized. Contusions of the anterior thigh are most common in the anterolateral aspect of the thigh or in the vastus medialis obliquus, although they can occur anywhere.

The mechanism of injury can usually differentiate between muscle strains and contusions. Muscle strains usually occur when the athlete is striving for greater speed while running or extra distance while kicking. The athlete usually remembers a specific event that causes pain and some immediate functional limitations. A contusion, however, is usually the result of a direct blow. The athlete's age and skeletal maturity may affect the type of injury seen, as injury patterns in adolescents differ from those in adults, such as avulsion fractures, seen in younger patients with open apophyses.

With severe injuries to the thigh, the athlete may not be able to continue the sporting activity. The athlete may be unable to go back to sports and may be unable to walk or run without pain. There may be swelling and bruising at the site of injury. Injuries to the thigh should initially be treated with the RICE (*r*est, *i*ce, *c*ompression, and *e*levation) regimen to decrease swelling. Factors such as hot showers/baths, heat rubs, excessive activity, or alcohol ingestion may worsen thigh injuries and prevent healing.

Certain sports make thigh injuries more likely, such as soccer, football, and hockey. Recent changes in the training regimen may contribute to injuries. Previous thigh injuries may predispose an athlete to recurrent injuries. The athlete's age is also important, as during periods of growth, children and adolescents may have muscle inflexibilities and muscle imbalances that may predispose them to thigh injuries.

Anterior or thigh pain that has a gradual onset and is poorly localized may indicate a stress fracture or possible tumor. If anterior or posterior thigh pain is variable, is poorly localized, and lacks specific aggravating factors, the pain may be referred. Bilateral thigh pain is usually referred from the lumbar spine. A high index of suspicion and an understanding of what structures can refer pain to the posterior thigh are essential to make the correct diagnosis. Any "red flag" symptoms, such as night pain, night sweats, weight loss, or neurological symptoms such as numbness or tingling, may indicate infection or cancer as a cause of thigh pain.

Physical Findings

In acute injuries of the thigh, the diagnosis is usually straightforward, and the injury is usually limited to local structures. When pain is more insidious, the cause of the injury may be less straightforward and may be referred from the hip, sacroiliac joint, or lower back.

Thigh injuries may result in bruising, swelling, atrophy, or other deformity to the anterior or posterior thigh. Comparing the injured leg with the uninjured leg can highlight any abnormalities. Athletes with thigh injuries may walk with a limp and be unable to move the leg normally. The range of motion of the hip and knee may be affected. With anterior thigh injuries, stretching of the quadriceps muscle (the athlete lies on his or her stomach and tries to bring the heel of the foot to the buttocks) may be decreased or may cause pain. With posterior thigh injuries, stretching the hamstring muscles (the athlete lies on his or her back and raises the affected leg to the point of pain and then to the end of range) may cause pain.

Thigh muscle strength may be decreased secondary to injury. The athlete may have muscle weakness or pain when trying to resist certain movements. For instance, with quadriceps injuries, the athlete may be unable to extend the knee against resistance when sitting with the hip and knee flexed to 90°. Similarly, the athlete may be unable to flex the hip against resistance. With hamstring injuries, an athlete may be unable to flex the knee against resistance while lying on the stomach. The athlete may be unable to squat, jump, hop, run, or kick secondary to pain or weakness.

Thigh injuries may be accompanied by tenderness, swelling, or defects in the muscle belly. Defects in the muscle belly may be more pronounced when the affected muscle is contracted. The origin of the hamstring at the ischial tuberosity may also be tender with hamstring injuries. In addition, the muscles of the buttocks (gluteal muscles) may be tender to palpation.

A stress fracture of the femur may cause pain in the thigh when a fulcrum test is performed. With the athlete sitting on the edge of the bed and the legs hanging over the edge, the examiner applies pressure over the distal femur. Reproduction of the athlete's pain in the thigh with this maneuver is suggestive of a stress fracture.

Sometimes thigh pain is related to a neurological problem. Certain tests, called *neural tension tests*, can help determine if the thigh pain is caused by damage to the nerves. With anterior thigh pain, a modified Thomas test can be performed with the patient supine and the legs off the end of the bed. The patient flexes the cervical and upper thoracic spine as the examiner passively flexes the patient's knee while extending the other leg. Reproduction of the patient's symptoms indicates nerve involvement. For posterior thigh pain, a slump test can be performed with the patient sitting on the edge of the end of the bed. The examiner flexes the patient's cervical and upper thoracic spine and then extends the patient's leg. Reproduction of symptoms suggests a neural component.

Investigations

In athletes with anterior thigh pain, investigations are usually not necessary. X-rays may indicate myositis ossificans (calcification of the muscle) in a quadriceps contusion that is not getting better. Ultrasound will confirm the presence of a hematoma and may show early calcification. Stress fractures may also be shown on X-rays. If X-rays are negative, bone scan should be performed.

If thigh pain is associated with an abnormal hip examination, hip X-rays should be obtained (Table 1). In adults, there may be evidence of arthritis. In younger patients, Legg-Calvé-Perthes disease or slipped capital femoral epiphysis may be shown.

Prevention of Injury

Many acute thigh injuries can be prevented with appropriate stretching, adequate strengthening, and proper warm-up. The proper safety equipment for the particular sport should be worn and properly maintained. Additionally, playing with athletes at the same skill level can help prevent acute injuries. Prevention of chronic thigh injuries can be achieved by instituting appropriate training programs and avoiding training errors. Common training errors include inappropriate progression of the rate, duration, and intensity of training.

Table 1 Common Anterior and Posterior Thigh Injuries

	Common	*Uncommon*	*Must Not Be Missed*
Anterior	Quadriceps contusion	Femoral stress fracture	Legg-Calvé-Perthes disease
	Quadriceps strain	Sartorius/gracilis muscle strain	Slipped capital femoral epiphysis (SCFE)
	Myositis ossificans	Rectus femoris apophysis avulsion	Tumors
		Referred pain (lumbar spine, sacroiliac joint, hip joint)	
Posterior	Hamstring muscle strain	Bursitis	Tumors
	Hamstring muscle contusion	Tendinopathy	
	Referred pain (lumbar spine)	Apophysitis/avulsion fracture of ischial tuberosity	
		Adductor magnus strains	
		Myositis ossificans	
		Nerve entrapments	
		Referred pain (sacroiliac joint)	

Targeting anatomical risk factors such as lower extremity alignment, muscle imbalances, poor conditioning, and inflexibilities can also help decrease thigh injuries. Other risk factors that should be addressed include inappropriate footwear, playing surfaces, and nutrition.

Return to Sports

For most minor injuries of the thigh, such as strains and contusions, a period of rest followed by appropriate therapy emphasizing stretching and strengthening will allow athletes to regain flexibility and strength. Before returning to sports following a thigh injury, strength and flexibility should be back to 80% to 90% of normal to prevent recurrent injury and allow effective movement. Pain should also have resolved. Regular physiotherapy can help monitor progress and determine the athlete's readiness to return to play. Following more serious thigh injuries, such as acute fractures and stress fractures, return to play should be delayed until pain has resolved, there is radiological evidence of healing, and risk factors have been addressed and modified.

Thighbone Fracture

Thighbone fracture refers to fractures of the femur, the sole bone in the thigh. They are caused by high-energy trauma or overuse. This entry reviews the basic types of fractures of the femur, fracture healing, fracture treatment methods, and general outcomes.

Fracture Types

Thighbone (femur) fractures are described by where they are located, how much out of place the bone is, and whether the bone has broken through the skin. In lay terms, it is sometimes assumed that a break is more serious than a fracture; to a physician, both refer to the same thing. A fracture that is incomplete, or not fully through the bone, may be called a *stress fracture.* This can occur in a runner from overuse, for example. A complete fracture, which is fully through the bone, may be described as either *nondisplaced* (hairline crack) or *displaced* (two parts not aligned), ranging from minimally displaced to widely displaced. *Comminuted fracture* refers to a bone being broken in many pieces rather than cleanly. The older term for a broken bone that went through the skin was *compound fracture;* now this is described as an *open fracture.* A fracture that does not pierce the skin is *closed.* Thus, when we say that a person has an open, widely displaced comminuted femur fracture, we mean that the person has a thighbone fracture that is badly out of place and the bone has broken in many pieces and gone through the skin.

In general, most thighbone (femur) fractures are caused by high-energy trauma. Thus, associated injuries in other parts of the body must be looked for too. For example, in a person involved in a high-speed motor vehicle collision, there may be internal bleeding and head injuries along with a thighbone fracture. These need to be managed first.

Fracture Healing

Thighbone fracture healing varies by age of the patient, location and severity of the fracture, and treatment method. In general, children's bones heal much faster than those of adults. In a baby a thighbone may heal in 1 month, while in a 6-year-old the same bone may take 6 weeks and in an adult 6 months to fully heal. When a bone fractures, first a blood clot forms, much like a scab forms on cut skin. Next, the cells in the blood clot recruit bone-forming cells (*osteoblasts*), which begin making new bone. At first, this bone is poorly organized and looks cloudy on an X-ray. This is called *callus*. Usually, the presence of callus allows weight bearing by 6 weeks after the fracture. Over time, this new bone solidifies and reorganizes into strong new bone. This is called *remodeling*. This takes from several months to several years after the injury. In children particularly, bones have wonderful remodeling properties. It is possible for a child to have a bone heal very crookedly at first and then straighten itself out without help over time. Good nutrition, in particular vitamin D (400 international units [IU]/day) and calcium (1,000 milligrams per day), is also very important for fracture healing.

Fracture Treatment Methods

Thighbone fracture treatment varies widely by the age of the patient and the severity of the injury. For a stress fracture (incomplete break in the thighbone), crutches may be all that is needed. For more severe fractures, surgery with rod or plate and screw fixation may be needed. The guidelines for fracture treatment are reviewed below.

Initial Treatment

The initial treatment when someone is injured should be to assess the injury and to stabilize the injured part, straightening it gently if it is bent or twisted. A removable stabilizing device, or splint, is applied. If an open fracture is present, the bone should not be put back through the skin. Instead, a clean dressing should be applied as well as a splint, and urgent transport to a medical center should be arranged. The portion of the leg below the thighbone fracture should be assessed for vascularity and nerve function by checking that the toes can move and are pink and warm. After the initial immobilization, the patient should be assessed by a physician. As thighbone fractures are generally the result of high-energy trauma, transport is generally by ambulance from the accident scene to the emergency room. Generally, X-rays are obtained, and sometimes other studies, such as computed tomography (CT) and magnetic resonance imaging (MRI) scans, are done to determine what kind of fracture is present. Once the fracture has been properly diagnosed, treatment can proceed. If other, more severe injuries are present, these are diagnosed and treated first.

Definitive Treatment

Stress Fractures

These are generally treated nonoperatively with rest, protected weight bearing, and time. For example, a (nondisplaced) stress fracture in the thighbone usually requires the use of crutches and should have no weight on it for 6 weeks. Some stress fractures at the top of the thighbone (hip area/femoral neck) may need screw fixation because of the high risk that they may break all the way through.

Displaced Fractures

Thighbone fractures that are out of place generally need to be straightened (this is called *reduction*) and may need surgery. In babies less than 6 months old, thighbone fractures may be treated in a soft brace called a *Pavlik harness*. In children aged 6 months to 6 years, displaced thighbone fractures can often be treated successfully with reduction and body casting (called a *spica*) for 6 to 12 weeks. In older children and adults, displaced thighbone fractures need surgical fixation for treatment. Fixation may be external fixators (pins that come out through the skin and hold the bone in place by attaching to a bar), plates and screws, or rods put down the hollow middle part (*medulla*) of the thighbone. Most adult thighbone fractures are treated with a strong rod down the middle of the bone. In image (a) on page 1479, a thighbone fracture X-ray is seen. In images (b) and (c), the fracture has been treated with a rod and has healed with a lump of new bone (callus). In severe injuries, the thighbone may be temporarily stabilized with an external fixator; then in a later surgical procedure, a rod or plate and screws may be applied.

Open Fractures

Fractures that come through the skin always need surgery to clean them. This is because they are at high risk of infection. After the surgical cleaning, the bones are fixed using the method most appropriate for the type of fracture.

Rehabilitation

If a thighbone is treated with a rod, immediate weight bearing with crutches is allowed. Early bone healing is present at 6 weeks, but it may take 4 to 6 months for the bone to fully solidify. Contact sports are not allowed until the bone is solidly healed. Rehabilitating the thigh muscles is equally important and often takes at least as long as the bone healing time. Usually, this involves physical therapy. A physical therapist is someone trained to guide patients through exercising the injured part according to their doctor's orders until return of full strength and function. After a high-energy thighbone fracture, it is often 4 to 6 months before patients can return to any sport. Limping may persist for 6 months to a year as well. In adults, the thighbone rods or other fracture fixation devices are usually left in place permanently unless they are bothersome, in which case they can be surgically removed. In children, some fracture fixation devices may need to be removed, while others may be left in place.

Outcomes

Most patients with thighbone fractures will go through a normal healing process, and the bone will return to a high functional level. Thus, most athletes sustaining a thighbone fracture can expect to return to their sport. However, some permanent quadriceps muscle weakness may be present, especially in severe fractures.

Thumb Sprain

A *thumb sprain* is a stretch or tear of a ligament located at one of the thumb joints. This traumatic injury is common, and athletes in sports such as skiing, football, and wrestling are frequently affected. In fact, in skiers, only the knee is injured more often than the thumb. This condition not only leads to time lost from sports until it is healed, but it also creates the potential for future disability if it is not properly identified and treated.

Thumb sprains can occur at any of the three thumb joints. A thumb sprain however, is synonymous with an injury to the inside ligament (ulnar collateral ligament, UCL) at the middle joint (metacarpophalangeal, MCP) of the thumb. Multiple names are used to describe UCL sprains, including "gamekeeper's thumb" and "skier's thumb." The term *gamekeeper's thumb* was coined after Scottish gamekeepers (ca. 1955) were found to be prone to these particular thumb sprains. Their repetitive practice of breaking the necks of small game by holding the animal in the web space between their thumb and pointer finger would injure the UCL. In recent times, this injury has been more commonly referred to as skier's thumb. Relatively frequent trauma and subsequent falls create a strong correlation between skiers and thumb sprains.

Anatomy

The thumb is composed of three bones and three joints. The bones of the thumb are the metacarpal, proximal phalanx, and distal phalanx. The metacarpal bone is the one closest to the wrist, the distal phalanx is at the tip of the thumb, and the proximal phalanx lies between these two bones. Connecting the thumb bones from the wrist to the tip of the thumb are the carpometacarpal (CMC), MCP, and interphalangeal (IP) joints, in that order. At each joint, there are multiple ligaments that provide stability to the thumb when traumatic or pinching forces are placed on it. They are the collateral ligaments, the volar plate, and the joint capsule. The collateral ligaments are located on the inner and outer sides of each thumb joint and provide side-to-side stability. The UCL is the collateral ligament closest to the little finger, and the radial collateral ligament (RCL) lies on the opposite side of the joint from the UCL. The volar plate is a ligament located on the palm side of each thumb joint and prevents hyperextension. Finally, the joint capsule is a saclike envelope that encloses the entire joint.

Type of Injury

The majority of thumb sprains occur at the UCL of the MCP joint. The second most common sprain occurs at the RCL of the MCP joint. The IP joint infrequently experiences ligament injury. Rarely are there isolated injuries to the CMC joint. The ligaments at this joint are well protected from trauma. Certainly, fractures and dislocations are associated with ligament sprains, but they are beyond the scope of this entry.

Clinical Evaluation

History

There are numerous traumatic mechanisms that can cause a thumb sprain. All, however, involve a side-to-side force that creates extreme thumb movement either toward or away from the hand. The collateral ligaments are naturally affected as they provide side-to-side stability at the thumb joints. Typical examples of these movements are a fall while holding a ski pole or a fall onto an outstretched and extended thumb.

After a thumb sprain, athletes will experience immediate pain and swelling at the joint. Activities such as pinching and gripping of the thumb will produce pain. If the injury is old and has not been treated, pinching weakness and degenerative arthritis are possible long-term complications. This weakness and instability can be debilitating in those sports that require strong pinching and grasping abilities.

Physical Examination

Swelling and bruising are common findings on physical examination. A finding of localized tenderness over a specific side of the joint is important in isolating the affected collateral ligament. Stress testing is used to assess ligament stability. This involves applying a bending stress to the ligament at 0° and 30° of flexion. When a ligament is completely torn, the joint will significantly "open up" as there is no ligamentous integrity to resist the stress testing. If there is only a partial tear or stretch, the ligament will withstand the applied stress and prevent the joint from moving. It is vital that stress testing is performed on both symptomatic and asymptomatic thumbs to compare results. Patients can have wide variations in their amount of normal joint laxity (looseness).

Diagnostic Tests

Obtaining plain radiographs is a routine part of evaluating a thumb sprain. An avulsion fracture has been found to be associated in 20% of ligament sprains. Some physicians advocate stress X-rays in addition to normal radiographs when the history and physical exam do not reveal a clear diagnosis. Stress X-rays look at the affected joint while a stress is applied similar to the physical exam maneuver above. These views provide additional information as to whether the thumb ligament is partially or completely torn. The benefit and accuracy of magnetic resonance imaging (MRI) in further defining the ligaments of the thumb have not been conclusively determined.

When significant ligamentous laxity is found on physical examination, the joint is said to be unstable, which likely indicates a complete rupture of the ligament. This raises the suspicion that a unique injury to the UCL, called a Stener lesion, is present. A Stener lesion occurs when the UCL tears and the surrounding tissue of an overlying thumb tendon gets lodged between the torn UCL fibers. Subsequently, the UCL is unable to come together and heal due to the interposed soft tissue. In addition to unstable stress testing, a Stener lesion is infrequently identified on physical examination as a mass on the hand side of the MCP joint. Unfortunately, the best way to visualize a Stener lesion is during surgery.

Treatment

The management of thumb sprains is divided according to the stability of the affected ligament. Stable thumb sprains are typically treated nonoperatively, while unstable thumb sprains are treated with surgery. Stener lesions are included in the unstable category and require operative intervention at the UCL.

Nonsurgical Treatment

Initial care of a thumb sprain includes rest, ice, elevation, and over-the-counter pain medication. If available, protection with a splint is helpful to control pain symptoms and reduce motion at the affected thumb joint. When the sprain has been determined to be stable according to the medical evaluation, the athlete is immobilized in a splint or cast that covers the thumb. At periodic follow-ups, the athlete's tenderness to palpation and joint stability are assessed. The thumb is typically immobilized for 4 to 6 weeks until the patient is nontender and the joint is stable. Rehabilitation for the wrist and thumb is often started at approximately 4 weeks with range-of-motion (ROM) and strengthening exercises. This is continued until full ROM and strength are achieved.

Surgery

Surgery of a thumb sprain typically consists of a primary repair. This refers to the reattachment of the two ends of the torn ligaments. A primary repair is most successful soon after the injury. In general, completely torn thumb ligaments can usually be repaired by 6 to 8 weeks after the date of injury. After surgery, the athlete will be immobilized for a period of time and then progressed to a rehabilitation program similar to the one described above.

When operative intervention is delayed or the athlete is not evaluated for a thumb sprain, there is a higher likelihood that the ligament is going to scar and shrink in size. As a result, the ligament ends become very difficult to sew back together beyond the 6-week time period. When this happens, more complicated surgeries are required for successful treatment. They include a reconstruction, where a portion of tendon from another body part is substituted to make a brand new ligament. The other option for delayed treatment is a fusion of the joint. This, however, may be optimally done after the athlete's athletic career is completed.

Return to Sports

Those athletes who are immobilized with a splint or a cast may be able to return to their sport as soon as their symptoms are controlled. In certain sports, athletes are allowed to compete while casted. For example, football players are allowed to participate with a splint or a cast if it is properly padded.

For the athlete who is unable to compete with a splint or a cast, a rehabilitation program is continued after immobilization. When full ROM and strength are achieved, sport-specific drills and a return-to-play progression are begun. For most sports, taping of the MCP joint to the index finger (buddy taping) should continue for up to 12 weeks after the injury.

Tibia and Fibula Fractures

The tibia and fibula, the two long bones of the lower leg, can be fractured during sporting activities. Although isolated fracture of either the tibia or the fibula can occur, most often both bones are fractured in the same injury. Early diagnosis and immediate treatment with splint immobilization are necessary for patient comfort and treatment. Emergent follow-up with an orthopedic surgeon is necessary to evaluate the patient and definitively treat the fracture(s).

Anatomy

The tibia, commonly called the shinbone, is the major weight-bearing bone of the lower leg. The part of the tibia that articulates with the femur at the knee is called the *tibial plateau,* the middle is the *tibial shaft,* and the lower portion, which articulates with the ankle joint, is called the *tibial plafond.* The inner aspect of the ankle bone that can be felt is part of the tibia and is called the *medial malleolus.*

The fibula is the smaller bone on the outer part of the leg. The part near the knee is called the fibular head, the middle is the shaft, and the part that articulates with the ankle is called the *lateral malleolus.*

The tibia and fibula are connected by the interosseous membrane, a broad plane of fibrous connective tissue, and multiple ligaments at the knee and ankle.

There is only a small amount of soft tissue between the tibia and the skin, which is the cause of many open tibia fractures. An *open fracture* occurs when the energy from the injury forces the bone through the skin. The fibula has more soft tissue surrounding it, so a fracture is less likely to be open. The exception to this is at the ankle, where the lateral malleolus is just underneath the skin, with a thin soft tissue layer.

Causes

Sports-related fracture of the tibia and fibula is a relatively low-energy injury. The fracture can occur from a direct blow on either side of the lower leg or by landing hard on the foot of the fractured leg. Additionally, a severe twisting injury can fracture the tibia and fibula.

Symptoms

Pain, swelling, inability to walk, and deformity are common signs and symptoms of tibia and fibula fractures. With an isolated fibula fracture, the athlete is often able to walk or run; therefore, the diagnostic process is much more difficult.

Diagnosis

The diagnosis of a tibia or fibula fracture can often be made based solely on history and physical exam. There is often gross deformity of the lower leg associated with bruising, swelling, tenderness, and occasionally a skin opening or laceration with protruding bone—clearly indicating an open fracture. Palpation along the tibia can reveal crepitance or gross movement of the bony fragments. During the physical exam, it is important to examine the knee for an effusion, and a detailed neurovascular exam of the foot is imperative. The neurovascular exam should include motor (wiggling of the toes) and sensory (testing whether the athlete can feel you touching his or her toes and heel) exams, as well as palpation of the dorsalis pedis and posterior tibial pulse and checking capillary refill. Along with the history and physical examination, radiographs including an anterior-posterior (AP) view and a lateral view can clinch the diagnosis. X-rays of the knee and ankle joint are recommended as well.

There are three types of tibial shaft fractures:

1. *Transverse:* straight perpendicular to the axis of the bone
2. *Spiral:* in a spiral pattern down the bone
3. *Oblique:* at an angle to the axis of the bone

For comminuted (multiple fracture fragments) tibial plateau and tibial plafond fractures (fractures that go into the joint surface of the knee and ankle, respectively), a computed axial tomography (CAT or CT) scan of these areas is often useful to further classify the fracture pattern for preoperative planning.

Treatment

After a thorough history and physical exam, the initial treatment of any tibia or fibula fracture includes reduction (if needed) and immobilization of the lower leg with a splint. Emergent reduction by a trained professional is needed if the athlete has a gross deformity or does not have a pulse in his or her foot or if the foot is discolored. If the athlete sustains an open fracture, a sterile dressing should be applied to the wound, and the leg should then be immobilized. In an appropriate setting (emergency department), the athlete's open wound should be irrigated with sterile saline solution and dressed with a sterile dressing. The athlete should also receive a tetanus booster, if not up-to-date, and intravenous antibiotics immediately in the emergency department and for several doses. The specific antibiotic(s) to be given should be decided on by the orthopedic surgeon and is determined by the severity of the injury and the contamination within the wound.

After reduction and/or wounds are addressed, the athlete should be placed in a long leg splint (from midthigh to the ends of the toes). There are a variety of splinting materials (prefabricated metal splints, plaster, orthoglass, inflatable plastic splints, etc.) that are available, and any form of immobilization will work in the emergent setting. It is important that the splinting material not wrap all the way around the leg and the leg not be wrapped tightly. Also, access to the foot and calf should be available to frequently check for pulses and check the leg for developing compartment syndrome. Compartment syndrome occurs when swelling increases the pressure in the leg compartments to the point where it exceeds the pressure needed to get blood to the muscles and nerves within the compartment. This leads to nerve and muscle death if not treated emergently with a surgical release of the involved compartments, called a fasciotomy. Compartment syndrome is an orthopedic emergency and is common in the setting of tibia and fibula fractures. Please see the entry Compartment Syndrome, Anterior for signs, symptoms, and treatment.

After immobilization, the athlete should be taken to the emergency department for an orthopedic evaluation and definitive management. Ice application and elevation are extremely important treatment modalities for all fractures and should be implemented immediately and used consistently for the first few days after injury.

Nonoperative Treatment by Fracture Type

Closed fractures of the tibia and fibula may be treated with conservative care and nonsurgical treatment. The question of surgical versus nonsurgical care for a specific fracture is decided by the orthopedic surgeon. The following are some conservative treatment modalities for the different types of tibia and fibula fractures.

Tibial Plateau (Knee Joint Surface of the Tibia). Nondisplaced or minimally displaced fractures (bony pieces touching or very close together in anatomical alignment) can be treated by keeping the athlete non–weight bearing in a knee immobilizer or hinged knee brace. Early ROM exercises and quadriceps muscle strengthening are encouraged. Partial weight bearing (~50% of the athlete's weight) is allowed at 8 to 12 weeks from the injury, with progression to full weight bearing as tolerated.

Tibial Shaft. Nondisplaced or minimally displaced fractures can be treated initially in a long leg splint. The athlete's knee should be flexed from 30° to 60° degrees so that he or she can ambulate with crutches. The athlete will be non–weight bearing for 4 to 6 weeks.

Two weeks after injury, the patient may be transitioned over to a long leg cast if the swelling has subsided. Four to six weeks after injury, transition to a short leg cast (below the knee) is permitted. Weight bearing is progressed in the short leg cast for an additional 4 to 6 weeks. The healing time for tibial shaft fractures is highly variable, with an average time of 16 ± 4 weeks. Fracture braces can be also used to give support while the fracture heals.

Fibular Shaft. Treatment is weight bearing as tolerated. The tibia is the main weight-bearing bone of the lower leg; therefore, a splint, cast, or brace is not necessary for healing. A short period of immobilization (below the knee) may be used to help minimize the pain.

Tibial Plafond (Ankle Joint Surface of the Tibia). Most of these fractures require surgery, even if the fracture is nondisplaced. However, if nonsurgical treatment is elected, the athlete is made non–weight bearing and placed in a long leg splint/cast for 6 weeks. Six weeks after injury, a fracture brace with physical therapy for ROM and strengthening is used, and weight bearing is progressed as tolerated once there is radiographic evidence of healing.

Surgical Treatment by Fracture Type

Open fractures of any type require irrigation and debridement under sterile conditions in the operating room. Irrigation involves washing the fracture and the wound with sterile saline, with or without antibiotics in the solution. *Debridement* is the removal of all debris, such as grass, mud, pebbles, and any dead tissue, from the wound. This should be continued until the wound is cleaned of all possible sources of infection.

Tibial Plateau. Displaced fractures need to be fixed with open reduction and internal fixation, meaning surgical incision, reduction of the fracture, and insertion of plates and screws to hold the pieces of bone together in anatomic alignment. The main goal is to reconstruct the articular surface of the knee. The surgeon may use bone graft or cement to fill any voids and add strength if he or she feels that it is indicated. If the fracture pattern is highly comminuted (lots of small pieces), the surgeon may elect to use an external fixator, which involves placing pins into the bones and bars outside the skin to hold the fracture in anatomic alignment.

Tibial Shaft. Depending on the fracture pattern (transverse or oblique), the amount of comminution, and the fracture location (*proximal,* closer to the knee; middle; or distal, closer to the ankle), the surgeon may choose to use an intramedullary nail, plates and screws, or an external fixator to hold the fracture in anatomic position. An intramedullary nail is a titanium nail introduced through an incision at the knee and placed through the center of the proximal tibia, past the fracture site, and into the distal tibia. Screws are then placed in the proximal and distal tibia so that the nail cannot rotate. External fixation is described above. The fibula fracture is usually not operatively fixed with instrumentation. By fixing the tibia, the fibula is kept in an appropriate position to heal. Since it is not the main weight-bearing bone and it is surrounded by soft tissue, it usually heals without the need for operative fixation.

Fibular Shaft. Isolated fibular shaft fractures rarely need operative intervention. If the fibular shaft fracture is coexisting with an ankle ligament injury (e.g., syndesmosis injury), the surgeon may opt to perform open reduction internal fixation.

Tibial Plafond. The goals of surgery are to maintain fibular length and restore the tibial ankle joint surface. Often, final surgery is delayed for several

(7–14) days to give time for the swelling around the ankle to decrease. The athlete may be placed in a long leg splint and sent home with strict instructions to ice and elevate the ankle at all times until the swelling decreases. Alternatively, the athlete may have staged surgeries with external fixation placement immediately after the injury, with or without open reduction and internal fixation (plates and screws) of the fibula fracture. The athlete then rests with the ankle iced and elevated until swelling is decreased. At that time, the athlete will return to the operating room to have open reduction and internal fixation of the tibial plafond and removal of the external fixator. Bone graft, bone graft substitutes, or cement may be used as necessary. A short leg splint is applied in the operating room after surgery. An external fixator may be used as definitive treatment depending on the fracture type and soft tissue status.

Postoperative Care by Fracture Type

Tibial Plateau. As in nonsurgical treatment, the athlete will be non–weight bearing in a knee immobilizer or hinged knee brace. Early range-of-motion exercises and quadriceps muscle strengthening are encouraged. Partial weight bearing (~50% of the athlete's weight) is allowed at 8 to 12 weeks from the injury, with progression to full weight bearing as tolerated.

Tibial Shaft. No splint/cast is needed; an intramedullary nail or external fixation is used; then a splint/cast may be used after the use of plates and screws. The surgeon will determine the athlete's weight-bearing status based on the fracture pattern and the type of fixation used. Again, average healing time is 16 ± 4 weeks.

Fibular Shaft. This fracture, too, rarely requires an operation, but a splint/cast may be used after the use of plates and screws. The surgeon will determine the athlete's weight-bearing status based on the fracture pattern and fixation type.

Tibial Plafond. The athlete will be non–weight bearing for 12 to 16 weeks. Initially, the athlete will be in a short leg splint and will transition to a short leg cast in 2 weeks. In 4 to 6 weeks, the athlete may be transitioned to a fracture brace/boot, and physical therapy range-of-motion exercises will be started to decrease the stiffness in the ankle. After 12 to 16 weeks, progression will be made to weight bearing as tolerated once there is radiographic evidence of healing.

It is important to closely monitor the athlete's neurovascular exam status after all types of surgery to avoid the complications of compartment syndrome.

Tibia and Fibula Stress Fractures

Stress fractures in the tibia and fibula are common in athletes. It has been reported that nearly 50% of stress fractures in the lower extremity occur in the tibia and up to 20% in the fibula. Sports such as cross-country and track account for a large number of these stress fractures, but any sports requiring repetitive running and jumping can result in a stress fracture of the lower extremity.

Most tibia stress fractures occur in the posterior medial tibia. Anterior tibia stress fractures are considered to be problematic, often needing a prolonged period of nonoperative treatment or surgical management to allow them to heal. Fibula stress fractures tend to occur about 5 to 6 centimeters above the lateral malleolus in athletes, but they can occur at any point along the fibula.

Pathophysiology

Many risk factors have been implicated in the development of stress fractures of the tibia and fibula. Some proposed risk factors include running surfaces, footwear, mileage, weight loss, osteopenia/osteoporosis, running mechanics, foot type (pes cavus or pes planus foot types), and muscle fatigue. None have been shown to be a definitive risk factor, but they are believed to often occur in combination. Excessive contraction of the ankle plantarflexors is thought to play a role in fibula stress fractures.

Presenting Signs and Symptoms

Athletes will typically present with progressively worsening pain in the shins with running. Typically with medial tibial stress syndrome, or "shin splints," athletes may have reduction of their pain with running. With stress fractures, the pain tends to get progressively worse with longer periods of impact, as in running or jumping. Often, there is a focal area of pain rather than a large, diffuse area, as is commonly observed in shin splints. The athlete may limp with activity and often will have pain most of the time with just walking. There may have been attempts at taking rest for several days to weeks, only to have the pain recur quickly with resumption of activity. A recent increase in activity or mileage may have occurred.

Physical Exam Findings

Often on exam, the athlete will have a focal area of tenderness to palpation where the stress fracture is located. Pitting edema may be present in the area of the stress fracture. A limp may be present. It has been reported that placing a vibrating tuning fork over the tender area will cause a significant increase in pain, aiding in the diagnosis. Attempting a single leg hop on the affected side often is positive for pain, and many athletes will not want to attempt this as they may have already experienced significant pain with a similar maneuver. Evaluation for foot pronation or supination should be done, but its usefulness may be limited as the athlete may be walking differently to avoid pain with walking.

Radiologic Findings

Initial evaluation should be done with plain-film X-rays. In the first few weeks of symptoms, it is not unusual to have normal X-rays. Many tibia stress fractures will not show up in radiographic images even after healing has begun. Fibula stress fractures will tend to give radiographic evidence of healing, evident by either a fracture line or callus formation, by 3 to 4 weeks after symptoms have started.

Early in the diagnostic process, it is often necessary to consider further imaging if the clinical suspicion is high for a stress fracture. Both bone scans and magnetic resonance imaging (MRI) scans are used, with MRI scans being slightly more sensitive and specific. MRI scans also have the advantage of being able to evaluate other adjacent structures besides the bone that may be causing pain, and there is no radiation involved. The MRI scan may also help distinguish between a stress reaction, where the bone has not progressed to failure of the cortical bone, and a true stress fracture.

Treatment

Essentially, all fibula stress fractures and the majority of tibia stress fractures are treated nonsurgically. Stress fractures of both the fibula and the tibia respond to rest from impact activity. Rest periods typically range from 4 to 6 weeks but may take up to 8 weeks. Athletes who are limping or having a difficult time with pain with general ambulation may need crutches, a pneumatic brace, or a walking boot for a few weeks to aid in the healing process and for pain relief. Avoidance of frequent use of anti-inflammatory medications is recommended due to the possibility of delayed healing that has been reported with the use of these medications for fractures.

Nonimpact cross-training, such as the use of an elliptical trainer, cycling, or swimming, should be recommended to maintain fitness. Once healing has occurred, gradual resumption of activity is recommended. Evaluation of footwear, running mechanics, and the potential need for over-the-counter or custom foot orthotics should be done to prevent recurrence.

Stress fractures of the anterior tibia frequently are treated surgically with an intramedullary nail. Nonoperative treatment may be undertaken, but it often takes 9 to 12 months for healing to occur.

Tibial Tubercle Avulsion Fracture

Avulsion of the tibial tubercle occurs when the traction on the patellar tendon exceeds the strength of the tibial tubercle. The majority of tibial tubercle avulsions occur in adolescents during jumping sports, particularly due to an eccentric load to the patellar tendon during landing. Tibial tuberosity fractures have been reported almost exclusively in males.

Anatomy

The patellofemoral joint is the articulation of the femur (thighbone) and the patella (kneecap). The patella is a sesamoid (floating) bone within a large thick tendon. Above the patella, this tendon is termed the *quadriceps tendon*, and the continuation below the patella is termed the *patellar tendon*. As the quadriceps muscle contracts, it pulls on the quadriceps and patellar tendon, causing the knee to straighten.

The patellar tendon inserts onto the tibia (shinbone) on the tibial tubercle. In the growing adolescent, the physis (growth plate) of the tibia is located just under the knee joint. Above the physis, there are two centers of ossification, the larger tibial epiphysis and the smaller tibial tubercle apophysis, although in older adolescents, they may coalesce to form a continuous epiphysis.

Causes

This is usually an acute injury caused by either violent contraction of the quadriceps muscle against a fixed tibia (as in jumping) or flexion of the knee against a contracted quadriceps.

Symptoms

There will be swelling and tenderness over the front of the tibia, just below the kneecap. Fluid may be present in the knee, and a triangular fragment of bone may be felt. The injured knee may be held in mild flexion, and there will be difficultly extending it.

Diagnosis

A complete physical exam is done to look for swelling and tenderness. The degree of patella alta (high-riding kneecap) will be proportional to the severity of the injury. The patient will be unable to fully extend the knee.

X-rays of the knee are mandatory, with the lateral projection being the most important (see X-ray below). The physician must be aware that in children and adolescents (ages 9 to 17), the normal tibial tubercle may not be fully ossified.

Several different classification systems, most commonly the Watson-Jones, are used for tibial tubercle avulsion fractures. In general, the most important point of difference is whether the fracture is nondisplaced or displaced.

Lateral view of a tibial tubercle fracture

Tibial tubercle fracture after open reduction and internal fixation with two screws and washers; (a) lateral view and (b) anteroposterior view

Source: Yi-Meng Yen, M.D.

Treatment

Closed Reduction and Immobilization

In cases where there is minimal displacement of the tubercle, it is important to understand that the tibial tubercle is still being pulled by the force of the quadriceps into a displaced position. A closed reduction can be attempted and the knee casted. Even in a long leg cast, with the knee in full extension, there can still be tension on the tibial tubercle, so these fractures must be watched closely.

Surgery

Most specialists recommend open reduction and internal fixation of all displaced tibial tubercle fractures. This consists of making a vertical midline incision over the fracture site. The fracture is reduced (put back into place), and metal screws or pins are used to hold the fragment. The patellar tendon and other soft tissues may be sutured down as well to ensure that the screws or pins hold the fragment in place (see images a and b, left).

After Surgery

Depending on the quality of the fixation, patients are placed in either a brace that limits motion or a cast in extension. Crutches are used for touchdown weight bearing for a period of 5 to 6 weeks, at which time progressive full weight bearing can begin. Physical therapy is initiated to help the patient regain knee motion and strength. The patient is not allowed to resume impact activities until motion and strength are regained and the fracture has healed. This typically takes between 3 and 6 months.

TITLE IX, EDUCATION AMENDMENTS OF 1972

Women's position within the world of sports has changed drastically over the past 40 years. This is in large part due to Title IX of the Education Amendments of 1972, legislation originally intended to provide women with improved access to higher education. Title IX states, "No person in the United States shall, on the basis of sex, be excluded from participation in, be denied the benefits of, or be subjected to discrimination under any education program or activity receiving Federal financial assistance."

Prior to this law, it was difficult to nearly impossible for a woman to pursue a career in any field other than nursing, education, social work, or library science. Females were also excluded from major sporting events. The first female to compete in an organized marathon was Kathrine Switzer, in 1967. She registered for the Boston Marathon as K. Switzer to hide her gender and avoid being denied participation. Title IX addressed this discrimination by including all federally funded programs within its purview, such as intramural sports, club sports, and varsity athletics. This new awareness of gender equity in sports led to the Amateur Sports Act of 1978. This act prohibits discrimination on the basis of gender, race, and physical disability in open, nonschool amateur sports. These would include Olympic, Pan American, world championship, and other international sporting events.

To further clarify the scope of this legislation, Title IX governs the overall equity of treatment and opportunity in athletics while giving schools the flexibility to choose sports based on the interests of the students, geographic influence, budget restraints, and gender ratio. In other words, it is a not a matter of women being allowed to participate in wrestling or that exactly the same amount of money is spent for a female as for a male basketball player. Instead, the focus is on the necessity for women to have equal opportunities with men on a collective, not on an individual, basis.

The impact of Title IX is far reaching. More females are participating in sports than ever before. In 1972, 1 in 27 high school girls played varsity sports. In 1988, this had improved to 1 in 3, whereas 1 in 2 boys participated in varsity high school sports. Women now view themselves as strong, competitive, and skilled athletes. In most circumstances, girls are encouraged by their parents at an early age to participate in sports. Parents have realized that the physical, psychological, and social well-being of their daughters is improved through sports participation. Adolescents who participate in sports are less than half as likely to get pregnant as those with more sedentary habits. They often have greater confidence, self-esteem, and pride; indulge less in high–health risk behaviors such as smoking, drinking, and illicit drug use; are more likely to achieve academic success; graduate from college at a significantly higher rate; and suffer less from depression than those who do not participate in sports. These benefits may be due, in part, to the added benefits of sports, such as teamwork, goal setting, the pursuit of excellence in performance, and other achievement-oriented behaviors necessary for success in the workplace. Parents also realize that the quality of life for their children will likely depend on two incomes. This necessitates the training of daughters as well as sons, and sports participation is an excellent vehicle. Women's participation in sports is now deeply entrenched in core family values, with families enthusiastically supporting the sports participation of both their daughters and their sons.

The academic impact has also been demonstrated. In 1994, women received 38% of medical degrees, compared with 9% in 1972; earned 43% of law degrees, compared with 7% in 1972; and 44% of all doctoral degrees received by U.S. citizens, up from 25% in 1977. These statistics support the previously noted benefits of sports, including higher college graduation rates and greater academic success.

Not only are women participating in larger numbers in a greater number of sports, but advertisers have found themselves a whole new world of focus—the female consumer. Women are buying sporting goods not only for themselves but also for their spouses and children. In fact, women make 80% of the household retail buying decisions. In addition, they buy disproportionately to their participation. For example, female golfers constitute only 20% of all golfers but buy 50% of all golf products with the exception of clubs. The economic power of the active female has led advertisers to focus more attention on the female athlete and sporting goods companies to produce high-quality equipment designed specifically with the female athlete in mind.

With few exceptions, female athletes are making good role models for young girls. The image of the female athlete is positive: nonviolent, appreciative, and hardworking. This is in stark contrast to the image of the professional male athlete, who is often viewed as selfish and arrogant. Although the influx of money and the popularity of women's sports may lead to negative behavior among some women athletes, this has not yet been the case. The general public embraces the spirit and effort with which females approach sports.

As of 2008, female participation in sports is the highest in history, at 9,101 intercollegiate teams and 8.65 women's teams per school. The most popular sport is basketball, followed by volleyball and soccer. In the past decade, 2,755 new women's teams have been created. This growth has been attributed to many factors, including mothers who have benefited from the Title IX legislation encouraging their daughters' sports participation, law suits supportive of Title IX, societal acceptance of females as athletes, improved and increased media coverage, and advocacy groups such as the National Association for Girls and Women in Sports and the National Association of Collegiate Women Athletic Administrators.

Women's sports participation has never been more encouraged and accessible than it is today. Women athletes now enjoy the support of their families, peers, and physicians. Every time a woman takes her place on the playing field, gets in the blocks for a race, or takes the court, she does so with a host of women who came before her paving the way for her to have the opportunity to participate, to be accepted as a viable athlete, and to further perpetuate a culture of athleticism for women. The full impact of a generation of women who are now maturing and who are growing up with opportunities that their mothers and grandmothers never dreamed of having remains to be seen.

Toenail Fungus

In the United States, an estimated 10 million individuals suffer from *onychomycosis,* a fungal infection of the nails. Although the exact incidence is not known, studies suggest that between 2% and 26% of the general population worldwide are affected. Onychomycosis is commonly seen in conjunction with tinea pedis or may occur secondary to trauma to the nail. Although both fingernails and toenails can be infected, onychomycosis occurs approximately four times more frequently in toenails than in fingernails.

A large survey done in Europe in 1997 through 1998 on patients presenting to general practitioners' offices clearly indicated that sports-active individuals have a higher incidence of tinea pedis and onychomycosis than do nonathletes people.

All athletes, regardless of age or type of sport, are at risk of developing onychomycosis. Fungi are known to thrive in moist, warm environments—conditions found inside an athlete's shoe or in the contact of bare feet with infected surfaces such as shower stalls, pool decks, and locker room floors. Trauma to the skin or nails from friction, rubbing, or maceration provides the portal of entry for fungi.

Athletes are also susceptible to toenail problems because of the speed and intensity of play (e.g., in running), the frequent starting and stopping in a game (e.g., in tennis and racquetball), and the type or absence of shoes (e.g., in ballet, gymnastics, or swimming).

Clinical Variants of Onychomycosis

There are four main types or clinical variants of onychomycosis:

1. *Distal subungual onychomycosis:* This infection starts at the hyponychium, the tip of the undersurface of the nail, and migrates proximally through the underlying nail matrix. This is usually caused by *Trichophyton rubrum.* This subtype is the most common (see the first photo).
2. *White superficial onychomycosis:* This variant accounts for 10% of onychomycosis cases. It is most commonly caused by *Trichophyton mentagrophytes* and invades the superficial layers of the nail plate, forming white islands.
3. *Proximal subungual onychomycosis:* This type is the least common in healthy people and usually occurs in immunocompromised patients. It is most commonly caused by *Trichophyton rubrum,* which invades the nail via the proximal nail fold and migrates distally.
4. *Candidal onychomycosis:* This type is seen in patients with chronic mucocutaneous candidiasis. The nail plate thickens and turns a yellow/brown color. This type generally involves all the fingernails.

Patient with distal subungual onychomycosis, the most common type of onychomycosis

Source: Peggy R. Cyr, M.D.

Differential Diagnosis

Not all thick, dystrophic toenails are caused by fungi. Fifty percent of thick nails are infected by fungi. The practitioner should perform diagnostic testing to determine if fungi are present. Psoriasis involving the nail is most commonly confused with onychomycosis, and the two diseases may coexist. Pitting of the nail plate surface is seen in psoriasis but not in onychomycosis. Eczema, lichen planus, or habitual picking of the proximal nail fold may induce dystrophic changes in the nail plate. Leukonychia are white spots or bands that are present in the proximal nail plate and grow out with the nail; they may be confused with onychomycosis.

Treatment

There are many options available today for treatment of onychomycosis. The athlete's medical history, concomitant illnesses, and medications must be reviewed carefully. Presenting the patient with published data on the effectiveness of each treatment, as well as the possible side effects, will lead to a joint decision on how to proceed.

Topical Agents

Ciclopirox nail lacquer 8% (Penlac) is approved by the Food and Drug Administration (FDA) for use in mild to moderate onychomycosis caused by *Trichophyton rubrum* with no lunula involvement. The medication is applied once daily to the nail, 5 millimeters of the surrounding skin, the nail bed, and the undersurface of the nail. A new coating is placed over the old one each day, and the medication is completely removed with rubbing alcohol once a week. Treatment extends up to 48 weeks, with periodic debridement of the infected nails. More aggressive debridement may increase the effectiveness of the medication. Published cure rates in the United States are 29% to 36%. In non-U.S. studies, the cure rates were higher; from 46.7% to 85.7%. This method will require a motivated patient to complete the treatment course. There are little to no side effects other than possible redness or irritation of the skin surrounding the nail.

Nail Avulsion Combined With Topical Treatment

This method should only be used for painful, severely affected nails as the procedure is temporarily disabling and painful. Complete toenail removal with phenol/alcohol nail bed ablation is considered in older athletes who have totally dystrophic toenails that are not growing or growing very slowly. Systemic antifungals are doomed to failure in this scenario since improvement depends on the dystrophic nail growing out and being replaced by a new nail proximally. After the procedure, activity must be limited until the nail bed heals. Then, for 6 to 12 months, a bandage must be worn over the freshly healed skin to prevent blistering. After that time, the skin would have developed enough anchoring fibrils, enabling the athlete to engage in any kind of athletic activity without limitation. Debridement of the part of the affected nail that is not attached to the nail bed is encouraged for all patients.

Oral Agents

Griseofulvin (Gris-peg) and ketoconazole (Nizoral) have been available for many years but are no longer considered first-line treatment due to the need for a prolonged treatment course (10–18 months), the low success rates, and the high rates of relapse. Studies show that 90% of patients who were clinically cured after prolonged griseofulvin therapy relapsed 1 to 2 years later.

The newer triazole and allylamine antifungals have replaced griseofulvin and ketoconazole in the treatment of onychomycosis. These drugs, terbinafine (Lamisil), itraconazole (Sporanox), and fluconazole (Diflucan), all promptly penetrate the nail and nail bed, persist for months in the nail after discontinuation of treatment, and have good safety profiles. Each agent has potential drug interactions as well as different dosing options. The FDA approves the use of all these agents, except fluconazole, in treating onychomycosis.

Terbinafine (Lamisil) is the preferred treatment for onychomycosis. Dosing options are 250 milligrams (mg)/day for 12 weeks for toenails and 6 weeks for fingernails. Cure rates are 71% to 82%. There are fewer interactions with this medication than with the other oral antifungals. Another dosing option is 250 mg/day for 1 week every month for 11 or more months until a new nail has grown. In one study, the cure rate was 90%. Headache, rash, and gastrointestinal upset are possible but infrequent side effects. Rare but serious complications include cholestatic hepatitis, blood dyscrasias, and Stevens-Johnson syndrome. It is prudent to take liver function tests and check complete blood count before treatment starts and every 6 weeks during continuous-treatment protocols. If liver functions rise greater than two times above the normal, the medication should be stopped.

Itraconazole (Sporanox) in doses of 200 mg/day for 12 weeks for toenails and 6 weeks for fingernails or pulse therapy at 400 mg/day in the first week of each month can be prescribed. Two to three pulses are recommended for fingernails and three to four pulses for toenails. Liver enzyme monitoring is recommended for continuous therapy but is not considered to be needed for pulse therapy. Published cure rates are 35% to 80%. Because itraconazole is metabolized by hepatic cytochrome P450, significant drug interactions can occur with anti-arrhythmics, HMG CO-A (3-hydroxy-3-methylglutaryl-coenzyme A) reductase inhibitors, benzodiazepines, histamine blockers, and proton pump inhibitors. These interactions make this drug less desirable.

Fluconazole (Diflucan) in doses of 150 mg once weekly for 6 to 9 months can be used. This medication is the treatment of choice for onychomycosis caused by *Candida* but is also effective against other dermatophytes. Published outcomes show clinical improvement in 72% to 89% of the cases. Significant drug interactions can occur with benzodiazepines, cimetidine, HCTZ (hydrochlorothiazide), hypoglycemics, rifampin, theophylline, and coumadin.

Prevention

Most cases of onychomycosis can be prevented by early recognition and treatment of tinea pedis. Any athlete with a rash on his or her feet should have a potassium hydroxide examination of skin scrapings. The rash of tinea pedis may be maceration in the web spaces of the toes, scaling with or without erythema along the lateral aspect of the sole, or inflammatory vesicles along the instep. Dry moccasin scaling is another variation on the appearance of tinea pedis. Tinea pedis can be treated with topical antifungal cream (Spectazole) and antifungal powder (Zeasorb AF). There are numerous over-the-counter antifungal preparations, such as clotrimazole (Lotrimin) and tolnaftate (Tinactin). A simple approach is to place antifungal powder in all shoes in one's closet every Sunday so that compliance is enhanced as different shoes are worn throughout the week. Compliance is the big issue when it comes to long-term prevention strategies. Resistant or severe cases may require oral antifungal agents.

Athletes should use cotton socks for wicking away moisture and wear sandals in locker rooms, pool decks, and shower stalls. Properly fitting shoes are important to prevent microtrauma to the nails. Daily laundering of socks is recommended.

Ciclopirox 8% applied to the nail and nail fold two to three times per week may prevent recurrence after successful treatment of onychomycosis.

Return to Sports

There are no specific return-to-play NCAA (National Collegiate Athletic Association) guidelines for onychomycosis. Wearing sandals in locker rooms and showers is important, particularly until an athlete has been successfully treated.

The toenails may be the starting place for developing tinea on the other parts of the body. Tinea corporis gladiatorum has been described in wrestlers. Though the toenails of wrestlers are covered by shoes, examination of wrestlers with onychomycosis will reveal that many have exposed patches of tinea. Clearing the toenails eliminates the reservoir for fungus in these athletes, decreases the opportunity for development of tinea on exposed surfaces, and therefore decreases the possibility of its spread to other athletes.

Torticollis, Acute

Acute torticollis, also known as *wryneck,* is a twisting of the neck causing the head to be tilted and rotated to one side. It is typically caused by spasms of the muscles on one side of the neck. Torticollis may be congenital (present at birth), but acute torticollis usually affects individuals between the ages of 30 and 60, with a greater incidence in females than in males. Athletes in any sport may develop torticollis for a variety of reasons. In contact sports, such as football or basketball, acute torticollis may develop from collisions to the head or torso, which strain the neck muscles. The effects of the collision may manifest immediately or even days later. In other sports, improper technique or overuse and repetitive motions, such as looking up during a tennis serve or shooting a rifle, place the neck in positions that may be prone to spasms.

Anatomy

The neck normally has seven vertebral bodies, which make up the cervical portion of the spine. A vertebral disk, which acts as a shock absorber for the neck and allows for smoother neck motion, separates each of the seven spinal segments. Attached to these segments are numerous ligaments, which provide stability, and muscles, which allow the neck to flex, extend, bend sideways, and rotate. The muscles that are primarily involved in acute torticollis, and can individually or collectively spasm, are the sternocleidomastoid, trapezius, occipitalis, splenius, and levator scapulae.

Causes

Acute torticollis involves irritation of the cervical nerves leading to abnormal neck contractions and is commonly, but not always, caused by some inciting incident, such as rapid head or neck movements or injury from whiplash or concussion. Often, individuals will develop acute torticollis from keeping their head and neck in awkward positions for prolonged periods of time (e.g., sleeping in a wrong position or on a new bed or pillow). If there is a history of forceful trauma to the neck, other etiologies to consider are fracture, dislocation/subluxation, slipped facets, or disk herniation. Medical causes that should not be overlooked and may have a similar presentation are bacterial or viral infections in the head or neck or underlying chronic inflammatory or neurologic diseases. Certain medications can also cause acute torticollis.

Symptoms

Acute torticollis typically presents 1 to 2 days following neck irritation, although symptoms may not develop for several weeks or months. It is usually painful in the neck muscles or down the spine, and the individual has difficulty turning the head to one side. The head may tilt in one direction as the chin tilts in the opposite direction. Involuntary head shaking may occur as a direct result of muscular spasm.

Diagnosis

Acute torticollis is diagnosed by a thorough medical history and physical examination. Special attention to recent or past neck injuries, acuity of onset, pain location and radiation, fevers, and medications can help in confirming the diagnosis. The presenting posture is the head bent sideways in one direction with the chin pointing in the opposite direction. Active range of motion of the neck is usually limited, and the examiner may be able to palpate spasm and elicit tenderness of the affected muscle. The physical examination should also include evaluation of the eyes, ears, nose, mouth, and pharynx. A complete neurologic examination, including the neck and upper extremity, should be performed, and if abnormalities are present, further workup is warranted.

X-rays of the cervical spine can be taken if there is a suspicion of fracture or subluxation. More advanced imaging studies, such as computed tomography (CT) or magnetic resonance imaging (MRI) scans, can be ordered if there is concern about infection (i.e., abscess) or deeper anatomic abnormalities (i.e., disk herniation). No specific laboratory studies are required for acute torticollis unless occult infection or chronic inflammatory conditions need to be ruled out. Electromyography (EMG) can be a useful tool to determine the degree of muscle or nerve involvement.

Treatment

Treatment for acute torticollis is primarily symptomatic. Frequently, the spasms will subside on their own after about a week. Noninvasive modalities include gentle passive stretching of the neck, massage, warm compresses, and a short course of wearing a soft cervical collar for comfort and to allow the muscles to relax. Medications that may provide some benefit include nonsteroidal anti-inflammatory drugs (NSAIDs) and benzodiazepines or other muscle relaxants. If symptoms are prolonged and continue for several weeks or months, botulinum toxin (Botox) injections can be administered, usually by a neurologist or other specialist. These injections help prevent involuntary muscle contractions.

Most of the time, acute torticollis improves with nonsurgical intervention. However, if the problem becomes chronic, selective denervation of the affected muscle (irreversibly severing the nerve supplying the contracted muscle) may be considered. Physical therapy involving manual stretching and strengthening and range-of-motion exercises are started after approximately 1 week.

Transsexual Athletes

In all but a few sporting disciplines, Olympic competition follows the tradition of segregation of the sexes, which has been defended on the basis of the physiological differences that exist between adult males and females. Prior to puberty, there are no significant differences between the performance abilities of boys and girls. However, during puberty hormonal differences emerge that form the basis for the superior strength, power, and aerobic capacity that males possess, on average, compared with the average postpubertal female. Interestingly, however, as females have come to enjoy greater opportunities in sports, the performance gap between elite female and elite male athletes has become noticeably narrower. Nevertheless, it is still commonly accepted that it would be unfair to permit males to compete against females in the "gender-affected" sports (defined as those sports in which the physical strength, stamina, or physique of average persons of one sex would give them an advantage over average persons of the other sex).

In an effort to maintain the level playing field promised by sex segregation, for nearly three and a half decades, many sports governing bodies and the International Olympic Committee (IOC) pursued a program of "gender verification." The fear was that unscrupulous men might masquerade as women to compete against the "weaker sex," thereby unfairly gaining the laurels of victory. Although the stated goal of gender verification seemed reasonable—given the accepted system of sex segregation—in practice, such testing earned a rather inglorious reputation for inappropriateness and inaccuracy. After repeated public calls for its discontinuation, the IOC finally abandoned routine sex testing prior to the 2000 Sydney Games. Interestingly, since the present doping code demands inspection of the external genitalia at the time of urine collection, a mechanism remains in place for randomly assessing an athlete's phenotypic sex. Olympic medical regulations permit further medical intervention to determine an athlete's true sex should there be medical suspicion of improper participation.

In retrospect, gender verification failed in part because the methodology employed failed to accurately identify those genetic intersex states that confer a performance advantage. The phenotypic and genotypic combinations that are associated with the intersex states confound the commonly accepted definitions of what constitutes male and female and thus challenge the simple binary understanding of sex that society has accepted as normal. Similarly, transsexualism blurs the physiological borders between male and female in ways that challenge our accepted beliefs about sex. Indeed, the issue of how to integrate transsexual athletes into elite sports has proven to be quite contentious. The critical question is whether transsexual athletes (particularly postpubertal male-to-female [MTF] transsexual athletes) have an unfair performance advantage over other female athletes.

Transsexualism refers specifically to individuals who identify with (and wish to be accepted as a member of) the sex opposite to that assigned to them at birth. As such, it falls at one end of the transgender spectrum. Our current understanding suggests that transsexuals feel compelled to transition from their assigned birth sex to the opposite sex out of a prevailing sense that their true gender is at odds with their birth sex, a condition known as gender identity disorder. The resulting gender dysphoria is considered to be incurable, and the interventions to transform one's sex—which include exogenous administration of hormones and surgical sexual reassignment—are therefore merely palliative. Once transitioned from their assigned birth sex to their acquired sex, the transsexual's genotype and phenotype are disconnected, and it is only through ongoing manipulation of their hormonal milieu that transsexuals are able to maintain their acquired physiology.

Exogenous administration of sex hormones therefore represents the cornerstone of therapy for gender identity disorder and is the mechanism for effecting the desired physiologic cross-sex transition. Sexual reassignment surgery is available to those who wish to complete the phenotypic conversion. Studies of postpubertal MTF transsexuals have documented the effects of prolonged androgen suppression combined with estrogen supplementation, including significant decreases in total and regional muscle mass, muscle strength, and bone density and significant increases in total and regional fat mass. However, no peer-reviewed studies have been published describing the effects of long-term cross-sex hormone therapy on sports performance.

Consequently, it is unclear whether any significant physiologic performance advantage exists for the fully transitioned MTF transsexual athlete over an elite athlete who retains her female birth sex. Of course, those MTF transsexuals who transition after puberty will (at least partially) retain the acquired skeletal effects of testosterone exposure (e.g., height), which could prove advantageous in selected sports. However, given the wide-ranging physiological differences that exist between elite athletes, it seems likely that the abilities of the vast majority of transsexual athletes will fall within the existing spectrum of sex- and sport-specific athletic performance capacity. As a case in point, consider the pioneering MTF transsexual athlete Renée Richards. Although she achieved considerable success in tennis, her level of accomplishment did not outstrip prior levels of accomplishment attained by other athletes (who were presumably females at birth). Unfortunately, Richards was forced to overcome daunting obstacles (not the least of which was public scorn) in order to compete in her chosen sport.

The debate over whether transsexuals should be permitted to compete in sports as members of their acquired sex seemingly intensified when the IOC decided to critically examine the issue. After considerable deliberation, in 2004 the Committee voted to permit transsexual athletes who meet strict criteria to participate in the Olympics (see Table 1). The IOC's decision (the "Stockholm Consensus") led to an outcry of protest from those who feared that the existing competitive balance in elite women's sport would be upset by the influx of poorly feminized transsexuals. Despite these concerns, such a competitive imbalance has yet to materialize at the Olympic level, as no openly transsexual athletes competed in the Games of Athens, Torino, or Beijing. It is not known whether this reflects transsexual athletes' unwillingness to publicize their status or other factors (e.g., failure to qualify or simply the low number of elite transgender athletes).

It appears unlikely that the question of whether it is fair for postpubertal transsexual athletes to compete in sports against athletes who share their acquired sex will be resolved unless convincing new information is brought to bear on the matter. Of course, the difficulty in agreeing on what is fair lies in the fact that fairness is a subjective value. Even so, research should help inform the constituents whether consistent sport-specific performance advantages exist for the transsexual athlete, and education can help correct the misinformation and alleviate the prejudice that inevitably accompanies consideration of this issue. Meanwhile, in the United Kingdom, politicians have entered into the discussion. Shortly after the Stockholm Consensus was announced, Parliament revised its statutes concerning sex discrimination. The Gender Recognition Act (GRA) of 2004 provided transsexuals with the important legal right to be identified as belonging to their acquired gender. However, Section 19 of the GRA specifies that "in certain circumstances" transsexuals may be restricted

Table 1 Olympic Eligibility Criteria for Transsexual Athletes, Based on the Stockholm Consensus

Birth Sex	*Acquired Sex*	*Timing of Intervention*	*Duration of Therapy*	*Sex Reassignment Surgery Required?*	*Legal Recognition*
Male	Female	Prepubertal	Ongoing	Yes	Required
Female	Male	Prepubertal	Ongoing	Yes	Required
Male	Female	Postpubertal	2 years minimum	Yes	Required
Female	Male	Postpubertal	2 years minimum	Yes	Required

from competing in certain gender-affected sports to "ensure fair competition."

Apart from the ongoing debate, from a practical standpoint, the sports medicine practitioner who encounters a transsexual athlete should remember the unique aspects of transsexual physiology. Hormonal therapy is not without undesirable side effects, including (but not limited to) effects on cardiovascular health and hepatic function. Interestingly, however, one study of 293 female-to-male (FTM) transsexuals failed to demonstrate any significant increase in cardiovascular disease compared with the general population. The effect of hormonal manipulation on transsexual injury risk and recovery from injury remains largely unexplored. It is also critically important for all involved to remember that to be eligible to compete in the Olympic Games, the FTM athlete must obtain a Therapeutic Use Exemption (TUE) permitting exogenous administration of androgens. Failure to do so would constitute a doping violation. Of course, in light of the Stockholm Consensus, gender identity disorder is now an IOC-recognized diagnosis, and thus, FTM transsexuals should be eligible for a TUE providing they satisfy the strict IOC criteria governing transsexual participation.

Travel Medicine and the International Athlete

Travel medicine is the discipline devoted to the maintenance of the health of international travelers through health promotion and disease prevention. It is a multidisciplinary field, encompassing a wide variety of specialties and subspecialties, including infectious and tropical diseases, public health and preventive medicine, primary care, and geographic, occupational, military, and wilderness medicine. Recently, travel medicine has broadened to include migration medicine, immigrant health, and a focus on the impact of travel on receiving countries. Unlike many other health care specialties, depending on the country, travel medicine is often practiced by both nurses and physicians.

The worldwide focus and knowledge base of travel medicine distinguishes it from most other fields of medicine and nursing. Travel medicine practitioners must be aware of infectious disease risks and their magnitude, patterns of drug resistance, current outbreaks of illness, civil and military conflicts, and political barriers to travel at border crossings. In addition, they must have access to the most up-to-date information on travel-related vaccines and medications.

Today, the focus of travel medicine is on recreational tourists, business persons, overseas volunteers, missionaries, and the military. In addition, the current era of the increasing popularity of ecotourism and extreme travel has added a new dimension to the field. Professionals counsel increasing numbers of immune-compromised individuals, such as those with HIV (human immunodeficiency virus) infection, cancer, autoimmune disease, or organ transplants.

Health Advice to Travelers

Health risks are increasing for travelers to developing countries. These can easily be overcome, however, through the dissemination of accurate information. Public health organizations have excelled in gathering information on the extent of disease prevalence and on prevention and treatment. They have made such knowledge readily available to hospitals, physicians, and the travel industry. The news media can do much to disseminate information in ways that enhance the enjoyment of travel to the developing world, instead of frightening people away.

Travel advice is based on the recommendations of the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) and is supplemented by information provided by International SOS.

Before Traveling Out of a Country

Before traveling abroad, it is important to schedule an appointment with a health care provider at least 4 to 6 weeks in advance to discuss any needed vaccines or medications to prevent disease while traveling.

People with medical problems such as arrhythmias, clotting disorders, lung problems, or heart failure should discuss travel plans with their doctor even sooner. Even within small countries, diseases such as malaria might be a risk in one city but not in another, so it makes a difference to know exactly where a person will be going and what he or she will be doing. Also, the person must bring along a copy of previous immunizations. For the traveler's own safety, it is necessary, for all travel, that he or she is up-to-date on routine vaccinations. Most doctors also recommend hepatitis A and B vaccines for travelers. Based on travel plans, the doctor will then make recommendations about taking drugs to prevent malaria or vaccines to prevent yellow fever, typhoid, and other infectious diseases.

There are very few actual required vaccinations for travel, but this again depends on where the traveler will be going and when. The physician may refer the person to a travel medicine clinic if certain vaccinations are needed that are not readily available in regular clinics.

Those with underlying health problems should, with appropriate pretravel planning and behavioral modification during travel, be able to minimize the health risks associated with the travel. However, they must have realistic expectations concerning health maintenance and travel restrictions. Those individuals at special risk have the option of making use of numerous resources that are now available to make travel an enjoyable and rewarding experience.

Travelers to developing countries, particularly those visiting friends and relatives, have the highest morbidity for infectious diseases, including typhoid, hepatitis A, malaria, tuberculosis, and HIV infection. This is associated with their lifestyle, behavior, culture, and beliefs. Improvements in travel medicine practice, including the development of new antimalarial drugs and novel vaccines, have been of little benefit to this group of travelers, as can be seen from the increasing trend of morbidity. Pretravel services are underused by this population, and there is little material adapted to the language and cultures of developing countries. A major shift in practice will be necessary to benefit these vulnerable travelers.

Preventing infection among business travelers is one of the key areas of the travel consultation. Prevention methods include timely vaccination, hygienic food and water, precautions against insects, and tuberculosis screening.

The business traveler, corporation, and medical practitioner have mutual responsibilities to ensure the health and safety of the traveler and consequently the success of the trip. The most effective way to manage this responsibility is through the use of medical practitioners with an expertise in both occupational and travel medicine. An effective travel consult should identify means for the prevention of disease and provide the appropriate anticipatory guidance to the individual who is travelling. In addition, the travel consultant should also address the potential health and safety liabilities to the company when clearing personnel for business-related travel. The corporate traveler and employer must have an effective plan for medical emergencies prior to the traveler's departure. On their return, long-term corporate travelers should have reentry physicals and health debriefings. Finally, to maximize preventive efforts, particularly in relation to future travel, business travelers should complete the vaccination series that were begun prior to travel.

Medical Support for Travelling Athletes

Professional and amateur sports require frequent travel. Athletes are confronted frequently with obstacles to optimal performance. The trainers, medical team, and staff face challenges in providing support while traveling and working.

Physical examinations should include screening, the review of past medical history and vaccinations, and physical and dental examination. This will help establish the team member's preparedness to face the challenges of international travel. This examination could identify medical problems such as travel anxiety, asthma, dental caries, gastrointestinal problems, allergies, diabetes mellitus, and coronary heart disease. All medical records of the athletes should be kept secure and accessible in the hand luggage during travel.

Large athletic events are frequently associated with outbreaks of infectious disease. All athletes and members of the team should have an up-to-date immunization status (i.e., measles, tetanus, diphtheria, polio, pertussis, rubella, and mumps). Medical team members and full-contact athletes (i.e., boxers, martial artists, and wrestlers) should have three doses of hepatitis B shots. Athletes traveling to developing countries should consider a hepatitis A vaccination. Athletes without any previous exposure to chickenpox should be vaccinated for varicella with two doses 4 to 8 weeks apart. Meningococcal and influenza vaccine should be considered. Vaccines against diseases such as rabies, typhoid, yellow fever, malaria, cholera, and Japanese encephalitis are recommended according to the guidelines of international agencies.

Education on preventing infectious disease during international competitions should be provided to athletes, coaches, and the staff accompanying the team. Recommended methods to prevent communicable disease during traveling are drinking bottled or purified water, hand washing with soap and water or using alcohol-based hand gel, washing or peeling fruits and vegetables before eating, eating fully cooked foods, and abstinence or use of condoms to avoid sexually transmitted infections.

The following measures should be taken to ensure preparedness for international travel. First, it should be assumed that nothing will be provided, regardless of the preparatory phase. Second, the teams should be self-sufficient. Third, communication with the host country is advisable beforehand (e.g., regarding electricity, water, telephones, the Internet, ice, examination tables, or towels). A travel health kit (first-aid items and antiseptic hand gel, antidiarrheal medication, thermometer) should be made available to athletes at all times. Medical health records of all athletes should be available. Weather forecasts should be reviewed before departure, and athletes traveling to high altitudes should have undergone acclimatization.

Problems arising during travel might relate to major time zone changes, modes of transportation, changes in climate and humidity, sun exposure, and differences in food, housing, language, and religion. Endemic infections such as hepatitis B, yellow fever, and typhoid may require clarification and appropriate immunization prior to travel. Immunization might require several months of preplanning to ensure adequate sero-conversion. Chemoprophylaxis for some diseases, such as malaria, should be initiated in advance.

Hygienic standards should be maintained during food preparation while traveling. At international competitions such as the Olympic Games, a diverse selection of food is available. This enables athletes and staff from around the world to have their normal diet.

Toxigenic *Escherichia coli* is a well-known agent responsible for "traveler's diarrhea." It can be communicated by contaminated water, so in case of any doubt about the safety of the water supply, the team should drink and brush their teeth only with bottled mineral water. Travel to a hot and humid environment warrants an adequate intake of fluid to prevent dehydration and hyperthermia. Sufficient consumption of fluids will change urine to a light color. This is a better indicator than thirst. Another monitoring method for dehydration is daily weight charting. Additional salt in the food or fluid is recommended.

It is important to plan air travel well to minimize the effects of traveling. Jet lag is due to the physiological changes that occur when the sleep-wake cycle is disrupted. Changes in hormone metabolism and body temperatures occur, which lead to feelings of confusion and exhaustion. Athletes should consider avoiding heavy training on arrival and instead participate in one or two light training sessions to ease their transition. It can take several days before these factors settle back into rhythm and maintain an appropriate balance. For every hour of time zone change, one day of accommodation may be required to overcome the effects of jet lag.

To minimize the effects of jet lag, athletes may try to adjust their sleep pattern over several days prior to departure to coincide with the time zone at the site of the competition. On the airplane flight, it helps to move around as much as possible, to avoid alcohol and coffee, and to ingest large amounts of fluid. It is recommended that athletes stay up on the day of arrival and try to adjust to the normal sleep pattern of the country in which they have arrived. Exercise after a long flight may prevent the malaise of jet lag. The use of high-protein meals and stimulating drugs such as caffeine, contained in beverages such as coffee and tea, may be temporarily useful for improving alertness at the time of arrival. Benzodiazepines could promote sleep during a long flight. Drowsiness and decrease of psychomotor performance are the side effects, which might decrease athletic performance. Therefore, these drugs should be reserved for traveling athletes with persistent insomnia, and their use should be supervised by a physician. Melatonin, a hormone that is secreted at night and plays a key role in circadian rhythms, is available as a drug. Conflicting evidence exists on the effects of melatonin on athletic performance and the amelioration of jet lag symptoms. Drowsiness and headaches might hinder sports performance if taken inappropriately. Athletes should use melatonin during flights if they are accustomed to the effects of this remedy. Long-distance travel should be interrupted for 1 to 2 days for a more gradual introduction to major time zone changes.

Motion sickness is another problem frequently encountered during traveling. Unstable air, mountainous roads, and heavy seas may trigger symptoms including nausea, vomiting, dizziness, headache, and malaise. Drugs such as dimenhydrinate, transdermal scopolamine, and meclizine when taken before travel may prevent symptoms of motion sickness.

Before setting off on the journey home, the same precautions for travel should be discussed with the team and athletes. Athletes with a medical problem or injury should be monitored closely, and preparations for their care at home should be made in advance. In case of a medical event, the team physician should prepare a health report on medical encounters, the type of injury or illness, treatments, and emergencies. The report may be presented to the local organizing committee and to the sports organizations back home. This approach will help explain the need for the medical services used and assist in preparations for future international athletic events.

Triangular Fibrocartilage Complex

The *triangular fibrocartilage complex* (TFCC) is a structure found in the wrist. The TFCC serves as the primary stabilizer of the distal wrist joint, as well as provides for cushioning from certain activities. It works in a similar fashion to the menisci found in the knee and is often called the "wrist meniscus." It can be injured either acutely during trauma or from repetitive overuse. There is some evidence that, over time, the TFCCs of all patients will begin to break down (usually beginning in the fourth decade of life) to a certain degree.

The TFCC is made up of several different structures. The primary components are the dorsal and palmar volar ligaments. These ligaments run from the radius to the ulna and provide for the structure of the TFCC. There is also a soft tissue disk that lies between these ligaments and provides extra support. Finally, a portion of the tendon sheath of the extensor carpi ulnaris (ECU) makes up a portion of the TFCC.

The TFCC can be injured either traumatically or through repetitive activity. Patients can suffer TFCC tears related to falls on their wrists and arms or from direct trauma to the ulnar side of the wrist. In particular, any trauma that results in the hand being forced downward against the ulna may result in a TFCC injury. TFCC injury from repetitive trauma and overuse is often seen in patients who perform activities that result in repetitive ulnar deviation of the wrist (e.g., lifting heavy weights, working with equipment such as hammers or drills). In addition, sports that result in repetitive compression of the wrist may result in TFCC tears; these sports include racquet sports, gymnastics, and diving. In addition, distal radius and ulnar fractures are often associated with TFCC tears.

The differential diagnosis of a TFCC tear includes, but is not limited to, fractures of the radius and/or ulna, tendinosis and tenosynovitis of the flexor or extensor tendons, displacement/snapping of the ECU tendon, injuries to other ligamentous or cartilaginous structures of the wrist (distal radioulnar joint [DRUJ], scapholunate, etc.), and arthroses of the wrist joint.

Diagnosis of a TFCC tear can be performed both clinically and radiographically. Typically, the patient will experience discomfort of varying degrees with palpation of the structure. Patients with small tears may experience little to no pain or limitations, while patients with larger and/or chronic tears may have constant debilitating pain both at rest and with use. The location of the tear will be important as well. Typically, the more peripheral a tear, the more likely it is to cause the patient discomfort; central tears of the TFCC can often be asymptomatic.

The outermost structure of the TFCC is easily palpated along the lateral wrist between the ulna and the lateral carpal bones (pisiform and hamate). Palpation of the structure can be accentuated with radial deviation of the hand. There may also be associated swelling around the structure, as well as "clicking" of the wrist, which may be heard or felt by the patient. Patients may also experience decreased grip strength and pain with resisted wrist dorsiflexion. The Apley Grind is the most commonly used diagnostic test. This test is usually performed with the physician gripping the hand of the patient and applying downward pressure, causing the hand to deviate toward the ulna. The hand can then have a twisting force applied to it, causing the TFCC to be compressed and exacerbating the pain.

Radiographic studies can also be of benefit in diagnosing TFCC injuries. Although the TFCC is a cartilaginous structure, X-rays can sometimes be helpful, for several reasons. With both trauma to the wrist and chronic pain, plain radiographs are often ordered to evaluate for bony injury. Evidence of an ulnar fracture of any form could alert the clinician to the possibility of a TFCC injury. More important, the shape of the ulna can help in making the diagnosis. In general, the lengths of the ulna and radius in the wrist are the same. However, in some patients, the ulna may be either longer or shorter than the radius; this is defined as positive or negative ulnar variance, respectively. Both positive and negative ulnar variance can be associated with a higher rate of TFCC injury.

To truly evaluate the TFCC, magnetic resonance imaging (MRI) is often required. This test allows visualization of the soft tissue of the wrist. This will often reveal swelling along the cartilage and sometimes a tear in the cartilage. The test can be made more accurate by the injection of contrast medium into the wrist. This procedure is called an *MR arthrogram*, and it can allow for better visualization of a TFCC tear, as the contrast material may actually track through the tear into other areas of the wrist where it was not injected. Computed tomographic (CT) arthrography may also be done, although it is typically not as accurate as MR arthrograms. Finally, the TFCC tear may be directly visualized through an arthroscopic procedure.

Treatment of TFCC tears can be both conservative and surgical. In general, nonoperative therapies are attempted first. Modalities such as protection from further injury, rest, and ice application are often helpful. Bracing is often used for mild and/or acute injuries as mild trauma to the TFCC may heal on its own. Bracing can be used with activities that cause pain and discomfort for the patient. At times, a cast can be used for a period of 2 to 4 weeks as well. This allows for immobilization as well as protection. This can be particularly helpful in cases of chronic TFCC injuries. Another option for treatment can be corticosteroid injection in or around the TFCC. This can be done for both diagnostic and therapeutic reasons. Also, both physical therapy and physiotherapy may be helpful. Finally, in cases that are resistant to conservative therapy, surgery can be an option. This surgery is usually accomplished arthroscopically and can be done for either acute or chronic tears. This intervention may result in either repair of the tear or excision of the fragments. Patients suffering from severe tears may be more likely to require surgical intervention. Also, if there are concomitant injuries to other structures of the wrist that require surgical intervention, then patients may undergo surgical correction of their TFCC injury at the same time.

Triangular Fibrocartilage Injuries

The *triangular fibrocartilage complex* (TFCC) is a complex ligament-cartilage complex that sits between the distal ulna and the ulnar carpus. It serves as the main stabilizer of the distal radioulnar joint (DRUJ) and plays an important role in load bearing across the ulnar wrist. Tears of the TFCC are an important cause of both acute and chronic ulnar-sided wrist pain. This entry reviews the anatomy of the TFCC and discusses the classification, evaluation, and treatment of TFCC tears.

Anatomy/Function

The TFCC was first described by A. K. Palmer and F. W. Werner in 1981 and consists of an articular disk, a meniscus homologue, ulnocarpal ligament, dorsal and volar radioulnar ligament, and the extensor carpi ulnaris (ECU) sheath. It originates from the ulnar fossa of the distal radius and inserts into the base of the ulnar styloid. It is 2 millimeters (mm) thick on the radial side and 5 mm thick on the ulnar side. Distally, it inserts onto the lunate via the ulnolunate ligament (UL) and the triquetrum via the ulnotriquetral ligament (UT). The UL and UT ligaments are located volarly and are referred to as the disk carpal ligaments.

Blood supply is via the dorsal and palmar radiocarpal branches of the ulnar artery and the dorsal and palmar branches of the anterior interosseous artery. These vessels penetrate 10% to 40% of the periphery, leaving the central disk and radial portion avascular. As in the knee meniscus, peripheral tears are amenable to repair, whereas the central avascular portion does not heal.

As stated earlier, the primary function of the TFCC is as a stabilizer of the DRUJ. The volar portion of the TFCC prevents dorsal displacement of the ulna, and the dorsal portion prevents volar displacement of the ulna. Stability is achieved through selective tightening of the dorsal and volar TFCC during pronation and supination. The TFCC also increases the gliding surface for the radius and acts as a buttress to the proximal carpal row.

Another major function is to cushion axial loading through the ulnocarpal axis. The majority (80%) of axial load is carried by the radius; however, this can vary based on ulnar variance. Ulnar variance is a measure of the relative length of the ulna in relation to the radius. Studies have shown that a positive ulnar variance of 2.5 mm can increase load transmission by the TFCC to 42% while a negative ulnar variance of 2.5 mm can decrease load transmission to 4%. The increased load across the TFCC that occurs with positive ulnar variance accounts for its increased association with TFCC tears.

Examination/Evaluation

The most common symptom of a TFCC tear is ulnar-sided wrist pain with grinding or clicking during wrist range of motion. The mechanism of injury may be an acute fall onto an outstretched hand; a rotational injury with forced ulnar deviation, such as batting a baseball; or axial loading, such as in gymnastics. Chronic injuries result from overuse with repetitive rotation and loading of the ulnar wrist, also common in gymnasts. Isolated pain with pronation and supination may indicate injury to the articular disk, while constant pain with limited range of motion is associated with more peripheral tear.

Examination should include inspection for gross deformity, soft tissue swelling, erythema, and ecchymosis. Active and passive range of motion should include flexion, extension, pronation, supination, and radial and ulnar deviation. Patients are usually tender distal to the ulnar styloid in the soft depression just proximal to the pisiform. A painful click may be reproduced with repetitive pronation and supination of a clenched and ulnarly deviated wrist. Pain and/or clicking with the TFCC compression test may indicate a TFCC tear. This test involves wrist extension, ulnar deviation, and axial compression. DRUJ instability may be present, as evidenced by a positive "piano key sign," in which there is increased displacement of the distal ulna as the radius is held stable and the examiner forces or "shucks" the ulna in the volar and dorsal direction. The ulna appears more prominent and ballottable, resembling a piano key.

Plain radiographs are a useful initial imaging modality for TFCC injuries because they may reveal a distal radius or ulnar styloid fracture and also allow for assessment of ulnar variance. The recommended views are zero-rotation PA (posteroanterior) and lateral. Triple-injection arthrography used to be the study of choice but has been shown to have poor correlation with arthroscopic findings and has fallen out of favor over the past 5 to 10 years. The utility of magnetic resonance imaging (MRI) is debatable, with sensitivity ranging from 17% to 100% in conflicting studies. A dedicated wrist coil can improve accuracy, but MRI is still not ideal for localizing tears. The gold standard is wrist arthroscopy, which can be used diagnostically and therapeutically.

Differential Diagnosis

Examination should also be centered on excluding other common causes of ulnar-sided wrist pain. Dorsal pain may be caused by tendinitis or subluxation of the ECU. Patients with ECU tendinitis will have pain with resisted wrist extension and ulnar deviation. Subluxation may be present with a palpable, painful snap when a flexed, ulnarly deviated wrist is supinated. Lunotriquetral (LT) instability should be evaluated for with ballottement and shuck tests of the LT joint. Volar pain may be caused by flexor carpi ulnaris (FCU) tendinitis or a fracture of the hook of the hamate or pisiform. FCU tendinitis will present with pain with resisted wrist flexion and ulnar deviation. Hook of the hamate fractures present with hypothenar pain and are often caused by direct trauma to the hypothenar region from grasping an object, such as the butt of a golf club.

Classification of TFCC Tears

In 1989, A. K. Palmer devised a classification system for TFCC tears, distinguishing acute tears from chronic tears and helping guide treatment strategies. Class I tears are acute, traumatic tears. They are further divided based on the location of the tear. Type IA tears are of the central, avascular portion of the articular disk. Type IB tears occur at the base of the ulnar styloid with or without a distal ulnar fracture. Type IC tears are of the ulnolunate or ulnotriquetral ligament at the carpal attachment. Type ID tears are radial sided with or without a sigmoid notch fracture.

Type II tears are chronic and degenerative in nature, describing a spectrum of damage by repetitive loading and positive ulnar variance called ulnocarpal abutment syndrome. Types IIA and IIB tears do not have frank perforation but thinning of the disk without and with chondromalacia of the lunate or ulna, respectively. Type IIC tears are frank perforations of the central disk with chondromalacia. Type IID tears are frank perforations of the disk with chondromalacia and a tear of the LT ligament. Type IIE tears describe end-stage disease with perforation, chondromalacia, LT tear, and ulnocarpal arthritis.

Treatment

The initial treatment for both acute and symptomatic chronic tears is a period of immobilization in a long arm cast for 4 to 6 weeks followed by physical therapy. A localized cortisone injection may provide some symptomatic relief as well. Acute, peripheral tears (Types IB and IC) that are not associated with positive ulnar variance do very well with nonoperative treatment. In contrast, acute avascular tears (Types IA and ID) and both acute and chronic tears associated with ulnar impaction do not heal well without surgical debridement and ulnar-shortening procedures. The emphasis should be on correcting positive ulnar variance as many studies have shown poor outcomes for simple TFCC debridement without ulnar shortening. Types IIA and IIB lesions may only require ulnar shortening without arthroscopic debridement as they do not have frank tears. Type IIC tears may be treated with a “wafer” procedure, in which a 2- to 4-mm section on the distal ulna is removed while keeping the styloid, TFCC, and ligaments attached. Type IID tears with LT instability require ulnar shortening along with LT ligament repair or possible LT fusion or pinning. Type IIE lesions require a salvage procedure.

The TFCC is a complex structure that stabilizes the DRUJ and supports axial load across the ulnar wrist. TFCC tears represent an important cause of ulnar-sided wrist pain. Injuries are often caused by acute falls on an outstretched hand or chronic overloading of the ulnar wrist. The most common symptom is pain with clicking during wrist motion, and examination will often reveal pain with a TFCC compression test. TFCC tears are associated with positive ulnar variance, which can be seen on plain radiographs. Tears are classified as acute and degenerative, and treatment for both types is a period of immobilization followed by therapy. Arthroscopy is indicated for unstable lesions and those refractory to nonoperative treatment. Ulnar shortening should be performed for those with ulnar impaction syndrome.

Triathlons, Injuries in

In the late 1970s, several endurance junkies started a contest to see who was tougher by swimming, biking, and running across the Hawaiian landscape. Over the decades that followed, the sport of triathlon has undergone a stunning rise in popularity. The individual medley of endurance sports (swim, bike, run) is now a well-accepted sport in the Olympics at the 1.5/40/10-kilometer distance and enjoys a wide and growing participation base across the world. Distances range from short, “sprint” races lasting less than 1 hour to longer-distance, “ironman” races that can take competitors up to 8 to 16 hours to complete. Some even extend this to ultradistances competed over several days. Races typically use road bicycles for the bike portion, but off-road races using mountain bicycles have been gaining in popularity as well. The medical and musculoskeletal issues that arise in the longitudinal care of triathletes are, for the most part, those that arise with training for each individual discipline. For those medical or other support personnel involved in race day coverage, however, a variety of other acute medical concerns may arise and need to be considered when planning for the medical coverage of such events.

Swimming

While competitive swimming involves training and racing using the four traditional strokes (butterfly stroke, backstroke, breaststroke, and freestyle) in an enclosed pool with clear, chlorinated water, a triathlon swim occurs in open water with variable conditions and with a multitude of other athletes. Mass start races are characterized by "pack" swimming, and this can occasionally lead to issues such as blunt trauma to the face/eyes and finger sprains from contact with other swimmers. Both hypothermia and hyperthermia have been seen during and after open-water swims. Triathletes will typically use wetsuits to combat the cooler water temperatures, and this will allow most athletes to tolerate long swims in temperatures as low as 10 °C (50 °F). Despite this, hypothermia can ensue both during the swim and after the swimmers exit the water, due to a phenomenon known as "after-drop." An athlete's core temperature can continue to drop after leaving the cold water as blood continues to perfuse the cooler extremities. This has led to injuries as athletes attempt to transition to the bike with impaired coordination and judgment as a result of hypothermia.

On the other end, the use of wetsuits in water greater than 25 °C (78 °F) can lead to elevations in core temperature and symptomatic hyperthermia (heat exhaustion, syncope, or heat stroke), and for this reason, wetsuit use is restricted above this temperature. Increases in core temperature and heat stress can be additive (from day to day and from event to event) and may progress during a race. Further elevations in core temperature accumulated during the bike and run segments could predispose an athlete to more symptomatic heat illness or exercise-associated collapse later. Heat exhaustion may present with confusion, weakness, cramping, or hypotension and may lead athletes to drop out of the race and present to the medical tent on their own. Heat stroke represents a progression of heat illness with system failure at the metabolic and organ levels. This is usually seen in the later stages of the run segment, with the athlete's collapse or severe deterioration in the medical tent.

To those athletes accustomed to training in clear water with orderly passing, the chaos of group swims and the unpredictable water conditions (cold temperature, waves, currents) can lead to anxiety and panic attacks. This problem can be exacerbated when warmer water conditions preclude wetsuit use. Many of the weaker swimmers depend on the additional flotation provided by wetsuit use, and a last-minute prohibition of its use can cause significant anxiety. Severe panic attacks in open water raise concerns about near-drowning events or severe exacerbation of asthma in the triathletes, and these should be accounted for when planning race management. Other, less common medical concerns during open-water swims include bacterial infections from poor water quality (*Escherichia coli, Leptospirosis*), sudden death from cardiac embolism or fatal arrhythmias, and marine animal stings or attacks (e.g., jellyfish, coral, sharks).

Triathletes, however, still need to put in a significant amount of distance in the pool during training (albeit less than their competitive swimmer counterparts due to the bike and run training) and thus experience the same range of overuse injuries as swimmers do. The shoulder is, by far, the most commonly injured or painful area in swimmers. Shoulder stability is maintained by both the joint capsule and the rotator cuff and can be lost when either of the structures becomes weakened. The rotator cuff is a group of four muscles deep inside the shoulder that helps provide stability by holding the humeral head inside its socket. It also helps initiate the overhead motion of the arm up to shoulder level. To achieve full overhead motion, the scapula must also retract and tilt the shoulder socket upward. The muscles that accomplish this are the rhomboids, trapezius, and cervical paraspinals.

The tendons of the rotator cuff are prone to overuse and inflammation with the repetitive overhead motion of the swim stoke. When this happens, the tired or inflamed muscle-tendon unit becomes weaker. As this progresses, the cuff muscles no longer constrain the shoulder effectively, and the head of the humerus may elevate with arm motion, causing a painful impingement against the undersurface of the acromioclavicular (AC) joint. Load may also shift to the joint capsule and ligaments, as well as the labrum (the cartilage rim around the shoulder joint). Such an imbalance can lead to painful multidirectional instability or labral tears. The scapular muscles must increase their share of moving the shoulder when the cuff is weak, and this can eventually cause overuse and lead to neck and upper back pain. The importance of a strong rotator cuff as a shoulder stabilizer becomes even greater in those with a high level of flexibility (congenital or otherwise) as these athletes cannot depend on the stabilizing effect of the shoulder capsule and ligaments.

Swimmers also experience injuries to various other structures. The repetitive lumber spine extension and rotation forces during a swim stroke can lead to stress injuries to the posterior elements of the vertebra itself and, ultimately, to spondylosis or spondylolisthesis. Injuries to the knee, such as patellofemoral pain or chondromalacia, can also be seen. These are usually seen with greater use of breaststroke or eggbeater kick, but can also be seen in those athletes concurrently training for bicycling, such as triathletes.

Cycling

Cycling injuries range from acute trauma to chronic overuse injuries. Triathletes, like cyclists, put in a lot of miles on the bike during the training process, and the old adage that "it is not *if* you will crash but *when*" holds true for triathletes. The most common crash-related injury is "road rash," which is a traumatic abrasion or contusion caused by the body scraping against the pavement. Appropriately treated with good wound care, it heals and rarely causes a significant loss of training time. Fractures of the wrist (distal radius, scaphoid), clavicle and AC joint, and elbow (radial head) are relatively common, and fractures of the pelvis have also been reported. The speed of a crash can increase the severity of a fracture; however, it is the mechanism of impact with the ground that determines whether a fracture will occur. Off-road triathlons have the added risk of collision with a fixed obstacle or even penetrating trauma from tree roots. Head injuries such as concussion also can result when a rider strikes the ground, even if he or she is wearing a helmet. Helmets are mandatory during competition and should be used during training as well.

Nontraumatic injuries, however, dominate in terms of frequency of cycling injuries. Chronic neck pain is a frequent complaint and can result from the prolonged neck extension required for straight-ahead vision with normal positioning on standard handlebars. This can be exacerbated by the increased torso flexion/flat-back positioning required with aerodynamic time-trial bars. The pain can be due to muscle spasm and/or trigger points in the levator scapulae, trapezius, or cervical paraspinal muscles, as well as from cervical facet arthrosis or degenerative cervical disk disease. To some degree, this can be minimized with more upright positioning on the bike.

The use of the hands and wrist to support the upper body on the handlebars can lead to both ulnar nerve impingement in the Guyon canal laterally in the wrist as well as median nerve irritation in the carpal tunnel. Consistent use of padded cycling gloves helps reduce trauma to the ulnar nerve. Frequent hand position changes and avoidance of extremes of flexion or extension help combat median nerve irritation. Groin injuries are also quite common in cyclists. Chronic irritation of the perineal skin due to friction can lead to skin breakdown and subsequent abscess formation. This can be minimized with proper bike positioning, padded cycling shorts, and chamois cream to soften the pad. Compression of the pudendal nerve can also cause transient numbness in the genital area. Such compression is more common in triathletes who tend to ride on the nose of the bike saddle.

Knee problems are also quite common in cyclists and triathletes. The pedal stroke can put tremendous load on the patellofemoral articulation, and proper pedaling mechanics and bike positioning are imperative to avoid overloading the joint. Even with good form, an overly rapid progression of high-power/low-cadence pedaling too early in the season can overwhelm the quadriceps muscle's ability to maintain normal patellar tracking. Inflammation of the patellar joint surface (patellofemoral pain) or softening/erosion of patellar cartilage (patellar chondromalacia) can occur. Once established, patellofemoral pain can take months to resolve. Chronic quadriceps muscle tightness can add to the problem by increasing baseline compressive stress on the joint. Similar cartilage erosions can occur on the femoral side of the joint as well. Chronic stress and overuse can also cause a painful intrasubstance degenerative change (tendinosis) within the patellar or quadriceps tendon. The same degenerative changes and inflammation that occur in the tendons of the knee also can occur in the Achilles tendon of the ankle with overuse. The iliotibial (IT) band attachment on the outside of the knee is also frequently injured with repetitive knee bending and friction at its attachment site.

Running

Run training can cause similar problems with knee pain. Patellar and/or femoral chondromalacia, IT band syndrome, and patellar/quadriceps tendinosis are all common overuse injuries in runners with normal mechanics. Those with poor mechanics that result in knee valgus (knock-knees), however, can experience increased patellar maltracking and pain. Such mechanical issues include abnormal foot pronation and weak core and/or gluteal muscles. Rapid increases in mileage, a large amount of downhill running, and uneven running surfaces all can increase the likelihood of developing patellofemoral pain as well. Since triathletes tend to have stronger abdominal, gluteal, and quadriceps muscles from biking and swimming, they tend to have more issues with overuse patellofemoral pain, IT band syndrome, or plantar fasciitis in the foot. To some degree, the cross-training required in triathlon helps strengthen the muscles that protect triathletes from the abnormal mechanics seen in solo sport competitors.

A relatively common and insidious concern for triathletes, or for any other endurance athlete for that matter, is overtraining syndrome. At its worst, this can present as severe, chronic stress with pituitary suppression (decreased hormone levels, increased cortisol). The athlete feels tired, can't recover from training sessions, has elevated morning heart rates, can't reach maximum heart rate during exercise, and has symptoms of depression. There is a continuum of impairment in terms of clinical symptoms from minimal, with minor deficits in performance and mild depressive symptoms, to more significant, with mild immunosuppression (increased infections, etc.) and possible cardiac arrhythmias. Unless the symptoms are very severe, laboratory values are all within normal limits and the diagnosis is clinical. A more acute cardiac version has been seen in long-distance triathletes, who, following a race, have shown transient (6–8 weeks) depressions in cardiac function that fully reverse with rest. Chronic issues with muscle strains of the calf, quadriceps, or hamstring can also relate to insufficient recovery time or overtraining. The likelihood of suffering a more severe tear of a muscle or tendon with training or competition is increased when muscle or connective tissue is compromised and unable to withstand previously tolerated stresses.

A more concerning overuse injury, largely secondary to running, relates to stress fractures. Bone is a dynamic organ, and when impact stress overloads a bone's ability to adapt, a mechanical failure of the structure can occur. This may initially present as an inflammation of the periosteum (the membrane covering the bone). When this happens along the back edge of the tibia, where the soleus and posterior tibial muscles attach, it is called "shin splints." Left unchecked, this accumulation of mechanical stress above that which can be repaired may progress to bone marrow edema and eventually to cortical fracturing. This can occur in the tibia, fibula, metatarsal bones of the foot, tarsal bones of the ankle, pubic rami and symphysis of the pelvis, and femur. As part of the process of adaptation to training, bones become denser and better able to handle the mechanical stress. Thus at a certain level, quality rest/recovery can become just as important as quality training.

Conclusion

In general, triathletes experience the same overuse and traumatic injuries that their single-sport compatriots do. They simply have a larger exposure by training in all three disciplines. There are a few unique aspects associated with the open-water swimming and transitions, but the similarities outweigh the differences.

Trigger Finger

Trigger finger is the most common atraumatic, painful complaint of the hand and the fourth leading reason a person is referred to a hand surgeon. Its incidence is 28 cases per 100,000 people per year, with a lifetime risk of 2.6%. Having diabetes increases this risk to 10%. Trigger finger initially starts as discomfort in the palm that worsens with movement of the digits and progresses to "locking" of the involved digit in flexion. Adults are affected more than children. Women are affected two to six times more than men. The dominant hand is the most commonly affected, and the digits that trigger in descending order of frequency are the thumb followed by the ring, middle, pinky, and index fingers. Peak age of incidence is 55 to 60 years, with a smaller peak under 8 years of age. The usual treatment involves a cortisone injection, which is curative up to 90% for all except individuals with diabetes mellitus and rheumatoid arthritis.

Anatomy

The flexor tendons connect the digits to the forearm muscles and are responsible for bending the digits. A membranous tendon sheath covers the outside of the tendon and is attached to the bones of the hand, starting at the metacarpal head (palm bone) and extending to the distal phalanx (last finger bone). Different areas of the tendon sheath are thickened and function as pulleys to direct the tendon in its path and to prevent bowstringing. Trigger finger occurs when there is a mismatch in size of the flexor tendon, most commonly caused by a nodule, and the pulley. The most common area for the tendon to get stuck at is the first annular (A1) pulley, located over the joint of the metacarpal (palm bone) and proximal phalanx (initial finger bone). Occasionally, triggering can occur at other pulley sites.

Causes

Trigger finger is often idiopathic. It does occur more commonly in people with metabolic problems such as diabetes mellitus and hypothyroidism and different rheumatologic conditions, including rheumatoid arthritis, psoriatic arthritis, amyloidosis, sarcoidosis, and pigmented villonodular synovitis. Interestingly, trigger finger is associated with duration of diabetes and not with sugar control in individuals with diabetes requiring insulin injection. Because repetitive finger movements due to one's occupation or sport can cause high tension across the A1 pulley, it is proposed to cause the development of fibrocartilaginous metaplasia of the pulley and tendon cells, thus creating the mismatch in size. Trigger finger commonly coexists with carpal tunnel syndrome, de Quervain tenosynovitis, and Dupuytren contracture. Sometimes, locking of the digit can occur if ligaments catch on the bony prominence of the metacarpal (palm bone) head, if there is swelling of the tendon at different locations, or if loose bodies are present in the metacarpal phalangeal joint. Rarely, a finger injury involving a laceration of the flexor tendon may present as a trigger finger from the cut portion of the tendon catching at the A1 pulley.

Symptoms

Initially, pain is only felt in the palm at the metacarpal phalangeal joint. The pain can also radiate along the palm or along the digit. Locking of the digit occurs during active flexion-extension activities, often reported to worsen on rising in the morning. The athlete may complain initially of painless clicking of the digit with flexion that progresses to painful catching. Long-standing cases of trigger finger may present as a stiff digit, which the person is unable to bend.

Diagnosis

Trigger finger is diagnosed clinically from a history of locking of the digit and observation of triggering in the physician's office. Sometimes, a nodule on the flexor tendon is felt at the metacarpal phalangeal joint. Snapping or crepitus may be felt along the flexor tendon at the A1 pulley while the finger is passively flexed and extended. Laboratory evaluation is only required if there is suspicion that the nodule is secondary to medical conditions such as diabetes mellitus, rheumatoid arthritis, hypothyroidism, or gout. Occasionally, a radiograph of the hand is performed to look for loose bodies in the metacarpal phalangeal joint and arthritic changes in the metacarpal head or accessory bones of the hand.

Treatment

If the triggering of a digit occurred with a specific activity, then avoidance of that activity will lead to resolution of the symptoms. Otherwise, the first-line treatment recommended involves an injection of steroid medication near the bump on the tendon. Oral or topical anti-inflammatory medications can be tried initially but are often unsuccessful. Splinting the involved digit with 15° of flexion at the metacarpal phalangeal joint can be tried, but this has a lower success rate in those with more severe disease, triggering of longer than 6 months' duration, and multiple trigger digits. Splinting needs to be done continuously for 6 weeks and has a success rate of up to 50%. Injection into the tendon sheath has a success rate of 90%, and if a second injection is required, it is half as beneficial as the first one. Steroid injection has a higher success rate in those with a palpable nodule, if the duration of symptoms is less than 6 months, and if the digit triggering is the thumb. Complications of steroid injection include dermal or subcutaneous fat atrophy, skin depigmentation, infection, and, very rarely, tendon rupture. If trigger finger persists despite the injection, surgical release can be curative and involves cutting the A1 pulley. This procedure is done under local anesthesia in the operating room as either an open or a percutaneous procedure. With the open technique, an incision is made over the A1 pulley site, and the pulley is divided under direct visualization. For the percutaneous technique, a 18-gauge needle is used to divide the pulley without direct visualization. Potential complications of either procedure include digital nerve injury, bowstringing of the tendon (especially if the A2 pulley is divided), infection, hematoma, and persistent pain. Other reasons for surgery to be considered include a digit that is stuck in flexion and cannot be reduced and trigger thumb in an infant. Occasionally, a reduction flexor tenoplasty is performed, which involves cutting out the bulbous swelling of the tendon so that the tendon is smooth and glides without hindrance through the pulley.

Trochanteric Bursitis

Trochanteric bursitis is inflammation of the bursa that lies on the outside (lateral) aspect of the hip, known as the greater trochanter of the femur bone. Bursitis can result from both overuse (chronic) and trauma (acute). It is common in all types of athletic and nonathletic populations.

Anatomy

Bursae are small fluid-filled sacs that are usually found around joints or bony prominences. Their purpose is to create lubrication between two uneven surfaces and provide frictionless movement. In this case, the bursa lies between the femur's greater trochanter, which is the hard bony prominence on the outside of the hip, and a strong tendon known as the iliotibial (IT) band. The IT band runs from the top of the hip, down the side of the leg, to the knee. Its main function is to abduct the leg as if to kick one's leg out to the side. However, when moving the hip forward and backward, as when walking, running, swimming, and biking, the IT band tends to rub over the greater trochanter and may irritate the bursa. When the bursa becomes inflamed, it swells and becomes compressed between the bone and the tendon, thus creating pain.

Causes

Trochanteric bursitis is most often caused by overuse or direct trauma. Direct trauma such as a fall that causes the patient to land on the lateral hip region or a direct blow to the outer hip is more common in women and in the middle-aged or elderly population. However, direct trauma is frequently seen in contact and collision sports as well. These falls or blows will cause bleeding (hematoma) into the bursa, which then results in swelling. Usually, these hematomas are rapidly absorbed by the body, but not infrequently, they may result in scarring, adhesions, and calcifications, leading to a more chronic type of bursitis.

More commonly, chronic repetitive trauma is involved, which can occur from merely running or walking. Conditions that predispose patients to this type of trochanteric bursitis include postural abnormalities, which can be caused by scoliosis, degenerative spinal conditions, a wide pelvis (female runners), hip and knee arthritic conditions, leg length differences, flat feet, high-arched feet, overpronation of the feet, or even oversupination of the feet at heel strike. Improperly fitting shoes, worn-out shoes, running on uneven or hard (cement) surfaces, and sudden increases or changes in training are other causes of trochanteric bursitis. Another cause occurs in cycling when the seat is too high and the cyclist has to rock from side to side when pedaling, which results in repetitive sliding of the IT band over the bursa. At times, the bursitis develops spontaneously without any apparent cause.

Symptoms

Patients affected by trochanteric bursitis will complain of a deep ache or burning pain over the greater trochanter on the outside of the hip. It will usually be worse with activity and may be worse both after rising in the morning or after prolonged sitting. It may get better after the first few steps only to recur later after walking for a ½ hour or more. The pain may radiate down the side of the leg toward the knee or ankle or into the buttock. The pain is usually worse at night while trying to lie on the affected side.

Diagnosis

The diagnosis of trochanteric bursitis is usually clinical. A typical history can be confirmed on physical examination. There will be maximal point tenderness to palpation directly over the greater trochanter. Point tenderness just superior to the trochanter is usually more indicative of gluteus medius tendinitis, while point tenderness just posterior to the trochanter is more indicative of piriformis tendinitis. Pain will also be present during gait when the hip goes from flexion to extension. Pain may occur with passive hip adduction, abduction, or external rotation but not with internal rotation. Pain may also be present with active hip abduction. Rarely, a limp will be present.

An X-ray can be obtained to ensure that there are no bone spurs, calcifications, or arthritis that could be contributing to the problem. Occasionally, a magnetic resonance imaging (MRI) scan or a bone scan may be done if the diagnosis is unclear or if the problem does not resolve with treatment. These tests will help rule out tumor, occult fracture, or necrosis of the bone.

Treatment

The goals for treatment include reducing pain and inflammation, as well as preserving mobility and preventing recurrence. Treatment recommendations may initially include a combination of rest, heat and/or cold application, stretching and strengthening exercises, activity and shoe modification, pain medication such as acetaminophen or ibuprofen, and osteopathic manipulation along with correction of any anatomical or biomechanical asymmetry (orthotics/heel lifts). Cross-training incorporating low-impact activity such as biking, swimming, or using elliptical machines can minimize the pain and allow for continued exercise. Typically, resolution of symptoms occurs within 2 to 6 weeks of treatment. For persistent symptoms, more advanced treatments may be required, such as physical therapy, cortisone injections, or surgery.

While only a limited number of controlled studies have proven the usefulness of physical therapy for this condition, a specific and goal-directed program can often reduce symptoms. Physical therapy can be incorporated to teach the patient a home exercise program, emphasizing stretching specific tendons, including the IT band and tensor fascia lata, as well as stretching the external hip rotators, quadriceps, hamstrings, adductors, and hip flexors. Strengthening exercises should focus on the lower abdominals and the gluteal muscles. Other modalities used in physical therapy can also be employed, such as *phonophoresis,* which uses sound waves to allow for deep penetration of topical medications, and *iontophoresis*, which uses an electrical current to allow corticosteroids to penetrate the skin and minimize the inflammation to the bursa. Ultrasound therapy and soft tissue massage may also be helpful.

Cortisone injections are an important option within the comprehensive treatment plan. Randomized, controlled clinical trials have shown that corticosteroid and lidocaine injection for trochanteric bursitis is an effective therapy with a prolonged benefit. Trochanteric bursa injections are often performed without radiographic guidance, and a local anesthetic can first be used as a diagnostic injection. The needle is advanced to the greater trochanter (with contact on the bone being made to confirm depth and appropriate placement) and is then withdrawn slightly so that it is located within the bursa. The local anesthetic can then be injected directly into the bursa. If appropriate relief is achieved, this would be considered confirmation of trochanteric bursitis as the cause of the pain. This injection of local anesthetic can then be followed by the administration of steroids. An injection of 12 to 24 milligrams (mg) of betamethasone or 40 to 80 mg of methylprednisolone is commonly used. This injection may be repeated at 4 to 6 weeks if pain relief has been less than 50%. In most cases, in which the diagnosis of trochanteric bursitis seems straightforward from the clinical evaluation, a diagnostic injection with local anesthetic is not necessary prior to the corticosteroid injection. Patients should be made aware of the risks of injection prior to the procedure.

Surgery is rarely indicated and is often reserved for severe cases that are recalcitrant to months of the conservative treatments discussed above. There are several surgical techniques that have been used in the past. One such technique involves excision of the bursa via incisions in the IT band over the greater trochanter. Another procedure is a trochanteric reduction osteotomy, which removes a portion of the trochanter. Arthroscopic bursectomy is the third option and allows for excision of the bursa using a scope. Finally, release and lengthening of the IT band is another surgical alternative. Surgical intervention carries the increased risk of anesthesia along with the direct surgical risks and should be considered only after appropriate nonoperative interventions have been exhausted.

Trunk Injuries

Injury to the trunk during sports is common and generally includes muscle and bone injury, but it can also include more serious injury to the internal organs. Examples of muscle injuries include strains of large muscle groups, such as the rectus abdominus and perivertebrals. Bones such as the lumbar vertebrae can sustain chronic injury, as in spondylolysis, or acute injury, as with transverse process fracture in blunt trauma. However, the predominance of musculoskeletal injuries may lead the practitioner to overlook a more serious injury. Below are some important and sometimes life-threatening injuries to be considered in the athlete with injuries to the trunk.

Pneumothorax

A pneumothorax may occur spontaneously during a sporting event or acutely after blunt or penetrating trauma in sports activity. It occurs when air is introduced between the lung and the pleura, the membrane that surrounds the lungs. Depending on the mechanism with which the contact between these two surfaces was compromised, air can accumulate and compress the lung, resulting in chest pain and shortness of breath. This can lead to respiratory failure. If enough air accumulates, the pressure from this trapped air can compress the heart and limit its ability to fill and then pump blood, leading to cardiovascular collapse and death.

Spontaneous pneumothorax is caused by a ruptured bleb at the surface of the lung and leads to escape of air from the lung into the space between the lung and the pleura. It is most common in tall, thin males but can occur in any age-group or gender. It can occur at rest and also during vigorous exercise and can be mistaken for a musculoskeletal chest pain. The athlete generally will complain of moderate to severe pleuritic sharp pain on the left or the right, associated with varying degrees of shortness of breath. Generally, a spontaneous pneumothorax is small and stable, but it can progress to the life-threatening complications described above. The patient needs to be transported to a medical facility where imaging can be done and a thoracostomy performed to relieve the pressure. In the event that immediate transport is unavailable and the patient is experiencing cardiovascular collapse, an emergent decompression needle thoracostomy can be performed by qualified medical professionals.

Traumatic pneumothorax can be caused by blunt or penetrating forces. The force required to cause a pneumothorax from blunt trauma is generally significant and has associated injury, such as rib fractures. Rib fractures require only pain medication as treatment, but all suspected rib fractures require a plain radiograph to rule out the diagnosis of pneumothorax. For penetrating trauma, such as skate-induced chest wall laceration in ice hockey, a plain radiograph should be ordered to rule out the diagnosis of pneumothorax even when suspicion is low for it. Any lacerations or punctures to the chest wall should not be explored, as this can cause a pneumothorax in some cases. Complications and treatment are the same as described above.

Cardiac Contusion

High-speed blunt trauma to the chest can result in injury to the heart, the most dramatic effect of which is sudden death, or commotio cordis. Cardiac contusion in sports is rare but occurs when forces are transmitted from the ballistic (as in baseball) or opposing player (as in American football) to the chest of the athlete. The myocardium is bruised, which causes pain and can affect cardiac output and in rare cases can lead to failure. The diagnosis should be considered in any athlete who complains of chest pain after a high-speed impact. Evidence of significant injury, as with sternal fracture/injury or multiple anterior rib fractures, should increase suspicion of cardiac injury. Emergency evaluation includes a chest radiograph, electrocardiogram, and cardiac enzymes. If there is a high suspicion of cardiac contusion, an echocardiogram may be taken and/or the patient may be kept under observation.

Solid Abdominal Organ Lacerations and Contusions

Blunt trauma to the abdomen can occur in all contact sports, including football, men and women's hockey and soccer, and countless others from professional-level activities to recreational sports such as bodyboarding. Forces transmitted from an object, such as a helmet or a knee, to the abdomen can be absorbed by the liver, spleen, or kidney. In the event that these forces are sufficient to cause bleeding, these organs may become bruised and occasionally lacerate. Lacerations can cause bleeding within the organ and impair the functioning of the organ itself. This is often seen with a kidney laceration, which results in decreased long-term renal function. Occasionally, the bleeding is not contained within the solid organ, and blood accumulates in the abdomen. If the bleeding is brisk or the injury is not identified in time, this bleeding can result in severe blood loss and occasionally in death. If surgery is indicated, attempts should be made to stop the bleeding and preserve organ function. As both are not always possible, occasionally the damaged solid organ will need to be removed.

Solid organ injury should be considered under the right clinical circumstances. In cases where solid organ injury occurs, the history will include a mechanism that fits clinically. Examples of mechanisms of blunt solid organ injury include the impact of a football helmet on the abdomen or back, a high-speed hockey puck to the stomach, or a bodyboard lodged between the abdomen and the beach sand. The athlete will complain of abdominal or flank pain with or without nausea or light-headedness. The abdomen or flank is usually tender, and in cases of significant bleeding, the pulse rate may be high and blood pressure low. Any patient with possible solid organ injury should be transported immediately to a local emergency room.

Hollow Abdominal Organ Injury

Hollow organ injury, specifically large and small bowel trauma, is unusual after blunt trauma in athletics. Historically, the athlete will have a mechanism in which a forceful blunt trauma is sustained to the anterior abdomen. Mechanisms that can cause hollow organ injury include a fall from a bicycle with impact from the handlebars, a surfboard wedged between the sand and the surfer's abdomen, or a knock from a football helmet to the abdomen. In mild cases, the athlete may complain of minimal pain associated with nausea, as in the case of a minor small bowel contusion. In case of a ruptured viscus, the athlete will have severe pain and vomiting. On physical exam, the mild small bowel contusions may be normal save for some tenderness to deep palpation. This is in contrast to the patient with a ruptured viscus, who will have severe tenderness to light palpation, rebound tenderness, as well as other evidence of an acute abdomen. The vital signs may be unstable, with a low blood pressure and fast heart rate. An initial, upright chest X-ray is the fastest and most specific way of determining if there is air in the abdomen, which would indicate a perforated viscus. Computed tomography is the most sensitive study to find evidence of a ruptured viscus, and it will also show evidence of hollow viscus contusion and injury to the solid organs. A hollow viscus perforation is a surgical emergency, whereas a contusion can be monitored clinically.

Turf Toe

The term *turf toe* has become a commonly accepted name referring to a sprain involving the hallux (great toe) metatarsophalangeal (MTP) joint of the foot. The name was first coined in 1976 after it was found that the frequency of injuries to the MTP joint was much greater during competition on artificial playing surfaces. The injury is fairly common; it is seen most often in football, but it also occurs in other sports such as wrestling, basketball, and dance, among others. Because this particular joint plays a key role in running, sprinting, and cutting, an injury can result in significant functional disability. It is thought to be underreported and not always appreciated as the significant injury that it may be or can become if it is not appropriately managed.

Anatomy

The anatomy of the forefoot is intricate and quite complicated. The MTP joint of the hallux involves a metatarsal (long bone) with a rounded, cartilage-covered surface at the end, which joins with the concave base of the phalanx (toe bone). Stability of the MTP joint comes from medial (inside) and lateral (outside) collateral and metatarsosesamoid ligaments in addition to a strong plantar plate. There are also several different muscle tendons that run along either side and underneath the joint, attaching onto the phalanx. These structures together make up the intricate capsuloligamentous complex of the first MTP joint.

Motion in the joint consists primarily of plantarflexion (downward) and dorsiflexion (upward). Passive range of motion varies widely from 3° to 43° of plantarflexion and from 40° to 100° of dorsiflexion.

Causes

The two primary causes of turf toe are the advent of artificial playing surfaces and the coinciding introduction of flexible-soled turf shoes. Artificial playing surfaces were introduced in the 1960s, and with that came a dramatic increase in the number of turf toe injuries. This is due to the increased friction caused by the artificial surface and shoe interface. When artificial turf was introduced, players were typically wearing a grass cleat with a metal plate in the sole, which attached to the cleats and added stability to the forefoot. After playing on the artificial surface, players complained of traction problems, which led to the introduction of a flexible turf shoe. Both caused the incidence of turf toe injuries to increase dramatically.

As artificial turf ages, it stiffens. This has also been thought to contribute to the increasing incidence of turf toe injuries, although studies have not validated this hypothesis. Since natural playing surfaces are once again becoming the standard, it is expected that turf toe injuries will also decrease.

Mechanism of Injury

The most common mechanism of injury is hyperextension of the great toe. This often occurs with tackling in American football, where the forefoot is fixed on the playing surface with the heel raised in a dorsiflexed position. A force from the tackler is thus directed down the lower leg into the foot, causing an exaggerated dorsiflexion and subsequent hyperextension of the great toe. This hyperextension can lead to varying degrees of injury to the plantar plate, capsule, and collateral ligaments or the cartilage surface of the bone.

Although most turf toe injuries occur with hyperextension, other mechanisms have been described as well. Hyperflexion, or "sand toe" (termed so because of its high propensity in sand volleyball players), injury is sometimes considered a variation of turf toe, although it often has a different clinical course and, thus, may need to be considered separately.

Varus (bending inside) and valgus (bending outside) are two other described mechanisms. Valgus is most commonly seen in a football lineman who is pushing off from a stance. Varus is rarely seen but can occur when an outward force is applied to a fixed forefoot.

Diagnosis

The diagnosis is made by first eliciting how the injury occurred and, if available, watching a video replay of the incident. Patients may present with a single acute or multiple episodes of trauma. Classically, the MTP joint will exhibit tenderness, swelling, and pain with movement. At this point, if a turf toe diagnosis is suspected, X-rays with several different views should be obtained to assess for a capsular avulsion, sesamoid fracture or migration, impaction injury, or separation of a bipartite sesamoid. A magnetic resonance imaging (MRI) scan is usually ordered if there are abnormalities on X-ray. MRI is the best tool to assess soft tissue and cartilage damage, as well as further evaluate for bony abnormalities. This will aid in grading the injury, as well as formulating a treatment plan and making an overall prognosis.

Most injuries are graded on a scale of I to III, with III being the most severe. Grade I is a stretch injury to the capsuloligamentous complex, with minimal symptoms associated with it. Grade II is a partial tear to the capsuloligamentous complex, with pain with weight bearing, bruising, and restricted range of motion. Grade III is a complete tear of the capsuloligamentous complex, with an associated disruption of the plantar plate from the metatarsal neck, impaction of the phalanx into the metatarsal head, and sometimes movement of the sesamoids. There is severe pain, swelling, bruising, and motion restriction, along with inability to bear weight.

Treatment

The initial treatment of an acute turf toe injury should include the RICE protocol of *r*est, *i*ce, *c*ompression, and *e*levation. Athletes with Grade I injuries often can return to play immediately, although often toe taping and/or using a stiff insole may be necessary or desired for protection. Grade II injuries will often require up to 2 weeks of rest. Patients with Grade III injuries should remain non–weight bearing for several days and have prolonged rest, usually for 4 to 6 weeks. The athlete should slowly progress from walking to running to cutting and, finally, sport-specific activities. Painfree range of motion of 50° to 60° of upward flexion has also been proposed as a criterion for returning to play. Operative treatment is reserved for the most severe turf toe injuries, including large capsular avulsions with an unstable joint and diastasis of a bipartite sesamoid, or after conservative therapy has failed.

U

Ulnar Neuropathy

Ulnar neuropathy is inflammation or compression of the ulnar nerve, resulting in paresthesia (numbness, tingling, and pain) in the outer (ulnar) side of the arm and in the hand near the little finger. The ulnar nerve provides motor control to the muscles in the forearm and hand. It also provides the sensations of touch, temperature, and texture to the volar surface, or undersurface, of the forearm, the palm, and specifically the fourth and fifth digits of the hand circumferentially. Ulnar neuropathy that originates at the elbow is most common, although it can also be caused by injury to the nerve as it passes through the wrist.

Approximately 40% of Americans experience some form of ulnar neuropathy at least once during their lifetime. While the ulnar nerve is structurally identically in men and women, men tend to develop ulnar neuropathy more than do women. The reason may be that men generally have less fat overlying the elbow to protect the exposed nerve, or it may be due to differences in work- or sports-related stresses. The onset of ulnar neuropathy is often insidious. As a result, many of those who are affected are middle-aged or older adults. Demographic risk factors include a family history of diabetes, alcoholism, and HIV (human immunodeficiency virus) infection. Direct compression from pressure on the elbow can trigger ulnar neuropathy; therefore, people who have desk jobs and spend extended periods of time working on computers are at risk of developing the disorder. Ulnar neuropathy is variously known as *bicycler's neuropathy, cubital tunnel syndrome, Guyon canal syndrome,* and *tardy ulnar palsy*. Its occurrence is most notable in cyclists from prolonged compression on the nerve while gripping the bicycle handlebars; yet it is often seen in sports such as tennis, baseball, softball, and golf, where a significant amount of time is spent gripping sports equipment.

Anatomy

The anterior primary rami of the eighth cervical and first thoracic (C8 and T1) vertebrae contribute to form the medial cord of the brachial plexus. The medial cord leaves the axilla as the ulnar and median nerves. Though the ulnar nerve starts from the cervical nerve roots, its target motor and sensory innervations are located in the medial forearm and hand. The ulnar nerve travels along the posteromedial aspect of the arm, pierces the intermuscular septum, and courses beneath the medial head of the triceps. It enters the elbow at the ulnar groove between the medial epicondyle and olecranon. Then the nerve passes through the cubital tunnel into the forearm deep into the flexor carpi ulnaris. At the wrist, the ulnar nerve enters the hand distal to the ulnar styloid through the Guyon canal. The ulnar nerve is most susceptible to injury at these two tunnel sites. The muscles innervated by the ulnar nerve are the flexor carpi ulnaris, the flexor digitorum profundus, the palmaris brevis, the interossei muscles, the medial two lumbricals, the flexor

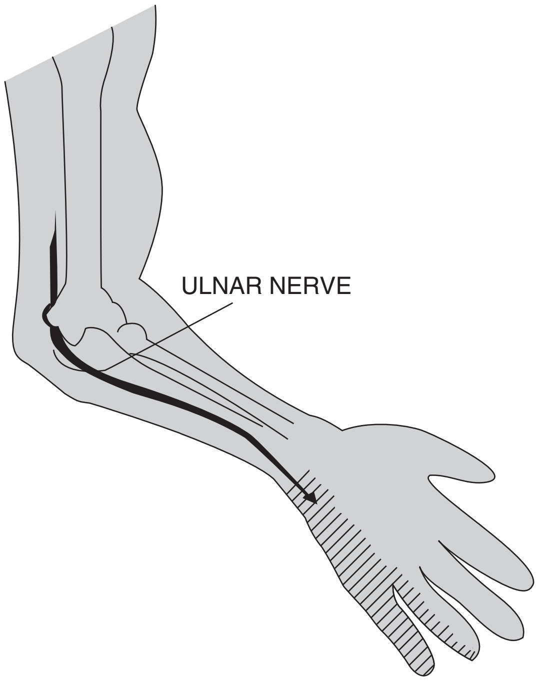

Figure 1 Course of Ulnar Nerve, Showing Sensory Innervation in the Forearm and Hand

pollicis brevis, the adductor pollicis, and the hypothenar muscle group. The ulnar nerve provides sensory innervation to the medial palmar and dorsal aspects of the forearm (including the elbow) and hand and supplies sensation to the small finger and medial one half of the ring finger (Figure 1).

History and Physical Exam

Ulnar nerve injuries can present initially as paresthesias anywhere along its sensory distribution. A typical complaint would be a feeling of "pins and needles" over the ring and small finger or medial forearm. Symptoms can include pain, weakness, and fine motor deficits. On examination, there may be clawing of the ring and small fingers or wasting of the intrinsic hand muscles.

Injuries at any point along the ulnar nerve can have distal manifestations in the hand and fingers. This makes it difficult to pinpoint the exact site where the ulnar nerve is injured. One exception is lesions that occur at the Guyon canal. The dorsal cutaneous sensory branch of the ulnar nerve leaves the main ulnar nerve prior to the Guyon canal. Therefore, lesions at or distal to the Guyon canal would not present with dorsal sensory deficits. Identifying the correct location where ulnar nerve function is compromised affects rehabilitation and treatment recommendations. Other conditions in the differential diagnosis for ulnar neuropathy should be worked up if suspected, including C8-T1 radiculopathy, brachial plexopathy, thoracic outlet syndrome, peripheral polyneuropathy, and overuse syndromes.

There are certain provocative tests that may trigger ulnar nerve symptoms and help localize the lesion. These tests include the following:

- *Elbow flexion test:* Similar to the Phalen test for the median nerve and carpal tunnel syndrome, this maneuver can elicit symptoms due to cubital tunnel syndrome. The elbow is placed in full flexion with wrist extension for 3 minutes. A positive test is when numbness, tingling, and/or pain occur over the ulnar distribution.
- *Froment sign:* The patient is asked to hold a piece of paper between the thumb and the index finger. Patients with ulnar nerve injury will have difficulty holding onto the piece of paper and will compensate with the flexor pollicis longus muscle by flexing at the thumb's interphalangeal joint.
- *Tinel sign:* Percussion over the ulnar groove, medial epicondyle, cubital tunnel, or Guyon canal may reproduce symptoms. This is a very nonspecific test with variable results.
- *Wartenberg sign:* The small finger is in an abducted position at rest due to muscle weakness and asymmetric pull from unaffected muscles.

Imaging and Testing

Radiographs of the upper extremity are often obtained, but in the absence of associated musculoskeletal trauma, they rarely demonstrate abnormalities that aid in the diagnosis or treatment of ulnar neuropathy. The most frequent findings demonstrate degenerative changes, fractures, or bone spurs that can contribute to nerve impingement. Conversely, electrodiagnostic tests, such as nerve conduction studies and electromyography

(EMG), are extremely helpful to accurately localize the lesion and determine the severity of injury. Occasionally, there are multiple sites of injury to the ulnar nerve that can be distinguished on electrodiagnostic testing.

Specific Ulnar Nerve Injuries

Some specific ulnar nerve injuries are listed below.

- *Ligament of Struthers.* As the ulnar nerve passes through the intermuscular septum in the upper arm, it passes under a tough fascia layer called the arcade or ligament of Struthers. Here, the ulnar nerve can become entrapped. Conservative management tends to yield poor results; therefore, a surgical release of the ligament is often necessary.
- *Ulnar Groove.* The ulnar groove is a common site for ulnar nerve injury. Here, the nerve is at risk of being injured by direct trauma (fractures), traction injury such as valgus stress at the elbow from throwing (valgus overload syndrome), and recurrent subluxation of the nerve in and out of the groove. Compressive injury can occur at this site from leaning on the elbows or from the application of a tight cast, splint, or brace. Elbow flexion often reproduces or exacerbates the painful symptoms. Treatment options begin with conservative pain management and occupational therapy to maintain elbow range of motion and forearm strength. Biomechanical evaluation and loose protective padding or splinting around the elbow can help reduce the symptoms. Surgery (ulnar nerve release or ulnar nerve transposition) may be indicated if conservative treatment fails.
- *Cubital Tunnel Syndrome.* The ulnar nerve enters the forearm through the cubital tunnel under the medial epicondyle and olecranon. The borders of the cubital tunnel are the two heads of the flexor carpi ulnaris, the medial collateral ligament of the elbow, and the pronator aponeurosis. Ulnar nerve entrapment can occur anywhere along this tunnel. Injuries are typically due to repetitive motion. Treatment tends to be conservative and similar to the treatment, described above, for ulnar groove injuries. A surgical cubital tunnel release is reserved for those who fail conservative management.
- *Guyon Canal Compression.* The Guyon canal is formed by the pisiform bone, the hook of the hamate, the flexor carpi ulnaris, and the carpal ligament. The dorsal cutaneous sensory branch of the ulnar nerve leaves the main ulnar nerve proximal to the Guyon canal. Therefore, compressive lesions at or distal to the Guyon canal would not present with dorsal sensory paresthesias. Bicycle riding (*handlebar palsy*), push-ups, ganglion cysts, or lipomas can all cause ulnar nerve compression at the Guyon canal. Treatment includes activity modification (wrist padding or holding the handlebar from the side position instead of the top), stretching exercises, and nonsteroidal anti-inflammatory drugs (NSAIDs). Surgical interventions can be considered if symptoms fail to improve.
- *Hypothenar Hammer Syndrome.* Hypothenar hammer syndrome is caused by repetitive impact on the hand causing ulnar nerve injury at the Guyon canal. In addition to nerve injury, there can also be distal ischemia with arterial thickening, thrombosis, and possible aneurysm formation. In addition to the symptoms above, other complaints may include cold intolerance and pain over the palm of the hand. Treatment adjuncts to the above include vasolytic agents or vascular repair.

Conclusion

Ulnar nerve injuries are common. While the presenting symptoms are similar in most cases, it is essential to identify the exact anatomic location of compression or injury in order to properly treat this condition. Athletes who present with signs and symptoms of ulnar neuritis or ulnar neuropathy are often difficult to treat due to the frequent repetitive nature of the trauma induced from gripping sport-specific equipment. Modifications in grip technique as well as padding and other adjustments may help significantly alleviate the symptoms of this condition. When the etiology of the ulnar neuropathy is unclear, electrodiagnostic testing is helpful and should be performed. Referral to a sports or orthopedic specialist is indicated for refractory and frequently reoccurring cases.

Ultimate Frisbee, Injuries in

Ultimate Frisbee (also known as *Ultimate,* in reference to a disc brand sometimes used in the sport) is a noncontact sport that is played in 42 countries by hundreds of thousands of men, women, and youth. In 2007, it was estimated that 824,000 people in the United States reported playing Ultimate at least 25 times a year. The Ultimate Player's Association (UPA) is the national governing body of the sport in the United States, while the World Flying Disc Federation (WFDF) provides international governance for the sport. Ultimate is played formally at the club, college, master's, and youth levels. In 2001, Ultimate debuted as a medal sport at the World Games in Japan.

Overview of the Sport

It is generally agreed that the sport was developed in 1968 on the east coast of the United States, and the first official rules for the game were codified in 1970. Despite having spread worldwide, the sport has had very little media coverage and is unfamiliar to many people. A brief overview follows.

The game is typically played by two teams of seven individuals on a regulation field that is 70 yards (yd; 64 meters [m]) by 40 yd (36.6 m) with end zones 25 yd (22.86 m) deep, approximating the dimensions of an American football field. Though any surface, indoors or outdoors, may be used, generally an Ultimate game is played outdoors on a grass field (variants of the traditional game include indoor and beach Ultimate). A plastic disc (the "Frisbee") whose regulation weight is 175 grams is used. Individuals try to advance the disc down the field, and scoring is achieved each time the offense completes a pass into the defense's end zone. Substitutions are allowed after scores or during injury time outs. A game is won when a specified number of points are accumulated (typically an odd number from 13 to 21), with two clear points on the opponents score, or after 80 minutes of play.

Physical contact between players, including picks and screens, is minimized in the game. The offense may advance the disc in any direction by completing a pass to a teammate. Players may not run with the disc after catching it. If a pass is not caught by a teammate, the defense immediately takes over possession and becomes the offense. Change of possession can also occur by the defense intercepting a pass or when an individual holds the disc for longer than 10 seconds. Ultimate is thus a transition game like basketball.

Several unique rules of Ultimate bear special mention. The game is self-refereed; that is, players are responsible for resolving any disputes at all levels of the game. Calls are typically made within the flow of play. There are clear rules for resolution of disputes, so self-refereeing does not lead to extended discussion or uncertainty about how to continue. The game, therefore, is interrupted much less frequently than many other team sports.

True to its origins in the countercultural 1960s, Ultimate is a sport that aims to be inclusive (teams are often of mixed gender) and in some important respects de-emphasizes competition. The sport places a high value on sportsmanship and fair play, codifying this in the rules as an overriding ethic known as the "Spirit of the Game." Ultimate players are often serious, motivated, and competitive athletes who nevertheless place a premium on the basic joy of play. According to Ultimate Players Association's *Official Rules of Ultimate* (11th edition), "such actions as taunting opposing players, dangerous aggression, belligerent intimidation, intentional infractions, or other 'win-at-all costs' behavior are contrary to the Spirit of the Game and must be avoided by all players" (sec. I. Introduction: B. Spirit of the Game, p. 2). Though this has not been studied, it may be expected then that there might be fewer injuries incurred consequent to fighting among players.

It can be difficult to find other sports with which to compare Ultimate. The sport combines the nonstop movement and athletic endurance of soccer with the aerial passing skills of football. Some commentators have even compared the game with rugby: Though widely dissimilar in their approach to contact, both games involve plenty of running and frequent, deliberate diving to the turf. Some rules of the game, such as self-refereeing and the codified sportsmanship ethic, are almost unique. Overall, Ultimate is a team sport fulfilling the expected requirements of a team sport such as soccer—for example, skill, fitness, sportsmanship, and organization.

Injuries

Like other sports defined as "noncontact," there is ample opportunity for Ultimate players to be involved in collisions, either with each other or with the ground. The nature of the game involves frequent cutting and sprinting, which can inevitably lead to muscle strains, ankle sprains, and knee injuries.

It is a common practice in Ultimate to dive full-length, propelling one's body horizontal to the ground, to catch a low disc. This maneuver is a signature moment in an Ultimate game, and is known as "laying out" or "going ho" (as in "going horizontal"). Laying out is a skill, like sliding in baseball, that can be taught properly: As the disc is caught, the whole body rolls in a twisting motion as it hits the ground, dissipating forces over a broad area from the ulnar aspect of the forearm to the torso and buttocks. Predictable consequences, including shoulder, arm, and rib injuries or severe friction injuries to the skin, can result if the layout is not executed correctly.

To perform at high levels, the player must be fit. As a transition game with little stoppage time, Ultimate places unresearched but predictable demands on the body. While on the field, players are almost continuously moving and are frequently sprinting. In terms of strenuousness, Ultimate would likely then have similar physiological demands to soccer, another high-dynamic/low-static sport. It would be expected that players attempting Ultimate without the requisite levels of endurance, strength, speed, and flexibility would put themselves at higher risk of injury.

Unfortunately, there has been little research done on the injury patterns seen in Ultimate. A review of the relatively sparse literature found two surveys of injuries seen in the sport; the references can be found in the Further Readings at the end of this entry.

The first survey, published in 1991, assessed injuries that occurred in tournaments played in Europe from 1986 to 1990. The survey reported the following:

- Of all injuries, 66.6% affected the lower limbs; the most common injury involved a strain of the thigh muscle.
- Skin injuries, including friction burns, occurred at a higher rate than seen in other similar sports.
- "Minor" knee ailments such as patellar bursitis were more common than "major" injuries such as anterior cruciate ligament (ACL) tears.
- The pattern of knee injuries in general was quite different from that of many other sports and was found to be predominantly overuse injuries.

This study noted that three factors appeared to have the greatest influence on the sport's injury pattern: (1) the preparticipation fitness level of the player, (2) the organization of a tournament and squad size (more games and smaller squads allowing fewer substitutions, resulting in more frequent injury), and (3) the state of the field (hard, packed, and stony fields causing more skin and soft tissue injuries).

The study went on to recommend injury prevention practices, including clothing such as bike shorts and soft protectors on the elbows and knees to minimize the skin exposed to trauma. Though this has not been studied, such protective measures would be expected to minimize the number of lacerations, abrasions, and incidents of bursitis seen in the sport.

The second study, published in 2006, was based on a self-reported survey administered to athletes at an American tournament sponsored by the UPA in 2002. The survey asked players to report retrospectively injuries sustained in their careers; the study reported the following:

- Of the players surveyed, 71% had sought medical care.
- Eighty-eight percent had missed an Ultimate game or practice due to injury.
- Injuries included muscle strains (76%) and ankle (65%), knee (53%), shoulder (37%), head (30%), and rib (21%) injuries.
- A third of shoulder injuries occurred from a "layout" maneuver.
- A third of head injuries resulted in concussion.

The authors concluded, "The results of this survey demonstrate that Ultimate Frisbee injuries are common, that players are plagued with recurrent injuries, and that medical care is often sought."

Both studies noted that hand injuries were surprisingly infrequent. Given the fact that players must catch a typically fast-moving, hard plastic disc or as defenders be expected to block a throw at the point of release, hand injuries might be expected to be more common; however, in the British study, the rate of injury to the hand was only 5.7%, and in the American study, the rate was 8%.

Ultimate, like many other sports, can put participants at risk from environmental hazards, such as heat illnesses and lightning strikes. Other entries in this encyclopedia can be consulted to review the management of these conditions.

An unusual tradition in tournament Ultimate bears a final note: One of the regular prizes given out at some tournaments is for the "worst injury." Like "extreme sports" such as snowboarding or surfing or like a conventional and rugged sport such as rugby, there is a cultural emphasis in Ultimate on injuries as almost a badge of honor. Injuries preventing participation are not valued as they keep the participant from playing; but a laceration or severe abrasion that does not prevent play can be storied. Some have speculated that in such sports, injury rates may be higher as participants seek this unique "reward," playing intensely or beyond the limits of their endurance. It would be interesting to do more research on this phenomenon.

Overall, much more study specific to sports medicine is needed in this relatively new and growing sport. Increased injury surveillance can better elucidate injury patterns, and subsequent preventive measures might be put in place. Research into preparticipation conditioning levels might inform injury prevention practices. Investigations into environmental hazards or protective clothing might likewise reduce injury rates. Unique aspects of the sport—the "Worst Injury of the Tournament" award and "The Spirit of the Game"—could be studied and their effect on injury patterns and athletic health elucidated.

Ultrasound

Ultrasound technology has been used widely in the medical field for visualization and diagnosis of many conditions, including pregnancy, abdominal problems, and blood clots. More recently, the use of ultrasound in diagnosing and treating conditions in sports medicine has become more prevalent. Ultrasound imaging provides excellent visualization of tendons, ligaments, muscles, nerves, certain joints, and bones. It is exceptionally helpful in diagnosing tendon damage, ligament tears, and muscle strains. Sports medicine physicians frequently use ultrasound to make a particular diagnosis and guide their treatment recommendations.

Ultrasound technique

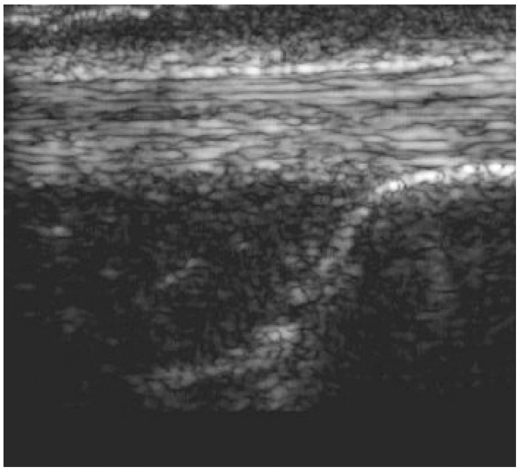
Source: Photo courtesy of Joel M. Kary, M.D.

Ultrasound Principles

An ultrasound machine uses a transducer that is connected to the monitor and computer of the machine (see photo, top of right column). The transducer is the device actually applied to the skin, using coupling gel, when images are being obtained. Electrical energy is transformed into sound waves by crystals in the transducer. This is called the piezoelectric effect and is fundamental to all ultrasound technology. Ultrasound is unique because it uses these sound waves to produce an image instead of using radiation, which is used for producing images for X-rays or computed tomography (CT). Ultrasound waves penetrate the skin and reflect back to the transducer after hitting certain tissues under the skin. This reflection of sound waves is converted into the images seen on the screen when performing a diagnostic ultrasound exam. Tissue that reflects the sound waves strongly appears bright white and is considered *hyperechoic*. (see image, bottom of right column). Tissue that poorly reflects sound waves appears dark and is considered *anechoic*. Tissue that falls somewhere in the middle of this spectrum is considered *hypoechoic*. Transducer frequency is an important concept for diagnostic ultrasound and is measured in megahertz (MHz). The higher the frequency of the transducer, the higher the resolution of the images obtained. However, higher-frequency transducers do not penetrate very deep, which limits the depth at which images can be obtained. Lower-frequency transducers penetrate deeper but do not provide as good image resolution as higher-frequency transducers.

Tendon Pathology

Athletes frequently encounter the pain of tendinitis when training and competing in their chosen sport. Tendinitis that does not heal well can become chronic, developing into tendinopathy. Tendinopathy occurs after the inflammatory response by the body has stopped but the tendon has not fully healed. Ultrasound demonstrates very well the changes associated with tendinopathy, such as partial tears, thickening, and cyst formation. Tendons normally appear as hyperechoic structures with fiber-like architecture and are imaged well with ultrasound due to their close proximity to the skin surface. A normal tendon will appear as smooth parallel lines of fibers without interruption or thickening, as demonstrated in the image of the Achilles tendon.



Normal Achilles tendon viewed with ultrasound. (Note that the image is necessarily of low resolution.)

Source: Photo courtesy of Joel M. Kary, M.D.

Tendinopathy, commonly found in patellar, quadriceps, and Achilles tendons, will appear thickened with areas of hypoechogenicity. Abnormal blood vessel formation sometimes occurs with tendinopathy, and this can be picked up using power Doppler settings. Power Doppler provides visualization of small blood vessels with slow flow rates, which is typical of abnormal blood vessels in tendinopathy. Ultrasound is superior to magnetic resonance imaging (MRI) when imaging tendons because it can provide high-resolution images of the individual fibers of the tendon. Tendon ruptures and tears also occur commonly in athletes. Once again, ultrasound images will clearly visualize the disruption of the tendon fibers and any blood filling the tear. In addition, the tendon can be viewed in motion while obtaining ultrasound images, providing a dynamic nature to the examination. This can be helpful in determining the size of the tendon tear and how many fibers are still intact. Rotator cuff tendon tears of the shoulder are common and are easily visualized using ultrasound.

Ligament Pathology

Ligaments appear as hyperechoic, tightly arranged, fibrillar structures providing a soft tissue connection between bones. Ligament sprains and tears occur in many sports, especially in those involving sprinting, sudden changes of direction, and jumping. Ultrasound provides excellent imaging of the superficial ligaments found in the elbow, ankle, and knee. Complete rupture of a ligament will appear as an interruption to the ligament fibers, usually with local fluid collection from the tear. Ultrasound provides an advantage, in comparison with other imaging modalities, when evaluating ligament tears. Because ultrasound allows for dynamic motion during evaluation, the ligament can be put under stress, and the amount of joint opening can be assessed. This is very helpful in determining the grade of a ligament tear and in prescribing appropriate treatment. Common ligament tears that can be diagnosed by ultrasound include the medial and lateral collateral ligaments of the knee, the ligaments of the ankle, and the ulnar collateral ligament of the elbow.

Muscle Pathology

Muscle tissue can be damaged during sports by a direct blow or sudden movements causing a tear. Muscle strains are exceedingly common in athletic participation and are readily visualized with ultrasound. Under visualization with ultrasound, muscle tissue appears as hypoechoic bundles separated by hyperechoic planes of tissue. Described another way, when viewed in long axis, muscle appears like veins in a leaf, and when viewed in cross section, it appears like a "starry night" pattern. A direct blow to a muscle can lead to accumulation of blood within the muscle tissue, known as a *hematoma*. This is seen as an anechoic or dark fluid collection within the muscle fibers and can be measured using ultrasound. Muscle tears are seen as discontinuity of the muscle fibers and can be accentuated by pressure from the transducer when doing an ultrasound examination.

Advantages of Ultrasound

The use of magnetic resonance imaging (MRI) or computed tomography (CT) in evaluating sports injuries can be quite expensive. In comparison, ultrasound is a less expensive imaging alternative providing superior images of many common sports injuries. Claustrophobia can be ruled out with patients undergoing ultrasound examination, which is done with the athlete seated or lying down on a comfortable exam table. Ultrasound examination can actually be performed as an extension of the physical exam, providing additional valuable information to the clinician. The body part being examined can be viewed in motion with ultrasound, observing the soft tissue and bony anatomy in "real time." This is particularly helpful in making the diagnosis of athletic injuries, the symptoms of which only occur when the tendon or muscle is in motion, such as a dislocating ankle tendon or a shoulder rotator cuff tendon getting compressed during the throwing motion. Another advantage of ultrasound is the ability to quickly perform comparisons of the injured body part with the uninjured side. As the technology has improved, ultrasound units have become more portable while still maintaining superior image quality. This portability is convenient in sports medicine as the unit can be used readily in the athletic training room or on the sideline. Ultrasound can be used to guide injections. The needle can be visualized during the entire injection, thereby ensuring accurate placement of the injection and avoiding damage to any nearby blood vessels or nerves.

Limitations of Ultrasound

The accurate use of ultrasound is operator dependent, and it requires extensive training and practice to become proficient. Errors can be made by not recognizing the difference between normal and abnormal anatomy. Athletes with a large body habitus provide a unique challenge as ultrasound waves have trouble penetrating deep enough to provide adequate images for diagnosis. Due to the inability of ultrasound waves to penetrate through bone, the visualization of deep joint structures and bone is best done using other imaging techniques such as X-ray, MRI, or CT.

Urticaria and Pruritus

Urticaria, or "hives," represents a dermatologic allergic reaction, of which there are specific types. They are typically pruritic, white, or red nonpitting plaques.

Urticaria is caused by dilation of blood vessels and edema within the epidermis. Classic hives are typically 10 to 15 millimeters (mm) in diameter, will blanch with pressure, and typically result from an allergic trigger. For athletes, classic urticaria may result from exposure to medications such as aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs), which may lead to mast cell degranulation. However, urticaria more commonly associated with exercise and sports are often smaller—2 to 4 mm typically. It is also known as *cholinergic urticaria.*

Cholinergic urticaria is part of a subgroup of urticaria known as *physical urticarias,* which are caused by physical stimulation. Physical urticarias represent 17% of all urticarias, and are most often seen in young adults. They include dermatographism, immediate-pressure and delayed-pressure urticaria, localized or generalized heat-induced urticaria, exercise-induced anaphylaxis, solar urticaria, X-ray–induced urticaria, and argon–laser induced urticaria. A person may have several types of physical urticarias, such as cholinergic urticaria along with solar urticaria. About 80% of all urticaria are idiopathic. About 10% to 20% of the population will suffer from urticaria at some point in their lifetime. If urticaria lasts for 6 weeks or more, it is defined as *chronic.* Chronic urticaria is most often idiopathic.

Cholinergic urticaria occurs when vasodilation of capillaries in the superficial dermis leads to increased transudate. It typically occurs when an antigen is bound by immunoglobulin (IgE) to release histamine from mast cells or basophils. As histamine levels increase, the level of pruritis also increases. Other factors, such as prostaglandins, leukotrienes, platelet-activating factor, and bradykinin and the complement system are also involved.

Cholinergic urticaria occur with any increase in core body temperature, which can occur with exercise. Aerobic activities and exercising in a hot environment are more likely to elicit urticaria. It is characterized by 2 to 4 mm wheals surrounded by large flares. It often starts within 2 to 3 minutes of exercise initiation, and starts on the thorax and neck and then spreads to the rest of the body. Tingling, itching, or a burning sensation on the skin may occur before the hives develop. The hives may coalesce, in which case they will resemble angioedema.

Wheezing and dyspnea may also develop in cholinergic urticaria. It may be difficult to identify cholinergic urticaria if the hives do coalesce. Those who are prone to cholinergic urticaria often also develop the same urticarial reaction with anxiety, a hot shower, sweating, or with any other elevation in body temperature. It is important to take a good history to determine if there are other triggers, such as with hot baths and showers, or with emotional stress and anxiety, or with ingestion of hot or spicy foods, to distinguish cholinergic urticaria from EIA (Exercise-induced anaphylaxis). Cholinergic urticaria is classically reproducible with exercise, stress, or hot showers, while EIA is not. There may be other signs of cholinergic stimulation, such as lacrimation, salivation, and diarrhea.

Cold urticaria is another type of urticaria that can be seen in athletes. It primarily occurs in cold-weather sports or in swimming. Wheals can be large or small, but they are generally confined to the area exposed to the cold. Diagnosis can be made with observation of hives on skin after 5 minutes of cold application and subsequent skin rewarming. The treatment consists of avoiding cold exposure and wearing protective warm equipment, as well as antihistamines.

The gold standard for diagnosis of cholinergic urticaria is passive warming, either in a warm bath or a sauna. An increase in the core body temperature of 0.7 °C to 1 °C is needed. In case there is a possibility that exercise-induced anaphylaxis is the true diagnosis, testing should be done under controlled conditions, with epinephrine, rescusitative equipment, and medical personnel at hand, and a IV set should be in place. Another test that is diagnostic is the methacholine test, where an intradermal injection of 0.01 milligram (mg) methacholine produces localized hives. However, the sensitivity is only about 30%. The passive heat challenge is the best test.

Treatment of cholinergic urticaria consists of avoidance of triggers primarily, such as bathing in hot water, and strenuous exercise in hot weather. Hydroxyzine, an H1 histamine antagonist, is an anticholinergic that has been shown to be most effective at reducing urticarial hives. Hydroxyzine, which is typically dosed at 100 to 200 mg over a 24-hour period, is most effective. In cases refractory to hydroxyzine, danazol anabolic steroid could be effective, but this treatment should be avoided at all costs, considering the side effects. Cyproheptadine may be used as adjunctive treatment if there is associated cold urticaria. Treatment of pulmonary symptoms with cromolyn sodium can be effective. For long-term treatment, an exercise program with gradual increases in duration and intensity may be effective in producing tolerance. Avoidance of obvious triggers, such as NSAIDs or aspirin before exercise is essential. Exercising with an EpiPen if there is any concern for EIA is important. However, care must be taken in athletes competing at NCAA (National Collegiate Athletic Association), Olympic, or professional levels to avoid certain medications that may be banned or restricted, such as anabolic steroids, albuterol, or decongestants.

Vegetarianism and Exercise

Vegetarian diets are common among athletes. A balanced vegetarian diet, meaning one guided by thoughtful and informed food choices, certainly may meet the needs of athletes and even be the foundation for some healthful lifelong habits. For young athletes, however, because growth is still occurring, the priority is to provide enough calories and nutrients for optimal growth and development while still supporting higher activity needs. This entry discusses the vegetarian diet as it relates to sports nutrition.

Individuals choose vegetarianism for a wide variety of reasons. Some of these include health benefits such as the prevention of certain chronic diseases, cultural beliefs, family practices, peer influences, and animal rights or environmental issues. Some athletes insist that a vegetarian diet may improve their performance. Others adopt a vegetarian diet to meet the increased carbohydrate demands of training or to assist in weight control. Of concern are those athletes who describe their dietary intake as "vegetarian" to hide restrictive dietary intake or to mask disordered eating behaviors.

Types of Vegetarian Diets

Many foods meet the criteria for a vegetarian diet. The term *vegetarian* is used to describe diets based exclusively on plant foods to those containing some animal foods. Table 1 outlines various vegetarian diets.

Vegetarian Diets and Performance

While there is no evidence that being a vegetarian gives any direct athletic advantage, healthy vegetarian athletes can perform as well as nonvegetarian athletes. A plant-based or vegetarian diet may be ideal for performance as it is generally high in complex carbohydrates. Only the caloric needs change, as plant-based diets are low in fats. Added fat, especially in the form of monounsaturated fats (olive oil, avocados, nuts, and peanuts), as well as essential fatty acids (fish and flax seed oils), may help provide additional calories to a vegetarian diet.

Vegetarianism does not greatly affect the fundamentals of optimal sports and performance nutrition. However, seeking advice from a dietitian may be beneficial in crafting an ideal performance nutrition plan.

Protein and Vegetarian Diets

Amino acids are the building blocks of protein. If a food contains the right combination of essential amino acids, it is called a *complete protein*. All animal-derived proteins and soy are complete. The remaining plant sources of protein contain many, but not all, of the essential amino acids and thus are considered *incomplete proteins*.

Previously, it had been suggested that vegetarians combine different plant foods at individual meals to ensure that all essential amino acids were provided at the same time. However, the American Dietetic Association has since stated that combining plant sources of protein meal by meal to meet

Table 1 Vegetarian Diets

Type of Vegetarian Diet	*Diet Description*
Fruitarian	Raw, dried, or cooked fruits, nuts, seeds, honey, and vegetable oils
Macrobiotic	Excludes all animal foods, dairy products, and eggs Uses only unprocessed, unrefined natural and organic cereals and grains Miso and seaweed are used as condiments
Vegan	Excludes all animal foods, dairy products, and eggs The vegan philosophy also excludes all animal products, including honey, gelatin, silk, wool, leather, and animal-derived food additives
Lacto-vegetarian	Excludes all animal foods and eggs Does include dairy products
Lacto-ovo-vegetarian	Excludes all animal foods Does include dairy products and eggs
Semivegetarian	Usually excludes red meat However, may include poultry, fish, eggs, and dairy products

the body's requirement for essential amino acids is unnecessary. Thus, as long as a variety of plant proteins are eaten throughout the day, adequate amino acids will be obtained.

A favorable eating regimen for vegetarian athletes is to ensure that protein-rich foods are included at each meal. Many athletes have limited time for meal preparation, particularly at lunch. Convenient and portable protein alternatives include ready-prepared beans (hummus, baked beans, and bean salad), nut and seed spreads (peanut butter and tahini), and ready-made luncheon meals made from soy or wheat gluten.

Along with including adequate protein, it is also crucial to obtain adequate calories so that protein is not used as an energy source. Athletes often have the misconception that the protein they consume is the only nutrient that is responsible for building more muscle. Actually, it is consuming enough calories that preserve protein for muscle repair and growth. Excess protein does not provide any advantage, and special protein supplements are generally not necessary. In summary, an athlete needs adequate protein, calories, and, most important, enough calories to spare, or make available, protein for growth and repair of tissues.

Meeting Vitamin and Mineral Needs

Athletes who are vegetarians have to include vegetarian alternatives in their diet that supplement certain vitamins and minerals that are commonly found in animal-based foods, such as vitamin D, riboflavin, vitamin B_{12}, iron, calcium, and zinc.

Vitamin D is important for bone health. Athletes need to ensure that they get adequate vitamin D from sun exposure and/or through fortified foods or supplements. Cow's milk, certain soy milks, and many breakfast cereals are fortified with vitamin D.

Riboflavin is low in vegetarian diets that do not include dairy products. It is an essential vitamin for the production of energy and thus important for athletes. Plant sources of riboflavin include fortified whole grains, soybeans, dark green leafy vegetables, avocados, nuts, and sea vegetables.

Vitamin B_{12} is needed for the production of normal red blood cells. Its deficiency may result in pernicious anemia and associated dementia. B_{12} is only found in animal products. The semivegetarian will obtain adequate B_{12} if fish and dairy products are consumed. The vegan will need to obtain B_{12}

through a supplement, nutritional yeast, fortified grains, or soymilk.

Calcium is essential for all athletes for optimal bone health. Vegetarians who do not include dairy products in their diet need to include calcium sources from plants or supplements. Athletes with low dietary calcium intake may have increased risk of bone fractures and stress fractures. Plant-based sources of calcium include kale, bok choy, turnip greens, and Chinese cabbage.

All athletes, especially female athletes, are at risk for iron deficiency. Iron plays a critical function in transporting oxygen throughout the body. There is also loss of iron due to heavy training. The absorption of iron from animal-derived foods is much higher than from plant sources. However, vitamin C significantly improves iron absorption from nonanimal sources. A diet rich in fruits and vegetables provides adequate vitamin C. Cooking in cast iron pots may also increase the iron content of certain foods. Iron-fortified breakfast cereals, spinach, beans, molasses, whole-grain products, textured vegetable protein, and some dried fruits (dried apricots, prunes, and raisins) are also good sources of iron.

In summary, with proper planning, athletes can choose a vegetarian diet that meets nutrient needs for athletic performance as well as for optimal health.

Volkmann Contracture

Volkmann contracture, also known as *Volkmann ischemic contracture,* is a permanent flexion contracture of the hand at the wrist, resulting in a clawlike deformity of the hand and fingers. It may affect a single finger or the flexor muscles of the entire forearm. It may result from injury to brachial artery and is usually associated with supracondylar fracture of humerus, sometimes consequent to a high-impact fall as in skateboarding or other sports. It can also result from an intense twist of the upper arm, falling on an outstretched hand, or severe contraction of muscles. Baseball pitchers and other athletes who participate in throwing sports such as javelin and discus are vulnerable to this condition.

Classification

Ischemia is defined as cell death due to lack of blood supply. The intensity of injury depends on the type of cell and its energy requirements.

Ischemic injuries are classified in various ways. One is according to the severity of involvement:

Grade I: Ischemia

Grade II: Ischemic contracture

Grade III: Ischemic contracture associated with nerve involvement

They may also be classified according to the structures involved:

Type I: Contracture involving forearm muscles with intrinsic muscles intact

Type II: Contracture involving forearm muscles associated with paralysis of intrinsic muscles

Type III: Contracture involving forearm muscles as well as intrinsic muscles

Type IV: Mixed type

Tsuge's classification comprises three types, according to the extent and the muscle groups involved.

Mild: It is characterized by flexion contracture of two or three fingers with minimal loss of sensation.

Moderate: The thumb gets stuck in the palm, and all fingers are flexed; the wrist may be flexed with associated loss of sensation.

Severe: All muscles in the forearm, including both the flexors and extensors of the wrist and fingers, are involved.

Anatomy

The brachial artery branches into the radial and ulnar arteries. The radial artery is superficially positioned, whereas the ulnar artery is deeply placed, passing deep into the pronator teres muscles. The ulnar artery gives rise to the common interosseous artery, which immediately divides into the anterior and posterior interosseous branches. The anterior interosseous artery provides blood supply to the flexors of the forearm and hand.

Causes

Ischemic contracture may be caused by the following:

- Fracture
- Compartmental syndrome
- Tight bandages
- Arterial embolus
- Arterial insufficiency
- Improper use of a tourniquet
- Improper use of a plaster cast

Volkmann contracture occurs when there is insufficient blood supply (ischemia) to the forearm and is the end result of an untreated or relatively inadequately decompressed compartment syndrome in which ischemic necrosis of muscles has developed. The key factor in all cases of ischemic contracture is reduction in compartment size or increase in the content of a closed, uncompromising osteofascial compartment, which is enough to cause occlusion of small vessels.

The blockade immediately results in ischemia of the nerve and muscle. If the pressure is not relieved in time, it may result in damage to muscle contracture and nerves.

Decrease in the compartment size can be attributed to the following causes:

- Constrictive casts and dressings
- Persistent localized external pressure
- Injuries due to heat
- Burn Escher
- Plastic surgery of facial defects

This can also be attributed to an increase in compartment content resulting from hemorrhage, bleeding diathesis, or anticoagulation.

Diagnosis

The hallmark symptom of Volkmann contracture is pain that does not improve with rest or nonsedative analgesics. It will continue to get worse as time passes, and if the pressure is allowed to persist, there will be decreased sensation and weakness.

Besides pain, symptoms include pallor, pulselessness, paresthesias (numbness), and paralysis. Aggravation of pain on passive stretch is the most reliable finding on physical examination. Other symptoms include decreased sensation, weakness, and induration of the forearm. Pulselessness and paralysis are late symptoms. The forearm may show swelling and is also shiny. There is a typical flexion contracture of the wrist along with clawing of the fingers.

An absolute diagnosis is made based on direct measurement of the compartment pressure. It is done by inserting a needle into the compartment that is attached to a pressure meter. When the pressure is above 45 millimeters of mercury (mmHg) or when it is within 30 mmHg of the diastolic pressure, a diagnosis of compartment syndrome is made. This is the general test to diagnose compartment syndrome.

Treatment

Early recognition and timely treatment of imminent Volkmann ischemia decrease the presentation and severity of late contracture and hand dysfunction. Ideal treatment requires a thorough examination of the extent of damage of the ischemia, followed by conservative therapy or operation.

Management presents considerable challenges. The success in achieving a potentially functional and aesthetically satisfactory result is greatest in the acute phase. A physician should be immediately consulted in case of an injury to the elbow or forearm and if swelling is also present.

Nonsurgical Treatment

If there is a forearm or elbow fracture, a proper initial splinting of the hand in functional position should be performed; the area must be kept still, and the arm should be raised above the level of the heart. This helps in preventing further injury and excessive swelling. When the extent of injury is determined, conservative treatment techniques such as rest and ice should be started to help decrease the swelling. Pain relief and anti-inflammatory medicines may be prescribed. Casts and surgery also may be indicated, depending on the injury. Bed rest or use of a protective device (a knee brace or wrist guard) is usually advised. Physiotherapy may also be of help in rehabilitation. Early mobilization, range-of-motion exercises, followed by stretching and strengthening exercises are part of rehabilitation.

Surgery

The best treatment is early surgical intervention to release the pressure in the forearm in order to prevent permanent injury to muscles and nerves. Reconstructive surgery to lengthen and sometimes transfer muscles may restore some hand function.

Muscle sliding is considered the most effective method. It results in the best preservation of resting length of muscle.

Other methods include the following:

- Tendon lengthening
- Neurolysis
- Scar excision
- Tendon lengthening
- Tendon transpositions
- Nerve grafting

Stage 1 Contracture

Muscle-sliding operation usually results in complete recovery. It consists of median nerve neurolysis and removal of necrotic debris. For isolated muscle injuries, tendon lengthening is recommended.

Stage 2 Contracture

Transposition of flexor tendons has an equal effect to muscle-sliding operation. It is an imperative procedure that helps in the prevention as well as control of imbalance deformity, its indication depending on the personal as well as professional profiles of the individual patient. A tendon transfer procedure alleviates the suffering from functional impairment and provides a far better alternative to permanent external splints. This is usually a secondary procedure for replacing function, which is done after evaluation of the functional motor loss.

Stage 3 Contracture

The primary treatment option is muscle-sliding operation. Some secondary procedures such as tendon transpositions and nerve grafts are often necessary.

Stage 4 Ischemic Contracture

Muscle-sliding operations may help in improving deficiency in extension; however, wrist arthrodesis is of great help. The aim of arthrodesis is to achieve a relatively painfree wrist by eliminating movement. In this procedure, the bones are fixed. This procedure is more beneficial for young, active patients or middle-aged patients but not for elderly patients. Extensor tendon transpositions may be of benefit.

Long-Term Prognosis

Prognosis is variable and depends on the severity of the disease and the stage at which intervention is made. If the pressure is released earlier by surgery, before the onset of any permanent damage, then the prognosis is excellent. High compartment pressure for a longer period of time can result in permanent nerve damage. Cubitus varus and loss of radial pulse are the other complications reported.

Volleyball, Injuries in

Volleyball is the sport with the highest rate of jumping during practice and competition. Jumping seems to be the riskiest activity in volleyball because the majority of injuries are associated with jumping and landing. Defense is associated with a small number of injuries, while serving, passing, and setting are associated with even fewer injuries.

Epidemiologic studies of volleyball injuries have identified some of the risks of injury in the sport. The highest rate of injury in volleyball is associated with blocking, followed by spiking. These are also the two sport-specific activities that require a jump with every repetition.

Injury rates during competition have been evaluated. An injury is defined as "any condition causing the athlete to present to the medical staff during a tournament." In high-level play, a rate of injury between 1 per 25 hours and 1 per 50 hours is common. Injuries in American intercollegiate play have also been studied. "Any condition that resulted in missing a practice or match" is how an American intercollegiate group defines injury. Each practice or match was counted as one exposure. The rate of injury was about 4 per 1,000 athlete exposures in women's intercollegiate training and competition. This ranked volleyball second to softball for the lowest injury rate among 15 intercollegiate sports. Playing on a softer surface, such as sand, also seems to decrease the risk of injury.

Ankle Sprains

In volleyball, 15% to 60% of recorded injuries are ankle sprains. Ankle injuries are almost always associated with landing from blocking or spiking in the front court. The most common mechanism of injury occurs when the blocking player lands on an opposing spiker's foot that has come underneath the net and across the center line in the "conflict zone." The rules of volleyball allow a player's foot to cross this line beneath the net as long as some portion of the foot remains in contact with it. It often results in an inversion injury, where the ankle rolls outward. The ligaments on the outside, or lateral side, of the ankle are injured.

An ankle brace or orthosis is often recommended while actively rehabilitating, as it decreases the reinjury risk. Stirrup-style braces, particularly pneumatic-type orthoses such as the Aircast® brand, have been shown to decrease injury risk fourfold. The risk of reinjury is greatest during the first year after an initial injury, so it is recommended that braces be worn for a year after an ankle sprain. Braces have not been shown to decrease risk of injury in ankles that have not been previously sprained.

It may be possible to prevent a significant number of ankle sprains with a fairly simple prophylactic program. First, advise all players not to allow any part of their foot to touch the center line during practice. Second, identify "problem attackers." These are players who jump forward (doing a broad jump) when spiking the ball. These players should be coached to take longer last-approach steps and jump straight upward instead of out. A twofold decrease in ankle sprains may be anticipated. It should be easy to convince players that this is a good idea, because this technique actually results in a higher vertical jump.

Patellar Tendinitis (Tendinosis)

Patellar tendinosis (*jumper's knee*) is by far the most frequent overuse injury in volleyball. It is probably so common because of the high frequency of jumping inherent in the sport. Patellar tendinosis has been found to be more common in players who play more than four times weekly and are 20 to 25 years old. Players who have been in the sport for 2 to 5 years are also more likely to have symptoms. Plyometric training has *not* been associated with patellar tendinitis in these elite players. Most players with this condition have pain at the bottom part of the kneecap.

It may be possible to identify players who are at increased risk for patellar tendinosis. Those who can generate the greatest amount of power during jumping have been found to be at greater risk. These are also the players with the highest vertical jumps. Perhaps, they may not need as much jump training as their teammates. Deeper knee flexion at takeoff for jumping may also place players at greater risk. Coaching attention to proper jumping technique might help these players avoid injury.

Patellar tendinosis can usually be managed conservatively with ice, short-term anti-inflammatory medication, and alterations in training activity. Closed-chain eccentric strengthening of the quadriceps muscle can result in stronger fibers in the patellar tendon. An example of this sort of exercise would be leg presses where the athlete "works the negative." These exercises should be used to rehabilitate this condition.

Shoulder Tendinitis (Tendinosis)

The most common shoulder injuries in volleyball players are rotator cuff and biceps tendinosis as a result of overuse. They account for 8% to 20% of injuries in volleyball. Repetitively striking the ball overhead places a cumulative stress on the shoulder. Striking the ball at the highest point in the arm swing may place the shoulder at particular risk in this sport. These forces predispose the shoulder tendons to impingement with spiking and overhead serving. The tendons get impinged between the head of the humerus, or arm bone, and the acromion process, which sits above the shoulder.

A player who has shoulder pain and/or weakness should be evaluated by a physician, athletic trainer, or physical therapist. Sometimes, the entire shoulder girdle (including the shoulder blade) moves in an abnormal pattern. A rehabilitation program will often be prescribed. Abnormal shoulder blade movement should be addressed first. This usually involves shoulder retraction exercises. Then, rotator cuff exercises will help stabilize the ball in the socket.

Suprascapular Nerve Injury: A Volleyball-Specific Injury?

An unusual condition that may be present in up to one third of elite volleyball players is suprascapular nerve compression. Several factors may be involved with this problem, but the nerve is usually compressed by the bone of the shoulder blade near where it innervates the infraspinatus muscle. This is the muscle that externally rotates the shoulder. So players typically have isolated weakness of external rotation when a trainer evaluates their shoulder strength. Interestingly, the majority of the players with this condition do *not* have shoulder pain.

Players with this condition who have no pain probably do not require further evaluation or treatment. Findings of isolated external rotation weakness and infraspinatus atrophy should be noted on preparticipation physical exam for future reference, in case the player develops symptoms. In those with significant symptoms, such as shoulder pain, magnetic resonance imaging (MRI) may be helpful if surgery is being considered, because up to two thirds of affected individuals may have an abnormality called a ganglion cyst compressing the nerve.

Other Injuries

Volleyball players often suffer relatively minor hand or back injuries. These injuries are common yet rarely result in time missed from the sport. Sprain of the outside ligament of the thumb (metacarpal-phalangeal radial collateral ligament) is the most frequent hand injury seen in volleyball players. It often occurs with blocking and may require splinting or taping.

Low back injuries account for up to 14% of volleyball injuries. In teenage athletes, back pain should be evaluated by a physician, because back pain is unusual in this age-group and almost always occurs secondary to a condition that may respond to treatment. One such condition is spondylolysis, which is essentially a stress fracture of the low back. Athletes who have pain when they bend backward with their lower back (lumbar extension) should be evaluated by a sports medicine physician. This may occur in hitters, when they must repeatedly reach back behind their heads to contact the ball.

Severe knee injuries requiring surgery on the anterior cruciate ligament (ACL) are also rare, but these injuries seem to be more common in female players. A good way to evaluate female athletes who may be at risk for this injury is to observe players as they land after jumping off of a box. Those whose knees come together (into valgus) and touch on landing—"kissing knees"—should be considered for a program of exercises to prevent ACL injury.

W

Warts (Verrucae)

Warts, or *verrucae,* are common skin findings that are often considered benign. However, in the athletic population they have the potential to cause significant pain and, thereby, impair performance. Although warts are found in every age-group, children and young adults are the most commonly affected, and athletes are at particular risk.

Human papillomavirus (HPV) is a virus that infects the skin and mucous membranes. There are more than 150 different types of HPV that cause warts in various areas of the body. Recently, several types of HPV have received additional attention because of their association with cervical cancer. The HPV vaccine is aimed at minimizing the spread of subtypes 16 and 18. The vast majority of HPV infect the skin and cause cutaneous warts. These types of HPV have virtually no potential to cause cancer.

Transmission of HPV occurs when the virus comes into contact with areas of damaged, even minimally damaged, skin. Transmission can be skin to skin or skin to fomite, such as shower room floors. Participation in sports can cause trauma to the skin, particularly to the feet and hands. In addition, the shared use of shower facilities and weight training equipment introduces multiple potential sources of exposure to HPV.

It is difficult to know exactly when an HPV infection occurs, because there is a lag time between exposure to the virus and the appearance of the resultant warts. The viruses commonly have an incubation period of between 1 and 6 months. Once individuals are infected, they risk passing this infection to other areas of their own skin through activities that cause minor skin trauma, such as shaving or scratching. Most subtypes of HPV cause specific types of warts that have predilections for certain areas of the body.

Symptoms

Two types of warts that frequently affect athletes are common warts and plantar warts. Common warts make up approximately 70% of cutaneous warts. They can be found anywhere on the body, but these most frequently affect the backs of hands and fingers. In children, these warts often appear on the face and neck. These warts are often described as "irregularly surfaced domed lesions."

One study looked at the acquisition of new common hand warts in runners and members of the crew team at a university. Rowers experienced hand trauma through weight training and rowing. Runners, on the other hand, experienced hand trauma from weight lifting alone. The study noted a significant increase in new common hand warts in crew team members compared with track team members. The authors postulated that trauma to wet, macerated hands made crew team members more susceptible to HPV and the resultant common warts.

Plantar warts are found on the sole of the foot and often cluster in the areas that bear significant pressure. The ball of the foot and the heel are the two most commonly affected sites. Because of their location, plantar warts can become callused and appear to grow into the foot. These warts are often found in small groups and can produce significant pain during weight bearing. Athletes with plantar warts may feel the sensation of having a pebble in their shoe while running or walking. Several factors predispose athletes to plantar warts, including communal showers, excessive perspiration, and repetitive microtrauma to the foot.

It is important to note that plantar warts can cause symptoms similar to stress fractures; therefore, plantar warts must not be overlooked when investigating plantar foot pain. A case report describes a 24-year-old female tennis player who was forced to stop play in the middle of a tennis match. She had tenderness over the ball of her foot, and it was suspected that she had a stress fracture. Following 2 weeks of rest, she returned to competition, and again the pain returned. Notably, she had calluses over the painful area of her foot. These calluses were pared down, exposing multiple dark spots (the "seeds" commonly found in plantar warts). Her plantar warts were treated, and she subsequently returned to play.

This situation illustrates how debilitating plantar warts can be for an athlete and the need to include plantar warts in the differential diagnosis for foot pain. Part of the difficulty in diagnosing plantar warts is that they are often covered with a callus. Once the callus is removed, plantar warts have a characteristic appearance: multiple black speckles, which are actually small blood vessels. These small blood vessels are the hallmark of plantar warts and differentiate them from other skin findings.

Treatment

There are several options available for the treatment of both common and plantar warts. Treatment can be broken down into three categories: (1) observation, (2) mechanical destruction, and (3) stimulation of the patient's immune system. Given the fact that cutaneous warts are caused by viruses, the immune system can potentially eradicate the viruses and the resulting warts. Warts affect patients with intact and impaired immune systems alike. However, individuals with impaired immune systems may never be able to mount an immune response significant enough to fight HPV.

Most warts in a healthy patient will resolve spontaneously (without intervention) over months or years. One study demonstrated the spontaneous resolution of two thirds of warts over 2 years. However, this process may take longer and be less successful than interventional measures. The longer the warts remain, the greater the potential for spread to different areas of the skin and to other people. Furthermore, the spread of warts may result in larger or more numerous warts, which may be more difficult to eventually remove.

Although most warts will resolve without intervention, the option of observation is much less desirable for athletes whose performance is impaired due to warts. These individuals may be more appropriate candidates for mechanical destruction. Mechanical destruction can be accomplished through a variety of measures. The most common types of mechanical destruction include topical acids, freezing, and curetting. However, it is important to note that destructive measures, particularly curetting, have the potential to leave a scar. Such scars, especially in the case of plantar warts, can be painful and can potentially inhibit the athlete's ability to run or even bear weight on the affected foot. Therefore, athletes must be cautious with more aggressive means of wart destruction.

Topical acids are effective, safe if properly used, and available over the counter. Salicylic acid is a common preparation often used as a first-line interventional treatment for both common and plantar warts. However, instructions for application can be complex and, thus, decrease patient compliance with treatment. To maximize the efficacy of salicylic acid, a regimen that includes daily soaking, debridement with an emery board, topical application of the acid, and occlusion with duct tape should be followed. This stepwise treatment should be repeated every 24 hours. Several studies have demonstrated that topical acids are more effective and faster at eliminating warts than simple observation (no intervention).

Freezing, or cryotherapy, involves the use of liquid nitrogen or nitrous oxide to destroy warts. The wart is frozen using a cryogun until the entire wart and up to 2 millimeters (mm) of the surrounding tissue turn white. A second freeze after thawing makes this method more effective. Following the freeze, the affected area will blister and then gradually slough and heal over the next few weeks. The freeze destroys the wart but also stimulates the immune system that aids in the destruction of any remaining HPV. Although much less complex than topical therapy, this method has the potential to cause blistering and pain, particularly in the case of plantar warts. While in training, athletes must decide whether the functional impairment from their warts is severe enough to warrant the potential complications of freezing.

Occlusion with duct tape alone has been used by many practitioners and has been the subject of several studies. Although the exact mechanism of treatment with duct tape is not known, several theories have been proposed, including suffocation of warts, immune response stimulation, and mechanical debridement. In 2002, a study compared the efficacy of cryotherapy with that of duct tape occlusion. The results showed that duct tape occlusive therapy was significantly superior to cryotherapy in resolving common warts. However, two other studies have questioned the efficacy of duct tape occlusion as a successful therapeutic intervention. These studies demonstrated no significant differences in the resolution of warts when compared with placebo treatments such as corn pads or moleskin coverings. Though they showed a nonsignificant initial resolution of the wart, return of the wart was equally demonstrated. Questions still remain as to whether differences in the type of duct tape, silver versus transparent, could account for the divergent outcomes of these studies.

There are also various methods that have been used to stimulate the immune system to facilitate the destruction of HPV and the resulting warts. These methods are directed at enhancing the immune response both locally and systemically. Injection of *Candida* into the base of a wart is one way to generate a local immune response. The body's natural response to the fungus will supply the injected region with host cells that target the *Candida* as well as the viruses causing the wart. Similarly, topical agents such as imiquimod cream and diphenylcyclopropenone generate a local inflammatory response that enhances virus destruction. Interestingly, the H2 antagonist cimetidine (a medicine frequently used for the treatment of heartburn) has been used in an attempt to stimulate human immune cells to facilitate the regression of warts. Although early uncontrolled studies supported the efficacy of high-dose cimetidine, more rigorous double-blind controlled trials have contradicted these findings.

Conclusion

Warts are a common skin finding that have the potential to cause pain and impair performance in athletes. Although there are several methods for treating warts, preventive measures can help athletes avoid an HPV infection. Athletes who use communal showers should wear sandals and avoid direct contact with shower floors. Athletes may consider the use of drying agents to avoid moisture, which, by leading to maceration of the skin, increases the likelihood of infection with HPV. If athletes do develop warts, they should take into account the potential for side effects when selecting a treatment modality.

WEIGHT GAIN FOR SPORTS

Many sports require an athlete to lose or maintain weight to optimize performance. Conversely, some sports and sports positions require weight gain for a greater competitive advantage. In some cases, the extra pounds can mean the difference between winning and losing. This entry describes how athletes may safely gain weight to achieve a competitive advantage.

Gaining weight is important for those who are underweight or who require greater strength. Gaining weight may also increase energy and endurance. Endurance is a person's ability to cope with intense and frequent exercise, such as distance running, swimming, or biking over long time periods or distances. Weight gain may also help an athlete to build muscle and increase strength. This strength may offer some athletes a protective advantage in sports such as football or hockey. The optimal time for gaining weight is during the off-season or at the beginning of the season.

Gaining weight may not be easy. In fact, often it is harder than losing weight, as athletes may use energy faster than they consume it. The question for the athlete is how to gain weight while still maintaining a healthful diet. In short, weight gain requires excess calorie intake. Each pound of weight gain requires 3,500 additional calories (cal; 1 cal = 4.2 joules). This is achievable by incorporating an extra 500 cal/day into the diet. If an athlete consumes an additional 500 cal/day for 1 week, then 1 pound (lb; 1 lb = 0.45 kilograms) of weight gain should be the outcome. Ideally, this should be combined with a resistance training program. The goal is not just to increase weight but also to increase lean muscle mass.

A combination of protein, carbohydrate, and fat is optimal for weight gain. The percentages of each of these macronutrients are approximately as follows: carbohydrate at 50% to 65%, protein at 15% to 20%, and fat at 25% to 30%. If these percentages are viewed as grams per day, the following is recommended: carbohydrate at 5 to 10 grams per kilogram per day (g kg^{-1} day^{-1}), protein at 1.0 to 1.7 g kg^{-1} day^{-1}, and fat at approximately 1 g kg^{-1} day^{-1}.

Maintaining a healthful diet of whole grains, fruits and vegetables, lean protein, and heart-healthful fats will help optimize performance. Weight gain, just like weight loss, takes time. The overall goal is to gain about 0.5 to 1 lb/week. Athletes trying to gain weight should consume three meals and two or three snacks each day. Skipping meals such as breakfast may make it more difficult to obtain the necessary calories needed to gain weight.

Weight Gain Methods

Many athletes think that additional calories should be obtained only from protein. Studies show that consuming excess protein (defined as more than 1.8 g kg^{-1} day^{-1}) may increase the oxidation of excess amino acids. Furthermore, excess protein may be converted to fat. Thus, a diet with too much protein has no advantage for muscle gain, when compared with a lower protein intake that is coupled with resistance training.

The speed at which weight gain occurs may depend on the athlete's genetic makeup, the calories consumed in excess of metabolic and training needs, the number of rest and recovery days per week, and the training program itself. Weight gain is achieved by ensuring that each meal and snack are made up of healthful, higher-calorie foods. Beverages are one easy way to increase calories. For example, instead of water, the athlete may add juice, milk, milk shakes, and instant breakfast drinks to meals or snacks. It is also important to snack regularly and carry healthful snacks each day to encourage snacking. Such snacks may include dried fruit, yogurt, cheese and crackers, nuts and peanuts, bran or fruit muffins, and multigrain bagels with cream cheese or nut butters.

Athletes may think that the need for extra calories gives them the right to eat whatever they want, but this may be detrimental to both performance and overall health. Substitutes may be found for many food items. For example, instead of using butter, canola or olive oil may be substituted. Mayonnaise may be replaced with avocado spread. Natural peanut butter may be spread on bagels, crackers, or bread instead of butter or cream cheese. Eating healthful foods in abundance is how an athlete gains weight safely and effectively. There is no need to add calories with fast food or junk food when calories are easily added by making favorable choices at meal and snack times.

Many athletes wonder whether protein supplements are helpful when trying to bulk up. These supplements are often marketed as ways to gain extra muscle quickly. However, the main reason why protein supplements help an athlete gain muscle is that they contain extra calories. Also, contrary to what some people believe, most athletes need only a small amount of extra protein to gain weight and muscle mass. The protein in the supplements is often too high. Caloric and protein needs may be met by eating a variety of healthy foods each day. If extra calories are needed, readily available weight gain drinks such as Ensure or Boost contain the extra calories and are marketed specifically for weight gain.

There are also unhealthful ways of gaining weight. A few of these are human growth hormone (HGH), anabolic steroids, and insulin. HGH use may increase the risk of diabetes, hypertension, joint pain, and possibly colon cancer. Anabolic steroids have been linked to many health problems, including breast growth and shrinking of testicles in men, voice deepening and growth of body hair in women, heart problems, liver disease, and aggressive behavior. Insulin is sometimes used in bodybuilding to increase the bulk of muscles. Insulin is a natural hormone secreted by the pancreas in response to high sugar levels. Its main use is to regulate sugar levels in the body. However, if one is not diabetic, taking insulin unnecessarily may cause the pancreas to stop producing insulin naturally, which might lead to diabetes.

Weight Gain Tips

Weight gain requires that an athlete eat consistently and not skip meals or snacks. Portions should be larger than normal, and calorically dense foods should be encouraged. Higher-calorie meals may also result from reading food labels to determine which foods have more calories than an equally palatable counterpart. For example, cranberry apple juice has more calories than does orange juice (170 vs. 110 cal/8 fluid ounces [oz; 1 oz = 29.57 milliliters]), granola has more calories than do Cheerios (700 vs. 100 cal/cup), and corn has more calories than do green beans (140 vs. 40 cal/cup).

In terms of individual food groups, the following guidelines may be helpful. Choose heavy breads such as honey bran, rye, and pumpernickel instead of lighter breads such as white bread. Choose cereals such as granola, instead of rice puffs or corn flakes. The caloric value of cereals may also be increased by adding nuts, raisins, and other dried fruits. When choosing fruits, bananas, pineapple, mangos, raisins, dates, and other dried fruits have more calories per serving than do watery fruits, such as watermelon, grapefruit, apples, and peaches. Starchy or sugary vegetables, such as corn, carrots, and peas, have more calories per serving than do less starchy vegetables, such as green beans, broccoli, and summer squash. Lentils, lima beans, chili beans, and other beans are also high in calories. These foods are good choices, because they also provide both carbohydrates and protein. In terms of other protein foods such as meat, fish, and poultry, certain types and cuts are higher in calories. Dark meat of poultry, fatty fish such as salmon and trout, and some cuts of lean red meat are high in calories, including round or sirloin steak, ground round, fresh or boiled ham, or center-cut loin chops.

Weight Lifting, Injuries in

Weight lifting is performed by itself as a competitive sport and by athletes in other sports as part of training programs to increase muscle strength, endurance, and power. The high amount of resistance and repetitive movements in weight lifting can cause both acute and chronic injuries to muscle, tendon, and bone. The body parts most commonly injured by weight lifting include the shoulders, knees, and lumbar spine. Although serious injuries can occur, most weight lifting injuries are relatively minor.

General guidelines should be followed to decrease the risk of injury from weight lifting. As in any other sport, athletes should perform a proper warm-up before weight lifting. This can

Personal trainer demonstrates proper technique for squat exercise with barbells.

include stretching, cardiovascular exercises, or performing several repetitions of lifting light weights with controlled movements.

Proper technique is also critical to minimize the risk of injury. A spotter should be used when appropriate. Young athletes should always be under direct supervision when lifting weights.

To avoid injuries from overtraining, adequate time should be given for muscle recovery. Performance-enhancing substances should be avoided. Specific injuries and prevention techniques are discussed in the sections that follow.

Shoulder Injuries

The inherent instability of the glenohumeral joint combined with the high amount of weight used during exercises involving movements of the glenohumeral joint place soft tissues around the joint at risk of injury. Strains of the rotator cuff and deltoid muscles are common. Weight lifting exercises, such as front and lateral deltoid raises, and military presses that involve resisted overhead movements can place the athlete at risk for subacromial impingement.

In addition to the glenohumeral joint, the acromioclavicular joint is also stressed with repetitive overhead movements, dips, and bench press. Osteolysis of the distal clavicle joint is a relatively common condition in weight lifters.

Anterior shoulder structures, including the glenohumeral ligaments, are stressed during weight lifting exercises where the arm moves beyond the body in the coronal plane. This movement occurs when performing a bench press, behind-the-head latissimus pull-down, pec deck machine, and dumbbell chest fly through a full range of motion. A back squat is an example of a lower extremity exercise that can also stress the shoulder joint as it places the shoulder in excessive horizontal abduction and extension. Athletes with glenohumeral joint laxity are predisposed to injury with these exercises.

A rupture of the pectoralis major muscle is an example of a traumatic upper extremity injury that can occur while weight lifting. Although it is not a common injury, the injury classically occurs while performing a bench press. Rupture of the pectoralis major insertion requires surgical repair.

Shoulder Injury Prevention

Minor modifications to traditional weight lifting exercises can decrease the stresses on the shoulder joint that lead to the injuries discussed earlier. During the latissimus pull-down, the bar should always be lowered in front of, not behind, the head. A narrow grip during the latissimus pull-down and bench press will decrease stress on the anterior shoulder structures and acromioclavicular joint. Decreasing the range of motion with a bench press, cable fly, pec deck machine, and dumbbell chest fly so the arm stays anterior to the coronal plane of the body will also decrease stress on the anterior shoulder structures. When performing overhead movements, externally rotating the humerus will rotate the greater tuberosity and minimize the risk of subacromial impingement.

Maintaining proper muscle balance will also help decrease the risk of shoulder injury. Specifically, strengthening of the rotator cuff and scapulothoracic muscles is needed to avoid muscular imbalance, as most common weight lifting exercises strengthen the deltoid and anterior chest muscles.

Knee Injuries

Anterior knee pain is a common complaint of weight lifters. Anterior knee pain can be caused by strain or injury to any of several structures, including the patellar tendon and patellofemoral joint. Patellofemoral joint stresses are high during deep knee flexion in weight bearing, such as squatting, leg press, and lunges, especially when the exercise is performed beyond 90° of knee flexion. Knee extensions strengthen the quadriceps in a non–weight-bearing position. With this motion, the patellofemoral joint stresses increase as the knee extends beyond approximately 45°.

The menisci in the knee are also susceptible to injury during weight lifting. Acute and degenerative meniscal injuries can occur due to high loads on the tibiofemoral joint with the knee in a flexed position, such as during squats and lunges.

Knee Injury Prevention

Avoiding deep squats and lunges (limiting knee flexion to less than 90°) will minimize stress on the patellofemoral joint and meniscus. Non–weight-bearing knee extension exercises should be performed from 90° to 45° of knee flexion to minimize patellofemoral joint stress.

Lumbar Spine Injuries

Exercises that place excessive forces on the lumbar spine include squats and deadlifts. The most common injuries to the lumbar spine during weight lifting are muscle strains and stress injury or fracture to the pars intraarticularis (spondylolysis). Spondylolysis results from repeated hyperextension of the spine.

Athletes should maintain a neutral spine position whenever possible with all types of weight lifting exercises. Co-contraction of the multifidus with the deeper abdominal muscles (transverse abdominis, internal and external obliques) will stabilize the lumbar spine and avoid excessive forces from hyperflexion and hyperextension movements during weight lifting exercises. Excessive hyperextension during exercises such as military press, bench press, and squats should be avoided.

Special Considerations

Competitive Weight Lifting

Competitive weight lifting consists of power lifting and Olympic weight lifting. Competitive power lifts include deadlifts, squats, and bench press. Olympic weight lifts consist of the clean and jerk and the snatch. Athletes in these two competitive weight lifting sports want to reach as high a one-repetition maximum as possible and often lift weights three to five times their body weight. This requires the athlete to generate extremely large muscle forces and high joint torques.

Injuries to the lumbar spine and knees are the most common in Olympic weight lifting, whereas injuries to the lumbar spine and shoulder are the most common in power lifting. When performing a squat, power lifters position the bar lower on their back and lean their trunk more forward, resulting in less ankle dorsiflexion and a more posterior hip position, ultimately leading to less knee extension torque and less risk of knee injury. In contrast, when weight lifters perform the snatch, they are in a position of deep knee flexion, which increases stress on the knee joint. Although the low bar squat position used by power lifters results in less stress to the knee joint, it does increase stress on the anterior shoulder structures.

Youth and Weight Lifting

Weight lifting can be safe and beneficial for preadolescents and adolescents. An appropriately designed program will improve muscle strength and have general health benefits. It will not have any adverse effects on growth or lead to any medical risk in an otherwise healthy child. The increases in muscular strength seen in preadolescents are likely due to neural gains (changes in motor unit activation and recruitment) rather than due to muscle hypertrophy.

Free weights, elastic bands, exercise machines, and body weight are all various modes of resistance that can be used. Body weight resistance exercise is beneficial to emphasize proper technique and incorporate core strength. If exercise machines are used, they must be sized appropriately.

A weight training program for youth should emphasize proper technique, which requires appropriate supervision. A low to moderate resistance level should be used, with a higher number of repetitions (2–3 sets, 8–15 repetitions). The program can be performed two to three times per week.

Weight Loss for Sports

Weight loss is a reduction of the total body weight. This reduction is due to a mean loss of fluid, body fat, or adipose tissue and/or lean mass—namely, bone mineral deposits, muscle, tendon, and other connective tissue. Weight loss can be unintentional or intentional. Unintentional weight loss refers to the involuntary loss of weight secondary to genetics, some medical conditions, activities, or medications that decrease body mass. Intentional weight loss refers to the voluntary loss of total body mass in an effort to improve fitness, health, and/or appearance. Intentional weight loss in sports refers to the intentional loss of total body mass in an effort to improve fitness or athletic performance and/or to meet a sport-specific weight requirement. Weight loss occurs when an individual is in a state of negative energy balance. When the human body is spending more energy in work and heat than it is gaining from food or other nutritional supplements, it will use the stored reserves of fat or muscle. Although weight loss may involve loss of fat, muscle, or fluid, weight loss for the purposes of maintaining health should aim to lose fat while conserving muscle and fluid.

Weight Loss Techniques

The most often recommended weight loss techniques are adjustments to eating patterns and increased physical activity. Other methods of losing weight include the use of drugs and supplements that decrease appetite, block fat absorption, increase metabolism, or reduce stomach volume. Finally, surgery may be used in case of morbid obesity.

Dieting

One of the aspects of energy balance that affects body weight is energy intake. An examination of the weight loss literature shows that changes in energy intake play a significant role in reducing body weight. The currently available scientific evidence appears to indicate that the macronutrient content of the diet will affect body weight only when there is also a reduction in the total energy intake.

Athletes usually require a greater caloric intake than nonathletes. The actual energy intake (number of calories) depends on the athlete's body composition, weight, height, age, stage of growth, and level of fitness as well as the intensity, frequency, and duration of exercise activity. Athletes need to eat enough to cover the energy costs of daily living, growth, building and repairing muscle tissue, and participating in sports. Athletes need to be informed that weight is not an accurate indicator of body fat or lean muscle mass and that body composition measurements can be more helpful.

When athletes regularly restrict energy intake to less than 1,500 kilocalories per day (kcal/day; 1 kcal = 4,184 joules) for women and less than 1,800 kcal/day for men, they are at increased risk of poor nutritional intake. This level of energy intake is too low to meet the nutritional needs of the body and fuel the body for exercise, especially if physical activity is high.

Commercial programs recommend various combinations of macronutrient compositions for weight loss, including high-fat, high-protein, and high- and low-carbohydrate diets. Despite the popularity of many of these dietary approaches, the optimal macronutrient composition of the diet for weight loss has not been determined. Despite the different potential mechanisms for how changes in protein intake may affect weight loss, evidence from clinical trials supporting optimal protein and carbohydrate intake for long-term weight loss and weight maintenance is lacking.

Exercise

Scientific evidence suggests that the combination of dietary modification and exercise is the most effective behavioral approach for weight loss, and the maintenance of exercise may be one of the best predictors of long-term weight maintenance. Despite the importance of exercise, there is little evidence that suggests that exercise alone produces magnitudes of weight loss that are similar to what can be achieved with dietary modification. Also, when examining the effect of exercise on body weight, it has been suggested that there may be "responders" and "nonresponders" to the same exercise intervention. In general, daily guidelines for exercise are 60 to 90 minutes to prevent weight gain and over 90 minutes to maintain weight loss.

Behavior Modification for Weight Loss

Behavior modification for weight loss means lifestyle changes to develop a long-term healthy eating plan and exercise program. There is evidence that including behavioral principles within a weight loss program improves long-term outcomes. Maintaining contact with participants long term improves long-term weight loss outcome, and this is considered an important component of behavioral weight loss programs. Another important component of behavioral weight loss programs is self-monitoring of eating and exercise behaviors. There is consistent evidence that individuals who self-monitor these behaviors are more successful at weight loss than those individuals who are inconsistent with self-monitoring. The use of portion control diets may also improve weight loss outcomes by minimizing choice and providing specific guidance to adults that precipitates weight loss.

Pharmacological Treatment

All current guidelines consider pharmacotherapy to be an adjunct to lifestyle modification interventions and limit its use to patients with obesity or overweight patients with additional comorbidities (e.g., hypertension, dyslipidemia, or Type 2 diabetes).

Despite the interest in the potential use of pharmacotherapy for the management of body weight, there are few drugs approved for this use, and their safety and effectiveness have not been established for use beyond 2 years. Most available weight loss medications approved by the FDA are appetite-suppressant medications. These include sibutramine, phentermine, phendimetrazine, and diethylpropion. Appetite-suppressant medications promote weight loss by decreasing appetite or increasing the feeling of being full. These medications make the patients feel less hungry by increasing one or more brain chemicals that affect mood and appetite. Phentermine and sibutramine are the most commonly prescribed appetite suppressants in the United States. *Amphetamines are a type of appetite suppressant. However, amphetamines are not recommended for use in the treatment of obesity due to their strong potential for abuse and dependence.*

Another category of medication used for weight loss is orlistat. This medication reduces the body's ability to absorb dietary fat by about one third. It does this by blocking the enzyme lipase, which is responsible for breaking down dietary fat. When fat is not broken down, the body cannot absorb it, so it is eliminated, and fewer calories are taken in.

All weight loss agents should be used only under the direct supervision of a physician.

Pathologic Strategies and Health Concerns

Pathologic weight loss strategies include any weight loss behaviors or actions that are potentially harmful to the athlete. These strategies include restrained eating, chronic dieting, bingeing and purging, skipping meals, fasting, excessive exercise, dehydration, and laxative, diuretic, and emetic abuse.

Nutritional Deficiencies

To lose weight, athletes frequently restrict food intake by skipping meals, eliminating food groups, fasting, or eating only one to three foods a day. Severe energy restriction is especially a problem for female athletes, and this pattern can lead to the female athlete triad (amenorrhea, eating disorder, and osteoporosis). Female athletes typically need less energy than male athletes due to their smaller body size. In addition, even female athletes who are not dieting frequently have energy and nutrient intakes that are below the recommended levels.

Disordered Eating

For some athletes, chronic dieting to maintain a low body weight can be the first step toward developing a clinical eating disorder such as anorexia nervosa or bulimia nervosa. Persistent dietary restriction can lead to binge and purge eating. Bingeing includes consuming large quantities of food at one time, followed by purging through practices such as self-induced vomiting; the use of emetics, laxatives, or diuretics; and excessive exercise. Bingeing and purging are extremely dangerous practices that can lead to clinical eating disorders, tooth decay, poor performance, dehydration, and even death due to fluid and electrolyte imbalances.

Dehydration and Laxative Abuse

Dehydration is a practice commonly used for rapid weight loss in athletes needing to "make weight." One way of doing this is by exercising intensely in hot environments while wearing vapor-impermeable suits. Also, some athletes combine this activity with fluid restriction and the use of diuretics, emetics, and laxatives. This practice is extremely dangerous and has resulted in several documented deaths.

Windsurfing, Injuries in

Windsurfing is a challenging and exhilarating aquatic sport that has gained worldwide appeal fairly quickly, including its introduction as an Olympic sport in 1984. There is something for everyone in this sport, whether you are a recreational amateur, Olympic competitor, or Professional Windsurfing Association champion. Exercise, excitement, thrill, and challenge are among the stimuli to participate, while trauma, injury, and overexposure to the elements represent the downside. Knowledge of the sport, proper equipment, and windsurfing skills help ensure that the positive aspects of windsurfing are enjoyed and the risks are avoided.

Windsurfing is an ingenious combination of Hawaiian-style wave surfing and the more accessible sport of wind sailing. The marriage of a one-person sailboard and a one-person sail by means of a universal (polyaxial) joint brought the intuitive burst to reality. Wave surfers are no longer limited to the few locations worldwide where the "perfect wave" might appear and impart massive kinetic power to propel a surfboard. Rather, one can now harness the more ubiquitous power of the wind to propel a sailor through the water and waves. The inception of the windsurfer was a "Eureka moment."

Basic Equipment

The sport of windsurfing requires a sailboard commonly referred to as a windsurfer and a rig consisting of sail, mast, and boom. The rig is attached to the sailboard by means of a universal joint that allows the rig to be tilted, pivoted, or flipped into various positions. The sailboard provides the flotation on which the sailor stands, sails, steers, and maneuvers through the water and waves. The rig supports the sail, which captures the wind power and allows the sailor to transfer it to the sailboard. Adjustments in the positions of the rig and sail provide the means by which to steer the board and finely balance the amount of wind power transferred to the board. A fin provides lateral resistance and lift to the board. Sail power and fin allow the windsurfer to hydroplane, making it the fastest sailing vessel on the water, capable of attaining speeds of over 50 miles (mi; 1 mi = 1.60 kilometers) per hour.

The booms may be aided by hand, or a harness may be worn to allow the sailor to hook into the straps attached to the booms. This permits the sailor to balance sail power against body weight, removing the burden from the arms and freeing the sailor to make fine adjustments to sail position. Foot straps are affixed to most sailboards, allowing the sailor to anchor his or her feet to the board and more efficiently transfer wind power to the board. Foot straps not only prevent the windsurfer from being thrown (catapulted) from the board but also provide a potential mechanism for injury to the lower extremities because they lock the feet in place and can thereby cause twisting injuries to the ankles and knees. Ancillary equipment includes gloves, booties, harness, wet suit, life jacket, and helmet.

The length and volume of windsurfers vary according to the ability of the sailor, the type of sailing intended, and the conditions of wind and water. Novice sailors and low wind conditions require larger boards for greater flotation and moderate-sized sails, which allow greater control. Slalom and freestyle sailing are accomplished on smaller boards, which are faster and more maneuverable but more difficult to sail. High wind days and wave sailing require that the smallest boards and sails be used. Sailors must carefully assess the wind velocity, water conditions, and local topography and their own sailing abilities prior to selecting the equipment used on any given day. Too small a board or rig on a low wind day may leave the sailor stalled or sunk (underpowered). Too large a board or rig on a high wind day may put the sailor in an uncontrollable situation, either blown off course or thrown about at the mercy of the wind and waves (overpowered).

What Can Go Wrong?

For the most part, windsurfing is a safe and enjoyable endeavor. Even an unsuccessful day of windsurfing is typically a “good day at the beach” with sun, water, waves, companionship, and recreation. Potential problems with equipment, weather conditions, or sailing ability may lead to injury. Medical studies estimate that the rate of injury to windsurfers is approximately 1.5 per year, with the majority of injuries being minor. These would include strains, sprains, contusions, or bruises, which rarely require medical attention. An ill-equipped novice sailor may develop hand blisters if improper gloves are worn or scrapes and scratches if no protective booties are worn. While

Windsurfer in Dingle Peninsula, County Kerry, in Ireland. Most of the injuries common to windsurfing are minor and include strains, sprains, contusions, or bruises.

Source: Ingmar Wesemann/iStockphoto.

learning to manipulate the sailboard and rig into correct positions, there is an intuitive inclination to force one's equipment into position rather than use simple physics and wind power to do the work. These undue efforts produce backaches, muscle strains, joint sprains, and contusions, which constitute the garden-variety problems that heal quickly. Beginners can avoid many of these struggles and injuries by taking lessons from certified instructors, consulting instruction manuals, or viewing the many excellent instructional videos that are available. *Windsurfing Magazine* and windsurf.com are good sources of information.

There are potentially serious, and frankly dangerous, situations that may lead to severe physical harm. Extreme overexposure to environmental elements can occur if a sailor is incapable of upwind sailing and consequently is blown downwind and away from the intended destination. Sailors have been stranded out at sea or even lost entirely. Equipment failure and major alterations in wind velocity or direction can produce similar results, blowing a sailor drastically off course. Prolonged exposure to the elements may lead to severe sunburn, dehydration, exhaustion, hypothermia, or drowning. These potential dangers underscore the importance of knowing your local conditions, the prevailing winds, the weather forecast, and equipment maintenance. Solo sailing is a hazard, and it is a windsurfing maxim to be with a "buddy sailor" and to know the whereabouts of rescue boats or vehicles. "Never leave your board" is another important maxim since it serves as your flotation device and may be kicked or paddled for long distances. Ancillary equipment such as a Coast Guard–approved life jacket, a wet suit, gloves, sunglasses, and booties help protect from exposure. Waterproof radios are expensive but may be crucial to the solo sailor who has ventured off course or become stranded. It is imperative to stay with your board, avoid solo sailing, and know the universal "sign of distress" to alert others to your plight. This involves sitting on your sailboard and raising both hands straight overhead and crisscrossing them back and forth.

Physical Injuries

Much of windsurfing's appeal is its overall safety. Being blown off course typically results in much paddling and walking rather than dramatic rescues. Similarly, most falls, collisions, or mishaps lead to splashy and refreshing immersions into the water, followed by uphauling or water starting to get back on course.

As a sailor progresses in his or her abilities, there is typically the urge to seek more challenge and greater speed and perform stylized turns, and wave jumping. Freestyle sailing involves phenomenal loops, rolls, and other aerial acrobatics. Higher speeds, crowded races, and advanced aerial maneuvers create the circumstances that may cause severe high-energy injuries. These injuries most frequently involve the lower extremities, affecting the knee, ankle, and foot. The lower extremity is placed at higher risk because of the foot straps that lock the foot onto the board. While the foot strap gives the sailor greater control over the board, the converse is unfortunately also true. Just as a ski bound to the foot of a skier can impart greater leverage and injury to the leg of a skier, the foot strap can impart greater leverage of the board and rig to the lower extremity of the sailor. If uncontrolled leverage due to a fall, aborted turn, or poor landing from a jump is transmitted to the vulnerable lower extremity, ligamentous tears may occur to the foot, ankle, or knee. Further leverage will cause complete rupture of ligaments or fracture of bone. Lower extremity injuries reported among windsurfers include midfoot sprains and complete disruption of the tarsal bones of the foot, known as Lisfranc fractures. The collateral ligaments of the ankle or knee may be disrupted, or the anterior cruciate ligament of the knee may be torn. Knee injuries of this severity are commonly associated with a "popping" sensation rapidly followed by pain, swelling, and difficulty bearing weight. Immediate emergency treatment involves *r*est, *i*ce, elastic *c*ompression, and *e*levation (RICE) followed by medical evaluation. Most sprains are partial tears and respond to rest, use of splints, and temporary use of a cane or crutches. Fractures, dislocations, or complete ligamentous disruption typically requires surgical treatment.

While most serious windsurfing injuries involve the lower extremity, other body parts are also at risk. The most common serious upper extremity injury is dislocation of the shoulder during high-velocity falls, catapults, or collision with other sailors. Chest wall contusions or rib fractures may result from collision with one's booms. Head, neck, and spinal injuries also have been reported and are typically associated with high-energy aerial acrobatics, collision with other sailors, or direct contact with the sea bottom. These catastrophic injuries may lead to concussions, skull fractures, vertebral fractures, spinal cord injuries, or death. Prevention, caution, and head protection are the keys to avoiding these catastrophic injuries. Windsurfers must follow sailing's "rules of the road," which determine who has the right of way on the water when conditions are crowded. Riders must know both their abilities and their limitations. Winds too strong, waves too high, and waters too crowded must signal caution. While helmets are not everyday requirements, they are an absolute must for high winds, crowded racing conditions, and freestyle sailing. Whenever in doubt, it is always prudent to decide on the side of caution.

Last, whether you are on home territory or on an exotic windsurfing vacation, it is important to do a little preparatory work researching your destination. Fortunately, most windsurfing destinations provide resources describing the local conditions, such as prevailing winds, water depths, rock or coral formations, and temperature extremes. Local flora and fauna may also provide potential hazards, such as sea urchins, needle fish, jellyfish, sharks, or marine bacteria, which may cause infection of scrapes or puncture wounds.

Women's Health, Effects of Exercise on

Cardiovascular disease (CVD) remains the leading cause of morbidity and premature mortality in women in the United States and most industrialized countries and, more recently, contributes to the significant disease burden in the developing nations. The prevalence of obesity and inactivity among Americans continues to rise. Exercise, for the physiologic reasons discussed below, has a beneficial effect in both preventing CVD among women and treating it once it occurs. Inactivity is also associated with multiple other cardiovascular risk factors, including obesity, diabetes, and hypertension. Furthermore, beyond its widely touted promotion of cardiovascular health among women, exercise has been shown to have multiple beneficial effects on other aspects of women's health. Among women, exercise has been shown to decrease the risk of colon and breast cancer, decrease the risk of osteoporosis, and boost cognitive and psychological well-being. In considering the myriad beneficial effects of exercise among women, it should be noted that these are independent of diet and weight loss.

Cardiovascular Adaptation to Exercise Training

Typical cardiovascular adaptations to regular aerobic physical training include lowered blood pressure and heart rate, mild increases in the dimensions of the heart cavity, augmentation of the amount of blood pumped by the heart, as well as increases in heart muscle mass. In addition to the structural changes that occur with training, changes in heart physiology also occur. These include an enhanced pumping and relaxation function of the right and left ventricles, the heart chambers that pump blood to the lungs and the aorta, as well as an increase in the amount of oxygen consumed by the body, known as the $\dot{V}O_2$max. $\dot{V}O_2$max is widely considered to be the gold standard metric for cardiovascular fitness.

While the majority of cardiovascular adaptations to training are similar between men and women, unique cardiovascular adaptations to exercise in women have been described. While both men and women exhibit increases in their heart chamber sizes and muscle mass, the body surface–adjusted increases in mass are not as substantial in women as in men. In addition, females exhibit lower $\dot{V}O_2$max compared with males, likely due to lower myocardial mass.

Additional physiologic differences between men and women may contribute to the improvement in $\dot{V}O_2$max observed with regular physical exercise. While the mechanism of increased $\dot{V}O_2$max in men appears largely due to increases in the volume of blood pumped by the heart, in women, the improvement appears to be related to the increased extraction of oxygen from muscle at the cellular level.

The Role of Exercise in the Reduction of Cardiovascular Risk Factors

Regular physical exercise is of great value in reducing established cardiovascular risk factors, including obesity, diabetes mellitus, and hypertension. In addition, there are a multitude of beneficial cardiovascular effects of regular physical exercise that result in physiologic, psychological, as well as biochemical improvements, all of which lead to a reduction in overall cardiovascular risk. These changes include reduction in the likelihood of obesity, improved blood pressure control in hypertensive individuals, reduction in serum cholesterol, decreased insulin resistance and other markers of inflammation, improved function and less stiffening of the large and small blood vessels, and reduction in the risk of pathologic blood clots. In contrast, physical inactivity and poor physical fitness are associated with a potentially harmful blood-clotting profile in middle-aged women with coronary heart disease.

Many women with multiple risk factors for heart disease are able to manage their risk factors through diet and exercise alone. For those women who require medical therapy to treat high cholesterol and high blood pressure, regular aerobic exercise provides an additional benefit.

Exercise in the Patient With Established CVD

CVD includes disease of the arteries of the heart, such as coronary artery disease (CAD), high blood pressure (hypertension; HTN), peripheral arterial disease (PAD), cerebrovascular disease, rhythm disturbances, diseases of the heart valves, and disorders of the small blood vessel not associated with actual blockages (small vessel disease). This entity of small vessel disease appears to be more common in women than men.

Exercise training is a significant component of rehabilitation of individuals who survive a heart attack (myocardial infarction; MI). Gradual, supervised regular physical exercise in survivors of MI not only introduces a healthy lifestyle habit to a potentially sedentary group but also enhances recovery from MI. Many of the benefits of exercise in this group include those described earlier but also include the psychological benefits afforded by regular physical activity. This is of particular value in this group due to the high prevalence of depression in survivors of MI and individuals who have undergone coronary artery bypass grafting. Female survivors of heart attack are much less likely than their male counterparts to participate in cardiac rehabilitation and currently miss out on the multiple beneficial aspects of this highly valuable but optional component of cardiovascular care.

The potential benefit of regular exercise in patients with PAD has also been demonstrated. A study examining the benefit of regular exercise in 118 patients with PAD demonstrated lower likelihood that the individuals who exercised would experience or die from a cardiovascular complication over the 5 years of follow-up.

Exercise can also lead to benefits among women with heart failure. Heart failure occurs when the heart can either not pump or not relax efficiently enough to deliver adequate blood supply to the body. Unfortunately, heart failure has reached epidemic proportions in the United States. Heart failure associated with abnormal heart relaxation (diastolic dysfunction) is common in women, particularly women over the age of 65. There is preliminary evidence available to suggest that regular physical activity not only treats the diastolic dysfunction but also treats the conditions that may be responsible for its presence in the first place, including obesity, high blood pressure, and diabetes. A recent large study examined regular aerobic exercise in men and women with reduced pumping function of the heart. This study found that regular aerobic physical activity leads to reductions in hospitalizations for heart failure and was not dangerous in this group of patients.

Exercise and Other Aspects of Women's Health

In addition to its beneficial effects on cardiovascular health, exercise has been shown to confer myriad other health benefits among women.

Exercise increases bone mineral density and, thus, prevents osteoporosis. Increased leisure-time activity, such as walking, has been shown to reduce the risk of hip fracture among postmenopausal women. It is worth noting that the beneficial effects of exercise may stem more from muscle strength, resistance, and balance training than from the intensity of the exercise itself. Furthermore, caution should be used in blanket recommendations to elderly women to exercise, as vigorous exercise among elderly patients may predispose them to the risk of falls and, thus, increase the risk of fracture.

In the realm of exercise and cancer, women who engage in regular physical activity have been shown to have a decreased risk of both colon and breast cancer. For women diagnosed with breast cancer, exercise has been shown to improve survival. As far as cancer risk is concerned, it is not entirely clear how much exercise confers risk reduction or at what stage of life. For breast cancer, it is postulated that exercise achieves this effect in women via reduction in adipose tissue and, thus, decreased overall estrogen production.

Finally, exercise has been shown to have numerous beneficial effects for women in terms of psychological well-being and cognitive function. Exercise has been shown to have utility in the treatment of major depressive disorder, with a dose-response effect, meaning that a certain level of exercise was necessary to achieve this response. Among women with premenstrual syndrome, exercise also seems to have a beneficial effect on both physiologic and psychological symptoms. Also for women with postpartum depression, a regular exercise program (three times per week) seems to mitigate depressive symptoms. Finally, among elderly women, a recent trial showed that a 6-month exercise intervention was associated with a modest improvement in cognitive function.

How Much and When?

Questions invariably arise when discussing the effects of exercise on women's health, namely, how much is exercise is enough and at what stage in life. These questions are difficult to assess because, as discussed earlier, exercise is associated with multiple different health benefits for women and each one may be associated with a different amount of exercise, at various stages of life. Thus, these questions continue to be investigated. For now, basic recommendations by the Centers for Disease Control and Prevention as well as the American College of Sports Medicine exist, suggesting at least 30 minutes of moderate-intensity physical activity on most days of the week. Indeed, a recent study following both men and women between the ages 50 and 71 years over time found that adherence to these guidelines, namely, engaging in moderately intense physical activity greater than 3 hours/week, led to a risk reduction of 27% in death from any cause among women in this age-group. This reduced risk was independent of other cardiovascular risk factors and body mass index.

Though these recommendations for a minimal amount of exercise exist, this does not mean that more exercise is not additionally beneficial. Again, the type of exercise, its intensity, and the age of greatest benefit depend on what outcome is being assessed. A recent prospective analysis among elderly women suggests that women who had previously had a sedentary lifestyle and began exercising after 65 years of age had reduced mortality.

Specifically, those women who increased their physical activity levels to a calorie expenditure equivalent to 1 mile (1.60 kilometers) per day of walking from their initial routine, to a follow-up 6 years later, had a reduction in cardiovascular mortality, cancer, and all-cause mortality. This benefit was not seen among women who began exercising after 75 years of age. Women who were consistently active, both before and after the 6-year intervention, had a similar risk reduction to those who only began exercising when the study began. Interestingly, recent physical activity levels were a better predictor of longevity than past. Another study, looking at 40,000 women, showed not only that there is a direct association between physical activity and decreased mortality but that the greatest benefit was seen among women who go from a sedentary lifestyle to one involving moderate physical activity.

Conclusions and Future Directions

In sum, exercise confers multiple health benefits for women. In the realm of cardiovascular health, exercise both prevents disease and improves outcomes among women with existing CVD. Exercise also has a role in mitigating cardiovascular risk factors, including hypertension, diabetes, and obesity.

Outside cardiovascular health, exercise has been shown to reduce the risk of osteoporosis, cancer, depression, and cognitive decline. Active investigation continues into optimal exercise regimens for women to achieve these health benefits, though research to date suggests that a clear health benefit occurs for most women who begin exercising, even if they have been inactive in the past.

World Anti-Doping Agency

The World Anti-Doping Agency (WADA) is a private Swiss law foundation, founded in 1999, responsible for ensuring fair competition in sports around the world. Its mission is to promote, coordinate, and monitor the fight against doping in all its forms. The WADA Code provides the basic framework for the agency's work, that is, "to protect the athlete's fundamental right to participate in doping-free sport and thus promote health, fairness, and equality for athletes worldwide." The objectives of the agency are to preserve the integrity and value of sports and youth, actively promote the "level playing field" philosophy, and act independently, professionally, and without bias or influence.

WADA is composed and funded equally by the Olympic movement and governments of the world. It is situated in Lausanne, Switzerland, and has its headquarters in Montreal, Canada. In 1999, the International Olympic Committee (IOC) held the first World Doping Conference in Sport in Switzerland. It was attended by the sports movement and representatives of several governments in an effort to establish an organized and cohesive plan to control a growing, complex problem in the world of competitive sports. There were several important results of this conference, including the establishment of the World Anti-Doping Code (the Code), the International Convention Against Doping in Sport (the Convention), and the Copenhagen Declaration on Anti-Doping in Sport (the Declaration).

Because many governments cannot be legally bound by a nongovernmental document such as the WADA Code, the International Convention was drafted under the auspices of UNESCO (United Nations Educational, Scientific and Cultural Organization), the body responsible for education, science, and culture. The Convention was unanimously adopted at the 33rd UNESCO General Conference in 2005. Separately, the Copenhagen Declaration was finalized at the World Conference on Doping in Sport in 2005. This declaration is the political document that signals a government's intention to formally recognize and implement the Code. As of 2007, 192 countries have signed the Declaration, and 80 UNESCO member states have become part of the Convention. In addition, more than 570 sports organizations have adopted the Code.

WADA is made up of a Foundation Board, an Executive Committee, and several other committees. The Foundation Board and Executive Committee comprise equally members of the Olympic Movement and governments. Government representation is allocated according to the five Olympic regions: Africa, Asia, the Americas, Europe, and Oceania (Australia and New Zealand). The Foundation Board has 38 members and is the agency's supreme decision-making body. The board delegates the management and running of the agency, including the performance of activities and the administration of assets, to the Executive Committee. Other committees such as the Athletic Committee or the Health, Medical and Research Committee act as advisors and provide guidance for WADA programs.

WADA received $18.3 million from the Olympic Movement to fund its first 2 years. Since 2002, funding was sourced equally from the Olympic Movement and the governments of the world. The governments agreed to a regional formula, and within each region, governments agree internally to each of their individual shares.

WADA prioritizes its work to focus on seven areas emanating from the Code.

1. *Code adoption, implementation, and compliance:* The agency ensures that sports and government agencies accept the principles of the Code. It assists in organizing a systematic testing process and ensures adjudication of results.
2. *Science and medicine:* WADA promotes global research to stay current on doping substances and methods. In addition, it maintains the annual List of Prohibited Substances and Methods, accredits antidoping labs worldwide, and monitors "therapeutic use exemptions."
3. *Antidoping coordination:* The Anti-Doping Development Management System (ADAMS) is the web-based database management system in place to assist stakeholders in coordination and compliance.
4. *Antidoping development:* The agency facilitates coordination of activities in regions where there are limited antidoping activities, so that resources can be pooled.
5. *Education:* WADA coordinates effective strategies and education to assist stakeholders in their education programs.
6. *Athlete outreach:* Antidoping experts take every opportunity, including one-on-one interaction at sporting events, to answer questions and educate athletes and stakeholders about the dangers and consequences of doping.
7. *Out-of-competition testing:* The agency contracts with stakeholders to help fulfill their responsibility for "no-notice out-of-competition" testing.

The Prohibited Substances and Methods list, as well as many other resources for athletes and stakeholders, is available on the WADA website and is updated annually (www.WADA-ama.org). The general categories of banned substances include androgenic anabolic steroids and other anabolic agents, hormones (e.g., growth hormone, erythropoietin, and insulin), hormone antagonists and modulators, beta-2 agonists, diuretics, and masking agents. Gene doping is specifically prohibited as well, although at this time, there is no reliable testing for this. Blood doping and other methods to enhance oxygen transfer are prohibited.

There is a process, of course, to ensure that an athlete who needs a substance that could be considered a doping agent for medical reasons, such as insulin or albuterol, can use it in a medically responsible way to treat an illness or condition. A Therapeutic Use Exemption (TUE) application is submitted to the athlete's local sports federation for review by a panel of independent physicians, called a Therapeutic Use Exemption Committee (TUEC). Preapproval, with possible monitoring of medication levels, is determined by the local federation. WADA does not accept TUE applications, but it has the power to overturn an exemption that has been granted or overturn a denial if it is determined that international standards were not followed.

There are three basic criteria to determine if an athlete will be granted a TUE: (1) the athlete would experience significant health problems without taking the prohibited substance or method; (2) the therapeutic use of the substance would not produce significant enhancement of performance; and (3) there is no reasonable therapeutic alternative to the use of the otherwise prohibited substance or method.

The problem of doping is an extremely complex one, often with enormous financial, political, and cultural implications. WADA has created an intricate system with checks and balances, as well as international representation to work for and protect athletes and sporting events, large and small, around the world.

Wrestling, Injuries in

Wrestling is a sport in which the clinician faces many unique challenges. A strong knowledge of infectious skin diseases and issues related to weight control is imperative for anyone concerned with this sport. Many common sports medicine injuries will be encountered in wrestling. One common injury definitively seen in wrestling is concussion.

Concussion

Concussion is defined as any impact to the head or to the trunk, chest, or neck that radiates force to the head. It is often believed that concussion needs to have loss of consciousness or amnesia associated with it, but this is not the case. Although common, these symptoms do not necessarily need to be present. Concussion is characterized by a spectrum of symptoms, including but not limited to headache, dizziness, nausea, vomiting, confusion, cognitive difficulties, and balance disturbances. These symptoms occur quickly after impact, are neurological in nature, and generally abate spontaneously over time. For an athlete experiencing symptoms, a complete physical examination, including a thorough neurological and mental status examination, should be performed. Diagnostically, a computed tomography (CT) scan or magnetic resonance imaging (MRI) scan is ordered by physicians to rule out further pathology, such as bleeding within the brain. Concussion is treated symptomatically. Only when an athlete is symptom-free, is not taking any medicines for symptom control, and has normal mentation can he or she be placed on a return-to-sport protocol. A symptomatic wrestler is never allowed to return to his sport.

Auricular Hematoma (Cauliflower Ear)

An auricular hematoma occurs from trauma to the cartilaginous portion of the ear. In this area, blood collects between the skin and cartilage. If not treated in a timely manner, the deformity to the ear can become permanent. Treatment is via aspiration of the blood before it clots and application of a pressure dressing or other device to avoid further bleeding and accumulation of blood.

Epistaxis (Nosebleed)

A nosebleed occurs most often when there is breaking of the small vessels at the front of the nose due to trauma. Quite often, wrestlers are prone to recurrent nosebleeds because of continued trauma to the nose. It is important to try to stop the bleeding as quickly as possible. This is done by tilting the head forward and pinching the nostrils until the blood stops. A cotton plug or dental gauze placed in the nose can continue to hold pressure so that a wrestler can finish the match. If the bleeding becomes recurrent, then cauterization of the nasal vessels can often lead to permanent relief of the symptoms.

Sprains and Strains

A sprain refers to an injury to a ligament where it is stretched or, in the worst case, completely torn. A strain refers to an injury to a tendon or muscle where it is "pulled" or partially torn. Sprains and strains can happen to any joint in the body and are common in wrestling due to the consistent contact between the wrestlers and the contact of the athletes with the mat surface. They are characterized by pain, swelling, redness, loss of motion, and loss of strength at a joint. During competition, sprains and strains can be treated by the PRICES protocol, which refers to *p*rotection of the joint, *r*est, *i*ce, *c*ompression, *e*levation, and *s*upport of the joint. Once a more severe injury is ruled out by either physical examination by a physician or further radiological studies, physical therapy, taping/bracing, and anti-inflammatory medications are used to try to treat these conditions. Unfortunately, many complete sprains, such as those of the anterior cruciate ligament, or tendon/muscle tears, such as that of the patella tendon, require surgical intervention to reestablish proper functioning of the affected joint.

Fractures

A fracture is a medical condition in which there is a break in the bone. It can happen to any bone in the body. In wrestlers, the bones that are frequently fractured are the nasal bones, the bones of the fingers or toes, and those of the wrist and ankle, though other bones may also undergo fracture. Fractures are identified by pain, swelling, bruising, and redness at a fracture site. Physicians are suspicious of a fracture if there is pain directly on a bone or if they can feel a break, or step-off, in the outer covering of the bone, or cortex, when they follow the smooth contour of a bone. There is also a loss of motion or strength if a joint is involved. In general, suspected fractures are splinted or braced at the site of competition, ice is applied, and the athlete is sent for confirmation of the fracture. X-rays, MRI, CT, or bone scan can confirm fracture in a wrestler. Fractures are treated by splinting or casting to allow bone alignment for healing. For those fractures whose alignment cannot be maintained by splinting or casting, surgery is necessary to insert hardware to keep the bone ends together in order to allow the fracture to heal.

Cervical Strain (Neck Strain) and Lumbar Strain (Back Strain)

This injury occurs when there is a strain or injury to the muscles of the neck/back, usually during a takedown or bridging. It is characterized by pain and sometimes spasm of the muscles that line the spinal column. As long as there is no injury to the spinal cord or column, this injury usually heals without much difficulty. Treatment is icing and anti-inflammatory medications to the neck/back as well as physical therapy to the neck/back muscles to stretch and strengthen them.

Dislocated Shoulder

This injury occurs when the humeral head, or top of the arm bone, becomes separated from the glenoid, or shoulder bone. There is often pain deep within the shoulder and possibly numbness down the arm on the same side. One can often see the top of the humerus, either in front or behind the glenoid. When this occurs, it is important to be sure that the athlete has normal neurovascular status and absence of obvious fracture before even considering reducing or putting the shoulder back in place. If there is no qualified person available, the arm should be splinted and the athlete sent to the hospital for reduction. An X-ray at the hospital can then aid in determining the position of the humerus, rule out fracture, and assist in the reduction. Once reduced, the shoulder is checked for further pathology with an MR arthrogram. If there is no further pathology, physical therapy should bring the shoulder back to normal function. If there is further pathology, often surgery is performed to repair the damaged soft tissue structures and prevent another episode of dislocation.

Acromioclavicular (AC) Separation (Separated Shoulder)

This occurs when a wrestler lands directly on his or her shoulder, usually during a takedown. This results in a sprain of the ligament between the acromium, or shoulder bone, and the clavicle, or collarbone. This is often demonstrated by the clavicle being elevated above the acromium. An X-ray can confirm this. This injury often responds well to physical therapy and usually does not require surgical intervention.

Brachial Plexopathy (Burner or Stinger)

This injury occurs when the neck is forcibly side bent as the shoulder on the same side of the body is depressed, causing a stretch of the brachial plexus, the site where the nerves that innervate the upper extremity on the affected side exit out the neck and through the shoulder area. This can happen when a wrestler is forcibly taken to the mat. The wrestler usually complains of burning pain from the base of the neck through the entirety of the affected extremity. The condition usually lasts seconds with an initial episode but takes longer to resolve after each successive episode. The pain usually resolves on its own in several seconds to several minutes depending on the number of past episodes a wrestler has endured. There is generally no work-up done by the physician unless the condition becomes chronic. In this case, X-rays are ordered to look for bony structural issues that may be causing the injury. These may be followed by MRI or CT scan to further evaluate both bony and soft tissue structures to determine if there is an anatomical reason for the injury and to determine whether the wrestler should be removed from the sport because of the danger of neurological damage from repetitive injury due to his or her anatomy. Initial stingers are usually returned to play once the symptoms have resolved. Those who have repetitive episodes will need further examination to make sure that anatomy is not contributing to the injury and usually undergo a cervical stretching and strengthening program to prevent further injury.

Ulnar Collateral Ligament Sprain of the Elbow

The elbow is essentially a hinge joint made from the coming together of the radius and ulna (the two smaller forearm bones and the larger humerus, or upper arm bone). Wrestlers typically suffer injury to the ulnar collateral ligament of the elbow, which is the ligament connecting the ulna and humerus, when posting after a takedown or during an arm chop when the wrestler is beginning on the bottom position. Both these maneuvers can lead to stress on this ligament and a possible stretch, sprain, or tearing of the ligament. The physician can check the integrity of the ligament by putting force on it. If moves and "gaps" are more than on the opposite side, there is concern for a sprain or tear. An X-ray can determine if this is due to fracture. MRI can show the extent of damage to the ligament. A complete tear would require surgical repair in a wrestler. A sprain would require possibly bracing to let the ligament begin to heal, followed by physical therapy to regain normal elbow function.

Ulnar Collateral Ligament Tear of the Thumb (Gamekeeper's Thumb)

This injury occurs when the thumb is abducted or forced away from the rest of the hand. This movement may sprain or tear the ulnar collateral ligament that connects the proximal phalanx of the thumb to the first metacarpal. Wrestlers with this injury cannot oppose the thumb. An X-ray can rule out fracture at the joint. MRI can show damage to this ligament. Treatment involves casting or splinting of the thumb for sprains and surgery for complete tears.

Back Pain

Back pain in wrestling is usually due to a muscle strain or "pulled muscle" during competition. Some forms of back pain in wrestling are not due to muscle strain. One such cause is herniation of a vertebral disk. Disk herniation occurs when the soft jelly-like part of the disk escapes through a tear in the annulus fibrosis, which is the tougher covering of the disk. When radicular symptoms, pain or numbness occurring in either lower extremity or both, are present, the pain may be due to a herniated disk causing stenosis or pressure on the nerve that innervates that particular lower extremity. A less common cause of back pain sometimes found in wrestling is a spondylolysis, or stress fracture of the pars portion of the vertebra. This can occur due to the consistent flexion and extension of the back while wrestling. Physical examination, X-rays, MRI/CT scans, and bone scans can often elucidate which of these conditions is causing the back pain. Muscle strains, herniated disks (with and without stenosis), and annular tears are usually treated conservatively with rest, icing, physical therapy, and anti-inflammatory medications. Epidural injections, injection of cortisone at the area of disk herniation, or surgery, may be needed if pain cannot be treated conservatively. Return to sports is usually guided by pain tolerance in the wrestler unless neurological symptoms occur. Spondylolysis treatment is more controversial. Many physicians recommend physical therapy and return to sports when painfree. Others recommend bracing followed by physical therapy and then return to sports. There is no consensus on treatment for this condition.

Trunk Pain

Pain in the area of the trunk is common in wrestling. This is often caused by movements in which one wrestler grasps the other wrestler, trying to expose his or her back. Pain in the rib area can be due to rib fracture or due to a strain of the small muscles between the ribs, the intercostals. It can also be due to strain of any of the abdominal muscles. Symptoms of rib fracture or muscle strains in the trunk can include pain at the site of injury, pain with movement, or difficulty breathing. With pain, an immediate physical examination should be performed, including listening to the lungs, to be sure that a fractured rib has not pierced a lung, creating a pneumothorax. X-rays are diagnostic of rib fractures. Treatment for rib fractures as well as strains includes rest, icing, medications for relief and pain, and physical therapy. Return to wrestling after a rib fracture is allowed when the fracture has healed, to avoid pneumothorax. Pain is the guide for wrestlers with simple strains.

Groin Strain (Groin Pull)

A strain of the muscles of the groin can occur in an area where the external rotators or flexors of the hip are located. This injury is characterized by movement in these planes. These injuries are usually self-limiting but can take several weeks to heal. Treatment is usually with rest, icing, anti-inflammatory medicines, and rehabilitation.

Knee Meniscal Tear

The meniscus is the shock absorber found between the femur, or upper leg bone, and tibia, or lower leg bone. There is one on the inside of the knee, or medial, and one on the outside, or lateral. Meniscal tearing occurs during a plant-and-twist injury, such as getting a foot caught in the mat when the wrestler is attempting to escape his or her opponent. Wrestlers often report feeling or hearing a “pop” or “tear.” This is often accompanied by swelling within the knee and pain at the knee joint line. Often, it is difficult to walk on the affected leg. Physicians can test the affected meniscus for tearing by performing the McMurray test. In this test, the physician attempts to catch a piece of the damaged meniscus between the femur and tibia by manipulating the knee. X-rays cannot reveal a meniscal tear. An MRI test usually can detect meniscal tears. Meniscal tears are treated usually by surgery to either repair the damaged meniscus, if good blood supply is present, or remove the damaged part of the meniscus in a procedure called a partial meniscectomy. Surgery is usually followed by physical therapy. Meniscal tearing that does not produce symptoms can also be treated by physical therapy with or without cortisone injection.

Patella Dislocation/Subluxation

The patella is also called the kneecap. It sits in the groove of the femur, or top leg bone, and aids in extension of the knee. It is stabilized at the top of the bone by the quadriceps tendon and on the bottom by the patellar tendon. With certain moves, the patella can reach the edge of the groove and almost slide over it, referred to as a subluxation. If the kneecap does in fact pass over the groove, it is referred to as a dislocation. The kneecap often moves laterally, or to the outside of the leg, with this movement. Patients often complain of hearing a “pop,” have immediate pain and swelling at the knee, and may visualize the kneecap on the outside of the femoral groove. Often, the kneecap will go back into place as the wrestler moves secondary to the pain he or she has from the displacement of the kneecap. If it does not go back into place on its own, the kneecap is often stabilized with an immobilizer or a brace. The physician usually performs an Apprehension Test, where he or she places outside stress on the kneecap to see if the symptoms of kneecap subluxation/dislocation can be mimicked. X-rays are often taken to ensure that there is no fracture, and the physician will manipulate the kneecap back into place. This may be followed by an MRI test to be sure that there is no subtle fracture that was missed by the X-ray or that there is no tearing of important soft tissue structures holding the kneecap in place. Surgery may be necessary to repair these tissues. Physical therapy is then done to maximize function and strength, either after surgery or in the absence of soft tissue damage after a patella dislocation.

Prepatellar Bursitis

The patella has a fluid-filled sac, called a bursa, between it and the underlying soft tissue. This bursa is necessary to allow the soft tissue structures above the patella to pass over the bone without causing injury. In competition, wrestlers often land directly on their knees, causing a compressing force on the bursa as it is trapped between the bone and the mat surface. This can lead to an inflammation of the bursa or bursitis. The hallmark of a prepatellar bursitis is swelling just above the patella. The swelling feels like a fluid-filled sack and renders the knee painful when one tries to kneel on the affected knee. There are usually no tests used to diagnose this problem as its appearance itself is diagnostic. Often, the bursal fluid will recede on its own. If the fluid does not recede on its own, it can be aspirated by a physician. Once recovered, the wrestler can return to competition. If the bursa becomes infected, the condition is called a septic bursitis. Antibiotics are usually given to the athlete to treat the infection, and aspiration is delayed until the infection has cleared.

Ankle Sprain

An ankle sprain is caused when the foot either turns out (or everts) or turns in (or inverts) during activity as the body weight passes over it. The athlete at the time of the sprain sometimes hears a "pop" followed by immediate pain and swelling in the affected area of the ankle. Walking, or ambulation, is often difficult, and crutches must sometimes be used. Once an ankle sprain occurs, the ankle is usually immobilized and iced immediately. The physician usually checks range of motion and strength to assess damage to the joint. Certain tests, such as the Anterior Drawer Test or Tilt Test, check the integrity of the ligaments after a sprain. X-rays are often ordered to rule out associated fractures. Weight-bearing X-rays may be performed to be sure that the bones of the ankle have retained their alignment or have held together the functioning unit of the ankle, called the *mortise*. MRI may be necessary to look at the soft tissue damage more intently or determine if there has been damage to the ligaments or soft tissue between the tibia and fibula that may necessitate early surgical intervention. Simple ankle sprains are generally treated with protection, rest, ice, compression, elevation, and support. Physical therapy is usually necessary to restore movement and function.

First Metatarsal Sprain (Turf Toe)

This condition refers to a sprain of the collateral ligaments—or ligaments that connect the two sides of a joint—that connect the first metatarsal, or last foot bone, to the proximal phalanx, or first toe bone. The condition gets its name commonly from football, where the first toe can be sprained when it gets caught in the artificial turf during play. The principle is the same in this case, as the toe gets caught in the mat and sprains the joint. The athlete commonly complains of loss of motion and/or strength, pain, swelling, and possibly redness at the site. After the physician checks motion and strength, X-rays may be obtained to be sure that there is no underlying fracture at the joint. If there is no fracture, treatment consists of applying ice to the joint, therapeutic taping, physical therapy, and sometimes shoe modification to make the sole of the wrestling shoe stiffer in order to keep the toe straight. Pain is usually the limiting factor for the athlete's return to play.

Wrist Dislocation

The wrist joint serves as a link between the hands and the upper body, and a great deal of force is transmitted through this joint. The specific arrangement of bones and the presence of ligaments provide flexibility to the joint. Although this flexibility helps in the movement of our hands and fingers, it also allows for dislocation.

Wrist dislocation means that the wrist bones have been knocked out of position or a bone has come out of place in the wrist joint. It is sometimes also referred to as carpal dislocation. Such an injury is common among athletes. It is usually experienced in sports with increased force vectors (height and speed), for example, adult inline skaters and football players. Other cases include falls from a height, as seen, for example, in gymnasts.

The most common cause of injury is high energy, but low-energy trauma has also been described as the cause of carpal dislocation in some reports.

Wrist dislocation is a serious injury and requires immediate emergency care. In a study by Larsen and Lauritsen, as many as 2.5% of all cases presented in various emergency departments of the United States are wrist injuries. Ten percent of all carpal injuries are subluxations and dislocations, perilunate dislocation being the most common type.

The initial evaluation and treatment of wrist injuries can be performed by emergency physicians and/or family practitioners. Early recognition of a dislocation and determination of proper treatment can prevent complications, including prolonged pain, discomfort, and surgery, and time lost from sports participation.

Anatomy

The wrist comprises 10 bones: 8 of these are the carpal bones, and the remaining 2 are (lower ends of) the forearm bones (see Figure 1).

The carpal bones are arranged in two rows and include the scaphoid, lunate, triquetrum, and pisiform in one row and the trapezium, trapezoid, capitate, and hamate in the other. The forearm bones are the radius and the ulna.

A complex set of ligaments holds the carpal bones together and assists in movement. These ligaments are named according to the bones they hold together. Dorsal ligaments are weaker than other ligaments; making this side of the joint more vulnerable to dislocations.

Types of Wrist Dislocation

Wrist dislocations can be divided into two types:

Perilunate dislocations: The lunate remains aligned with the radius, but the capitate dislocates. It is more common than lunate dislocation as the radial-lunate ligaments are stronger than the lunate-capitate ligaments. Seventy-five percent of the cases are associated with scaphoid fractures (known as trans-scaphoid perilunate dislocation).

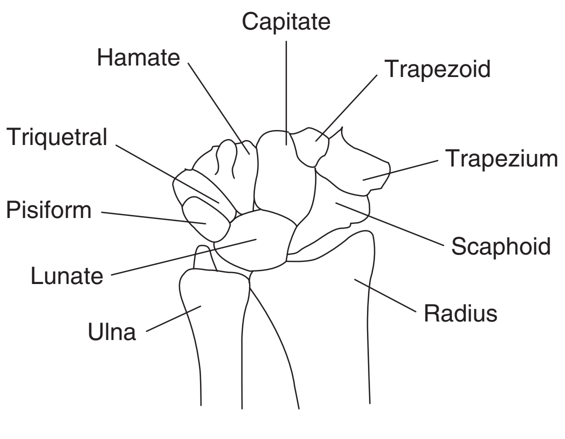

Figure 1 Bones of the Wrist Joint

Lunate dislocations: In these, the lunate bone dislocates, and the other carpal bones remain in alignment. This type of dislocation is less common than perilunate dislocation.

Causes

Wrist dislocation can occur as a result of either of two causes:

1. *Repetitive activity:* Repeated stress on the carpal ligaments renders them more prone to injury, especially in athletes. In some cases, the overuse may be so great that the wrist bones slip.
2. *Trauma:* Sudden extreme pulling or stretching of the ligaments or a severe blow to the bones, commonly due to falling on an outstretched arm, can result in dislocation. This type of dislocation most commonly involves displacement of the lunate bone, but other bones of the wrist can also be involved.

Stages of Dislocation

Mayfield and coworkers have classified wrist dislocation into four stages:

Stage I: Scapho-lunate dislocation due to a tear in the ligaments holding these bones together

Stage II: Lunate-capitate subluxation that results from injury to the capito-lunate joint

Stage III: Lunate-triquetral dislocation resulting from injury to the ligament

Stage IV: Lunate dislocation resulting from injury to the dorsal radio-lunate ligament (the ligament that holds the lunate against the radius)

Clinical Evaluation

The evaluation of a wrist dislocation begins with a history and physical exam.

History

The typical history is one of a person who attempts to brace for a fall. The force of the body landing on the palm results in a dislocation. Sometimes athletes can dislocate their wrist on falling on an outstretched hand when they have mistimed a landing, as in gymnastics. Wrist dislocation is also seen in football, where defenders try to stop oncoming forces with resistance. Often the resistance is great enough to lead to a wrist dislocation.

Physical Examination

On physical examination, the following signs and symptoms are observed in a case of wrist dislocation:

- Extreme pain at the time of the injury that worsens with movement
- Loss of wrist and hand mobility or decrease in the range of motion
- Deformity or contortion of the wrist
- Tenderness around the wrist and hand area
- Swelling of the wrist
- Hand weakness (unilateral)
- Decrease in grip strength
- Numbness and paralysis of the hand in case of severe injury (due to pressure, pinching, or cutting of blood vessels or nerves)

Sometimes neither the patient nor the physician is able to appreciate the severity of the trauma, and the dislocation may present itself after a delay. Therefore, during the evaluation of a patient with wrist injury, dislocation should always be suspected.

Diagnostic Tests

Sometimes tests are required to make the diagnosis of a wrist dislocation. Tests that can be done include the following:

X-rays of the wrist: Radiographs of both hands are taken for comparison, and bone alignment is checked along various planes/axes.

Bone scan: A radioactive tracer is injected into the blood and gets attached to all the bones of the body. A computer scan generates a picture of the skeleton by reading the radiation levels. Any abnormalities are easily observed.

Magnetic resonance image (MRI) of wrist: An MRI scan provides good resolution of soft tissue as well as bone.

Wrist arthroscopy: This is a surgical procedure used to diagnose and treat problems inside a joint. Small incisions are made around a joint, and a pencil-sized instrument called an arthroscope is inserted. The arthroscope contains a miniature lens and camera, which project the three-dimensional images of the joint onto a screen.

Arthrography: It is useful in detecting tears of the ligaments.

Treatment

Nonsurgical Approach

All types of injuries need to be assessed by a physician. If there is no evidence of fracture and the injury is not very severe, the wrist bones may align themselves properly and heal with time. There may be a need for repositioning the bones to reduce the dislocation. If there is an associated wrist fracture, surgery is performed to restore the joint to its normal position.

Surgical Approach

Surgical reconstruction or replacement of the joint is required in acute or recurring dislocations. It is performed under anesthesia. The surgeon opens the hand and wrist area and aligns the bones properly. In case of major damage, other devices such as surgical screws may also be used.

Associated Measures

Along with treatment, the following measures should be incorporated to enhance successful healing:

- Elevation of the wrist
- Rest and immobilization, perhaps with a sling for 2 to 8 weeks
- Ice, which helps in reducing acute pain and swelling
- Compression of the wrist (cold compresses may be used)
- Elastic (ACE) wrap
- Cast or splint for a wrist dislocation
- Physical therapy for a wrist dislocation, including exercises designed to build up the muscles of the hand and wrist, helpful in restoring full functional strength and motion in the hand and wrist
- Occcupational therapy for a wrist fracture

Symptomatic Treatment

The following medications may be included in this treatment:

Nonsteroidal anti-inflammatory drugs (NSAIDs): These lower the elevated body temperature and relieve pain without impairing consciousness and have anti-inflammatory effects.

Narcotic pain medication: These are strong pain relievers and cause loss of feeling.

Prevention

Use of gloves, wrist guards, or tapes, if the sport permits, can provide some protection to the wrist. Implementation of proper technique and maintenance of good strength and good flexibility can prevent wrist injuries. In case of an injured wrist, the patient should return to play only after achieving full recovery.

Return to Sports

The dislocated joint and the injured ligaments require a minimum of 6 weeks for complete healing. On returning to work, the patient may support the wrist with a tape or a brace initially if he or she is required to perform lifts or bear weight on the involved wrist.

Sometimes, undergoing special exercise programs, physical therapy, or occupational therapy to restore full strength may be necessary. A physician should be consulted in all cases before resuming routine physical activities.

Wrist Fracture

In sports, the wrist is one of the most vulnerable parts of the body. Wrist fractures are among the most common sports-related injuries. Surveys have shown that women, beginners, and younger athletes are more prone to wrist injuries, and it is recommended that they wear wrist guards that help protect the wrist from injury.

Wrist fracture is the most common fracture in patients under 65 years of age and accounts for about one sixth of all factures seen in hospital emergency departments. It is defined as a break in one or more of the bones in the wrist, but when clinicians are describing wrist fracture, they are usually referring to a fracture of the distal end of the radius (one of the two bones in the forearm, the other being the ulna). The other bones of the wrist joint may also be broken, but the term *wrist fracture* usually implies a fracture of the end of the long bone of the forearm.

Fractures of the wrist most commonly occur as the result of a person extending his or her hand to break a fall, due to which a large amount of force is applied to the wrist, causing the fracture (usually seen in sports where a fall on a hard surface is likely, such as skating, basketball, and hockey); or they may be due to a large force being directly applied to the wrist (e.g., a direct blow during contact sports or a blow from a stick, as in hockey or lacrosse). Injuries related to sports, car accidents, and falls from a height are important contributing causes of wrist fracture. In older individuals, osteoporosis may play a significant role by making the bones brittle and more susceptible to fractures, even with minor trauma.

Anatomy

The wrist is made up of two long bones in the forearm (ulna and radius) and eight short bones (carpal bones). The radius is located on the thumb side of the forearm, while the ulna is located on the side of the little finger. The carpal bones are situated in two rows (four in each) at the wrist joint and have synovial joints between them, but movement at these joints is restricted. The ulna and radius are joined at the proximal radio-ulnar joint near the elbow and the distal radio-ulnar joint at the wrist.

The wrist joint is a complex synovial joint between the distal end of the radius and the end of the ulna with the proximal row of carpal bones (the distal row of carpal bones make the carpo-metacarpal joints with the metacarpal bones of the hand). The joint between the radius and ulna is fixed due to the articular disk covering the end of the ulna. The surfaces of carpal bones form a convex contour that articulates with the concave surface of this articular disk and radius. At each joint, the end of the bones is covered by a cartilage, which allows for smooth movements. The bones are held together by ligaments. The joint cavities are filled with synovial fluid, which reduces friction. This arrangement allows for movement at the wrist around two axes, side to side, and the bending and straightening of the wrist. Rotation of the wrist is brought about by combinations of these movements.

In addition, there are a number of nerves and blood vessels traversing this region that may be damaged due to injury to the wrist.

Classification of Wrist Fractures

Generally, the different patterns of fracture of the wrist are the Colles fracture, the Smith fracture, the Barton fracture, and the Chauffer fractures. The classification of fractures is based on the pattern of injury involved, the behavior and outcome of that pattern, and the need to distinguish between conditions requiring different treatment strategies. Furthermore, the fracture may be extraarticular or intraarticular (extending into the joint cavity or not), it may be a closed injury or a compound fracture, and comminution (the amount of crumbling at the fracture site) may be extensive or minimal.

In assessing the stability and determining treatment, many features of the fracture must be considered, such as radial shortening, radial angulation, comminution, articular incongruity, accompanying soft tissue injuries, and associated ulnar fractures.

In addition, other bones of the wrist may also be broken in wrist fractures, the most common being the scaphoid (carpal bone articulating with the radius) (Figure 1a) and the "hook" of the hamate (Figure 1b).

Symptoms and Evaluation

Wrist injuries inflicted in vehicle accidents or sports or in any other way can result in wrist fractures. The first symptom experienced by the person is pain that occurs immediately after the injury and does not subside. The intensity of pain varies with different kinds of fractures and from person to person. Other symptoms may be swelling and tenderness around the wrist, bruising around the wrist, limited range of motion of the thumb and wrist, and visible deformity of the wrist. These symptoms can also be due to other conditions, so it should not be assumed that there is a fracture. A doctor should be consulted.

Diagnosis can be made by observing the deformity of the distal radius, but it should be confirmed by an X-ray. Computed tomography (CT) scans and magnetic resonance imaging (MRI) can also be helpful in confirming the diagnosis if fractures are not seen on X-ray immediately after the injury.

Treatment

The treatment differs widely depending on the nature and severity of the injury. The treatment plan consists of the following:

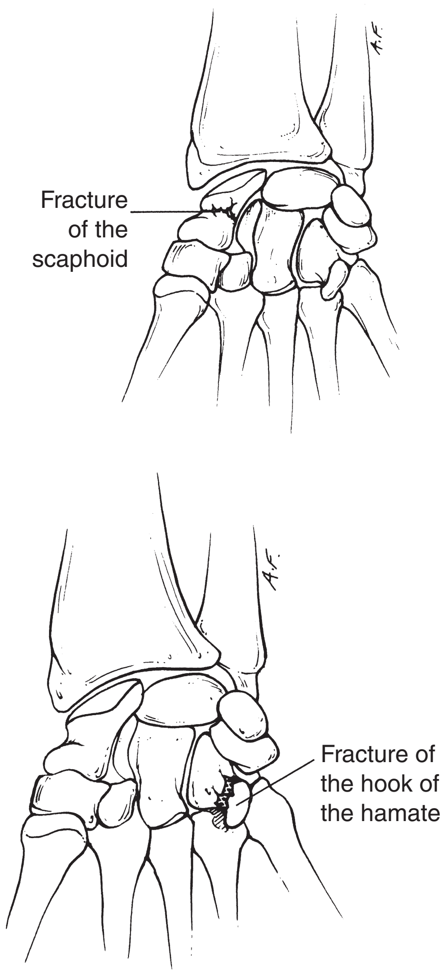

Figure 1 Wrist Fractures

Note: (a) Fracture of the scaphoid and (b) fracture of the hook of the hamate.

- It involves approximating the pieces of the fractured bone together, which may require anesthesia and also may require surgery.
- The pieces of bone should be kept in position while the bone heals and the ends join.

After the reduction of the fracture, different modalities may be employed to hold the bone in place (stabilization):

- A cast may be used with or without surgery.
- Internal fixation may be done with a metal plate and screws.

- Percutaneous pin fixation may be done.
- External fixation may be done.
- A combination of these modalities may also be used.

The typical treatment is immobilization with a plaster of paris cast for 5 to 6 weeks to allow union of the bones. The use of other modalities depends on the nature and extent of the injury, and appropriate treatment for each case is determined by the surgeon. For athletes requiring the use of their wrist, such as in tennis, motocross, or cycling, recovering from a fracture without stiffness is important. This is done by performing surgery only when necessary to realign the bones and treating postsurgery without a cast to allow early motion of the wrist and fingers. Due to the functional importance of the hand, the period of immobilization is kept to a minimum to avoid dysfunction of the hand and wrist. The more motion these patients have, the easier it is to resume their sport.

Follow-Up and Recovery

It is common practice to repeat X-rays at about 1 week during the follow-up period. Follow-up is also needed to determine when the cast may be removed, when the fracture has healed and the rehabilitation is complete. Removal of the cast is followed by rehabilitation for 1 month or more, a short period of which may involve the use of a wrist brace for comfort.

Return to sports should be decided by the patient's physician. Braces should be used to stabilize the wrist during sports or even normal activities. In most cases, athletes can return soon after the immobilization with some protection for the wrist or after adequate postoperative healing, as recommended by the doctor. When the pain subsides, the athlete should work on strengthening the wrist and improving its function, as directed by the doctor. This is usually achieved by performing stretching exercises such as

- wrist range of motion,
- wrist stretch,
- wrist extension stretch,
- wrist flexion stretch, and
- forearm pronation and supination.

These are followed by strengthening exercises such as

- wrist flexion,
- wrist extension, and
- grip strengthening.

It is important during fracture healing that the flexibility of the fingers and hand be maintained. The patient may start hand and wrist exercises as soon as the wrist is stable, to recover the flexibility, strength, and function of the wrist. It is recommended to stay off sports for 6 weeks at least, but the time for recovery varies according to the severity of injury, on any associated injury, and on factors related to the individual. Full recovery may take 6 to 12 weeks, when the patient may resume normal activities, but it is not unusual for maximal recovery from a wrist fracture to take several months. Some patients may, however, have residual stiffness or pain, and even arthritis may develop. On occasion, reconstructive surgery or additional treatment may be required.

Prevention

Certain risk factors increase the chance of developing wrist fractures:

- Advancing age
- Postmenopause
- Poor nutrition
- Osteoporosis
- Decreased muscle mass
- Contact sports such as soccer or rugby
- Skating, bike sports, skateboarding
- Vehicle accidents

Risk of injury may be avoided by following these simple guidelines:

- Putting oneself at risk for trauma should be avoided.
- The diet should include adequate calcium and vitamin D.
- Proper safety equipment should be used in sports training and contests.
- Fair play and a healthy competitive spirit should be practiced.

- Rules must be enforced to minimize risk of injury to players.
- The athletes should be provided proper coaching and training by qualified specialists.

Prompt medical attention should be easily available to the athlete at all times, especially in cases of emergency.

Wrist Injuries

The wrist is frequently injured in sports. Sprains are the most common wrist injury, accounting for 20% to 50% of injuries, followed by contusions (15%–30%) and fractures (5%–35%). Distal radius fractures are the most common fracture seen in emergency departments; scaphoid fractures are the most common carpal fracture. Acute injuries of the wrist occur in sports such as football, hockey, and snowboarding, most often from falls. Falls resulting in wrist injuries can also be seen in recreational activities such as rollerblading and biking. Overuse wrist injuries occur in sports such as golf, gymnastics, and racquet sports. It is important to recognize wrist injuries and ensure appropriate treatment to avoid impairments that may affect not only sports participation but also activities of daily living.

Wrist injuries are more common in children and adolescents than in adults participating in sports. Wrist and hand injuries account for between 3% and 20% of all athletic injuries in the younger population. Possible reasons to explain this increased frequency of wrist injuries in young athletes include increased sports participation by younger athletes; the increased popularity of "extreme" sports; the use of age- or size-inappropriate equipment; increased risk of injury of the immature musculoskeletal system in children, particularly with excessive frequency or intensity of certain sport-specific activities; and poor sport-specific techniques, poor supervision, and inadequate coaching.

Anatomy

The joints of the wrist include the radiocarpal joints and the distal radioulnar joint. The radius articulates mainly with the scaphoid. The ulna articulates primarily with the lunate. Movement at the radiocarpal joints includes flexion-extension and radioulnar deviation. Movement at the distal radioulnar joint includes pronation-supination.

The carpal bones in the wrist consist of a proximal row, including the lunate, triquetrum, and pisiform, and a distal row, including the trapezium, trapezoid, capitate, and hamate. The proximal and distal rows of carpals are bridged by the scaphoid bone. The ossification centers of the carpal bones appear on X-rays in a predictable pattern. The capitate appears first at less than 1 year of age, followed by the hamate, triquetrum, lunate, scaphoid, trapezius, trapezoid, and pisiform. All ossification centers are apparent on X-rays by 10 years of age. The distal radial epiphysis appears by 1 year of age, whereas the distal ulnar epiphysis becomes visible by 6 to 7 years of age. These physes close by 16 to 18 years of age, when skeletal growth has been completed. Knowledge of the appearance of these ossification centers and epiphyses can help avoid confusion between normal structures and possible fractures and bony injuries in children and adolescents.

Wrist stability is imparted by several extrinsic and intrinsic ligaments. The carpal bones are stabilized by the intercarpal ligaments and allow for transmission of forces across the wrist. There are many extrinsic tendons that traverse the wrist, including the wrist flexors (flexor carpi radialis, palmaris longus, flexor carpi ulnaris) and wrist extensors (brachioradialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor carpi ulnaris).

Evaluation of Injuries

Details of Injury

The mechanism of injury, including the position of the wrist, the direction and magnitude of the involved force, and subsequent symptoms of weakness, pain, or instability, can help determine the cause of wrist pain. Acute injuries are usually the result of a *f*all *o*n an *o*ut*s*tretched *h*and (FOOSH). Striking a solid object with a piece of equipment, such as a bat, golf club, or tennis racquet striking the ground, can result in a fracture of the hook of the hamate. Rotational stress to the distal radioulnar joint, as well as forced ulnar deviation and rotation, may result in a tear to the triangular fibrocartilage complex (TFCC). More severe wrist injuries may prevent an athlete from returning to activity immediately following injury.

The exact location of pain helps narrow the differential diagnosis. Wrist injuries may result in mechanical symptoms such as clicking, snapping, or swelling. Previous injuries to the upper extremities may predispose an athlete to wrist injuries. Other important details such as hand dominance, type of sport, position played, level of performance, and occupation may affect management of the injury.

Physical Findings

Wrist injuries may cause obvious deformity, swelling, or bruising of the wrist. The athlete may hold the wrist in various positions to avoid pain. The range of motion of the injured wrist may be decreased flexion-extension, supination-pronation (hand down/hand up), and radial-ulnar deviation. Normal range is 20° of radial deviation and 60° of ulnar deviation. Comparing the range of motion of the injured wrist with that of the uninjured side can emphasize any decreased movement of the injured wrist. Decreases in wrist movement can also be seen when the hands are placed in the "prayer position" and "reverse prayer position." The prayer position evaluates wrist extension. The patient apposes the palms with the elbows flexed and the wrists extended. Normal range of motion is 70° of wrist extension. The reverse prayer position evaluates wrist flexion. The patient apposes the dorsal aspects of the hands with the elbows and wrists flexed. Normal range of motion is 80° of wrist flexion.

Bony injuries of the wrist may result in tenderness to palpation or deformity. Bony prominences that may be tender to palpation include the distal forearm, the radial snuffbox, the base of the metacarpals, the lunate, the head of the ulna, the radioulnar joint, the pisiform, and the hook of the hamate.

Special tests of the wrist that may point to a specific injury include the Watson test and TFCC integrity. The Watson test evaluates scapholunate stability. The examiner places a thumb on the scaphoid tuberosity with the patient's wrist in ulnar deviation. The wrist is then deviated radially while the examiner applies pressure on the scaphoid. A positive test for scapholunate dissociation occurs if the patient feels pain dorsally over the scapholunate ligament or the examiner feels the scaphoid move dorsally. Assessment of TFCC integrity involves placing the athlete's wrist in dorsiflexion and ulnar deviation and then rotating the wrist. A positive test for a tear of the TFCC occurs when overpressure causes pain and occasional clicking at the ulnar aspect of the wrist.

Wrist injuries may result in nerve damage or injury to the blood vessels in the wrist as well.

Investigations

In the setting of a traumatic wrist injury, routine X-rays can show possible fractures. X-rays should include posterior-anterior (PA), lateral, and PA with radial and ulnar deviation views. If a ligament injury is suspected, a PA view with a clenched fist can indicate possible injury. The normal PA view should demonstrate a smooth line joining the proximal ends of the proximal row of carpal bones and the "C" shape of the midcarpal joint (the Gilula arcs). On the normal lateral view of the wrist, the proximal pole of the lunate fits into the concavity of the distal radius, and the convex head of the capitate fits into the distal concavity of the lunate. These bones should be aligned with each other and the base of the third metacarpal.

Specialized X-ray views can be ordered for specific suspected injuries. If a scaphoid fracture is of concern, scaphoid views should be obtained. A carpal tunnel view with the wrist dorsiflexed allows the hook of the hamate and ridge of the trapezium to be inspected.

Other modalities that are helpful to diagnose wrist pain, such as ganglions or occult fractures, include ultrasound, radionuclide bone scan, computed tomography (CT) scan, and magnetic resonance imaging (MRI). Ultrasonography is helpful to assess soft tissue abnormalities such as tendon injury, ganglions, synovial cysts, or thickening. Bone scans are helpful to rule out subtle fractures. CT scans can also evaluate fractures that may not be apparent on plain films. MRI can evaluate soft tissue injuries, such as a tear of the scapholunate ligament, more effectively than CT. Arthroscopy is an increasingly used procedure for diagnosis and therapy. It is an excellent tool for detecting scapholunate tears and is the investigation of choice for patients with ulnar-sided wrist pain that persists following an acute injury (see Table 1).

Prevention of Injury

Many wrist injuries in sport can be prevented. The use of protective wrist guards has been shown to reduce wrist fractures in sports such as snowboarding and inline skating. Studies have shown that the incidence of wrist fractures was reduced by half in participants who wore wrist guards while snowboarding. Similar studies on inline skating found that athletes who did not wear wrist guards were more than 10 times more likely to injure their wrist than those who did wear wrist guards.

In younger athletes, it is important to use age- and size-appropriate equipment to reduce injury. For instance, studies on youth soccer have shown that distal radius fractures are more common in younger children using an adult-sized ball than in those who use a junior-size ball.

Return to Sports

Return-to-play recommendations vary somewhat according to the specific injury, the treatment modality, and the sport-specific demands of the individual athlete. In general, full unprotected return to play is not allowed until the athlete has regained full active and passive range of motion and almost full strength of the affected wrist. Bony or ligamentous injuries usually require 3 to 6 weeks to heal. Athletes should not participate in sports unless the injury is appropriately immobilized in a cast or splint. Wrist injuries do have the potential for delayed or failed healing despite appropriate initial

Table 1 Types of Wrist Injuries

Acute	*Chronic*
Distal radius fracture	Ganglion cyst
Scaphoid fracture	Intersection syndrome
Wrist ligament sprain/tear	Kienböck disease
Hook of hamate fracture	de Quervain tenosynovitis
Triangular fibrocartilage complex (TFCC) tear	Dorsal pole of lunate and distal radius impingement (gymnasts)
Distal radioulnar joint instability	Tendinopathy (flexor carpi ulnaris, extensor carpi ulnaris)
Scapholunate dissociation	Posterior interosseous nerve entrapment
Carpal bone dislocation	Inflammatory arthropathy
Carpal tunnel syndrome	Degenerative joint disease
	Nonunion of scaphoid fracture

treatment, requiring subsequent surgical intervention. Therefore, early referral to an orthopedic or hand surgeon is recommended for follow-up. Another consideration in determining when an athlete is ready to return to sports is the safety of the injured athlete as well as the other participants. If an athlete is considering returning to sports wearing a protective device, permission should be obtained from trainers, coaches, and officials.

Wrist Sprain

A *sprain* is an injury to a ligament. Ligaments are a type of tissue that connects bones to bones and provides stability to joints. One may think of ligaments as analogous to ropes. *Sprain* comes from the French word *espraindre,* which means "to wring." A wrist sprain is an injury to the ligaments of the wrist. Often, sprains occur from falls or sports-related injuries that involve forcibly bending the wrist backward (hyperextension) or excessive pressure through the long axis of the joint (axial loading), with subsequent damage to the ligaments of the wrist joint.

Anatomy

The wrist comprises many different types of structures, including eight small bones (called carpal bones), multiple ligaments, cartilage—a firm covering of the bones (e.g., the tip of your nose), and specific junctions with the bones of the hand (metacarpals) and forearm (radius, ulna). The joint where the radius and ulna are connected near the hand is called the distal radial ulnar joint (DRUJ). This joint is particularly susceptible to injury during falls.

Several structures in the wrist deserve particular mention, including the triangular fibrocartilage complex (TFCC). The TFCC is a special type of tissue (a mix between fibrous tissue and cartilage) that absorbs stress during axial loading of the wrist and limits lateral movement of the carpal bones. Throwing a "jab" or "punch" in boxing, for example, would be axially loading the wrist joint. This special cartilage (TFCC) also stabilizes the DRUJ.

There are two types of ligaments in the wrist—extrinsic, which connect the radius and ulna to the carpal bones, and intrinsic, which connect the carpal bones to each other.

Extrinsic ligaments have two components, *volar*—the palmar or underside of the wrist and hand, and *dorsal*—the backside (knuckle side) of the wrist and hand.

The volar radiocarpal ligaments are stronger and thicker than the dorsal and so provide the majority of motion stability in the wrist. The most important ligament of this group is the radioscaphocapitate, which attaches the radius (forearm bone) to the scaphoid and capitate (carpal bones). Intrinsic ligaments are also called interosseous ligaments. They originate on the carpal bones and are within the capsule of the wrist.

The most common ligament indicated in wrist sprains is the scapholunate, which is an intrinsic ligament between the scaphoid and lunate bones. It comprises dorsal collagen bundles that provide a structure that lends to its superior stability. Another important interosseous ligament is the lunotriquetral, connecting the lunate and triquetrium carpal bones.

Classification of Injuries

Sprains are classified based on severity, ranging from mild to moderate to severe injury. Typically, Grade I sprains represent the least amount of injury—a stretching of the ligament fibers—and result in minimal or no loss of function at that joint. Grade II sprains usually equate to a partial tearing of the ligament. This may be observed by increased swelling and pain of the joint along with moderate dysfunction. The most serious of wrist sprains would be a complete tear of the ligament, a Grade III sprain. This results in an unstable joint and requires immobilization (splinting) and often referral to a specialist.

Injury Setting and Symptoms

Wrist sprains occur in many settings and due to a variety of reasons, including direct injury, chronic repetitive trauma and loading activities, or falls and sports-related injuries. Sprains are more common in adults than in children due to the different anatomy of the developing bones in children. In younger populations, similar injuries more often produce fractures of the immature bone rather than damage to the ligaments. Commonly, skiing, skating, snowboarding, and inline skating are sports associated with wrist sprains, but they can occur in any contact or noncontact sports under certain conditions. At times, specific wrist injuries are classified as *f*alls *o*n an *o*ut*s*tretched *h*and (FOOSH), such as fractures of the scaphoid bone or disruption of the scapholunate ligament.

Patients with wrist sprains may report feeling a tear or hearing a pop during the event. Areas of the wrist or hand may swell, demonstrate bruising, or be painful to touch. Patients have difficulty and pain with movement of the wrist. Wrist and hand anatomy is intricate, and diagnosing an injury may present a difficult task, so an evaluation should include a detailed history, a careful physical exam, and often radiographs. The exam should consist of general inspection, a neurovascular evaluation, palpation of bony prominences and ligaments, and assessment of joint range of motion and stability.

Treatment

Sprains usually heal completely within 4 to 6 weeks. Conservative treatment involves splinting in a neutral position with either a brace or a compressive elastic wrap, rest from painful activity, application of ice packs, and taking nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce swelling and for pain relief. After a period of immobilization and before returning to full activity, patients should exercise to improve wrist range of motion and strength. This may include work with a resistance band or weights for wrist extension, flexion, and ulnar and radial deviation (ulnar deviation: side movement in the direction of the little finger; radial deviation: side movement in the direction of the thumb).

Grade III sprains or complete tears of ligaments may require surgical correction and repair. These injuries represent unstable joints, and the wrist must be immobilized at the discovery of injury to prevent additional or more serious injury.

While most wrist sprains heal with conservative therapy and without other intervention, some important conditions must not be missed due to varying treatments and risk of adverse events. These include injury to the TFCC, carpal bone dislocation (displacement), DRUJ, or any fracture of the carpal bones or forearm bones (radius or ulna).

Wrist Tendinopathy

Overuse wrist tendon injury, or *tendinopathy,* occurs regularly in athletes participating in sports with repetitive wrist and hand movement. Unlike more proximal tendinopathies (e.g., rotator cuff), which are typically degenerative and noninflammatory, symptoms from wrist tendinopathy frequently involve inflammation of the outer tendon sheath, known as paratenonitis. The most common wrist tendinopathies in athletes involve the dorsal/extensor aspect of the wrist, such as de Quervain disease, intersection syndrome, and extensor carpi ulnaris (ECU) paratenonitis.

Risk factors for athletic wrist tendinopathy include muscle weakness or imbalance, overuse from training load, improper technique or equipment, and inadequate rest. The accurate diagnosis of wrist tendinopathy requires skilled history taking and physical examination, and advanced imaging is infrequently necessary. Treatment of inflammatory tendinopathy of the wrist includes rest, noninvasive anti-inflammatory modalities (e.g., ice, anti-inflammatory medications), risk factor modification, and occasional local corticosteroid injection. With an accurate diagnosis and a treatment plan customized for the athlete, the sport, and the severity of the condition, most athletes with wrist tendinopathy return to their sport quickly and very rarely have long-term limitation.

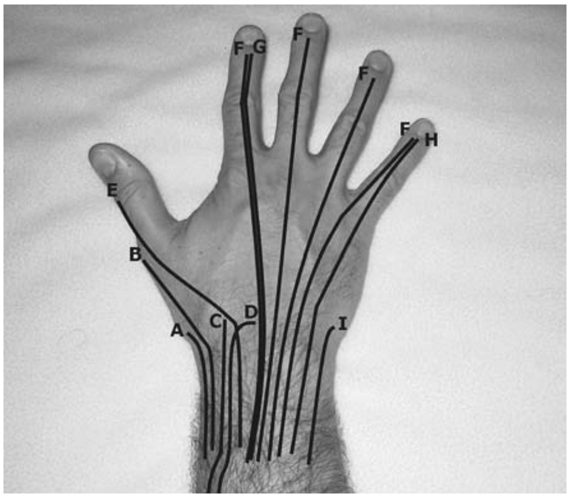
Anatomy

Tendons consist of longitudinally oriented, closely grouped collagen bundles with an outer covering called the paratenon. In areas such as the wrist, where tendons bend at acute angles over bone, the paratenon is thicker and lined with synovium and is called a tendon sheath. The synovium of the tendon sheath both provides mechanical resistance to shearing forces and produces synovial fluid, lubricating the tendon to decrease frictional injury.

Wrist tendons are divided into extensor tendons, which run over the dorsal aspect of the wrist, and flexor tendons, which run over the volar/palmar aspect of the wrist. The side of the wrist closest to the radius (and thumb) is referred to as the radial aspect of the wrist, and that closest to the ulna (and fifth finger) is referred to as the ulnar aspect of the wrist. The relative anatomic course of each of these wrist and finger tendons is represented in Figure 1 (extensors) and Figure 2 (flexors). The dorsal/extensor wrist is divided into six compartments, numbered from the radial to ulnar aspects, the first two of which are frequently involved in athletic wrist tendinopathies. The first dorsal compartment consists of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons. The second dorsal compartment includes both extensor carpi radialis brevis (ECRB) and extensor carpi radialis longus (ECRL) tendons.

Pathology

Tendinopathy is a broad term that includes tendinitis, tendinosis, and paratenonitis. *Tendinitis*



Tendons of the dorsal aspect of the wrist: (a) abductor pollicis longus, (b) extensor pollicis brevis, (c) extensor carpi radialis longus, (d) extensor carpi radialis brevis, (e) extensor pollicis longus, (f) extensor digitorum, (g) extensor indicis, (h) extensor digiti minimi, and (i) extensor carpi ulnaris

refers to inflammation of the tendon substance and rarely occurs without the presence of underlying degenerative tendon change, or *tendinosis*. *Paratenonitis,* or alternatively *tenosynovitis,* involves inflammation of the paratenon/tendon sheath, can occur alone or in combination with tendinosis, and constitutes the majority of wrist tendinopathy. However, elite and older athletes also often have some component of underlying tendinosis contributing to their symptoms.

De Quervain disease and intersection syndrome are the two most common athletic wrist tendinopathies. De Quervain disease is a paratenonitis of the tendons in the first dorsal compartment. Intersection syndrome, while not a classic paratenonitis, represents inflammation of the crossover area where the musculotendinous junctions of the first dorsal compartment meet with the tendons of the second dorsal wrist compartments. Less common wrist tendinopathies in sports include the separate syndromes of ECU and FCU (flexor carpi ulnaris) paratenonitis along with the infrequent flexor carpi radialis (FCR) paratenonitis and carpal tunnel syndrome from paratenonitis of the digital flexor tendons.

Causes

Wrist tendinopathy in athletes results from chronic microtrauma due to tendon overuse. While athlete ageing and tendon underuse can contribute to degenerative tendon changes, most wrist tendinopathies are caused by a combination of numerous factors, the most important being excessive repetition of wrist and hand motion. Such motion is required in many sports, including racquet sports (tennis, squash), golf, baseball, volleyball, gymnastics, rowing, and rock climbing. Other factors contributing to wrist tendinopathy include muscle imbalance or weakness, improper technique (e.g., excessive wrist radial deviation on the tennis forehand), improper equipment (e.g., size of the bat or racquet handle), and inadequate recovery time.

Causative sports for specific wrist tendinopathies are those that involve motions isolating the involved tendons. For example, de Quervain disease affects two tendons exerting their action on the thumb and is common in sports that require strong or repetitive thumb motion, such as racquet (tennis) and other hand grip sports (rowing and golf). Intersection syndrome involves tendons that act on both the thumb and the radial aspect of the wrist, is caused by repetitive wrist extension in radial deviation, and is encountered in many of the previously mentioned sports, along with weight lifting and downhill skiing. ECU paratenonitis and tendinosis occur from excessive wrist extension in ulnar deviation and are seen especially in racquet sports, golf, and rowing. FCU paratenonitis is also common among golf and racquet sport athletes.

Clinical Evaluation

History

Suspicion for wrist tendinopathy in an athlete generally stems from pain over the involved tendon(s). Pain from paratenonitis is typically constant and proportional to activity level and can be seen in athletes of all ages. Patients with paratenonitis usually report a recent increase in the duration or intensity of their sports activity and often note accompanying swelling, stiffness, and wrist "squeaking." Alternatively, athletes with tendinosis will complain of more intermittent pain and will usually have a remote history of overuse. Patients with tendinosis will also typically complain of pain that starts during the warm-up phase, decreases during activity, and increases during the cooldown and recovery phases. Finally, patients with tendinosis will describe a course of pain that begins as sharp and intense and becomes more dull and achy over time. Because paratenonitis can be seen in combination with tendinosis, symptoms from both processes can co-occur.

Accompanying symptoms such as paresthesia, weakness, radiation of pain, blunt trauma, fever, and overlying skin changes should be ruled out in the athlete with tendon pain. The presence of these symptoms should prompt consideration of more extensive differential diagnosis and work-up. Of note, rheumatologic conditions such as rheumatoid arthritis affect the synovium, causing both arthritis and paratenonitis, and should be suspected in an athlete with recurrent or diffuse paratenonitis.

Physical Examination

A thorough examination of the affected forearm, wrist, and hand along with comparison with the nonaffected side is necessary in evaluating athletes with suspected wrist tendinopathy. They will have pain to tendon palpation, especially under tension with manual muscle testing. As with most inflammatory conditions, patients with wrist paratenonitis will have associated palpable swelling and increased temperature over the affected area of the tendon. Patients with wrist paratenonitis can also have crepitus and occasional catching with passive movement of the involved joint, as in passively flexing and extending the wrist in ulnar deviation to evaluate ECU paratenonitis. Finally, the athlete will often have pain with the tendon in full stretch, such as the Finkelstein maneuver, in which the patient is asked to make a clenched fist about the adducted thumb and the examiner subsequently places the patient's wrist in ulnar deviation. Pain over the radial styloid (distal radius) with this maneuver is highly specific for de Quervain disease.

Imaging

Clinical assessment with history and physical examination is usually sufficient for accurate diagnosis and classification of wrist tendinopathy. Plain radiographs in tendinopathy are routinely negative, and advanced imaging is rarely required. However, in cases recalcitrant to initial therapy or where more significant tendon disruption is suspected, magnetic resonance imaging (MRI) and ultrasound can serve as helpful adjuncts. On the MRI scan, paratenonitis demonstrates increased (fluid) signal in the tendon sheath on T2 and STIR (short inversion time inversion recovery) sequences, whereas tendinosis shows less uniform increased intratendinous signal on the same sequences. Ultrasound examination of paratenonitis demonstrates anechoic signal (representing fluid) in the surrounding tendon sheath, and in tendinosis, it shows hypoechoic intratendinous regions.

Treatment

The mainstay of wrist tendinopathy treatment is conservative therapy relying on relative rest, ice, analgesics (e.g., oral or topical nonsteroidal medications), physical therapy, and short courses of wrist bracing or splinting, to include thumb spica immobilization in cases of de Quervain disease. In paratenonitis, use of topical (e.g., iontophoresis) or systemic corticosteroid treatment can be beneficial, and local injections of topical anesthetic and corticosteroid into the tendon sheath by skilled hands are often effective in confirming the diagnosis and treating the condition. In cases with underlying tendinosis, anti-inflammatory treatments do not treat the underlying degenerative pathology and cannot prevent recurrence. The most widely accepted treatment modality for tendinosis is eccentric muscle strengthening of the affected muscle-tendon unit. In all tendinopathies, adjustment of the underlying modifiable risk factors, such as errors in technique, training schedule, or equipment, must always be addressed for adequate treatment and prevention of recurrence. In rare cases where the athlete's wrist tendinopathy does not respond to conservative treatment, surgical release of the tendon sheath or debridement of the degenerative tendon may be indicated.

Conclusion

Wrist tendinopathy from tendon overuse commonly affects athletes participating in tennis, golf, and other sports requiring repetitive wrist and hand motion. Inflammation of the tendon sheath surrounding the tendon, or paratenonitis, is the most common underlying pathology in these cases and often responds to conservative therapy with relative rest, analgesics, and anti-inflammatory modalities without long-term sequelae.

Y

Young Athlete

Youth participation in sports has increased dramatically in recent years. Children are becoming involved at younger and younger ages and are training with increasing intensity. Understanding their unique needs with respect to injury patterns, changing body habits, and psychological development is key to dealing with the child athlete. A sensible approach to training that takes into consideration skill level and motivation, as well as physical and emotional development, will help prevent injuries and promote enjoyment of the sport. For the child who becomes involved in competition, acquisition of skills and fitness must be balanced with avoidance of overtraining. It is important to have some knowledge of the types of injuries our young athletes sustain and an understanding of the prevention and rehabilitation of these injuries. Finally, the most influential people in the child athlete's life, coaches and parents, need to help the child keep winning in perspective.

Uniqueness of the Child Athlete

Growth and development are the most important features that distinguish young athletes from adults. The changing mechanical properties of growing bones and tissues give rise to maturation-related injuries. Bone growth occurs first, followed by a secondary lengthening of muscle–tendon units and ligaments. Many experts feel that during a growth spurt, there is a relative decrease in flexibility before the soft tissues catch up with bone growth. This decrease in flexibility places the child at risk for injuries such as Osgood-Schlatter apophysitis or patellofemoral pain. The imbalances in muscle strength and flexibility that occur during these periods of growth are risk factors for both sudden (acute) injuries and overuse injuries. Growing bones themselves are weakened because bone matrix formation and mineralization do not occur at the same rate. As a result, children's bones are less dense than those of adults.

The types of bony injuries sustained by children are quite different from adult injuries. For example, a similar mechanism of injury may produce a displaced or comminuted fracture in an adult bone, but it may only cause bending (plastic deformation) of the softer bone of the child athlete. The inherently weak growth plate (physis) is involved in 30% of all fractures of the long bones of children. During different stages of development, the relative strength of the physes changes, with the time of the greatest vulnerability to injury being the onset of the adolescent growth spurt. At such times, if stressed, the musculoskeletal system will break down at the growth plates before the adjacent ligaments tear. In prepubescence and again in late pubescence after growth has slowed, the physes may actually be stronger than the adjacent ligaments; therefore, true sprains are more likely to occur than injuries to the physes.

The main concern with growth plate injuries is the potential for altered growth. This also depends on the child's stage of development. For example, repetitive microtrauma to the wrists in gymnasts during early puberty may result in a temporary decrease in growth of the growth plate at the lower portion of the forearm (the distal radial physis). Normal growth is restored once the trauma stops. The same injury to a midpubertal gymnast may result in permanent loss of growth.

Other areas of growth tissue occur at the tendon insertions of large muscle groups. These sites are known as apophyses and are subject to injuries unique to the growing athlete. A common site of apophyseal injury is the insertion of the patellar tendon into the top of the shin (tibial tubercle). Repetitive stress at this site can cause either apophysitis or avulsion fracture. Apophyseal injuries will be discussed later in this entry. It is important to remember that the tissues of the young athlete are in transition, which has a great bearing on the types of injuries sustained.

The child athlete differs from the adult in other ways as well. The response of the cardiovascular system and the body's control of temperature (thermoregulation) to exercise in children is different from that in adults. Thermoregulation will be discussed in greater detail later. Regarding cardiovascular differences, children generally use more oxygen for a given activity and rely on anaerobic metabolism less than adults do during exercise. They tend to have higher heart rates and pump less blood from the heart with each beat (lower cardiac stroke volume) as well. This can affect how well the child tolerates physical activity. In addition, reaction time decreases as the child matures.

With increasing strength and endurance, particularly in the latter half of childhood, speed of movements and general skills increase. Thus, the innate tools that the child athlete has at his or her disposal vary with physical maturation. This should be kept in mind when setting goals for the child in sports.

Thermoregulation: Exercise in the Heat

Approximately 80% of energy released during exercise is in the form of heat. If the mechanisms for heat loss are not functioning properly, the athlete may experience a 1 °C increase in body temperature per 5 minutes of activity. If this is allowed to continue, it would be potentially fatal within 20 minutes. Mild dehydration, as little as 1.2%, may make it even more difficult to control body temperature. Once water deficits are greater than 3%, there is a significant risk of heat illness. Heat-related illnesses include a spectrum of conditions ranging from heat cramps, which are painful, sustained muscle contractions, to life-threatening heat stroke.

Uniqueness of Children

The thermoregulatory mechanisms in children are slightly different from those in adults. Compared with adults, children produce more heat per kilogram (kg) while walking and running. They begin to sweat at a higher core temperature and sweat less per square meter. They have a lower cardiac output at a given metabolic level and less blood flow to the skin for removal of heat by convection. Their larger body surface area per kilogram results in increased heat exchange between the environment and the skin, causing greater heat stress. Their thermoregulatory impairment from dehydration is also greater.

Children are slower than adults to acclimatize to heat. Acclimatization involves physiologic changes that increase tolerance to exercise in the heat. This adaptation is influenced by age, duration of exposure to heat, rate of body heat production, severity of environmental stress, and the preexisting level of conditioning of the athlete. These differences in thermoregulation place the child athlete at increased risk of heat illness, especially in extreme heat.

Prevention of Heat Illness

Prevention of heat illness addresses environmental conditions, hydration, clothing, conditioning, and acclimatization. Activity should be modified in the face of high ambient temperature or humidity. For temperatures less than 19 °C (67 °F), the players most susceptible to heat stress should be under close observation. Unlimited supplies of drinking water should be available on the field, and athletes should be encouraged to take fluids when ambient temperatures are between 19 and 25 °C (67 and 77 °F). Water breaks should be scheduled every 20 to 25 minutes. For temperatures above 25 °C (77 °F), practice sessions should be reduced and, if possible, scheduled for early morning or late afternoon. Susceptible players, such as those with a history of heat illness, should be withheld from participation. At any temperature, if relative humidity is greater than 95%, activity should be modified as per the requirements for temperatures >25 °C.

Athletes may lose 2% to 3% body weight before thirst develops, at which point performance is already impaired. To ensure adequate hydration, adolescent athletes should be encouraged to drink 235 milliliters (ml; 8 ounces [oz]) of water 10 to 15 minutes prior to workout and 235 to 350 ml (8–12 oz) at 20- to 30-minute intervals throughout the practice. Younger, smaller athletes will need slightly less than this amount (approximately 150 ml of cold tap water every 30 minutes for a 40-kg child). After workout, drinking to quench thirst will replenish only one third to one half of fluid losses; therefore, athletes should weigh themselves before and after workout (without clothes) and should drink 1 liter/kg lost (2 cups/pound). Plain water is adequate for most activities of young athletes.

Appropriate clothing for training in the heat is lightweight, single layer, and absorbent. As much skin as possible should be exposed to air, and sweat-saturated articles of clothing should be changed. If helmets are worn, they should be removed between drills, because a significant proportion of heat loss occurs via the head. Sauna suits for weight reduction should never be permitted.

Athletes should start the season as physically fit as possible. A preseason conditioning program will give the child a good baseline fitness level, which will not only decrease the risk of heat illness but also help prevent other problems such as overuse injuries. An attempt should be made to acclimatize the athlete before beginning a strenuous program or before travel to a warm climate.

Common Injuries Associated With the Child Athlete

Several injuries occur more frequently, or in some cases uniquely, in the skeletally immature athlete. These injuries can be divided into either acute or overuse types. Acute bone injuries encountered exclusively in the child athlete include *growth plate* (physeal) *injuries* and *apophyseal avulsion fractures,* which occur when large tendons pull off (avulse) fragments of bone and growth cartilage at the sites where tendons and bones join. Other fractures seen in children (torus, greenstick, plastic deformation) occur because of a lesser degree of mineralization and thinner cortices than in adult bones. There are also several overuse injuries that are seen primarily in young athletes. The most common of these are discussed in this section.

Acute Injuries

Growth Plate Injuries

At certain times during development, growth plates are weaker than the surrounding soft tissues; therefore, when a joint is placed under abnormal stress, such as a sudden, forceful inversion of the ankle, the result is a fracture through the growth plate. This is accompanied by swelling and tenderness on the outer aspect of the ankle. There may be some tenderness over the ligaments, but if there is bony tenderness over the lateral ankle, it is likely to be a growth plate injury. This relative weakness of the physes is maximum at the onset of the growth spurt. Immediate management includes ice, elevation, and compression. Immobilization and crutches may be necessary for pain control. Early institution of physical therapy will restore function and help prevent reinjury. It is possible for young athletes to sprain ligaments rather than injure physes, particularly adolescents nearing physical maturity and prepubescent athletes.

Avulsion Fractures

Children with open physes also have apophyses at the insertion of large tendons into bone. Like growth plates, these cartilage structures are subject to injury, particularly during rapid growth. The most common acute injury to the apophysis is an *avulsion fracture*. Avulsion fractures are typically seen in 14- to 17-year-old males. These occur frequently around the pelvis, into which several large muscles insert. These athletes will complain of severe pain at the affected site and inability to continue activities. Pain will worsen with contraction of the muscle responsible for the avulsion injury. Athletes should apply ice and use crutches during the acute phase. Relative rest with early institution of physical therapy will hasten the recovery. Full range of motion and normal strength should be regained prior to return to sports participation.

Overuse Injuries

Overuse injuries result from repetitive microtrauma to bones and soft tissue. Growth is a risk factor for overuse injury in the young athlete. Growth cartilage is inherently weak when compared with the adjacent bone and is unable to withstand excessive repetitive stress. Many experts feel that flexibility decreases with growth, as muscles and tendons are stretched by the growing bones. Muscle tightness is a well-known risk factor for overuse injury among athletes of all ages. Training error is another recognized risk factor for overuse injury. Examples of training errors include sudden increases in training intensity or duration. These errors are encountered frequently in the context of summer sport camps, where children may increase their participation in a given physical activity from a few hours per week to a few hours or more each day.

Little League Elbow

Little League elbow refers to a number of different conditions that cause pain about the elbow. The forces generated during throwing result in valgus stress to the elbow, with compression on the outer aspect and tension on the inner aspect of the joint. Specific diagnoses can include medial epicondyle apophysitis, overgrowth of the radial head, osteochondritis dissecans of the radial head, and premature closure of the radial growth plate at the elbow. If there is swelling and decreased range of motion in the joint, there may be a problem with the cartilage and bone of the joint or there may be a loose body in the elbow. The child should be referred to a physician for evaluation, and further pitching should be avoided until an assessment has been done. Management includes avoidance of aggravating activities and initiation of physical therapy for range of motion followed by strength exercises. Once pain has resolved, range of motion is full, and careful evaluation of the throwing technique to correct errors that may have contributed to the injury is done, *gradual* return to play is possible. If the number of throws per week is limited to not more than 300, it may help prevent some of these injuries.

Osgood-Schlatter Apophysitis

Osgood-Schlatter apophysitis is a painful response to repetitive stress at the patellar tendon/tibial tubercle junction. Injury of the apophysis results in pain with jumping and running and tenderness to touch. Swelling may be seen over the tibial tubercle on the upper portion of the lower leg. This condition is most often observed in young athletes who have patellar maltracking or who have recently undergone a growth spurt. In the latter situation, muscles about the knee become very tight, placing added stress on the extensor mechanism. A similar stress injury (Sinding-Larsen-Johansson syndrome) occurs at the lower pole of the patella. The presentation of Sinding-Larsen-Johansson syndrome is similar to that of Osgood-Schlatter, except that the point of maximal tenderness is the lower portion of the patella. Reassurance is the first part of treatment for Osgood-Schlatter apophysitis. Athletes and their parents need to know that this condition will resolve when growth is complete. In the meantime, attempts must be made to decrease pain and secondary inflammation and to prevent recurrence. The child should be advised to stop any jumping or running activities until the pain and swelling have subsided. Application of ice three or four times per day while the symptoms are severe may be enough to reduce the pain. Nonsteroidal anti-inflammatory drugs, or NSAIDs, are of limited use other than as analgesics, unless there is significant secondary soft tissue swelling present. A home exercise program must begin immediately to work on hamstring and quadriceps stretching. When the pain has decreased, strengthening of these muscles can begin. The athlete is permitted to return to full activity only when jumping and running are pain free. A strap brace may be placed over the patellar tendon to reduce the pull of the quadriceps on the tibial tubercle. A knee pad to protect the tibial tubercle from direct trauma may reduce incidence of flare-ups. This condition can recur and occasionally can lead to avulsion fractures of the tibial tubercle.

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is an injury that affects a localized area of cartilage on the joint surface (articular cartilage) of bone, along with a small portion of underlying (subchondral) bone. Although the exact cause of this condition is not entirely clear, there appears to be some localized insufficiency of the blood supply to the bone, likely exacerbated by repetitive trauma or compressive forces. As the bone loses its blood supply, the overlying articular cartilage and subchondral bone may become unstable. In more severe cases, the bone and cartilage fragment becomes a loose body in the joint. OCD in the knee usually occurs on the inner aspect of the lower end of the thighbone (femur). This condition is also seen in the outer aspect of the elbow in Little League elbow and in the ankle (talus). A child with OCD of the knee may present with intermittent joint swelling, pain, and limited range of motion. Management depends on the severity of the OCD and the maturity of the child. In a growing child with intact cartilage overlying the bony defect, full range of motion, and no locking, nonsurgical treatment may be adequate. The child is restricted from impact activities such as jumping and running, and early physical therapy is initiated to maintain or regain range of motion. Other treatments may include limitation on weight bearing or use of bracing. Resistive weight training should be withheld for 6 to 12 weeks until bone healing occurs. It may be as long as 6 to 12 months before the athlete can resume full activities. Arthroscopic surgery may be necessary in the presence of mechanical symptoms such as locking, if magnetic resonance imaging (MRI) suggests an unstable fragment, or if more conservative treatment does not result in healing after 3 to 6 months.

Sever Apophysitis

Sever apophysitis is an injury to the calcaneal apophysis that results in tenderness at the insertion site of the Achilles tendon in the heel. Children will usually present with posterior heel pain after activity. The condition occurs in both feet in two thirds of cases and typically occurs between 7 and 14 years of age. On examination, the most tender point is the back of the heel at the Achilles tendon insertion. There may be pain with passive stretching of the calf muscles or with active plantarflexion of the ankle (downward). Squeezing the heel (squeeze test) is usually painful. To unload the painful heel, weight bearing and gait may be altered. This may result in pain and tenderness of the Achilles tendon or under the arch of the foot, clinically suggestive of Achilles tendinosis or plantar fasciitis. Treatment includes heel cups to decrease stress on the apophysis, cessation of all painful activities, and institution of physical therapy. The therapy is aimed at reducing secondary inflammation through application of ice, as well as increasing the flexibility and strength of the calf muscles. When the pain has subsided, the athlete can increase physical activity as long as the pain does not recur.

Spondylolysis

Spondylolysis is a stress fracture of the pars interarticularis, which is one of the posterior elements of the spine. This injury is most commonly encountered in sports that require repetitive extension of the spine, such as gymnastics, figure skating, and ballet. Football and hockey players may also develop this injury from the repetitive stress of sled training or body checking, respectively. The athlete will complain of low back pain with extension movements of the spine. The athlete may note tightness of the hamstrings on the affected side. On examination, there is often some degree of muscle spasm alongside the defect in the lower back. Provocative tests such as extension of the spine (arching backward) will reproduce the symptoms. There will be a relative tightness of the hamstrings on the affected side. When dealing with gymnasts and dancers, it is important to remember that they are usually extremely flexible; therefore, left and right asymmetry should be noted.

Plain X-rays may show the fracture, but a special bone scan, SPECT (single-photon emission computed tomography), will be able to definitively diagnose the lesion. Treatment involves cessation of the offending activities. A rigid, custom polypropylene brace is often used to limit extension. The brace is worn for 23 hours a day, with 1 hour out for physical therapy and showering. Once the athlete is painfree in the brace, return to modified activity is allowed. Duration of bracing is generally 6 months to allow for bony healing. Many athletes are able to return to their sport while wearing the brace.

"It Is Not Whether You Win or Lose . . . "

It has been shown that children have a much greater likelihood of dropping out of sports where the greatest emphasis is on winning. It is easy for the child athlete to begin to equate winning with success and losing with failure. Fear of failure places an enormous amount of stress on the child athlete. If a child feels that his or her "success" depends on a win, then every competitive situation becomes even more stressful and every loss adversely affects self-worth. Winning is an important goal in competitive sports, but it needs to be kept in a healthy perspective. While striving to win, the sense of success should come from putting out maximal effort. Young athletes should feel that even though they make mistakes or lose games, as long as they are trying their best, their parents and coaches will approve. This will greatly enhance the child's enjoyment of the sport, making continued participation much more likely.

Prevention Techniques

When discussing prevention in sports, one must differentiate between physical and psychological injury. The physical injuries discussed in this entry include overuse and acute trauma, as well as heat illness. Prevention of overuse injuries involves addressing risk factors before they become problematic. Preparticipation physical examinations can identify muscle imbalances and other physical factors that may predispose the athlete to injury. Preseason conditioning can reduce the risk of injury to muscles and tendons. Athletes should be educated regarding specific preventative techniques such as stretching muscles when warm and aggressively working on flexibility during growth spurts. To allow tissues to adapt to increasing work loads, training should not increase more than 10% per week. Prevention of acute injuries involves ensuring adequacy of equipment (e.g., football helmets) and striving to ensure that young athletes are matched up based on size and maturation rather than age. Rules that are meant to minimize serious trauma (e.g., no spear tackling in football) should be adhered to. Prevention of heat illness was covered earlier in this entry.

Prevention of psychological injuries is an important part of dealing with young athletes. Psychological stress occurs when athletes perceive that the demands placed on them exceed their skills. If failure is perceived as catastrophic, the stress on the athlete increases significantly. If personal value becomes dependent on success, this also adds to stress. As a result, if stress levels become too high for the athlete to cope with, he or she may withdraw from sports. If training continues, the child may develop physical symptoms such as headache or abdominal pain as a direct result of the stress or as a mechanism to avoid participation. Such situations can be avoided by addressing the causes of stress. De-emphasizing winning can significantly reduce stress. Coaches play a key role in reducing stress among athletes by enhancing enjoyment of the sport. They can provide immediate reinforcement for good plays and good efforts. Correcting errors should be done in a positive way by explaining how correct techniques will be beneficial. Coaches should not emphasize the errors that the young athlete has made. Mistakes should never be met with disapproval or yelling.

Parent-induced stress can be difficult to address. This occurs in situations where the child becomes an extension of the parents, who want their little athlete to either follow in their footsteps ("star" athlete parents) or succeed where they have fallen short. The following guidelines for parents may be helpful in these situations.

1. Parents should remain seated in the spectator area during the contest.
2. Parents should not yell instructions or criticism to their children.
3. Parents should make no derogatory comments to players, parents of the opposing team, officials, or league administrators.
4. Parents should not interfere with their children's coach. They must be willing to relinquish the responsibility for their child to the coach for the duration of the contest.

Conclusion

Because of the many benefits, both physical and mental, of sports participation children need to be encouraged to become involved. Ideally, the sport should choose the child, which means that the suitability of the child for a particular sport is considered before he or she begins. For example, a child with pes cavus (high-arched feet) may be better suited to swimming than running; however, in most cases, the child is already involved in his or her sport when problems arise. It is the role of the coach, parent, and physician to monitor the effects of the activity on the child. Intervention before problems arise can be accomplished by addressing risk factors early. When injuries occur, adequate rehabilitation will help prevent recurrence. The concept of "winning at all costs" should not be ingrained in the child athlete; rather, enjoyment of the sport should be the primary goal. It is important to remember that the elite young gymnast is not only an athlete but a child as well.

Youth Fitness

Fitness is a state of well-being that allows the body to function efficiently and effectively during school, work, leisure, and sports activities. In general, there are two main categories of fitness. *Health-related fitness* is said to include cardiorespiratory endurance, muscular strength, muscular endurance, flexibility, and body composition, whereas *skill-related fitness* components include agility, coordination, reaction time, balance, speed, and power. Both are associated with numerous physiological and psychological benefits during childhood and adolescence. In addition, positive behaviors that are acquired during the school-age years are likely to be carried over into adulthood. Thus, youth who enjoy fitness activities and learn how to live a physically active life are more likely to become active, healthy adults.

Current Health and Fitness Status

Although youth tend to be more active than adults, nowadays fewer children and adolescents walk or ride their bicycles to school, and sedentary pursuits such as television viewing and "surfing" the Internet have decreased youngsters' need to move. A majority of children do not participate in any organized physical activity during nonschool hours, and physical education and recess periods are unfortunately viewed as expendable in some school districts. It is becoming more apparent that the lack of daily physical activity along with the greater accessibility to energy-dense foods is contributing to the increasing prevalence of obesity among school-age youth.

These trends have significant implications for the present and future health of children and adolescents, given the increased prevalence of cardiovascular disease risk factors and obesity-related comorbidities such as Type 2 diabetes, heart disease, and cancer. If current trends continue, the health-related consequences of physical inactivity and childhood obesity will likely pose an unprecedented burden on youth, their families, and our health care system. As a result, the promotion of safe, effective, and enjoyable fitness activities for children and adolescents with different needs, goals, and abilities has become a major public health issue.

General Youth Fitness Guidelines

Children and adolescents should be encouraged to be physically active as part of play, recreation, sports, and school activities. Researchers and health care providers recommend that school-age youth participate daily in 60 minutes or more of moderate to vigorous physical activity that is developmentally appropriate, that is enjoyable, and that involves a variety of activities. This recommendation provides a reasonable standard that even sedentary boys and girls can achieve with a modest commitment to physical activity and support from their parents and schools. Youth can increase the amount of time they have for physical activity by reducing sedentary leisure pursuits such as television viewing, computer use, telephone conversations, and video games. Sedentary youth should gradually increase the amount of physical activity by about 10% per week until they reach the 60-minute goal.

Since youth will rarely perform prolonged periods of physical activity without rest or recovery, youth should be encouraged to accumulate their physical activity requirement throughout the day rather than perform a continuous bout of physical activity at a predetermined intensity. While continuous moderate-to-vigorous physical activity is not physiologically harmful, it is not the most appropriate method of exercise for youth, who tend to enjoy nonsustained activities or games. Watching children on a playground supports the premise that youth tend to have short bursts of physical activity followed by brief rest periods to recover and recharge. Participation in age-appropriate fitness activities is more likely to become a lifelong habit if youth experience success, gain confidence in their physical abilities, establish a base of general fitness, and become aware of the health benefits of physical activity.

Health- and Skill-Related Fitness Activities

Unlike most adult fitness programs that isolate fitness components, youth fitness programs should provide participants with the opportunity to improve both health- and skill-related components of fitness. While the components of health-related fitness relate specifically to health enhancement and disease prevention, skill-related components are necessary to perform daily activities as well as recreational pursuits and sports skills.

Health-Related Fitness Activities

While most youth can accumulate 60 minutes of daily physical activity, health-related activities including aerobic games, strength training, and flexibility exercises must be punctuated with brief rest periods. Stop-and-go games or circuit training activities that alternate higher-effort and lower-effort segments have proven to be effective. While the standard means of assessing aerobic exercise intensity in adults is heart rate monitoring, this type of assessment is problematic for healthy children, who have great difficulty finding and counting their pulse rate during exercise. Moreover, there is little need for healthy children to monitor their heart rate response because adult target heart rate formulas are inappropriate for youth under 16 years of age. Generally, simple observations may be sufficient for determining physical exertion during youth fitness activities.

Despite traditional concerns associated with youth strength training, research clearly demonstrates that strength training can be a safe, effective, and worthwhile activity for children and adolescents provided that age-appropriate training guidelines are followed. Although there is no scientific evidence to suggest that the risks and concerns associated with youth strength training are greater than those of other sports and recreational activities in which children and adolescents regularly participate, youth strength training programs must be competently supervised, properly instructed, and appropriately designed. In general, if a child is ready for participation in some type of sport activity (generally at age 7 or 8), then he or she may be ready to strength train. Different types of equipment, including free weights (e.g., barbells and dumbbells), child-size weight machines, elastic bands, medicine balls, and body weight exercises, have proven to be safe and effective for children and adolescents.

While flexibility is a well-recognized component of health-related fitness, long-held beliefs regarding the traditional practice of warm-up static stretching have been questioned. Research findings suggest that static stretching immediately before exercise has no significant effect on injury prevention and can have a negative influence on strength and power performance in children and adolescents. Children and adolescents should perform low- to moderate-intensity dynamic activities (e.g., walk, jog, hop, skip, and jump) during the warm-up period and static stretching exercises during the cooldown period. Because gains in flexibility are specific to the flexibility exercises performed at each joint, youth should perform a variety of static stretches for the upper body, lower body, and midsection. The cooldown may actually be the ideal time to perform static stretching exercises because the muscles are already warmed up and participants need to recover from the exercise session with less intense activities.

Skill-Related Fitness Activities

Most youth programs focus primarily on enhancing the health-related components of fitness and underemphasize the importance of developing skill-related fitness abilities that are characteristic of how children move and play. Games, activities, and exercises that involve skipping, hopping, twisting, kicking, and throwing can help youngsters develop the necessary prerequisite movement skills prior to facing the demands of more demanding fitness programs and sports training sessions. With competent instruction and quality practice time, children and adolescents can learn the skills needed for successful and enjoyable participation in recreational activities and organized sports.

Leadership and Instruction

The challenges associated with promoting youth fitness should be met with enthusiastic leadership, creative programming, and effective age-specific teaching strategies. A major objective of youth fitness programming is for physical activity to become a habitual part of children's lives and, if possible, persist into adulthood. With this objective in mind, parents, teachers, and youth coaches must strive to increase participants' self-confidence in their physical abilities. To achieve this objective, clear instructions should be provided so that participants can experience success and develop a sense of mastery of a specific skill. Thus, the focus of youth fitness programs should be on positive experiences instead of stressful competition in which most children fail.

Professionals should understand the uniqueness of childhood and adolescence and should genuinely appreciate the fact that youth are active in different ways and for different reasons compared with adults. Professionals who choose to work with children and adolescents need to relate to youth in a positive manner and understand how they think. Participation in a youth fitness program is a personal choice. Thus, it is unlikely that children will continue in a program if they do not understand the games or are unable to perform the exercises. Along with the primary objective of engaging youth in fun physical activities, professionals who work with children and adolescents are also responsible for class management, quality instruction, transition periods, and skill development. Needless to say, the development of successful youth fitness programs requires preparation, coordination, and understanding of the physical and psychosocial uniqueness of childhood and adolescence.

Glossary

acclimation The process of adjusting physiologically or psychologically to different environmental conditions, such as altitude or temperature

acetabular labrum A ring of fibrous cartilage that runs along the socket of the hip joint

acetabulum The socket of the hipbone in which the head of the femur rests, forming a ball-and-socket joint

achondroplasia The most common form of dwarfism, a genetic disorder that affects the development and maturation of bone from cartilage

acromioclavicular (AC) joint The joint located at the top of the shoulder between the acromion and the clavicle

actinic conjunctivitis An eye disease characterized by inflammation of the conjunctiva due to prolonged exposure to ultraviolet light

acute fracture Break of bone or cartilage in which the fracture line is sharp and the surrounding bone appears normal

acute injury An injury that occurs with a rapid onset after a single event

adhesion Fibrous band of scar tissue that forms between tissues not normally bound together, often resulting from injury

agonist A contracting muscle that is resisted by an antagonist muscle

air embolism Any obstruction of the circulatory system caused by the entry of air bubbles into the bloodstream, often through ruptured alveoli

all-around development The emphasis on the development of the three primary attributes of athleticism, flexibility, and musculoskeletal and cardiovascular capacities

allograft The surgical transplant of tissues or organs between different individuals of the same species

ALPSA (anterior labral periosteal sleeve avulsion) A lesion at the distal end of the shoulder associated with shoulder dislocation

alternative medicine Healing practices that fall outside the realm of conventional medical practice, such as homeopathy, acupuncture, naturopathy, or herbalism

alveoli Tiny air sacs within the lungs that facilitate the exchange of carbon dioxide and oxygen; the terminal points of the airways within the lungs

amenorrhea The absence or abnormal cessation of a menstrual period in a premenopausal female when menstruation should be present

anabolic-androgenic steroid A synthetic drug that is used to stimulate muscle and bone growth by mimicking the male hormone testosterone

anaerobic threshold The point during exercise when the body begins to work the muscles without the use of oxygen; the limit at which aerobic exercise can be maintained

aneurysm An abnormal blood-filled swelling of an artery or vein from weakness of the blood vessel wall

ankle inversion test A range-of-motion test performed on the ankle; positive tests reveal a potential tear of the calcaneofibular ligament of the ankle

annular ligament A strong band of fiber that surrounds the wrist or ankle joint

anomalous coronary arteries Congenital variation in the origin, pathway, termination, number, or structure of the coronary arteries; most anomalies are clinically silent and do not affect quality of life

anorexia athletica A condition in which people engage in excessive exercise to lose weight, typically associated with anorexia nervosa

anorexia nervosa A condition in which people intentionally starve themselves for fear of gaining weight, usually characterized by extremely low body weight and body image distortion

antagonist The counterpart of the contracting, or agonist, muscle responsible for the lengthening or stretching of the agonist

anterior apprehension test A clinical test for assessing the instability of a shoulder, in which apprehension with abduction and external rotation of the joint suggests anterior instability

anterior drawer test A measure of the stability and integrity of the anterior cruciate ligament of the knee

aortic stenosis A cardiovascular disease characterized by the abnormal narrowing of the aortic valve between the left ventricle and the aorta

Apley grind test A commonly applied diagnostic test in which the physician grips the hand of the patient and applies downward pressure, causing the hand to deviate toward the ulna

Apley scratch test A clinical test used to assess the range of motion of the shoulders by asking the patient to scratch his or her back

Apley test A clinical test used to assess knee or shoulder injuries

apophysis A natural swelling or outgrowth, or protuberance, on any part of a bone

apophysitis An inflammation of an apophysis

apprehension test A clinical test used to assess the location and severity of injuries, which is performed by manipulating a patient's joints and gauging his or her pain response

arachnoid mater The weblike protective covering of the brain and spinal cord; the middle of the three layers of meninges

arrhythmogenic right ventricular dysplasia A genetic disorder of the heart that is characterized by abnormal, arrhythmic ventricular contractions

arteriovenous malformation A congenital disorder characterized by an abnormal connection of veins and arteries, often resulting in internal bleeding and headaches

arthrofibrosis A condition most often associated with the knee, characterized by the growth of scar tissue resulting in limited joint mobility

arthroscopic portal Small incision through which arthroscopic surgery is performed

arthroscopy A minimally invasive surgery that allows the physician to examine the interior of a joint and diagnose and treat common knee, shoulder, and other joint problems

articular (hyaline) cartilage A tough, fibrous connective tissue that forms on the surface of bones within joints and aids in joint mobility

aseptic necrosis A condition in which the lack of blood supply to the bone may cause bone tissue death

ataxia The lack of motor coordination or the inability to coordinate skeletal muscle contractions

athlete's heart syndrome A medical condition in which the heart enlarges in response to the physiologic stresses of strenuous physical training; typically benign but difficult to distinguish from more serious cardiovascular illnesses

athlete's nodules A general term for relatively hard, discrete, roughly spherical, abnormal cutaneous masses occurring in individuals who engage in sports

athletic pseudonephritis The occurrence of protein and white and red blood cells in the urine in response to strenuous physical activity, often mimicking the problems associated with kidney disease but clearing up completely after 3 days of rest

atlantoaxial instability Increased flexibility of the ligaments between the atlas and the axis, the two bones at the top of the spinal column, with neurologic symptoms occurring when the spinal cord is affected

atlas (vertebra) The uppermost cervical vertebra of the spine

atopy An allergic reaction that becomes apparent almost immediately in response to a stimulus; genetically determined hypersensitivity to an allergen

ATP (adenosine triphosphate) A complex chemical compound derived from adenosine that is formed by the energy released from food and is used to perform cellular metabolic functions; energy molecule of a cell

auditory exostosis Benign bony growth located in the external auditory canal; frequently present in athletes who engage in water sports

autograft Tissue that is taken from one site and grafted onto another in the body of the same individual

avascular necrosis Death of the cells in a bone or joint due to depletion of blood supply

avulsion A painful separation of a muscle from its attachment to a bone

avulsion fracture Bone fracture that occurs when a tendon pulls off a piece of bone from a larger bone mass, usually as a result of a violent or forceful muscle contraction

axial compression test A test performed by pressing on the top of the patient's head with his or her neck in a neutral position; test is positive if the pain is aggravated

axial pain (syndrome) Pain referring to the central part of the body; back pain distinguished from the limbs

axis The second uppermost cervical vertebra, which provides a pivot for turning the head

axon A long extension of a neuron responsible for conducting a signal away from the cell body

balance The capacity to remain in a controlled position without falling or losing coordination

Bankart lesion A tear of the anterior glenoid labrum that is caused by violent movement of the arm

Basilar skull fracture Fracture that occurs at the base of the skull or the portion underneath the brain

belly press test A clinical test used to assess the function of one of the four muscles of the rotator cuff located within the shoulder, the subscapularis; performed with the patient in a standing position with his or her hand on the stomach, pushing as hard as possible

Bennett fracture A bone fracture of the first metacarpal between the thumb and wrist

bipartite Consists of two parts or divisions

Blount disease A growth disorder of the tibia in which the lower leg angles inward; characterized by a bow-shaped lower leg

bony Bankart lesion A fracture of the front lower portion of the glenoid; *see* Bankart lesion

bony edema A swelling of a bone that occurs following an injury

boutonniere deformity A deformity of the finger in which the joint nearest to the knuckle is bent inward due to misalignment of the tendons

bowlegs Legs that bend outward instead of angling inward; the opposite of knock-knees

boxer's fracture A fracture in the fourth or fifth metacarpal, which comprises the knuckles

brachial plexus An arrangement of nerves that conducts signals from the spine to the shoulder and allows for movement of the arm

bronchitis A respiratory disorder characterized by inflammation of the mucus membranes lining the bronchial tubes

bronchoconstriction Constriction of the bronchioles (airways in the lungs) due to the tightening of surrounding smooth muscle; can cause coughing, wheezing, and shortness of breath

bulge Swelling or outward protrusion

bulimia nervosa An eating disorder characterized by episodes of binge eating followed by behaviors designed to prevent weight gain, such as purging, fasting, or excessive exercise

bursa (*pl.,* bursae) A small, fluid-filled sac that provides a cushion between bones and tendons and/or muscles around a joint. Aids in reducing friction between bones and allows free movement

bursitis Painful inflammation of a bursa caused by pressure, repetitive stress from overuse, or infection

cam impingement An abnormal shape of the proximal femoral epiphysis that causes the femoral head to fit awkwardly within the socket, resulting in mild to severe pain

capsulorrhaphy arthropathy A disease afflicting the shoulder characterized by deterioration of the joint surface due to previous repairs of recurrent dislocations

cardiovascular drift A phenomenon that describes an increase in heart rate with prolonged exercise (greater than 10 minutes) despite the exercise continuing at the same intensity

catharsis In psychiatry, the process of release of repressed memories, ideas, or emotional tension

cauda equina syndrome A serious neurological condition characterized by a dull pain and numbness in the buttocks, genitals, and/or thigh with uncontrolled bladder and bowel function due to compression of the spinal nerves

central nervous system The part of the nervous system consisting of the brain and spinal cord; responsible for integrating environmental signals

cerebral edema An excess accumulation of fluid in the intracellular and extracellular spaces of the brain; a serious condition requiring emergency treatment

cerebrospinal fluid The fluid surrounding the brain and spinal cord that protects the spinal cord and provides nutrients

cervical spine The part of the vertebral column comprising the first seven vertebrae inferior to the skull

chair sign A clinical test to check for elbow stability and integrity, in which the patient is seated with elbows flexed at 90°, with forearms supinated and arms abducted, and then tries to rise from the chair pushing down only with the arms

chiropractic An alternative or complementary medical system that focuses on maintaining correct alignment of the musculoskeletal system; spinal manipulation is the most common treatment method, and many people visit chiropractors for treatment of low back pain

chondrolysis Disappearance of the cartilage on the joint surface of the femur (articular cartilage) as a result of disintegration or dissolution

chondromalacia A degeneration or softening of the articular cartilage

chondromalacia patella A softening of the cartilage on the articular surface of the patella that causes pain, particularly during flexion

chondroplasty The smoothing of torn cartilage on the joint surface

chronic exertional compartment syndrome An exercise-induced neuromuscular condition that causes swelling and pain in the arms and legs

closed fracture A fracture that does not pierce the skin

coarctation of the aorta A congenital disorder characterized by narrowing of the aorta, thereby decreasing blood flow to the body

coccyx The end of the spinal column; the base of the spine where the vertebrae are fused

co-contraction A type of contraction when both agonist and antagonist muscles fire at the same time

Colles fracture A fracture to the distal end of the radius bone located in the forearm

comminuted fracture A fracture involving extensive fragmentation of bone

commotio cordis Sudden heart failure due to a severe blow to the chest; most common in extreme contact sports

compartment A group of related muscles found in the same area of the body

compartment syndrome An acute medical issue characterized by the overuse of the same muscle or muscle group and decreased blood flow in a confined anatomical space

complementary medicine A diverse set of systems of holistic medicine based on philosophies other than those used in conventional Western medicine; often called *preventive medicine*

compound fracture The former term for a broken bone that has gone through the skin; now called *open fracture*

concentric movement The part of the movement where the agonist muscle contracts, for example, the lifting motion of an exercise

concussion An injury to the brain caused by a violent blow or rapid shaking; a mild concussion may involve no loss of consciousness; severe concussion may cause prolonged unconsciousness. An athlete who has had a concussion should return to play only with a physician's approval

conditioning Development of physical fitness through adaptation of the body and its various systems to a program of exercise

conduction The act of transmitting heat, sound, or nervous impulses from one area of the body to another

condyle A rounded epiphysis of a bone usually encased in the articular cartilage

contralateral Of or relating to the opposite side

contusion A blunt force injury that does not break the skin but causes underlying tissue damage, with bleeding under the skin (bruising)

convection The transfer of heat via gas or liquid

coordination The ability to conduct more than one set of muscle movements in unison

coracoid The bony prominence of the scapula

costochondritis An inflammation at the point where the ribs fuse with the sternum

crepitus A grinding noise or sensation within a joint or the lungs

cruciate Cross-shaped

crutch palsy Compressive injury to the nerve complex (the brachial plexus) located in the underarm

cyanosis A medical condition characterized by a bluish discoloration of the skin or mucous membranes; a symptom that indicates a dangerously low level of oxygen in the discolored area

de Quervain disease *See* de Quervain tenosynovitis

de Quervain tenosynovitis A painful inflammation of the tunnel that surrounds the two tendons that control the movement of the thumb

debridement Surgical removal of dead, damaged, or infected tissue and foreign matter from a wound or burn

deep vein thrombophlebitis The formation of a blood clot within a vein, typically located in the leg; causes the extremity to become swollen, painful, red, and/or warm

dehydration An excessive deficiency of body water

dens A superior projection of the vertebral body that goes up into the anterior ring of the atlas

depressed skull fracture A skull fracture in which fragmented bones press into brain tissue and cause neurological trauma

dermatophyte A parasitic fungus that infects the skin

dermis The deep vascular layer of the skin located beneath the epidermis

diabetes mellitus A condition characterized by hyperglycemia, resulting from the inability to appropriately control blood sugar and regulate insulin levels

diaphragm A muscular partition between the thoracic and abdominal cavities that regulates breathing

diaphragmatic breathing The act of breathing deep within the lungs by focusing on lowering the diaphragm rather than expanding the chest

diaphysis The main shaft of a long bone

diastatic skull fracture Fracture that occurs along the growth plates or sutures of the skull

disability A physical or mental impairment that prevents a person from performing one or more major life activities

disk herniation A condition of the vertebral column in which a tear in the outer, fibrous ring (nucleus pulposus) of an intervertebral disk allows the soft, central portion (anulus fibrosus) to bulge out, commonly known as a *slipped disk*

disk-osteophyte complex A medical condition where the soft tissue of the intervertebral disk extrudes beyond its normal parameters

displaced Pertaining to the removal from the normal position, location, or place

distraction test An orthopedic test performed on the knee; positive tests indicate a ligamentous injury of the knee

diuretic Any substance that increases the amount of urine production by the kidneys and reduces the amount of water in the blood, thereby decreasing the blood volume

dorsal Pertaining to the back surface of a body part, such as the backside (knuckle side) of the wrist and hand

dorsiflexion Backward flexion or bending toward the dorsal side; flexing the ankle and pointing the toes upward

drawer test An orthopedic test that is used to detect torn cruciate ligaments in the knee

dura *See* dura mater

dura mater The outermost layer of the meninges, the membranes surrounding the brain and spinal cord

dysesthesia A condition characterized by an unpleasant, abnormal sensation such as burning, caused by lesions of the nervous system

eccentric contraction A condition that occurs when the force generated by the muscle cannot overcome the resistance placed on the muscle; also, a lengthening contraction of the muscle

eccentric movement A movement in which the agonist muscle elongates

ecchymosis The escape of blood within subcutaneous tissue that results in discoloration or bruising

echocardiogram A sonar imaging scan used to study the structure and motions of the heart

edema A swelling of tissue due to the accumulation of excess fluid

effusion The discharge or outpouring of a fluid into a body cavity

electrocardiogram A medical record that is used to measure the electrical rhythms of the heart

endogenous Produced, occurring, or caused by factors within the body of an object or organism

endotenon A thin retinacular structure investing each tendon fiber

endurance The ability to withstand stress and hardship or sustain an activity over time; a measure of stamina

epicondyle A protrusion of a bone above the condyle that provides the surface area to which ligaments and tendons can attach

epidermis The outermost layer of the skin surface of vertebrates, which is on top of the dermis

epidural space The space between the dura mater and the lining of the spinal canal

epiphysis The rounded end of a long bone

epitenon A component that surrounds the tendon and contains the vascular, lymphatic, and nerve supply and is in turn surrounded superficially by the paratenon

erythema An abnormal red discoloration of the skin due to the dilation of cutaneous blood vessels

euhydration A normal state of body water content

evaporative heat loss The loss of body heat due to the evaporation of sweat from the body

excision Surgical removal of a portion or all of an organ or other structure

exercise-associated hyponatremia Dangerously low levels of sodium within the blood due to excessive exercise

exercise-induced hematuria The presence of blood within the urine due to excessive exercise

exogenous Produced, occurring, or caused by factors outside the body of an object or organism

extra-axial hemorrhage Blood loss within the intracranial space; increases pressure, causing headaches

extreme-risk injury Injury needing immediate medical attention

extrusion A bulge or protuberance, pushing out

facet joints Small joints located between adjacent vertebrae

fascia A continuous sheet of connective tissue that separates and bonds together muscles and other organs

fasciotomy A surgical procedure in which fascia is removed from the body to relieve tension and pressure

female athlete triad A medical condition seen in some female athletes, characterized by disordered eating, amenorrhea, and osteoporosis

FEV_1 (forced expiratory volume in 1 second) The volume of air an athlete can expel in the first second of a forced expiration; the most important parameter examined in determining airway obstruction

first-degree strain A minor strain characterized by only a few muscle fiber tears

flail chest A severe medical condition characterized by fragmentation of the ribs due to stress

flexibility The ability of a muscle or extremity to relax and yield to stretch forces

focal fibrocartilage dysplasia An uncommon, normally harmless bone lesion that causes deformity of the long bones in youth

fontanelle The gaps located between the bones of the cranium in an infant or fetus

foramen (*pl.*, foramina) Any opening or orifice within the body

Freiberg disease An osteochondrosis affecting the metatarsals (long bones of the foot)

Freiberg sign The reproduction of pain caused by passive internal rotation of the hip with the leg in an extended position

fulcrum test By placing the left hand under the glenohumeral joint to act as a fulcrum, the apprehension test becomes a fulcrum test

functional limitation Any health problem that prevents an individual from completing a task

ganglion cyst A small, abnormal, fluid-filled sac (usually less than 2 centimeters) that develops near a joint capsule or tendon sheath

gastrocnemius soleus (calf muscle) strain A strain or tear, with the sensation of a pop being felt, due to the simultaneous stretching and active contraction of the muscle

genu valgum A medical condition characterized by an inward curvature of the legs so that the knees touch when a person is standing straight; commonly known as *knock-knees*

genu varum A medical condition characterized by an outward curvature of the legs; commonly called *bowlegs*

GLAD lesion (glenolabral articular disruption) Lesion characterized by a labral tear associated with an injury to the glenoid articular cartilage

glenohumeral joint The shoulder joint that functions as a ball-and-socket joint; composed of the glenoid socket and the humeral head

glenohumeral ligaments Three bands of connective tissue that strengthen the glenohumeral joint

glenoid Any shallow depression of a bone resembling a pit or socket

glenoid labrum A rim of articular cartilage that surrounds the margin of the glenoid cavity in the shoulder blade

glial cell Nonneuronal cell that provides nutrients and removes waste from other neural cells

glycogenolysis The process by which glycogen is broken down in the liver into individual molecules of glucose

gout A form of arthritis caused by a buildup of uric acid in the joints

gradual progressive throwing A shoulder rehabilitation technique in which throwing motions help stabilize the shoulder

gray matter A large component of the central nervous system comprising glial cells, neuronal cell bodies, dendrites, axons, and capillaries

grind test A clinical test used to determine the integrity and problems associated with the meniscus of the knee

Hawkins-Kennedy test A test that attempts to cause external compression of the rotator cuff and consequently re-create the patient's pain

hemarthrosis Bleeding into joint spaces

hematocrit The volume percentage of red blood cells in a blood sample

hematoma Swelling formed by excess accumulation of blood

hematopoiesis The production of blood cells

hemorrhage A copious discharge of blood from the blood vessels

hemothorax Accumulation of blood located within the pleural cavity, or the area surrounding the lungs

hepatitis Inflammation of the liver caused by certain viruses or other factors such as alcohol abuse or medications

hepatomegaly Abnormal enlargement of the liver

heterotopic bone formation/ossification The formation of bone in abnormal locations, such as in soft tissue or muscle

Hill-Sachs lesion A depression in the head of the humeral epiphysis due to a forceful impact against the glenoid rim

hip dysplasia An abnormal formation and deterioration of the hip socket that is characterized by excessive pain and arthritis

hip impingement A condition that is characterized by excessive friction within the ball-and-socket hip joint

hip quadrant test A clinical test that indicates arthritis, avascular necrosis, and/or an osteochondral defect within the hip

Homans sign A sign of deep vein thrombosis; is positive when pain is located within the calf muscles

hop test A clinical test used to measure the horizontal and vertical power of the legs by performing three consecutive jumps

hydrogenation A form of chemical reduction, a chemical reaction between molecular hydrogen (H_2) and another compound or element, usually in the presence of a catalyst; commonly employed to reduce or saturate organic compounds

hyperpronation The extreme inward rotation of the foot during gait

hyperalgesia An increased response to pain caused by damage to the peripheral nerves

hyperesthesia A state of abnormal increase in sensitivity to sensory stimuli

hyperlipidemia An excess quantity of lipids in the blood

hypertrophic cardiomyopathy A condition where the heart muscle becomes abnormally enlarged, limiting the amount of blood that can enter the heart and thereby reducing pumping ability

hyphema A collection of blood in the anterior chamber of the eye often caused by trauma; causes blurry vision, pain, and tearing

hypodermis The lowermost subcutaneous level of the three skin layers

hypohydration *See* dehydration

hypothalamus The part of the brain responsible for the control of endocrine glands and the autonomic nervous system

hypoxia Decreased availability of oxygen to body tissues

iatrogenic Describing inadvertent harmful consequences or complications resulting from medical treatment

idiopathic A disease of an unknown origin

iliotibial band A band of fascia that spans from the iliac crest of the pelvis region to the knee joint; can become inflamed due to excessive running

impingement Striking or excessive pressure on a tissue, often from encroachment by adjacent structures

infective endocarditis An inflammation of the membrane that lines the cavities of the heart and forms part of the heart valves, generally caused by an infection

influenza An acute, highly contagious viral disease; also referred to as the *flu*

inguinal hernia A protrusion of the intestines through the inguinal canal where the flesh of the abdomen meets the thigh

injury, catastrophic An extremely serious injury that may result in disability and loss of bodily functions, with full recovery doubtful

injury, nonfatal A broad range of types of injury from acute to catastrophic with no life-threatening issues

injury, serious An injury in which mortality is probable

integrative medicine A combination of alternative and conventional medicine to provide a more comprehensive healing plan for the patient

intersection syndrome Inflammation of the crossover area where the musculotendinous junctions of the first dorsal compartment meet with the tendons of the second dorsal wrist compartments

interval training An exercise strategy in which an athlete raises his or her exercise intensity above the anaerobic threshold for a short period of time and then dips back below the threshold and keeps exercising

intervertebral disk A fibrocartilaginous disk that provides cushion and support between two adjacent vertebrae

intervertebral foramen An opening between vertebrae that transmits nerves from the spine throughout the body

intraarticular dilation An expansion within the joint

intra-axial hemorrhage A hemorrhage that takes place within the central part of the body

iontophoresis Therapy that uses small electric currents to deliver medicine into tissues of the body

ipsilateral Positioned on or affecting the same side

irrigation Cleansing injured tissue by rinsing with sterile saline, with or without antibiotics in the solution

ischemic necrosis A condition in which the lack of blood supply to the bone may cause bone tissue death

isometric contraction A contraction that generates muscle force but in which no joint movement occurs, such as holding a squat for 10 seconds

isotonic contraction A contraction that occurs when the muscle contracts and joint movement occurs

jerk test A clinical test used to determine the integrity of the knee joint (possible torn meniscus), also called Hughston's jerk test, to distinguish from the simple knee-jerk test of neurological reflex by tapping the patellar tendon.

Jobe's empty can test A clinical test used to determine the integrity of the supraspinatus tendon

joint aspiration The removal of fluid from within a joint

joint effusion The escape of intraarticular fluid

joint integrity A measure of the stability and durability of a joint

joint of Luschka Small synovial joints between adjacent lower-cervical vertebral bodies—a frequent site of arthritis formation

Jones fracture A fracture of the fifth metatarsal of the foot

knock-knees A condition in which the legs curve inward at the knees; *see* genu valgum

kyphosis An abnormal backward curve in the spinal column

labrum A thickened portion of connective tissue that surrounds the sockets of the shoulder and hip joints

Lachman test A test that is used for examining the integrity of the anterior cruciate ligament of the knee

lactate threshold The point at which lactic acid buildup in the muscles begins to impair performance

lamina (*pl.*, laminae) A broad plate which extends from the pedicle to the median line of the vertebra, two laminae fusing to complete the roof of the vertebral arch

laminectomy Surgical removal of any part of the lamina

lateral epicondylitis A painful inflammation of the tendon that wraps around the elbow; also called *tennis elbow*

lateral pivot-shift test A clinical test used to evaluate the anterolateral structures of the knee

lift-off test A clinical test used to check the stability of the shoulder

ligaments Fibrous connective tissues responsible for connecting bones, cartilage, and other structures

linear fracture A fracture that runs parallel to the axis of the bone

load and shift test An orthopedic test used to check for the stability and integrity of the shoulder

loose body A free-floating piece of bone or cartilage that has broken away and is moving around a joint

lordosis An inward forward curve of the lower spine

lucid interval A temporary improvement in a patient's condition following a traumatic brain injury, after which the patient's condition deteriorates

Ludloff sign A test checking the ability to flex the thigh while sitting down; is positive if patients fail to perform the test, and negative if performed effectively

lumbar The portion of the spinal column between the thorax and the pelvis, commonly called the lower back

luteal phase The second half of the menstrual cycle lasting from ovulation to menstruation

malleolar bursitis Swelling and pain over the ankle bone caused by irritation of the bursa, a fluid-filled sac that aids in reducing friction between moving bones

McMurray test A test used to determine whether a meniscal tear is present in the knee by bending the lower leg, straightening it out, and rotating it; is positive if pain is found around the area of the meniscus

medial and lateral patellar glide test A test used to determine the stability of the lateral retinaculum in the knee and the medial aspect of the knee

medial epicondylitis An overuse injury, commonly known as *golfer's elbow,* that causes pain in the inside of the elbow

medial tibial stress syndrome An overuse injury, commonly known as *shin splints,* causing irritation in the shinbone, which is located in the front of the lower leg

mediastinum The central cavity surrounded by the lungs, containing the heart, proximal aorta, and vena cava and lined by a protective tissue, the pericardium

meninges Protective coverings of the brain and spinal cord, consisting of three layers from outermost to innermost—namely, the dura mater, arachnoid, and pia mater

meniscal cartilage The cushioning tissue of the knee between the femur and the tibia

meniscus A structure consisting of both the lateral and the medial cartilage of the knee, acting as a pad between the joints of the femur and the tibia and providing a smooth surface for the joints to glide on

menorrhagia Excessive menstruation that lasts for more than 7 days

metabolic ketoacidosis A condition that usually affects patients with diabetes when the body has very low levels of insulin and starts to break down body fat, leading to the formation of a high concentration of ketone bodies, and thus causing the blood to become too acidic

metaphysics The study of reality in relation to such questions that may not be answered scientifically; also, the study of subjects relating to mind and matter

metatarsalgia An overuse injury that causes pain in the middle region of the forefoot

microfracture A surgical technique in which tiny holes are made in the exposed bone in an area of the joint where the full thickness of the cartilage has been completely damaged

microtrauma The term given to microscopic injuries such as microtears in muscles, tendons, and tissues

milk test An orthopedic measure to test elbow instability

Monteggia fracture A break in the ulna bone of the forearm, along with dislocation of the radial head

Morton neuroma Irritation, pain, and swelling of the nerve located between the third and fourth toes of the foot

moving valgus stress test A test used to determine whether the medial collateral ligament (MCL) of the elbow is torn

MR (magnetic resonance) arthrogram A test used to examine the joints in the body, such as the knee or shoulder, in which a contrast-enhancing dye is injected to facilitate viewing by magnetic resonance imaging

muscle hypertrophy The increased cross-sectional size of the muscle fibers

muscle strength The ability of the muscle to create force against physical objects

muscular endurance The ability of a muscle to perform and maintain repeated muscle contractions over long periods of time

myocarditis An inflammation of the heart muscle (myocardium)

myocardium Cardiac muscles that make up the bulk of the heart wall

myofascial release The adding of pressure with the thumb over the muscle spasm to decrease the contraction

myositis ossificans The formation of bone within muscle tissue; occurs after the tissues surrounding the muscles are damaged in a traumatic injury

Neer test A test that attempts to cause external compression of the rotator cuff and consequently recreate the patient's pain

nerve impingement (or "pinching" of the nerve) Refers to pain in or impaired function of a nerve that is under pressure

nerve root A part of a collection of nerve fibers that branch off from the spinal cord. Dorsal roots are composed of sensory fibers that bring information into the spinal cord. Ventral roots are composed of motor neurons that carry commands from the spinal cord to the muscles and internal organs

nerve tracts A collection of nerve fibers located in the central nervous system (CNS)

neurons Nerve cells; the conducting cells of the nervous system that receive and transmit information through chemical and electrical signals

Noble compression test A test used to check for iliotibial band syndrome

nondisplaced A type of fracture in which the bone maintains its normal alignment after breaking

nonpurging-type bulimia nervosa An eating disorder involving excessive eating along with attempts to compensate afterward through diet pills, fasting, or excessive exercise

nonunion A fractured bone that failed to heal properly

nuchal ridge A thick crest located on the back of the neck and base of the skull (occipital bone)

nucleus pulposus A gelatinous substance found in the center of intervertebral disks of the spinal column; aids in shock absorption

Ober test A test used to evaluate the shortening of the iliotibial tract muscle

O'Brien test A test used to evaluate acromioclavicular joint injury in the shoulder

OCD *See* osteochondritis dissecans

occipitocervical injuries An injury of the cervical spine in which the cranium dislocates from the neck, a severe injury that can be fatal if not treated immediately

odontoid process A toothlike structure found in the second vertebra of the neck

open fracture A fracture in which the bone penetrates through the skin, also called a compound fracture

orthorexia nervosa An eating disorder characterized by an excessive concern with eating healthy foods (not officially recognized as a medical diagnosis)

orthosis A support device used to brace or correct the function of specific limbs—for example, arch supports that are used to correct foot function

os acromiale Pain in the shoulder due to the failed fusion of the bone at the front of the shoulder roof known as the acromion

os odontoideum A separation of the top of the dens from the C2 vertebral body

ossicle The smallest bones in the body, of which three are located in the middle ear

osteoarthritis A form of arthritis; a degenerative disease that affects joints and also leads to the gradual breakdown of cartilage and the formation of "bone spurs" on joints

osteoblasts Cells in the body that are responsible for bone formation

osteochondral injury An injury that affects the articular cartilage and the bone underneath

osteochondritis Inflammation of bone and cartilage

osteochondritis dissecans (OCD) An injury in which fragments of cartilage and bone are separated from the end of the bone and are loose in the joint space

osteochondrosis The necrosis or breakdown of growth centers in the pediatric or skeletally immature patient followed by regeneration or healing

osteoclast A body cell that not only breaks down bone tissue but also absorbs it back into the body

osteolysis The active resorption of bone matrix by osteoclasts as part of an ongoing disease process

osteonecrosis A condition in which the lack of blood supply to the bone may cause bone tissue death

osteopenia A condition in which the level of bone mineral density is below normal levels, but not as severe as in osteoporosis

osteophyte An abnormal growth of bone in damaged joint areas, more commonly known as a *bone spur;* commonly seen in osteoarthritis due to the nature of degenerative joints

osteoporosis A disease that causes bones to lose density, strength, and tissue over a period of time, leaving bones fragile and more susceptible to injuries such as fractures

osteotomy A surgical procedure that involves cutting the bone to promote proper alignment and healing in the affected joint area; can be used for arthritis treatment and to fix bones that may have grown incorrectly

otalgia Ear pain, of which there are two types: (1) pain originating from the outside of the ear, or *referred otalgia*, and (2) pain that originates from within the ear, or *primary otalgia*

otorrhea A discharge of fluid from the ear canal

Ottawa ankle rules A set of guidelines established to help physicians determine whether X-rays are needed to diagnose possible fractures in the foot or ankle

Ottawa knee rules A set of guidelines established to help physicians determine whether X-rays are needed to diagnose knee injuries

outer annulus The outermost layer of fibrocartilage in an intervertebral disk, tears or ruptures of which may permit extrusion of the nucleus pulposus into the surrounding tissue

overreaching A condition in which an athlete trains excessively, causing stress, fatigue, and sometimes poor athletic performance

Pace sign A test used to determine whether a patient has piriformis syndrome, a compression of the sciatic nerve by the piriformis muscle of the thigh

paraplegia Partial or complete paralysis of the lower extremities caused by a spinal cord defect or traumatic injury

paratenon The external covering of the entire tendon

paratenonitis Inflammation of the paratenon, the outermost layer of the tendon

paresthesias The occurrence of abnormal nerve sensations such as tingling, burning, itching, and "pins and needles," sometimes caused by nerve damage

parietal pleura A specialized skinlike surface that lines the thoracic cavity

patellar tendinosis Inflammation or long-term damage to the tendon that connects the bottom of the kneecap to the top of the shinbone

patellar tendon The attachment of the quadriceps muscle to the tibia

patellar tilt test A test used to assess the tightness of the lateral side of the knee and also pain around the kneecap (patella)

Pavlik harness A soft brace used for babies less than 6 months old with thighbone fractures

periodization The process of splitting up time into blocks; in sports medicine, the splitting up of a training regimen into phases

periosteum A membrane/tissue covering all bones

peripheral nervous system Composed of the nerves outside the brain and spinal cord, which also connect the central nervous system to the sensory organs, limbs, and muscles

pertussis A contagious bacterial disease that causes violent coughing, commonly known as whooping cough

pes planus A condition in which the arch of the foot collapses and touches the ground, commonly called *flat feet*

petechiae Round red spots that are visible on the skin due to bleeding under the skin

phalanges (*sing.*, phalanx) The bones of the fingers and toes

pharmacokinetics The study of what happens to a drug after it is taken into the body, that is, how it is metabolized

phonophoresis A technique using ultrasound to help the body absorb therapeutic drugs through the skin

physiatrist A physician who specializes in physical and rehabilitation medicine

physis The growth plates at the ends of long bones

pia mater The innermost layer of the meninges, the membranes surrounding the brain and spinal cord

pincer impingement A form of hip abnormality in which the front edge of the hip socket sticks out too far

piriformis sign A test used to determine whether the pain originating in the gluteus maximus causing referred pain down the leg is due to piriformis syndrome

pivot-shift test A test used to determine the stability of the anterior cruciate ligament (ACL) in the knee

plantar fascia A series of connective tissues that start from the heel and support the arch in the foot

plantarflexion Bending of the foot in a downward direction

pleura A membrane that surrounds the lungs and also covers the diaphragm and lines the inner chest wall, forming a potential space for lung expansion

pleural cavity The body cavity that surrounds the lungs

plica syndrome An inflammation of the plica (*see* plicae) found in the knee

plicae Bands of synovial tissue located in the lining of a joint

plication A surgical procedure used to tighten tissues by folding them into tucks and suturing them

pneumomediastinum A pathological condition consequent to trauma to the chest in which air leaks from the injured lungs into the middle of the chest (mediastinum)

pneumonia An inflammation of the lungs caused by infection

pneumothorax A serious condition that occurs following the collapse of a lung, in which air collects in the pleural space surrounding the lungs and makes breathing difficult

popliteal Refers to the structures in the back of the knee, such as veins, nerves, arteries, and so on

positive J sign A test that shows the patella tracking laterally as the knee changes from flexion to extension

posterior drawer test A test to evaluate the posterior cruciate ligament (PCL) in the knee, especially for tears and ruptures

posterior Lachman test A test used to diagnose a torn anterior cruciate ligament (ACL)

posterior sag test A test used to determine instability in the posterior cruciate ligament

posture The position in which the body is held upright against gravity while standing or sitting down

power A force that is exerted over a period of time

progressive muscle relaxation A set of skills whereby the athlete is trained to control the tension of his or her muscles by alternatively consciously flexing them, holding the tension, and then slowly releasing them

progressive overload The increased stress placed on the body during exercise

prolotherapy A form of therapy that involves injection of a substance into the body to strengthen weakened tissues and also alleviate pain

proprioception The ability to sense the position and movement of muscles

protrusion An extension beyond the usual limits

pseudocyst An abnormal sac that resembles a true a cyst but lacks membranous lining

pterygium An abnormal growth that begins on the white of the eye and invades the cornea, the clear tissue covering the iris and the pupil, which may result from overexposure to sunlight and can be surgically removed. May also refer to a winglike triangular membrane abnormally occurring in the neck, eyes, knees, elbows, ankles, or digits

pudendal nerve compression syndrome Pain in the pelvic area due to compression activities such as cycling

pudendal nerve entrapment syndrome Chronic pain in the pelvic area due to stretching, inflammation, or compression of the pudendal nerve

pulmonary contusion Bruising of the lungs that causes pain and difficulty in breathing

pulmonary edema Excess fluid buildup in the lungs; can be caused by circulatory problems such as congestive heart failure

pulse oximetry A method in which the oxygen saturation of the hemoglobin is monitored

purging-type bulimia nervosa A type of disorder in which the bulimia patient uses vomiting, laxatives, diuretics, or enemas to rid the body of consumed calories

purpura Bleeding under the skin characterized by purple or red discoloration spots

push-up sign A test for posterolateral instability in the elbow

pyrogen A substance that causes a rise in body temperature and subsequent fever; released by certain bacterial infections

quadriceps tendon The tendon above the patella (kneecap)

radiation heat loss The loss of heat from the body, most significant between sunset and sunrise, due to infrared emission

radicular pain Muscle weakness, tingling, numbing, and pain due to the compression of a spinal nerve root

radicular symptom Pain manifested in the legs or arms due to a compressed spinal nerve root

radiculopathy The inflammation of spinal nerve roots

reduction The technique of returning a fractured bone to its proper alignment

release test A test in which a force that decreases the patient's pain is removed, causing the pain to return

relocation test A test used to determine whether anterior instability is present within the shoulder

Renee creak test A test used to diagnose pain and tightness in the iliotibial band; is positive if pain is present when standing on the affected leg with knee flexion at 30°

retromalleolar groove A concavity located in the fibula, which when abnormally shaped can lead to tearing of the peroneus brevis (PB) tendon

reversibility Reduction or complete loss of fitness as the result of not training

rheumatoid arthritis An autoimmune disorder that causes chronic inflammation in the joints and can also affect other organs in the body

rhinitis An inflammation of the mucous membrane inside the nose, commonly known as a stuffy nose, that is associated with the common cold and allergies

rhinorrhea Fluid nasal discharge; "runny nose." Following head injury, may indicate leakage of cerebrospinal fluid, a serious condition requiring prompt medical attention

ribs, false Five ribs, located inferiorly to the true ribs, called "false" because not directly connected to the sternum

ribs, floating The lowest two sets of ribs attached to the vertebrae in the lower back

ribs, true The uppermost seven pairs of ribs, attached to the sternum

rickets A disorder that leads to the weakening and softening of bones in children; caused by lack of vitamin D and, in some cases, lack of adequate calcium intake

righting reflexes A neuromuscular response that enables the body to regain its normal position when it has been displaced

rotator cuff A structure composed of four muscles that stabilize the shoulder joint and allow shoulder movement, namely the supraspinatus, infraspinatus, teres minor, and subscapularis

sacrum The triangular bone located in the base of the spine, composed of five fused sacral vertebrae forming the rear of the pelvis

sarcopenia The degenerative loss of muscle mass and strength due to aging

second-degree strain An injury in which the muscle is overstretched, causing inflammation and pain; involves most of the muscle fibers tearing and difficulty performing certain movements

second impact syndrome A condition involving a second concussion before the first has properly healed; a serious, often fatal injury in which the brain rapidly swells up, causing an increase in the intracranial pressure

secretory phase The second half of the menstrual cycle

septal hematoma Bleeding within the nasal septum

sequestration An abnormal separation of a part from a whole, such as a portion of a bone by a pathological process or a portion of the circulating blood into the surrounding soft tissue from a broken blood vessel

Sever disease Pain in the heel due to the inflammation of the growth plate (calcaneus) located in the back of the foot

shear injury An axonal injury to the brain due to accelerated rotational forces

shoulder capsule A structure that provides extra stability to the shoulder joint

SLAP lesion (superior labrum anterior-posterior) An injury to the glenoid labrum, located in the shoulder

slipped disk A condition of the vertebral column in which a tear in the outer, fibrous ring (nucleus pulposus) of an intervertebral disk allows the soft, central portion (anulus fibrosus) to bulge out. *See* disk herniation

slump test A physical examination to evaluate the sciatic nerve in cases of pain in the spinal and lower extremities

Smith fracture An injury to the distal radius (forearm bone)

spasm An involuntary contraction of a muscle

specificity A measure of a test's ability to rule out a disease

Speed test A test to evaluate whether pain is present in the bicipital groove of the shoulder

spica A body casting to treat fractures

spinal stenosis A narrowing of the space enclosed by the spinal column, causing pressure on the spinal cord

spirometry A test used to measure the breathing capacity of the lungs

spondylolisthesis Forward displacement of a vertebra over a lower segment due to a congenital defect or fracture in the pars interarticularis

spondylolysis The breaking down of a vertebra, usually leading to small stress fractures from an overuse injury

spondylolytic A term used to describe a patient with a degenerative disorder of the pars interarticularis, a structure found in the vertebrae

spondylosis A degenerative disorder that affects the intervertebral disks in the spine, often referred to as spinal osteoarthritis

sports concussion A head injury caused by either mild or severe impact during sports activity that causes the brain to shake violently within the cranium

sports hernia A condition that occurs when muscles and tendon in the lower abdomen become weakened, usually causing chronic groin pain in athletes; not a true hernia

Spurling test A test for pain in the neck originating from the spinal nerve roots

Stener lesion A condition that occurs when the ulnar collateral ligament (UCL) tears and the surrounding tissue of the overlying thumb tendon gets lodged between the torn UCL fibers

stenosis A condition in which the blood vessels and tubular organs become narrowed and constricted

strain The stretching or partial tearing of the muscle, resulting in inflammation and pain

strength The ability of a muscle to generate and resist physical force

stress fracture A small crack in a bone, usually caused by overuse

stress fracture test A bone scan used to evaluate the injured area on the bone

stretch reflex A muscle contraction in response to stretching within the muscle; also known as a myotatic reflex

stroke volume The amount of blood that is pumped out of a ventricle in the heart during a contraction

structural tolerance The ability to withstand weeks or months of high-volume training without the incidence of injury, illness, or fatigue that may lead to overtraining

Stryker notch view An X-ray view used to evaluate for Hills-Sachs lesion after a dislocation

subacromial impingement Pain in the shoulder caused by friction between the rotator cuff and acromion

subarachnoid space The meningeal space located between the arachnoid and the pia mater

subchondral bone A bone layer that underlies the articular cartilage

subcutaneous emphysema A pathological condition that occurs when air is trapped beneath the tissues in the skin of the chest, neck, and face

subdural space The space between the dura mater, the outermost meningeal layer, and the underlying arachnoid mater, caused by an injury or a pathologic process such as a subdural hematoma

subluxation A condition that occurs when the patella, commonly called the kneecap, becomes partially dislodged from its normal position

subtalar neutral position The normal position of the foot when one walks

sulcus sign A test to evaluate the presence of inferior instability within the glenohumeral joint

superior retinaculum The ligament binding the extensor tendons closest to the ankle joint

surfer's ear A condition that occurs when the ear canal becomes blocked due to abnormal bone growths, called exostoses, caused by prolonged exposure to cold water and wind

surfer's myelopathy A nontraumatic spinal cord injury in which blood flow to the spine is interrupted when the back is hyperextended, sometimes causing partial or complete paraplegia

swan-neck deformity A hand deformity in which the distal joint of the finger is pointed inward and the proximal joint outward

synchondrosis A cartilaginous joint that joins bone to bone, such as the sternocostal joints where the first ribs join the sternum

syncope A temporary loss of consciousness, commonly known as fainting

synostosis A condition in which two separate bones fuse together as one

synovial cyst A cyst that is filled with synovial or joint fluid to produce its characteristic bulge

synovial fluid The lubricant that serves to reduce friction of the articular cartilage within the joint capsule

synovial tendon sheath A membrane consisting of an outer fibrotic sheath and an inner synovial sheath, which may be found in areas subject to increased mechanical stress where efficient lubrication is required

synovitis An inflammation of the synovium, the tissue that lines the joints

synovium A soft tissue that lines the joints and produces synovial fluid

syringomyelia A disorder characterized by the formation of a cyst in the spinal cord

tachycardia A heart rate faster than normal

tarsal coalition A condition in which two bones in the back of the foot (tarsal bones) are fused

tendinitis The inflammation of the tendon; rarely occurs without the presence of underlying degenerative tendon change

tendinopathy Tendon injuries such as tiny tears, pain, and inflammation

tendinosis A noninflammatory repetitive injury to the tendon resulting in microtears that do not heal properly

tendon A band of fibrous connective tissues that connect a muscle to a bone

tenodesis stabilization Procedures that are indicated for patients with lateral ankle instability with failed anatomic repair; consists of a suture of the end of a tendon to a bone

tenosynovitis An inflammation of a tendon and its sheath

tenotomy A surgical procedure that involves cutting or releasing a tendon

tension pneumothorax A condition that forms a one-way valve, allowing air to enter the pleural space but not to escape; the buildup of air within the pleural space producing pressure on the lungs, thus making breathing difficult

tetraplegia A traumatic spinal injury that causes complete paralysis of all limbs

therapeutic exercise A therapy with goals such as improving musculoskeletal function, recovering from injuries, and providing relaxation

thermoregulation Control of body temperature

third-degree strain The most severe type of strain, which occurs when a muscle has been completely ruptured due to an injury

Thomas test A test used to evaluate whether a patient can extend the hips

Thompson test A test used to evaluate for an Achilles tendon rupture

thoracic kyphosis An abnormal forward curvature of the upper back region

thoracic spine The middle region of the spine, consisting of 12 vertebrae

tibia vara A growth disorder of the upper shinbone, causing a bowlegged appearance

tinea capitis A contagious infection of the scalp caused by a fungus, commonly called ringworm

tinea corporis A contagious fungal infection affecting the skin, commonly known as ringworm

tinea cruris A fungal infection affecting the groin area, commonly called jock itch

tinea pedis A fungal infection of the foot, commonly known as athlete's foot

Tinel test One of two tests used to diagnose the presence of carpal tunnel syndrome

tophi The buildup of uric acid in joints, bones, and cartilage

torticollis A pathological condition involving uncontrolled spasms of the neck muscles so that the neck remains in a twisted position with the head tilted and turned to one side

toss The act of disengaging a member of a cheerleading team from either a pyramid or a base arrangement

traction apophysitis An inflammation of an unfused apophysis caused by excessive pull of an attached tendon

training load The product of all three fundamental components of training: frequency, duration, and intensity

trans fat An unsaturated fat that is made into a solid by adding hydrogenated oils during manufacturing

Trendelenburg test A test to evaluate hip function, specifically of the gluteus medius muscle, in which the patient is asked to stand on one leg

triangular fibrocartilage complex A structure found in the wrist that is made up of several different structures, the primary components are being the dorsal and palmar volar ligaments

trochanter Two bony projections located near the end of the thighbone

trochlear groove The concave surface in the knee joint where the patella makes contact with the femur

tuberosity A protuberance on a bone, especially where a muscle or ligament is attached

turf toe Pain at the base of the great toe caused by jamming the foot

uncinate process Any hooklike process, such as that keeping a vertebra from sliding backward off the vertebra below it

uric acid A heterocyclic compound of carbon, nitrogen, oxygen, and hydrogen with the formula $C_5H_4N_4O_3$; a chemical created when the body breaks down substances called purines

valgus Bowlegged position

valgus stress test A test to evaluate the medial collateral ligament (MCL) in the knee

varus Knock-kneed position

varus stress test A test to evaluate the lateral collateral ligament (LCL) in the knee

vertebra (*pl.,* vertebrae) Any of the separate segments comprising the vertebral column; there are normally 33 of them, differing in size and structure according to location

vertebral foramen The opening in the center of the vertebra through which the spinal cord passes

vesicle A small sac containing fluid

visceral pleura A membrane covering the lungs and lining the inner wall of the chest

$\dot{V}O_2$max Refers to the peak oxygen uptake and the body's ability to use it during exercises that increase in intensity over time

volar Refers to the the palmar surface, or underside of the wrist and hand

volar plate A thick ligament found in the fingers preventing hyperextension injuries

West Point view A specially positioned X-ray view used to detect a Bankart lesion of the shoulder

white matter The portion of the brain containing myelinated nerve fibers; also part of the central nervous system

"winging" Lifting off of the medial border of the scapular shoulder

xerosis A condition in which the skin is abnormally dry

Yergason test A test that is conducted by having the patient flex the elbow and rotate the hand from a palm-down position to a palm-up position while the examiner resists the motion

Zanca view An X-ray view used to evaluate the acromioclavicular (AC) joint in the shoulder

Appendix A

Taping and Bracing Techniques

The step-by-step procedures in this appendix describe the basic taping and bracing techniques used today in sports medicine. The following table lists the various supplies typically used in these procedures.

Table 1 Taping Supplies and Equipment

Type	*Properties*	*Size*	*Brands*	*Uses*
Adhesive spray	Typically aerosol spray that makes the skin more adhesive	Cans come in various sizes of 4 to 12 oz	Tuff Skin	First step before applying any tape or elastic wrap. Always ask about potential allergy before applying
Elastic wraps	Made of cotton with elastic properties	Can vary in size from 2 to 6 in. and length of 5 to 11 yd	Ace Wrap	Can be used for initial injury for compression or used for spicas and wraps to provide support
Adhesive stretch tape	Stretchy tape with adhesive properties to stick to skin or other products such as padding	Can vary from 1 to 4 in. and 2.5 to 5 yd	Powerfast Lightplast	Can be used for compression or to secure padding
Nonadhesive stretch tape	Stretchy tape that sticks to itself	Can vary from 1 to 4 in. and 2.5 to 5 yd	Powerflex Activ-Flex Cohesive stretch tape	Can be used for compression or used as the basis of some tape jobs when prewrap is not needed
Prewrap	Made of foam and provides an under layer before the tape is applied	2¾ in. × 30 yd	Mueller Cramer	Placed under most taping procedures to decrease chafing and blisters
White zinc tape	Nonelastic tape with adhesive properties to stick to skin or other products	Can vary from ½ to 4 in. and 2.5 to 5 yd	Coach Zonas Jaybird Cramer	Used as the primary tape in most procedures due to its nonelastic properties

Note: 1 inch (in.) = 2.54 centimeters; 1 yard (yd) = 0.91 meters; 1 ounce (oz) = 28.35 grams.

This appendix includes discussions of 19 of the most common taping procedures, organized by body region:

1. great toe taping
2. arch taping
3. closed basket weave
4. Achilles taping
5. medial tibial stress syndrome taping
6. McConnell taping
7. knee hyperextension taping
8. medial collateral ligament taping
9. patellar tendinitis strap
10. thigh compression wrap
11. hip spica for adductor strain
12. rib compression wrap
13. shoulder spica for acromioclavicular taping
14. elbow hyperextension tape
15. ulnar collateral ligament taping
16. lateral epicondylitis strap
17. wrist hyperflexion taping
18. buddy taping
19. thumb spica

Great Toe Taping

Great toe taping is applied after injury to the first metatarsophalangeal (MTP) joint of the great toe after a hyperextension or hyperflexion injury and is associated commonly with "turf sports," such as football, soccer, and field hockey. The goal of taping is to limit excessive and/or painful extension or flexion of the MTP joint.

Procedure

Materials. Adhesive spray, 1½-inch (in.; 1 in. = 2.54 centimeters [cm]) white tape, 1-in. white tape.

Positioning and Preparation. The patient is made to lie in the supine position with the knee in extension, foot in relaxed position, and great toe in neutral position. Apply adhesive spray to the foot and great toe where the tape will be applied.

Application

1. Apply an anchor around the midfoot with the 1½-in. white tape. Apply the second anchor with the 1-in. tape around the great toe distally.

1.

2.

2. Apply a fan strip with the 1-in. white tape from the second anchor on the distal great toe. Position the great toe into slight flexion within the painfree range. Secure the first fan strip to the initial anchor. Repeat two to three times with additional fan strips to secure the great toes in painfree position.

3.

3. To secure the fan strips, place the 1½-in. white tape over the initial anchor and the 1-in. white tape over the second anchor.

Final Assessment. Check for circulation and ensure that the application has limited the painful motion and is functional for the athlete.

4.

Additional Notes

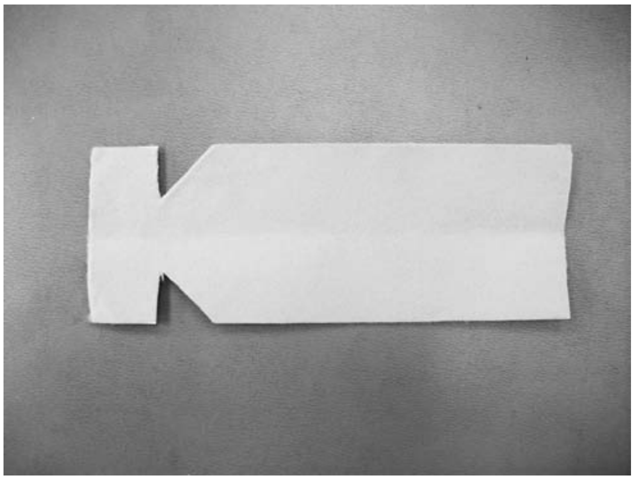
4. To limit painful flexion, reverse the fan strips, applying ventrally while placing the great toe in slight extension.

5. To gain additional support for cases of multidirectional instability and/or pain, apply toe spica consisting of two 1-in. white tape strips crossing over the medial MTP joint of the great toe prior to the final anchors. Secure with anchors as described above.

5.

**Custom/Prefabricated Items.* Great toe extension may also be limited by prefabricated steel inserts or a precut plantar fascia strip.

*



Arch Taping

Arch taping is applied to those individuals who require additional support to their arch in an effort to prevent excessive pronation. With this goal, excessive motion may be limited during gait, and pain in the lower extremity structures irritated by this motion may resolve.

Procedure

Materials. Adhesive spray, 1½-in. white tape, 1-in. white tape.

Positioning and Preparation. The patient is made to lie in the supine position with the knee in extension and the foot in relaxed position. Lightly spray the arch with the adhesive spray, and let it dry.

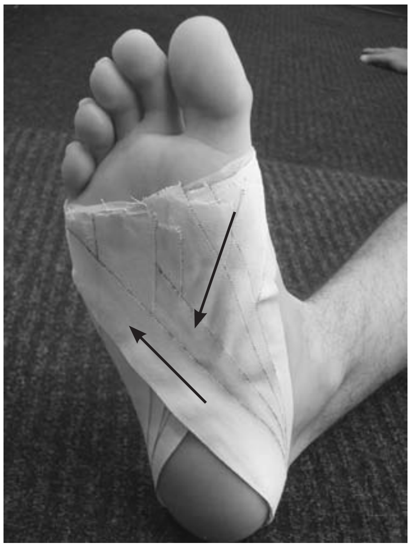
Application

1. Gently apply a half-anchor of the 1½-in. white tape around the metatarsal heads, pulling from the lateral to the medial direction.

2. Apply the 1-in. white tape in an X pattern with three "Xs" running from the first metatarsal head around the heel and returning to the fifth

1.

2.



metatarsal head and three “Xs” running from the fifth metatarsal head around the heel and returning to the first metatarsal head. Overlap each “X” while filling in the arch space. Use a minimum of six “Xs” to fill in the entire arch space.

3. Apply the 1½-in. white tape half-anchors, pulling lateral to medial to cover the arch. Anchors should start proximal and continue distally. Be sure to cover all the loose ends.

4. Complete by securing with two full 1½-in. white tape anchors around the metatarsal heads.

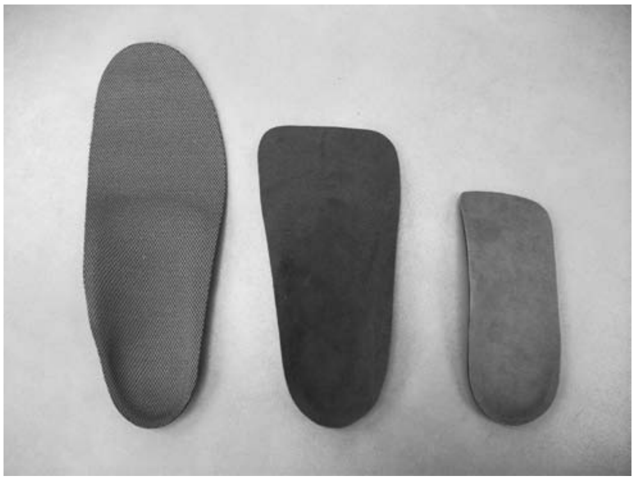
Final Assessment. Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

**Custom/Prefabricated Items*. Supporting the arch can also be achieved by purchasing off-the-shelf orthotics or custom shoe inserts.

3.

4.

*



Closed Basket Weave

The closed basket weave is used after an inversion ankle sprain and is one of the most commonly seen tape procedures in sports medicine. It can be used both as a prevention measure and to limit inversion after injury.

Procedure

Materials. Heel and lace pads, adhesive spray, 1½-in. white tape, prewrap.

Positioning and Preparation. The patient is made to lie in the supine position with the knee in extension and ankle in a dorsiflexed position. Lightly spray the ankle with the adhesive spray, and let it dry.

Application

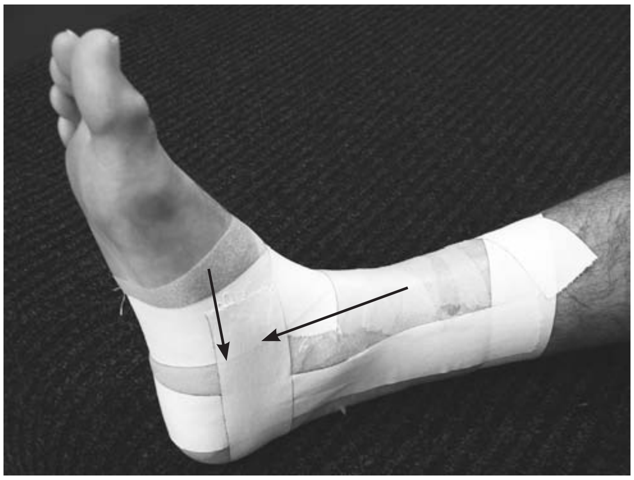
1. Apply at least one heel and lace pad at the front of the ankle and the other at the back where the Achilles tendon inserts into the calcaneus. Secure the pads with the prewrap, and cover the area where the tape will be applied.

2. Apply one anchor of the 1½-in. white tape 6 in. above the malleoli, adhering the prewrap to the skin. The second anchor should be placed around the midfoot while avoiding direct compression of the base of the fifth metatarsal.

3. Apply a stirrup running from the medial to lateral direction, from the medial proximal anchor to the lateral side, extending just above the anchors on both sides; this should cover the posterior one third of the malleoli. Apply the first

1.

2.



3.

horseshoe starting directly on the metatarsal anchor along the first metatarsal, traveling behind the heel, and ending along the fifth metatarsal. Apply horseshoes always from the medial to lateral direction unless your goal is to limit eversion, in which case the pull would be in the opposite direction.

4. Apply each additional stirrup in the same fashion while overlapping by half the width of the tape. The second stirrup should cover the middle one third of the malleoli, with the third stirrup covering the anterior one third. Apply horseshoe strips in the same manner, with each strip slightly shorter than the previous, leaving a staircase appearance. Apply the stirrups and the horseshoes in an alternating fashion.

5. Follow the third horseshoe up the leg until you have completely enclosed the ankle and have ended just past your initial anchor. These strips should continue to be applied by overlapping half the width of the tape. Apply additional arch support until the bottom is enclosed.

6. Start applying the tape on the lateral malleolus, and pull around the arch of the foot to begin a figure-eight pattern.

4.

5.

6.

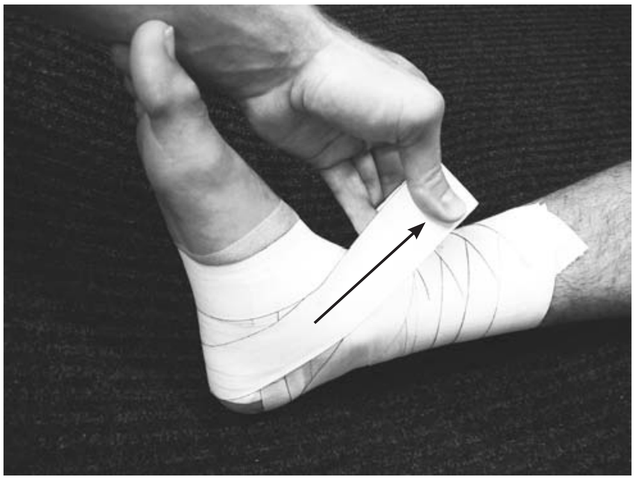
7. Continue the figure-eight pattern by completing a full turn around the ankle so that the roll of tape ends on the medial side, moving downward toward the medial malleolus.

8. From this position, direct the roll of tape to the outside of the heel, and apply a heel lock, ending with the roll of tape moving in a caudal position.

9. Continue by pulling the tape up and around the ankle with a complete turn.

7.

8.



9.

10. Once around the ankle, continue along the lateral ankle, moving toward the medial side of the heel, and apply another heel lock.

11. Once around the ankle, the tape may finish anywhere. Additional figure-eight and heel locks may be added depending on the severity of the injury or the size of the athlete.

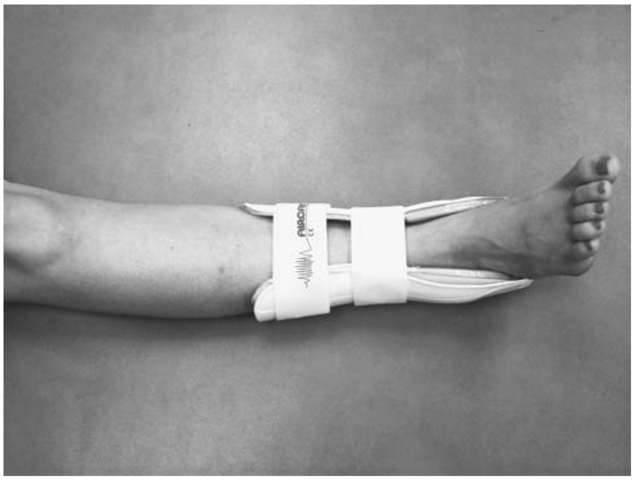
Final Assessment. Check for circulation, and ensure that the application has limited either the painful motion or the inversion and is functional for the athlete.

**Custom/Prefabricated Items.* A number of ankle braces can be purchased with the benefits of self-application and increased cost-effectiveness.

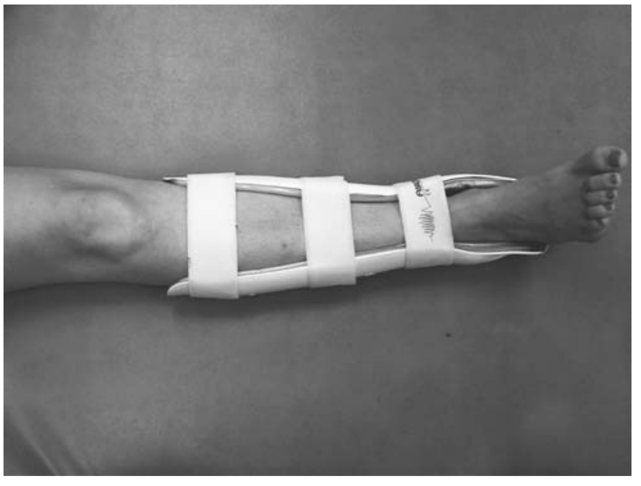
10.

11.

*



*



*

*

Achilles Taping

Achilles taping is applied to those individuals who suffer from pain with plantarflexion and where additional support and help with this motion are required. The goal of this tape job is to assist in the motion of plantarflexion and alleviate pain and discomfort.

1.

2.

Procedure

Materials. Prewrap, adhesive spray, 1½-in. white tape, 3-in. heavy-duty tape.

Positioning and Preparation. The patient is made to lie in the prone position with the knee in extension and the foot in relaxed position, slightly plantarflexed. Lightly spray the foot and ankle with the adhesive spray.

Application

1. Apply the prewrap around the foot, ankle, and lower leg. Apply an anchor of the 1½-in. white tape around the metatarsal heads and the other anchor 6 in. above the malleoli. Starting dorsally on initial anchor, apply the 3-in. heavy-duty stretch tape running to the anchor on the lower leg while the foot maintains a relaxed position. The first strip should run in a straight fashion.

2. Apply two additional 3-in. heavy-duty stretch tape strips with each crossing over the painful site to form an X pattern.

3. Cover the anchors with the 1½-in. white tape, ensuring that there are no loose ends.

Final Assessment. Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

3.

Medial Tibial Stress Syndrome Taping

Medial tibial stress syndrome (MTSS) or shin splint taping is applied to those individuals who suffer from pain in their lower leg during activity. Also known as an *open spiral*, the goal of this taping is to compress the musculature of the anterior lower leg to alleviate pain.

Procedure

Materials. Adhesive spray, 1½-in. white tape.

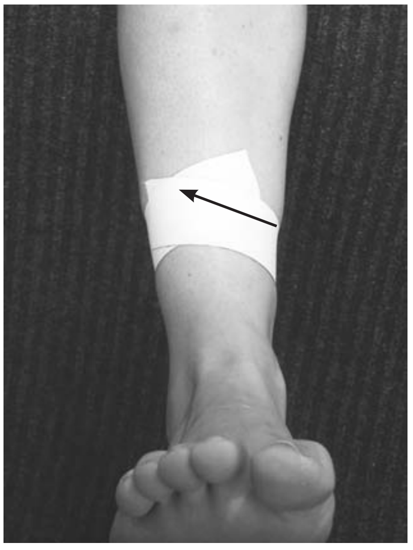
Positioning and Preparation. The patient is made to lie in the supine position with the knee in extension and foot in relaxed position. Lightly spray the lower leg with the adhesive spray, and let it dry.

Application

1. Apply a strip of the 1½-in. white tape starting laterally, or opposite to the painful side and 2 in. below. Wrap the tape around lower leg while squeezing the Achilles tendon, and end the strip just past the starting point. Always pull the tape so that the painful area moves toward the tibia.

2. Continue to apply additional strips in the same fashion. Be sure to overlap

1.



2.

half of the previous strip. Each strip is applied tightly. Continue strips application until you are 2 in. above the painful site. Each individual strip should overlap and enclose the previous strip. Complete by applying a full anchor on both proximal and distal ends.

Final Assessment. Check for circulation, and ensure that the application causes limited pain and is functional for the patient.

**Custom/Prefabricated Items*. A number of commercial compression sleeves are available that re-create the same effect.

*

McConnell Taping

McConnell taping is applied typically to treat patellofemoral stress syndrome (PFSS), which typically occurs with abnormal tracking of the patella. The goal of taping the patella is to restore proper tracking mechanics of the patella and to decrease or relieve painful knee biomechanics.

Procedure

Materials. Adhesive spray, 2-in. coverall, 1½-in. leukotape, scissors.

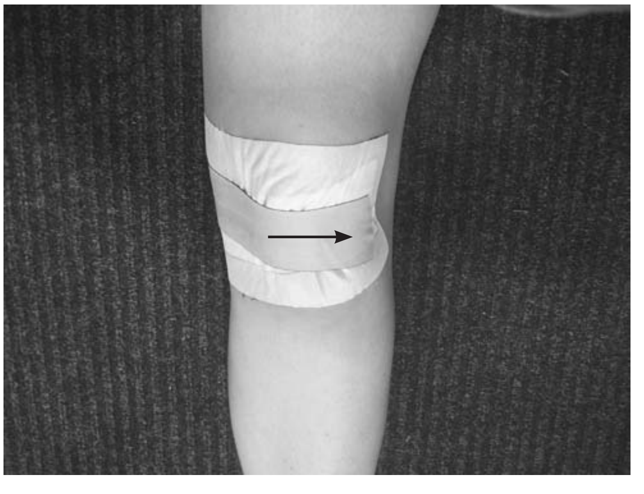
Positioning and Preparation. Check the skin for wounds and irritation. Remove excessive hair with a razor. The patient should be made to lie in the supine position on a table with the knee fully extended; the quadriceps should be fully relaxed to allow patella mobility. Apply adhesive spray to the knee where the tape will be applied, and allow it to dry.

Application

1. Cut strips of coverall long enough to cover the patella and the medial knee. Then apply these strips as a base covering the patella and medial knee.

1.

2.



2. To limit lateral tracking, apply a strip of leukotape laterally on the patella, then pulling medially and placing the other end over the medial knee. Cut off the excess tape.

3. Apply two or three more strips as described above, covering the patella.

Final Assessment. Check the range of motion (ROM) of the knee and the comfort of the tape. Ensure that the application has limited the painful motion and is functional for the patient.

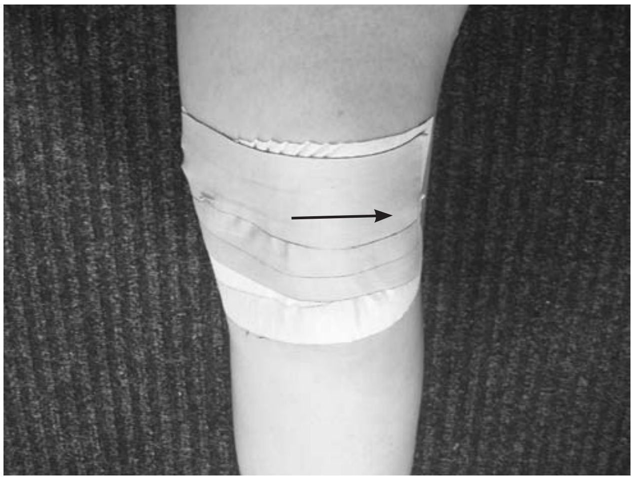
Additional Notes

4. To ensure that the tape will remain on and not fall off prematurely during activity, you may wrap it with nonadhesive stretch tape.

5. To limit tilting in other directions, pull the leukotape in the opposite direction of the motion that you are trying to limit.

**Custom/Prefabricated Items.* Abnormal patella tracking can also be altered by using a commercial brace with a patella buttress.

3.



4.

*

*

*

Knee Hyperextension Taping

Knee hyperextension taping is applied when a knee hyperextension injury has occurred. The goal of this tape job is to limit painful knee extension.

Procedure

Materials. Adhesive spray, prewrap, 2-in. heavy-duty elastic tape, 3-in. adhesive elastic tape, scissors.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should be standing with the affected knee flexed 25° to 35° or within a painfree ROM. The patient should have a good portion of his or her weight over the affected leg and with the quadriceps contracted so that the wrap is not too tight. Apply adhesive spray to the lower leg and thigh where the tape will be applied.

Application

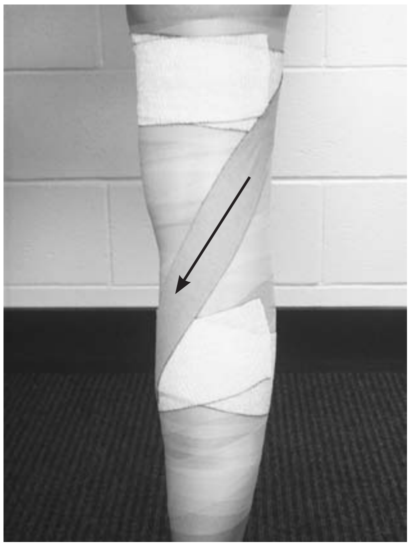
1. Apply the prewrap over the entire area that will be taped, starting at the midthigh and continuing distally to the midgastrocnemius. (*Note:* The longer the level of the tape job, the more effective it will be in preventing painful ROM.) Apply two anchors with the 3-in. adhesive elastic tape over the prewrap, one on the midthigh and the other on the midgastroc.

2. Apply strips of the 2-in. heavy-duty elastic tape in an X pattern behind the knee. The first strip should be applied laterally on the thigh anchor, crossing the posterior knee and ending at the medial anchor on the gastrocnemius. Cut off the excess heavy-duty elastic tape.

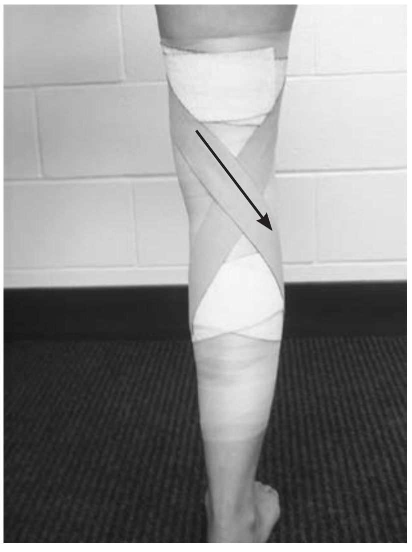
3. The second strip is applied medially on the thigh anchor, crossing the posterior knee and ending on the

1.

2.



3.



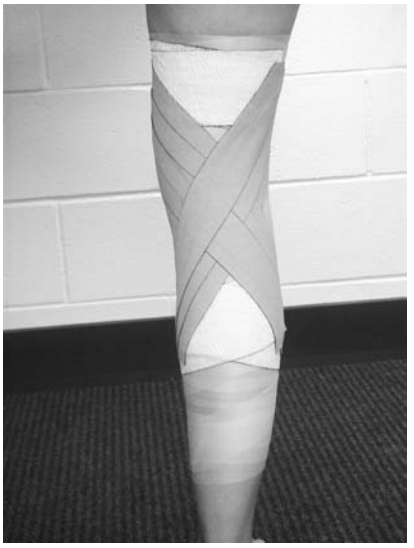
lateral anchor on the gastroc. Cut off the excess heavy-duty elastic tape.

4. Apply two more strips as described above, creating an X pattern behind the knee.

5. Cover the distal anchors up to the tibial tuberosity with the 3-in. adhesive stretch tape. Cover the proximal anchors distally with the 3-in. adhesive stretch tape, ending 3 in. above the superior patella. *Note:* To ensure normal tracking of the patella, do not cover the patella with the tape.

Final Assessment. Check the ROM of the knee and the comfort of the tape. Ensure that the application has limited the painful motion of the knee and is functional for the athlete.

4.

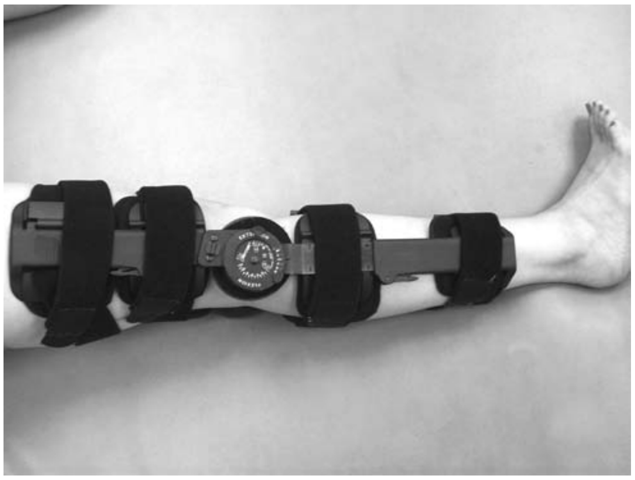


5a.

5b.

**Custom/Prefabricated Items.* Off-the-shelf braces with an ROM lock can limit the painful ROM—such as a knee immobilizer.

*



Medial Collateral Ligament Taping

Collateral ligament taping is applied when either the medial collateral ligament (MCL) or the lateral collateral ligament (LCL) is sprained. The goal of this tape job is to protect the ligament from further injury.

Procedure

Materials. Adhesive spray, prewrap, 1½-in. white tape, 3-in. adhesive elastic tape.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should be standing with the affected knee slightly flexed and within a painfree ROM. The patient should have a good portion of his or her weight over the affected leg and with the quads contracted so that the wrap is not too tight. Apply adhesive spray to the knee and thigh where the tape will be applied.

Application

1. Apply the prewrap over the entire area that will be taped; starting at the upper thigh and continuing down to the midgastrocnemius. Apply two anchors with the 3-in. adhesive elastic tape on the upper thigh and midgastroc.
2. Apply strips of the 1½-in. white tape in an X pattern over the MCL.

1.

2.

The first strip will be applied on the anterior thigh anchor, crossing the medial joint line and ending at the posterior anchor on the gastrocnemius.

3. The second strip will be applied on the posterior thigh anchor, crossing the medial joint line and ending on the anterior anchor on the gastroc.

3.

4. Apply two or three more strips as described above, creating an X pattern over the medial joint line.

4.

5. Cover the distal anchors up to the tibial tuberosity with the 3-in. adhesive stretch tape. Cover the proximal anchors distally with the 3-in. adhesive stretch tape ending 3 in. above the superior patella. *Note:* Do not cover the patella with the tape, to ensure normal tracking of the patella.

5.

Final Assessment. Check the ROM of the knee and the comfort of the tape. Ensure that the application is functional for the patient and gives support to the MCL.

Additional Notes

To tape for an LCL sprain, follow the previous steps, with the X pattern applied over the LCL.

Custom/Prefabricated Items. Off-the-shelf braces with a medial stabilizer can be applied.

*

Patellar Tendinitis Strap

A patellar tendinitis strap is applied for a patient suffering from patella tendinitis (jumper's knee) or Osgood-Schlatter disease. The goal of this tape job is to decrease pain by applying pressure to the tendon and decreasing the stress of the tendon on the tibial tuberosity, where it inserts.

Procedure

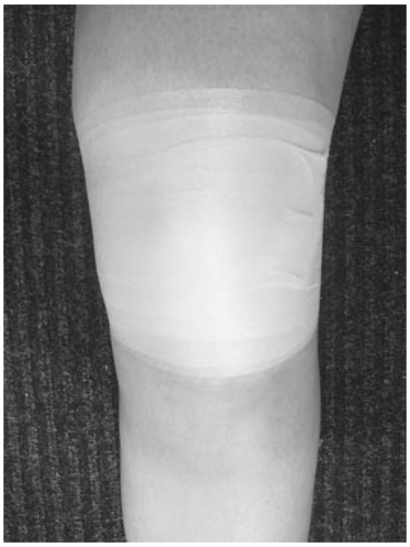
Materials. Prewrap, 1½-in. white tape.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should be standing with the affected knee slightly flexed and within a painfree ROM.

Application

1. Apply the prewrap, encircling the knee over the patella six to eight times with equal tension.
2. Apply three strips of the 1½-in. white tape anteriorly in the center of the prewrap.

1.



2.

3. Roll the prewrap and tape from the proximal to distal direction to create a strap. Place the strap over the patellar tendon.

Final Assessment. Check the ROM of the knee and the comfort of the tape. Ensure that the application has adequate pressure on the patellar tendon and is functional for the patient.

**Custom/Prefabricated Items*. Jumper's knee straps can be purchased over the counter to re-create this tape job.

3a.

3b.

*

Thigh Compression Wrap

A thigh compression wrap may be applied after an injury such as a contusion or muscle strain to either the hamstring or the quadriceps muscle group. The goal of this wrap is to compress the muscle group and the origin of pain while providing support.

Procedure

Materials. Adhesive spray, 6-in. single elastic bandage, 1½-in. white tape. *Note:* Depending on the size of the patient, you may have to use a larger elastic wrap, 6 in. × 5 yards (yd), 6 in. × 11 yd, or 4 in. × 11 yd (1 in. = 2.54 cm; 1 yd = 0.91 meters [m]).

Positioning and Preparation. The patient should be standing with the involved knee flexed between 20° and 30° while keeping the majority of the patient's weight on the involved side. Apply spray on the area to be wrapped, and allow it to dry.

Application

1. Begin distal to the site of pain, and apply the compression wrap around the area to be treated in a herringbone fashion with the "Xs" central over the site of pain.
2. Continue proximally overlapping the compression wrap by half the width of the wrap.
3. Secure the wrap with the 1½-in. white tape by placing an "X" over the painful area, and anchor at the top and bottom.

Final Assessment. Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

1.

2.

3.

**Custom/Prefabricated Items.* Commercial compression sleeves, both with and without additional padding, are available.

*

Hip Spica for Adductor Strain

A hip spica may be used for a number of conditions, including support of the adductor and hip flexor groups in addition to securing padding after an injury to the hip bone, or "hip pointer." The goal of this supportive wrap is to compress the muscle group and origin of pain while providing support and aiding in the natural motion of the muscle group.

1.

Procedure

Materials. Adhesive spray, 4-in. double-elastic bandage, 1½-in. white tape. *Note:* Depending on the size of the patient, you may have to use a larger elastic wrap, such as 6 in. × 11 yd.

Positioning and Preparation. The patient should be standing with the involved leg placed in an internally rotated position. Ask the athlete to assume a slightly forward-lunge position that flexes the knee and causes the hip to adduct. Gently spray the thigh area that will be wrapped, which acts as the anchor for this tape procedure. *Note:* For maximum support, have the athlete wear spandex or tight shorts so that the wrap can be as close to the body part as possible.

Application

1. Secure the wrap to the leg by anchoring the wrap around the thigh while pulling laterally to medially.

2. Continue wrapping up and around the trunk, crossing deep in the groin over the adductor muscle group.

3. Finish the wrap on the thigh, and secure with the 1½-in. white tape by tracing the pattern once around the thigh and trunk. Add more tape strips as needed.

4. To secure the wrap further, you can trace the pattern of the wrap with the 3-in. adhesive elastic tape.

Additional Notes

To provide supportive taping for the hip flexor, begin in a similar fashion to the hip adductor wrap but with the patient in a slightly forward-lunge position with a slight forward bend at the trunk. Pull the wrap from medial to lateral, and place an "X" over the site of pain or the hip flexor group.

Custom/Prefabricated Items. Commercial compression garments can be purchased that offer focal and general compression.

2.

3.

4.

Rib Compression Wrap

A rib compression wrap is used to relieve the pain of a rib fracture or intercostal strain, secure a protective pad over an injured site, or control swelling. The goal of the wrap is to provide support to the injured area and decrease pain.

Procedure

Materials. Adhesive spray, 4-in. × 5-yd elastic wrap, 1½-in. white tape. *Note:* Depending on the size of the patient, you may have to use a larger elastic wrap, 6 in. × 5 yd, 6 in. × 11 yd, or 4 in. × 11 yd.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should be standing with the arms abducted. Apply adhesive spray to the torso where the elastic bandage will be applied.

Application

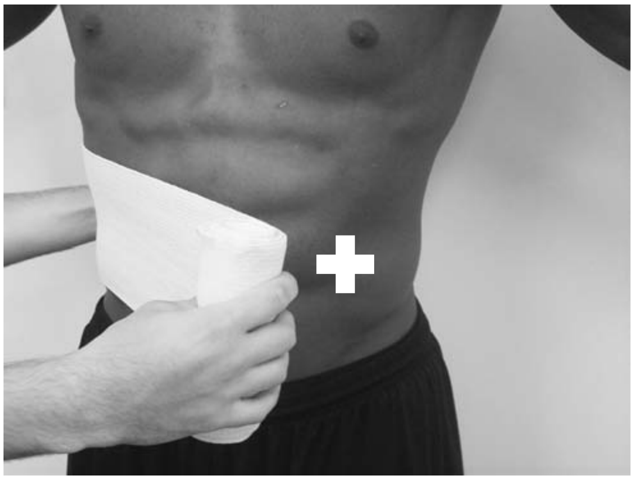
The procedure described below is for a rib fracture. The injured area is marked "+."

1. Start the wrap superiorly to the injured site, encircling the torso and overlapping about 2 in. each time around.

2. Work your way caudally, covering the injured site and ending over the wrap superiorly to the injured area.

3. Apply two to three strips of the 1½-in. white tape at the end of the wrap to secure it.

1.



2.

3.

4. To secure the wrap, you may encircle the wrap and tape with the 3-in. adhesive elastic tape.

Final Assessment. Check the ROM of the torso and the comfort of the athlete during respiration. Ensure that the application provides support to the injured site and is functional for the athlete.

**Custom/Prefabricated Items.* Rib belts can be purchased off the shelf to obtain similar results.

4.

*

Shoulder Spica for Acromioclavicular Taping

The acromioclavicular (AC) wrap may be applied after an injury to the AC joint from direct contact, such as tackling in football or forced horizontal adduction. The goal of this wrap is to provide protection and general compression to the AC joint and shoulder in general.

1.

Procedure

Materials. Adhesive spray, compression wrap (various widths and lengths), 1½-in. white tape.

Positioning and Preparation. The patient should be placed in a standing or seated position with the involved arm at the side and the hand on the hip.

Spray the humerus with the adhesive spray, as this will act as the anchor for this tape procedure.

2.

Application

1. Begin wrapping the midhumerus in a clockwise fashion (lateral to medial), and continue in a spiral fashion while overlapping by half the width of the wrap, moving distal to proximal for at least two times around the humerus.

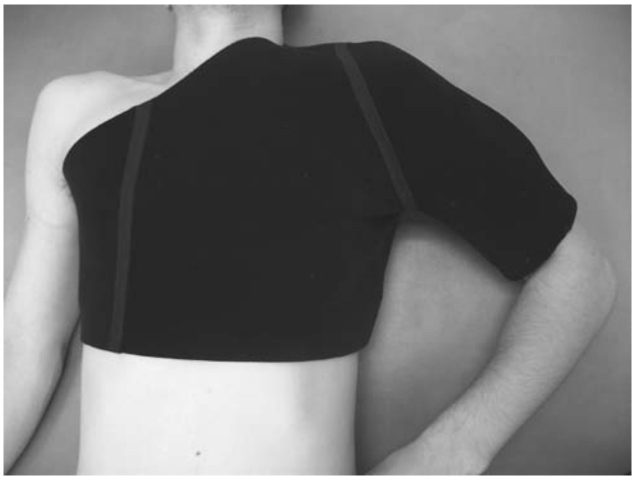
2. Pull medially across the chest and under the opposite axilla, and continue around the torso. Apply the greatest amount of tension over the shoulder and the least amount of tension as you wrap around the torso. Encircle the humerus again.

3.

3. Repeat the pattern at least twice or as needed depending on the size of the patient and the support needed. End the wrap on the arm. Secure the wrap with the 1½-in. tape by tracing the pattern on the humerus.

Final Assessment. Check for circulation, and ensure that the application has limited the painful motion and is functional for the athlete.

*



Additional Notes

In association with many AC joint injuries, an "AC pad" is often applied directly over the AC joint to provide padding to the injured joint below. Apply the AC pad if needed prior to securing the AC wrap.

**Custom/Prefabricated Items*. Other commercial items that are commonly used to support the shoulder either after injury or during actual play include the Sully Stabilizing Brace.

Elbow Hyperextension Tape

Elbow hyperextension taping is very similar to the knee hyperextension taping technique. This is applied when an elbow hyperextension injury has occurred, with the goal of limiting painful extension.

Procedure

Materials. Adhesive spray, prewrap, 2-in. heavy-duty adhesive elastic tape, 3-in. adhesive elastic tape, scissors.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should have the affected elbow in slight flexion within a painfree range and supinated. Apply adhesive spray to the forearm and humerus where the tape will be applied.

Application

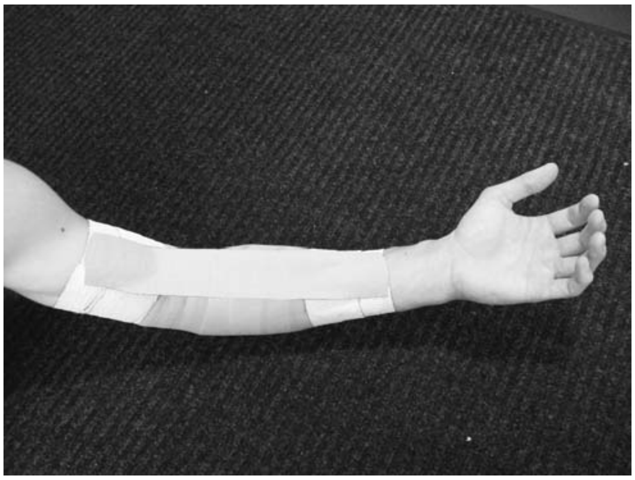
1. Apply the prewrap over the entire area that will be taped; starting at the midhumerus and continuing distally to the midforearm. (*Note:* The longer the level of the tape job, the more effective it will be in preventing painful ROM.) Apply two anchors with the 3-in. adhesive elastic tape, one on the midhumerus and the other at the midforearm.

2. Apply a strip of the 2-in. heavy-duty adhesive elastic tape over the anterior elbow. The first strip will begin on the anterior anchor of the humerus and follow the midline of the humerus distally to the forearm, where it ends at the second anchor at the midforearm. Cut off the excess heavy-duty elastic tape.

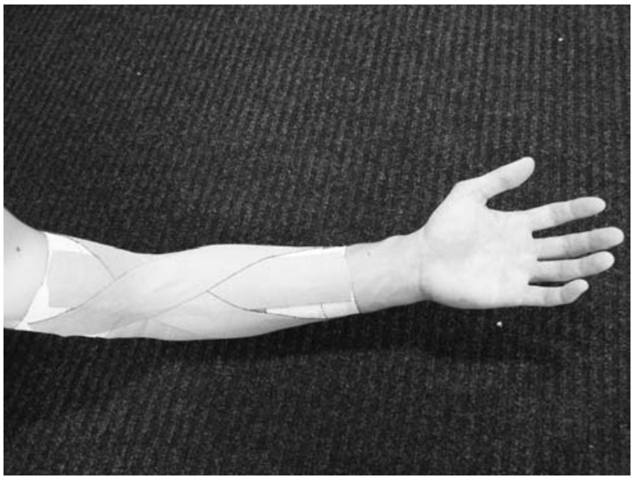
3. The next two strips will create an X pattern over the anterior elbow. The second strip will be applied laterally on the distal humeral anchor, crossing the anterior elbow and ending at the medial anchor on the forearm (ulna). The third strip will be applied medially on the

1.

2.



3.



distal humeral anchor, crossing the anterior elbow and ending at the lateral anchor on the forearm (radius). Cut off the excess heavy-duty elastic tape.

4. Cover the tape job with the 3-in. adhesive elastic tape. *Note:* Do not cover the olecranon process with the tape, to ensure ease of movement.

Final Assessment. Check the ROM of the elbow to make sure that it is within the painfree ROM and functional for the patient. Check the distal capillary refill and the comfort of the tape for the patient.

**Custom/Prefabricated Items.* Off-the-shelf braces with an ROM lock can limit the painful motion of the elbow.

4.

*

Ulnar Collateral Ligament Taping

This taping procedure is similar to the collateral ligament taping of the knee. Collateral ligament taping is applied when either the ulnar collateral ligament (UCL) or the radial collateral ligament (RCL) is sprained. The goal of this tape job is to protect the ligament from further injury.

Procedure

Materials. Adhesive spray, prewrap, 1½-in. white tape, 3-in. adhesive elastic tape.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should be standing with the

1.

affected elbow slightly flexed within a painfree ROM and supinated. Apply adhesive spray to the forearm and humerus where the tape will be applied.

Application

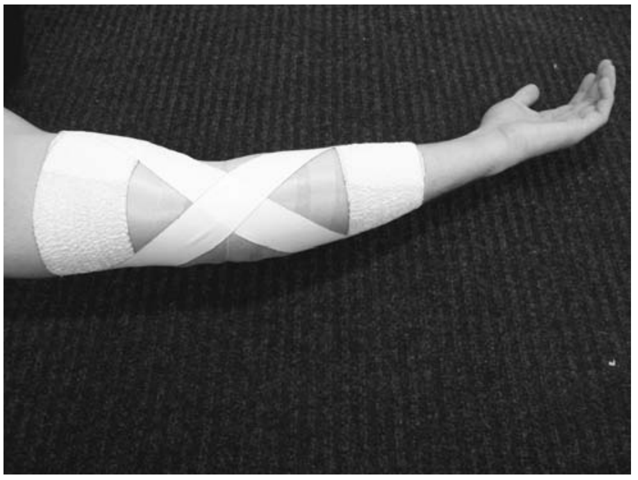
1. Apply the prewrap over the entire area that will be taped, starting at the midhumerus and continuing distally to the midforearm. Apply two anchors with the 3-in. adhesive elastic tape over the prewrap, one on the midhumerus and the other on the midforearm.

2. Apply strips of the 1½-in. white tape in an X pattern over the UCL. The first strip will be applied on the anterior humeral anchor, crossing the medial joint line and ending at the posterior anchor on the forearm.

3. The second strip will be applied on the posterior humeral anchor, crossing the medial joint line and ending on the anterior anchor on the forearm.

2.

3.



4. Apply two or three more strips as described above, creating an X pattern over the UCL.

4.

5. Cover the tape job with the 3-in. adhesive elastic tape. *Note:* Do not cover the olecranon process with the tape, to ensure ease of movement.

5.

Final Assessment. Check the distal capillary refill and the comfort and function of the tape for the patient.

Additional Notes

To tape for an RCL sprain, follow the previous steps but with the X pattern applied over the RCL.

**Custom/Prefabricated Items*. There are various off-the-shelf braces that can be purchased that will re-create the function of the tape procedure for the UCL.

*

Lateral Epicondylitis Strap

A lateral epicondylitis strap is used for a patient suffering from lateral epicondylitis (tennis elbow). The goal of this tape job is to decrease pain by applying pressure to the common extensor bundle to decrease the stress of the extensor muscles on the bony attachment.

Procedure

Materials. Prewrap, 2-in. adhesive elastic tape, 1½-in. white tape.

Positioning and Preparation. Check the skin for wounds and irritation. The patient's arm should be in a relaxed supinated position.

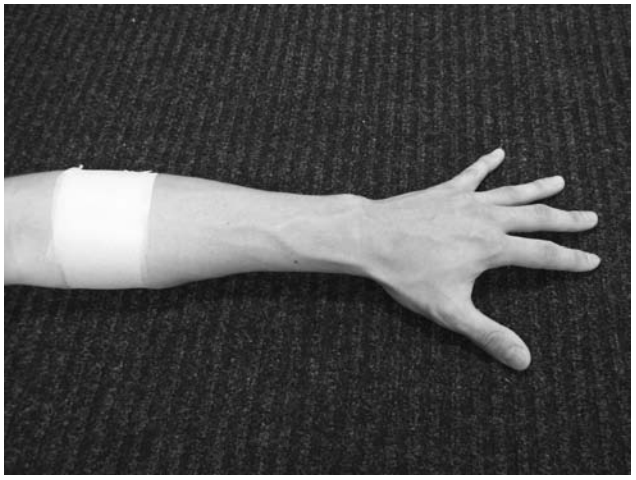
Application

1. Apply the prewrap around the elbow two to three times distal to the lateral epicondyle, approximately ½ in.

2. Apply six strips of the 1½-in. white tape in the center of the prewrap distal to the lateral epicondyle.

3. Cover the prewrap and the 1½-in. white tape strips with the 2-in. adhesive elastic tape.

1.



2.

3.

Final Assessment. Check the distal capillary refill and the comfort and function of the tape for the patient.

**Custom/Prefabricated Items*. Prefabricated lateral epicondylitis straps can be purchased over the counter.

*

Wrist Hyperflexion Taping

Taping to the wrist is applied after an injury to any of the carpal bones or the wrist in general or to limit painful motion. The goal of this tape job is to provide stability and limit painful motions about the wrist to allow it to be used in athletic participation.

Procedure

Materials. Adhesive spray, 1½-in. white tape, prewrap.

Positioning and Preparation. Place the patient's wrist in a neutral position with the fingers abducted. Spray the area to be wrapped, and apply the prewrap as needed.

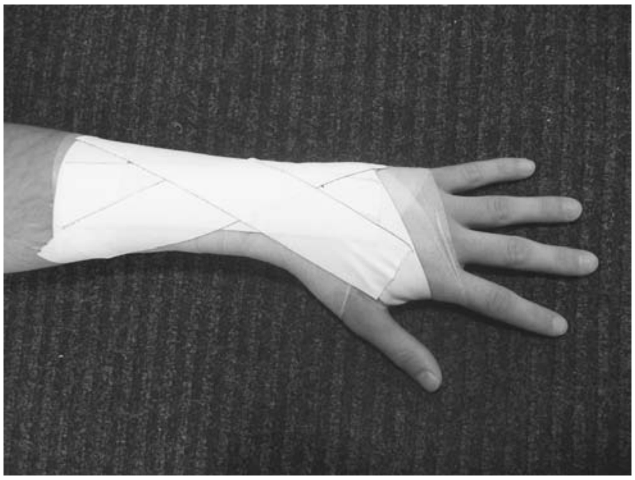
Application

1. Begin by applying two anchors on the midforearm and one around the hand just proximal to the metacarpophalangeal (MCP) joints. Be sure to keep the MP joints uncovered while slightly folding the tape before it crosses the thumb crease.

1.

2. Apply parallel strips starting at the anchor on the hand and running to the anchor on the forearm. Complete

2.



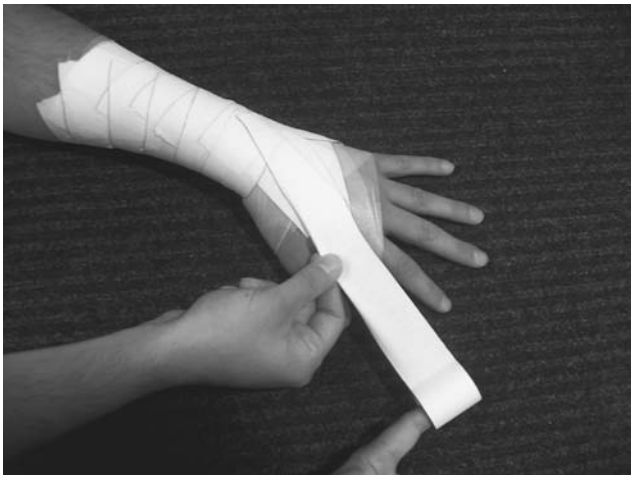
by applying at least two "Xs" in a similar fashion, crossing over the carpals. Apply parallel strips and "Xs" to the opposite side. If needed, add additional strips to the side in which you intend to limit the most motion (the dorsal side to prevent flexion and ventral side to prevent extension).

3. Close the entire forearm with the anchors.

4. Apply two figure-eight patterns starting on the dorsal side at the ulnar styloid process. Pull the tape between the thumb and the index finger, making sure that you place a small fold in the tape as it crosses through.

3.

4a.



4b.

5. Continue to pull the tape across the palm to the dorsal side of the hand.

6. Continue to pull around the wrist, and end on dorsal side of the wrist. Repeat as necessary.

Final Assessment. Check for circulation and ensure that the application has limited the painful motion and is functional for the athlete.

**Custom/Prefabricated Items.* Various prefabricated splints are available, such as the wrist splint. The velcro allows effortless application by the patient.

5.

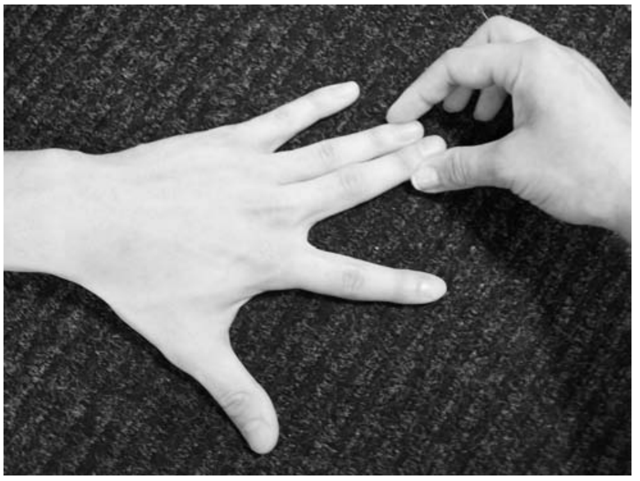
6.

*

Buddy Taping

Buddy taping is the easiest and most common taping procedure for a patient to apply. It is typically used when an interphalangeal (IP) joint has been sprained. The goal of this tape job is to use one digit as a support for the injured digit to protect the sprained IP joint from further injury.

1.



2.

3.

Procedure

Materials. Adhesive spray, 1-in. white tape.

Positioning and Preparation. Check the skin for wounds and irritation. The patient's hand should be relaxed and placed in a painfree position. Apply adhesive spray to the digits where the tape will be applied.

Application

The following taping procedure is for a sprained proximal IP of the fourth digit. For any other digits, simply repeat the steps as indicated.

Additional Notes

This is typically a procedure for a sprain in the second to fifth digits; this procedure is not used for the first digit. For a sprained first digit, see the section Thumb Spica.

1. Place the third digit next to the fourth digit in a comfortable, painfree ROM.

2. Apply a strip of the 1-in. white tape to encircle the proximal phalanges of the third and the fourth digits.

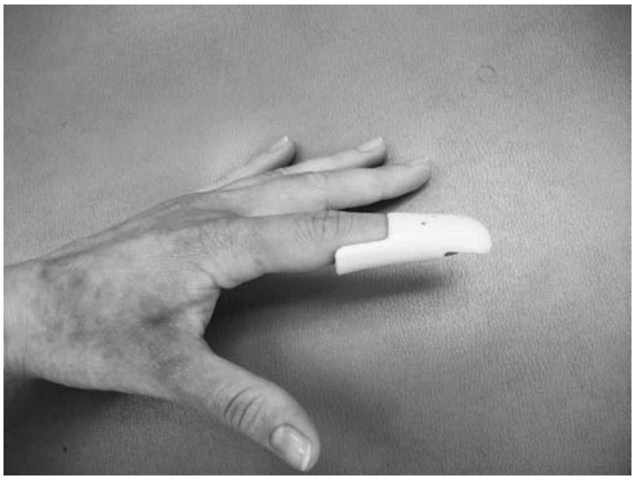
3. Apply a second strip of the 1-in. white tape to encircle the middle

phalanges of the third and the fourth digits.

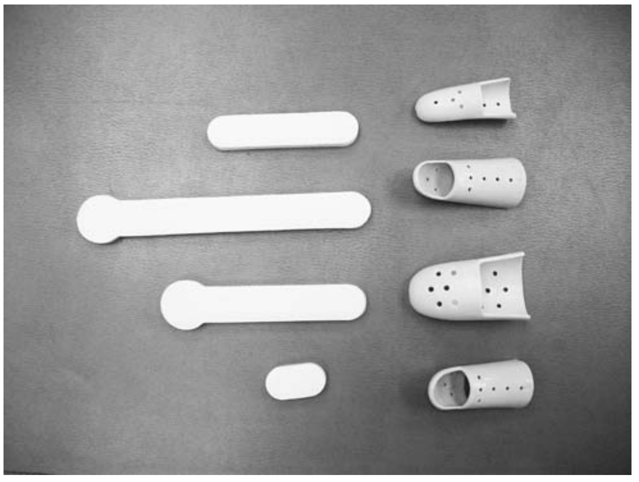
Final Assessment. Check the distal capillary refill of the third and fourth digits. Ensure that the tape is giving support to the fourth digit and is functional for the patient.

**Custom/Prefabricated Items*. Various prefabricated splints are available, such as the aluminum finger splints and the Stax plastic finger splints.

*



*



*

Thumb Spica

The thumb spica is used when the MCP joint of the first digit has been sprained. The goal is to limit multidirectional instability and prevent painful motion.

Procedure

Materials. Adhesive spray, prewrap, 1-in. white tape, 1½-in. white tape.

Positioning and Preparation. Check the skin for wounds and irritation. The patient should be relaxed, with his or her thumb slightly abducted and extended into a painfree position. Apply the adhesive spray to the first digit and the distal wrist where the tape will be applied.

Application

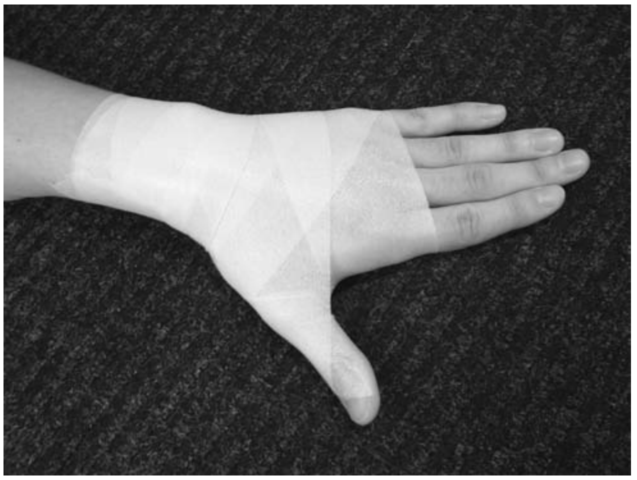
The following procedure is for a hyperflexion injury to the MCP of the first digit. To prevent hyperextension of the joint, follow the steps below, but place the X pattern on the volar aspect of the thumb.

1. Cover the thumb, the proximal hand, and the distal wrist with the prewrap.

2. Place two anchors with the 1½-in. white tape encircling the wrist.

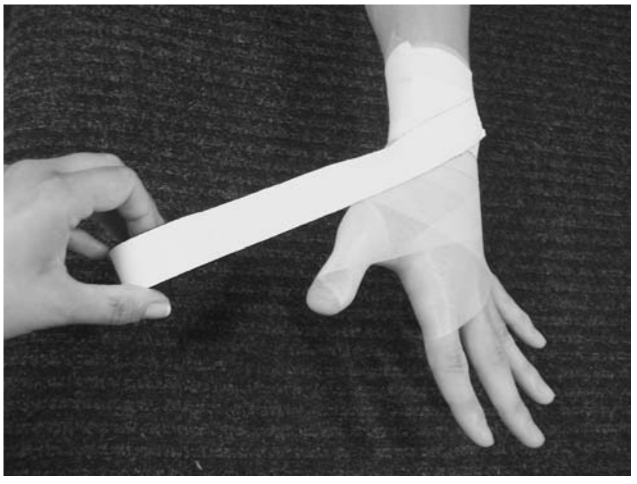
3. Begin a strip of tape on the dorsal aspect of the anchors on the distal wrist. Continue this strip distally, crossing the lateral joint line of the MCP joint of the first digit.

1.



2.

3.



4. Continue the tape around the joint, crossing over the posterior aspect of the MCP joint of the first digit and ending on the volar aspect of the anchor on the wrist. You should have created an X pattern on the dorsal aspect of the MCP joint of the first digit.

5. Apply one or two more strips as indicated above, moving more distally on the first digit. *Note:* Do not cross the IP joint of the first digit.

6. Cover the anchors on the wrist with the 1½-in. white tape.

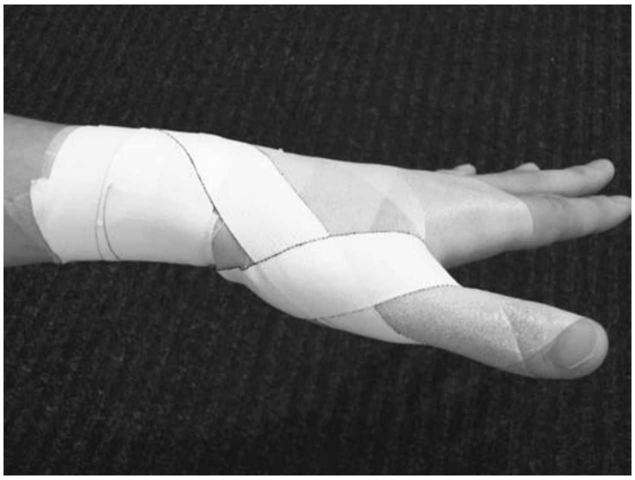
Final Assessment. Check the distal capillary refill of the first digit. Ensure that the tape prevents painful hyperflexion and is functional for the patient.

Additional Notes

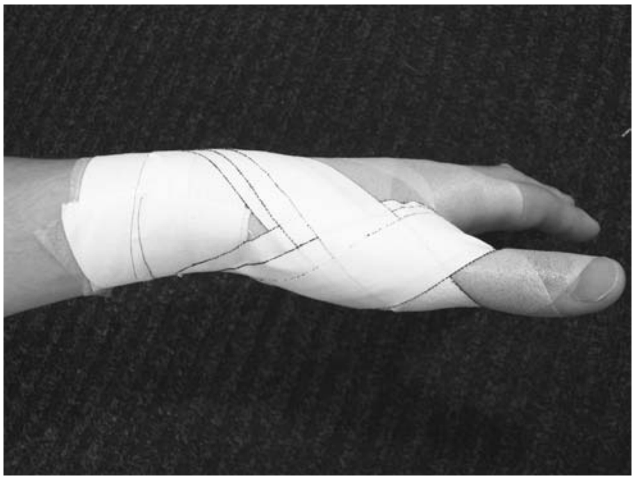
Use caution when removing the tape from the first digit, so as to prevent damage to the distal phalanx; removing the tape with scissors is recommended.

4a.

4b.



5.



**Custom/Prefabricated Items.* Prefabricated thumb braces can be purchased to obtain similar results.

6.

*

Conclusion

Just as all medical procedures have evolved, so too has the advancement of both taping and bracing applications. Although taping after the initial injury is rare, taping and bracing for support and protection during athletic participation and activities of daily living is a well-established practice that continues to undergo refinement based on sound knowledge and the practical experience of trained practitioners.

Appendix B

Organizations

Health, Fitness, and Safety

American Alliance for Health, Physical Education, Recreation and Dance (AAHPERD)

Website: http://www.aahperd.org
Publications: *Research Quarterly, Health Education*; *Journal of Physical Education, Recreation and Dance*

An alliance of associations providing support to professionals involved in physical education, recreation, fitness, sports and coaching, dance, and health education and promotion.

American Association for Physical Activity and Recreation (AAPAR)

Website: http://www.aahperd.org/aapar

An association linking professionals in education with community-based programs, promoting creative and active lifestyles through physical activity and recreation across the life span.

American Council on Exercise (ACE)

Website: http://www.acefitness.org

A nonprofit organization that protects against ineffective fitness products, while also providing ongoing public education, outreach, and research, and sets certification and continuing education standards for fitness professionals.

American School Health Association (ASHA)

Website: http://www.ashaweb.org

An association that organizes and advocates for effective school health policies that contribute to optimal health and academic outcomes for all school-age children.

American Sport Education Program (ASEP)

Website: http://www.asep.com

An organization providing an educational program for coaches based on sports sciences such as sport physiology, sport psychology, and sport biomechanics.

American Swimming Coaches Association

Website: http://www.swimmingcoach.org
Publication: *Journal of Swimming Research*

A swimming association dedicated to enhancing coaching and building a stronger swimming community.

Canadian Fitness Professionals (CAN-FIT-PRO)

Website: http://www.canfitpro.com

An organization providing education and certification for fitness professionals throughout Canada.

Cooper Institute for Aerobics Research

Website: http://www.cooperaerobics.com

A nonprofit, founded in 1970, that has established an international reputation for research and education in preventive medicine.

Exercise Safety Association (ESA)

Website: http://www.exercisesafety.com

A national organization for fitness professionals providing certification and membership as well as fitness instructor training.

International Fitness Professionals Association (IFPA)

Website: http://www.ifpa-fitness.com

An association affiliated with Doctors Fitness Centers (DFC) and the Fitness Institute of Technology (FIT), providing fitness professionals the education and certification necessary to treat more than 65 different diseases, disabilities, and dysfunctions.

Joint Commission on Sports Medicine and Medical Science

Website: http://www.jcsportsmedicine.org

A voluntary forum that meets annually to discuss current issues in the profession as well as those that concern the future of sports medicine.

National Alliance for Youth Sports (NAYS)

Website: http://www.nays.org

An organization whose aim is to make the sports experience safe, fun, and healthy for youth by ensuring that the adults involved have proper training and information.

National Association for Health & Fitness (NAHF)

Website: http://www.physicalfitness.org

A nonprofit organization that promotes physical fitness, sports, and healthy lifestyles by fostering and supporting governors' and state councils and coalitions that promote and encourage regular physical activity.

National Association of Speed and Explosion (NASE)

Website: http://www.naseinc.com
Publication: *Sportspeed*

An educational organization and certification agency that includes coaches, strength and conditioning coaches, personal trainers, educators, and physicians focusing on the improvement of speed in short sprints to enhance athletic performance.

National Athletic Trainers' Association, Inc. (NATA)

Website: http://www.nata.org
Publication: *Athletic Training Journal*

A professional membership association for certified athletic trainers geared toward enhancing and advancing the athletic training profession.

National Council of Youth Sports (NCYS)

Website: http://www.ncys.org

An organization that represents more than 185 organizations (44,000,000 youth in organized sports) in the youth sports industry and promotes physical activity in youth via organized sports.

National High School Coaches Association (NHSCA)

Website: http://www.nhsca.com
Publication: *Coaches Quarterly Magazine*

A national nonprofit association that centers on the influence and professionalism of coaches and provides insurance coverage and educational programs for its participants.

National Institute for Fitness and Sport (NIFS)

Website: http://www.nifs.org

An Indiana-based nonprofit organization that conducts research for enhancing health and athletic performance and provides physical fitness programs and health and fitness education for individuals and corporations.

National Operating Committee on Standards for Athletic Equipment (NOCSAE)

Website: http://www.nocsae.org
Publication: *NOCSAE Manual*

A committee that develops performance standards for the protective equipment used in a variety of sports and commissions scientific research on the mechanisms of athletic injuries.

National Strength and Conditioning Association (NSCA)

Website: http://www.nsca-lift.org
Publications: *National Strength and Conditioning Association Journal, Journal of Applied Sport Science Research*

An association that promotes and disseminates research on strength and conditioning to improve athletic performance and fitness.

National Youth Sports Safety Foundation (NYSSF)

Website: http://www.nyssf.org

A national nonprofit organization working to minimize the number and severity of sports-sustained youth injuries.

President's Council on Physical Fitness and Sports (PCPFS)

Website: http://www.fitness.gov
Publication: *PCPFS Newsletter*

A volunteer committee working with the U.S. Department of Health and Human Services to engage, educate, and empower Americans of all ages to adopt a healthy lifestyle that includes regular physical activity and good nutrition.

Sport in Society, National University Consortium for Sport in Society

Website: http://www.sportinsociety.org
Publication: *Journal of Sport and Social Issues*

An organization based at Northeastern University that promotes the use of sports to help prevent interpersonal violence, improve the health of impoverished youth, and foster social diversity.

U.S. Consumer Product Safety Commission (USCPSC)

Website: http://www.cpsc.gov

The U.S. federal agency charged with protecting consumers and families from products that may pose a hazard or threat.

Sports

Amateur Athletic Union of the United States (AAU)

Website: http://www.aausports.org
Publication: *InfoAAU*

A national nonprofit, volunteer, multisport organization dedicated to the promotion and development of amateur sports and physical fitness programs.

American Junior Golf Association (AJGA)

Website: http://www.ajga.org
Publication: *AJGA Tour Talk Newsletter*

A nonprofit organization dedicated to the growth and development of competitive junior golfers striving to earn college golf scholarships.

Canada Games Council

Website:
http://www.canadagames.ca

The governing body for the Canada Games: a private, nonprofit organization that promotes ongoing partnerships with organizations at the municipal, provincial, and national levels and provides support in organizational planning, ceremonies, marketing, and sponsorship.

Canadian Association for the Advancement of Women and Sport and Physical Activity (CAAWS)

Website: http://www.caaws.ca/e

An association supporting and promoting women in sport while providing leadership and education.

Canadian Blind Sports Association (CBSA)

Website: http://www.canadianblindsports.ca

The national governing body for goalball, advocating for the blind and visually impaired within the sports system.

Canadian Centre for Ethics in Sports (CCES)

Website: http://www.cces.ca

A nonprofit organization devoted to promoting ethical conduct in sport and responsible for the implementation and management of Canada's Anti-Doping Program.

Canadian Colleges Athletic Association (CCAA)

Website: http://www.ccaa.ca

The national governing body for college sports in Canada.

Canadian Deaf Sports Association (ASSC-CDSA)

Website: http://www.assc-cdsa.com

An organization that supports deaf athletes who meet the requirements for participating in international competitions, especially the Pan American Games for the Deaf, the Deaflympics, and the World Deaf Championships.

Canadian Interuniversity Sport (CIS)

Website: http://www.cis-sic.ca

The national governing body of university sports in Canada, comprising 52 member universities.

Canadian Wheelchair Sports Association (CWSA)

Website: http://www.cwsa.ca/en/site

A national sports organization, founded in 1967, representing wheelchair athletes.

Coaches of Canada

Website: http://www.coachesofcanada.com

The national organization that represents, promotes, and regulates the profession of athletic coaching in Canada.

International Amateur Swimming Federation (IASF)

Website: http://www.fina.org

The world governing body for swimming, diving, water polo, synchronized swimming, and open-water swimming, promoting the development of swimming worldwide.

National Association for Girls and Women in Sports

Website: http://www.aahperd.org
Publication: *The Women in Sport and Physical Activity Journal*

An association within the American Alliance for Health, Physical Education, Recreation and Dance that advocates for girls and women in sports.

National Association for Sport and Physical Education (NASPE)

Website: http://www.aahperd.org/naspe
Publication: *Journal of Physical Education and Recreation*

An association within the American Alliance for Health, Physical Education, Recreation and Dance dedicated to enhancing knowledge and increasing support for quality physical education programs.

National Collegiate Athletic Association (NCAA)

Website: http://www.ncaa.org

The national governing body for intercollegiate athletics in the United States.

National Dance Association (NDA)

Website: http://www.aahperd.org/nda
Publication: *Journal of Physical Education, Recreation, & Dance*

An association that strives to promote quality dance by providing leadership, disseminating research, and collaborating with external partnerships.

National Federation of Interscholastic Coaches Association (NFICA)

An association that aims to improve the athletic participation experience while establishing consistent standards and rules for competition.

National Intramural-Recreational Sports Association (NIRSA)

Website: http://www.nirsa.org
Publications: *NIRSA Journal*, *NIRSA Newsletter*

A research and educational resource for collegiate recreational sports that promotes superior recreational programs, facilities, and services for diverse populations.

Special Olympics

Website: http://www.specialolympics.org

An international organization that holds a competition every 2 years as well as yearlong training for people who have intellectual disabilities.

Special Olympics Canada

Website: http://www.specialolympics.ca

A national nonprofit organization that provides sports training and competition opportunities for athletes with intellectual disabilities.

United States Olympic Committee

Website: http://www.teamusa.org

A committee responsible for training, entering, and underwriting the full expenses for the U.S. teams in the Olympic, Paralympic, Pan-American, and Parapan-American Games, as well as overseeing the process by which U.S. cities seek to be selected as a host to these games.

United States Soccer

Website: http://www.ussoccer.com

The governing body for soccer in the United States, promoting the development of soccer at all recreational and competitive levels.

United States Sports Academy

Website: http://www.ussa.edu

An independent, nonprofit, accredited sports university providing programs in instruction, research, and service to prepare those pursuing careers in the profession of sports.

US Figure Skating (USFS)

Website: http://www.usfsa.org

The national governing body for figure skating and a member of the International Skating Union (ISU) and the U.S. Olympic Committee (USOC), comprising member clubs, collegiate clubs, school-affiliated clubs, and individual members.

USA Athletic Congress (USAAC)

Website: http://www.usaac.org
Publication: *American Athletics Annual*

An association that promotes good sportsmanship by recognizing athletes who have excelled within their respective sports, working in conjunction with international federations and national governing bodies to improve sports participation around the world.

USA Gymnastics

Website: http://www.usa-gymnastics.org

The national organization for gymnastics, encouraging participation and excellence and setting the rules and policies that govern gymnastics in the United States.

USA Swimming

Website: http://www.usaswimming.org

The national governing body for swimming in the United States.

USA Volleyball

Website: http://www.usavolleyball.org

The national governing body for volleyball in the United States.

Women's Sports Foundations (WSF)

Website: http://www.womenssportsfoundations.org
Publications: *Women's Sports and Fitness, Headway*

A foundation that advocates for equal opportunity for women in sports, focusing on the psychological, physical, and social benefits of sports participation.

Sports Medicine

Academy for Sports Dentistry (ASD)

Website: http://www.academyforsportsdentistry.org
Publication: *Sports Dentistry Newsletter*

A forum for medical professionals, coaches, and trainers to exchange ideas pertinent to sports dentistry, as well as for the collection and dissemination of research regarding the prevention and occurrence of dental injuries among athletes.

American Academy of Orthopaedic Surgeons (AAOS)

Website: http://www.aaos.org
Publications: *AAOS Report*, *The Bulletin*

An association of musculoskeletal specialists that provides education and practice management services for orthopedic surgeons and allied health professionals, advocates for enhanced patient care, and disseminates orthopedic knowledge to the public.

American Academy of Pediatrics (AAP) Committee on Sports Medicine & Fitness (COSMF)

Website: http://www.aap.org/sections/sportsmedicine

A division of the American Academy of Pediatrics, providing educational programs, policy statements, collaborative partnerships, media outreach, advocacy work, and research awards to promote safe physical activity and the highest level of treatment in pediatrics.

American Academy of Physical Medicine and Rehabilitation (AAPMR)

Special Interest Group on Sports Medicine

Website: http://www.aapmr.org
Publications: *Archives of Physical Medicine and Rehabilitation*, *Journal of Physical Medicine*

An academy representing patients with, or at risk for, temporary or permanent disabilities and helping physicians acquire the continuing education, practice knowledge, leadership skills, and research findings needed to provide quality patient care.

American Academy of Podiatric Sports Medicine (AAPSM)

Website: http://www.aapsm.org

An academy that helps further the understanding, prevention, and management of lower extremity injuries in sports through professional education, scientific research, public awareness, and membership support.

American College of Sports Medicine (ACSM)

Website: http://www.acsm.org
Publications: *Medicine and Science in Sports and Exercise*, *Sports Medicine Bulletin*, *Exercise and Sport Sciences Reviews*

An association that promotes healthy lifestyles through the diagnosis, treatment, and prevention of sports-related injuries as well as the advancement of exercise science and the dissemination of research.

American Medical Society for Sports Medicine (AMSSM)

Website: http://www.amssm.org

A forum for primary care sports medicine physicians to promote professional relationships and advance the discipline of sports medicine through education, research, advocacy, and quality patient care.

American Optometric Association (AOA) Sports Vision Section (SVS)

Website: http://www.aoa.org/x4787.xml
Publication: *SVS News and Views*

An association that is specific to optometric sports vision, striving to advance care through education, injury prevention, and enhancement of visual performance.

American Orthopaedic Society for Sports Medicine (AOSSM)

Website: http://www.sportsmed.org
Publication: *American Journal of Sports Medicine*

A national organization of orthopedic surgeons committed to sports medicine education, research, communication, and fellowship.

American Osteopathic Academy of Sports Medicine (AOASM)

Website: http://www.aoasm.org
Publication: *Clinical Journal of Sports Medicine*

An educational forum for primary care physicians and health care professionals to attend to the quality of health care, promoting fitness and exercise guidelines and providing a collegial environment to expand the knowledge of sports medicine.

American Physical Therapy Association (APTA)

Website: http://www.apta.org
Publication: *Physical Therapy*

A national organization committed to the advancement of physical therapy practice and research, promoting the prevention, diagnosis, and treatment of movement dysfunctions and the improvement of the physical health and functional abilities of all members of the public.

British Association of Sport and Exercise Medicine (BASEM)

Website: http://www.basem.co.uk

The oldest sport and exercise medicine association in the United Kingdom (founded in 1953) and the official UK representative to both the European Federation of Sports Medicine Associations (EFSMA) and the International Federation of Sports Medicine (FIMS), dedicated to the promotion of good health through physical activity and the provision of sports medicine expertise to optimize athletic performance at all levels.

Canadian Academy of Sports Medicine (CASM-ACMS)

Website: http://www.casm-acms.org

An organization of physicians dedicated to the practice of medicine as applied to all aspects of physical activity, including health promotion and disease prevention.

Canadian Athletic Therapists Association (CATA)

Website: http://www.athletictherapy.org/en/index.aspx

A nonprofit organization dedicated to promoting injury prevention, emergency services, and rehabilitative techniques for active individuals.

Canadian Physiotherapy Association (CPA)

Website: http://www.thesehands.ca

An association of physiotherapists, physiotherapy support workers, physiotherapy students, and affiliate members dedicated to advancing the field of physiotherapy and improving the health of all individuals.

Canadian Society for Exercise Physiology (CSEP)

Website: http://www.csep.ca
Publication: *Canadian Journal of Applied Physiology*

An organization of professionals involved in the scientific study of exercise physiology, exercise biochemistry, fitness, and health.

Gatorade Sports Science Institute (GSSI)

Website: http://www.gssiweb.com

A research and educational facility that studies with scientists around the world the effects of exercise, the environment, and nutrition on the human body.

International Federation of Sports Medicine (FIMS)

Website: http://www.fims.org

An international organization dedicated to the study of sports medicine as well as the dissemination of findings to help athletes maximize their potential.
